# Evolution of the Pallium in Birds and Reptiles

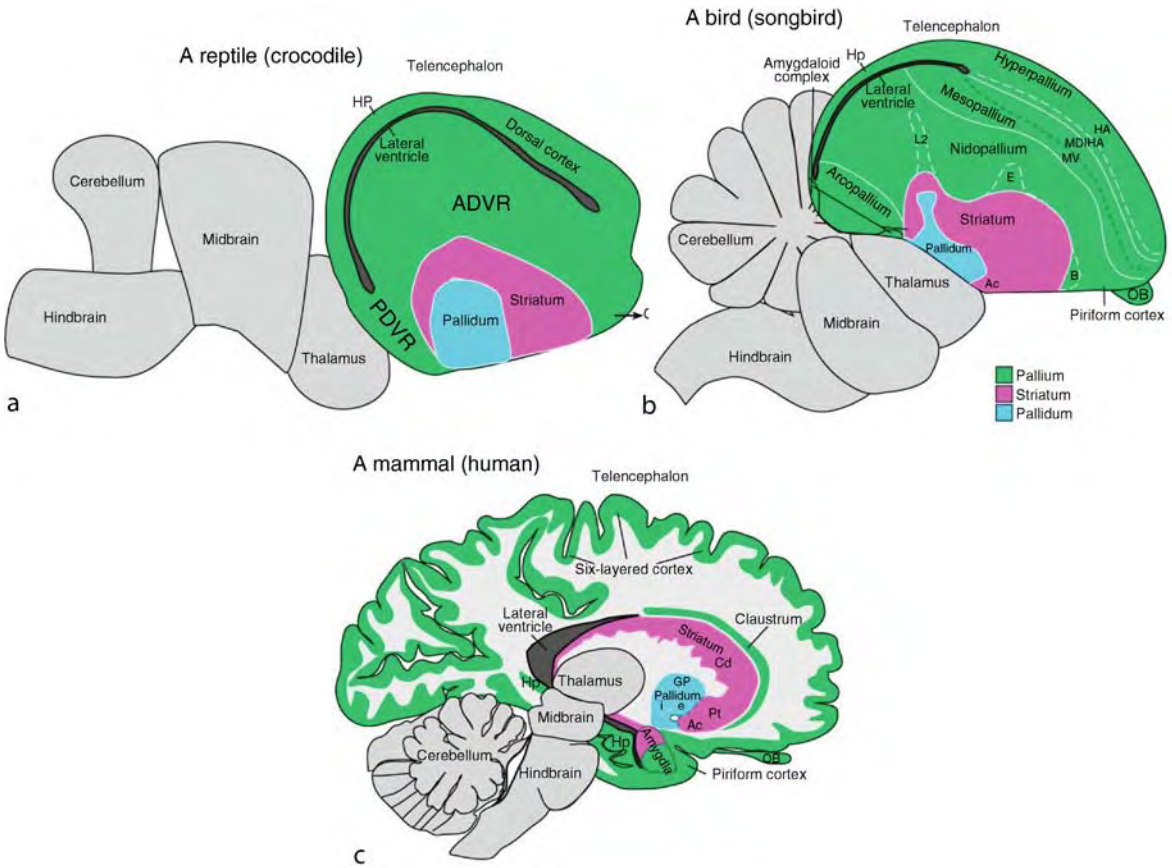
Erich D. Jarvis
Department of Neurobiology, Duke University Medical Center, Durham, NC, USA

## Definition

The telencephalon of amniotes (reptiles, birds, and mammals) consists of two major subdivisions: the pallium and the subpallium. The subpallium, also called the basal ganglia, is further divided into two main subdivisions: the striatum and pallidum (Fig. 1). The striatum and pallidum are also thought to contribute to the septum and subpallial amygdala (central and medial nuclei). The subpallial components are relatively conserved in its organization among amniotes (Fig. 1). The pallium, however, which is the topic of this essay, is relatively diverse in its organization. The bird pallium consists of four major subdivisions – hyperpallium (hypertrophied pallium), mesopallium (middle pallium), nidopallium (nest pallium), and arcopallium (arched pallium)- as well as olfactory, hippocampal, and pallial amygdala regions (Fig. 1b) as defined in the new avian brain nomenclature [1,2]. The organization of the reptile pallium is not yet as well defined, but it consists of what has been called the dorsal cortex and the dorsal ventricular ridge (DVR), as well as olfactory, hippocampal, and pallial amygdala regions (Fig. 1a). Various hypotheses have been proposed for similarities and differences in the organization of the reptile, bird, and mammalian pallia, which contribute towards an understanding of the evolution of the pallium [1,2].

## Characteristics

Reptiles and birds belong to the vertebrate class called sauropsids (Fig. 2). Although birds are now sometimes classified as reptiles, birds and reptiles are referred to here as separate groups belonging to sauropsids, one group with feathers and the other with scales, respectively. The sauropsids belong to the larger group

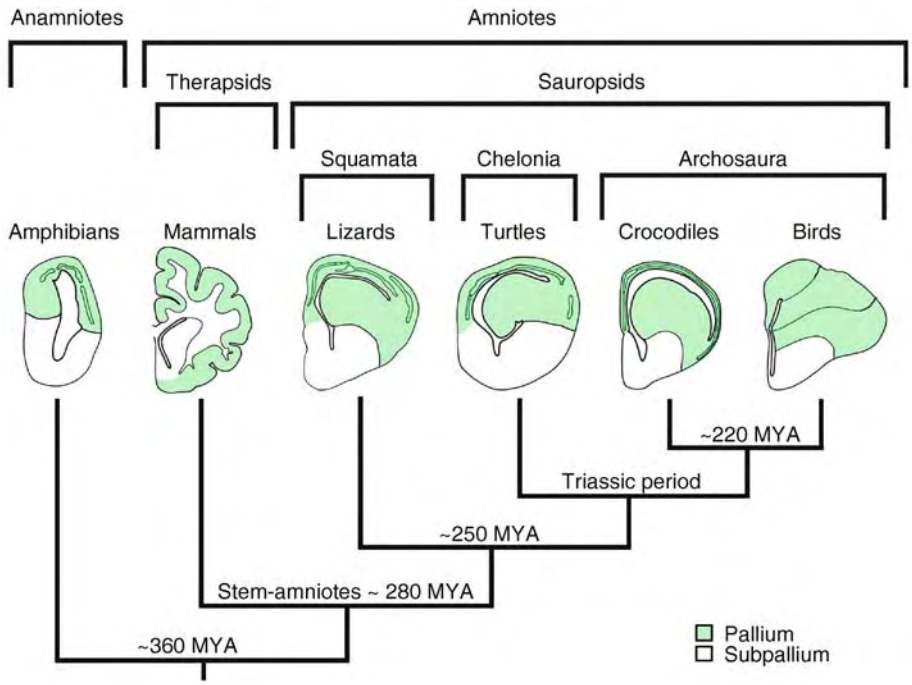


**Evolution of the Pallium in Birds and Reptiles. Figure 1** Comparable organization of adult telencephalon of reptiles (a), birds (b), and mammals (c). Shown are sagittal views. Color-coding indicates pallial, striatal, and pallidal telencephalic domains. Pallial organization is well known for birds and mammals but not yet for most reptiles. The schematics represent the modern and recently revised view of vertebrate brain organization and evolution [1,2]. Abbreviations: *Ac* accumbens; *B* basorostralis; *Cd* caudate; *E* entopallium; *GP* globus pallidus, internal (i) and external (e) segments; *IHA* interstitial hyperpallium apicale; *HA* hyperpallium apicale; *Hp* hippocampus; *L2* field L2; *MD* dorsal mesopallium; *MV* ventral mesopallium; *OB* olfactory bulb; *Pt* putamen. For birds, some confusion exists in the literature as to whether the MD is hyperpallium densocellulare (HD) or is a separate structure.

called amniotes and share a stem amniote ancestor with mammals (Fig. 2). The pallia in developing embryos of reptiles, birds, and mammals are more similar than they are in their adult forms, consisting of a ventricular zone (VZ) and, in birds and mammals, a sub-ventricular zone (SVZ; Fig. 3), from which most pallial neurons emerge [3]. In the adult form, however, major differences are found in sauropsids relative to mammals. In sauropsids, the pallium is mostly nuclear in cellular organization, whereas in mammals it is mostly layered (Fig. 1) [1]. Among sauropsids, there are several types of nuclear organizations: type I found in turtles and some lizards, where neurons are relatively uniformly distributed within each brain subdivision, and type II found in other lizards, birds and crocodiles, where neurons are more concentrically organized relative to the lateral ventricle within brain subdivisions (Fig. 4) [4]. Despite these organizational differences, neural connectivity and/or gene expression profiles indicate shared features in the type I and type II pallia of birds and reptiles and with the pallium of mammals. The shared features with mammals have led to investigators to propose differing hypotheses on the evolution of pallial subdivisions or neuron types from the stem amniote ancestor of birds and reptiles with mammals [1]. These features and hypotheses are discussed in this essay.

## Development

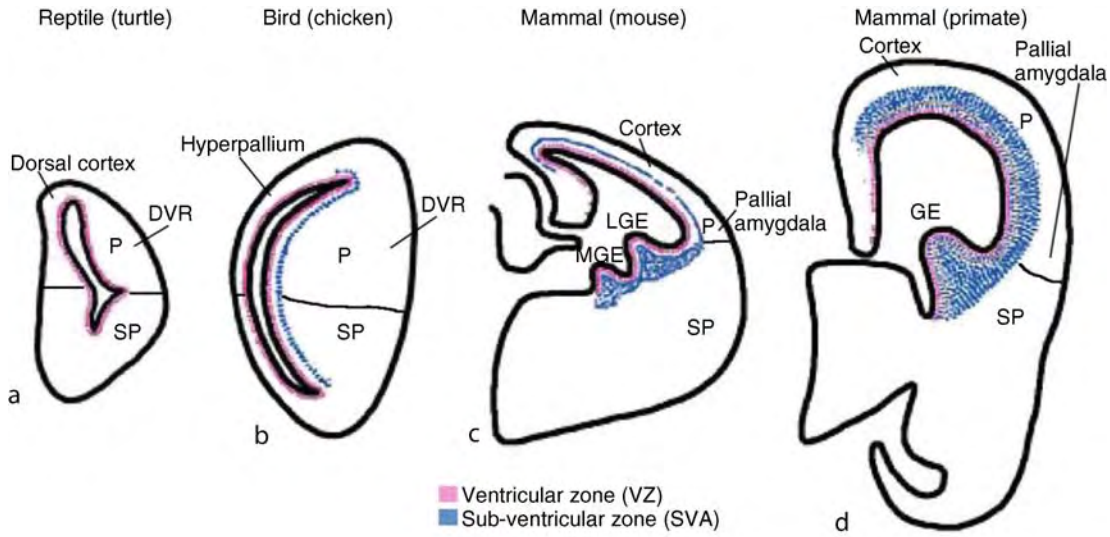
The embryonic pallium of reptiles (studied mostly in turtles), birds, and mammals consists of a neurogenic zone near the lateral ventricle, the VZ (Fig. 3). Stem cells in the VZ divide to give rise to daughter stem cells, neurons, and glia. The neurons and glia migrate away from the VZ to make up the pallial parenchyma. In addition, mammals have a transient SVZ, and birds



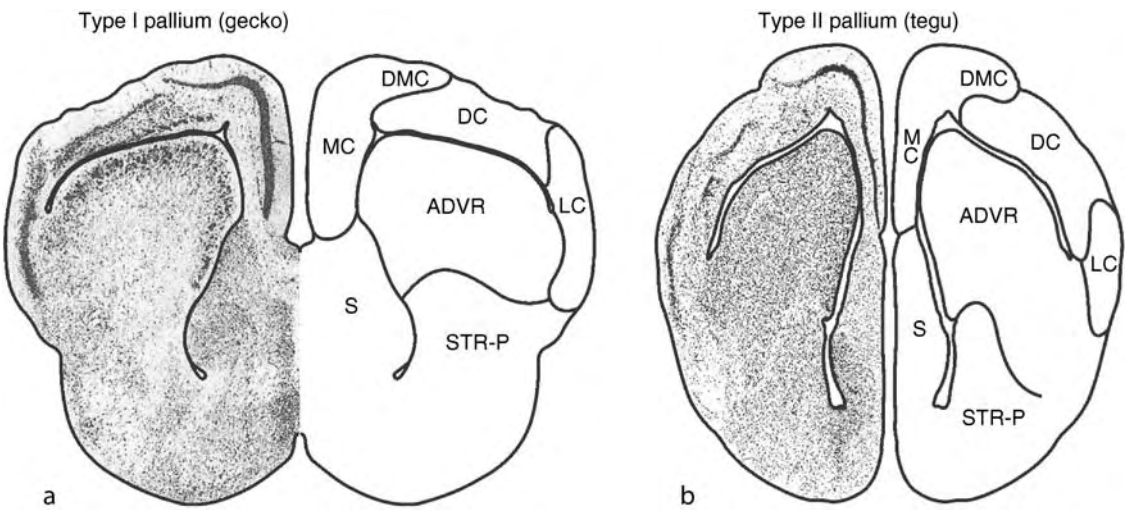
**Evolution of the Pallium in Birds and Reptiles. Figure 2** Simplified modern view of tetrapod vertebrate evolution and general pallial shape in examples of living forms. As indicated by the phylogenetic trees, ancestral tetrapods are thought to have given rise to amphibians and to stem amniotes. Stem amniotes then split into at least two groups: the synapsid line leading to therapsids, which, through a series of now-extinct intermediate forms, evolved into mammals, and the diapsid line to sauropsids, which gave rise to all modern reptiles and birds. Among sauropsids, birds and crocodiles comprise the archosaurs and, along with the tuatara (not shown) and turtles, constitute one major clade, while the squamates, snakes (not shown) and lizards constitute the other major clade. This tree represents a recently revised view of reptilian phylogeny [8,9]. MYA, million years ago. For the brain examples, frontal views of anterior right hemispheres are shown; medial is left, dorsal is up. Note that the pallium (*green*) for large mammals (as shown here) is folded and thin; that of sauropsids below the lateral ventricle (open space) is nuclear and thick. For the sauropsids, only well-defined pallial subdivisions are known for birds. The subpallium in this plane of section includes the striatum (right of ventricle) and septum (left of ventricle, which is also thought to consist of striatal and pallidal parts). Figure modified from [10], with revisions based upon [1,2,8].

have a long-lasting SVZ located ~100 μm away from the VZ that also gives rise to new neurons that contribute to the pallium. In mammals, the SVZ is present in pallial regions dorsal and ventral to the lateral ventricle and is transient, whereas in birds it is mainly ventral to the lateral ventricle and lasts throughout adulthood. In mammals, the thicker the SVZ, the larger the brain and cortical folding that develops, and this may also be the case for birds since their pallia tend to be relatively larger than many reptiles (Fig. 3) [3]. These findings suggest that the either the SVZ evolved independently in birds and mammals or was lost in at least type I reptile (turtle) pallia. Neurons from the pallial VZ of developing birds and reptiles (and from the pallial SVZ of birds) are added to the pallium in an *outside-in* pattern as the pallium expands away from the lateral ventricle, with oldest neurons situated farthest away from the ventricle. In mammals, neurons are added instead in an *inside-out* pattern, with the oldest neurons situated closest to the ventricle. These findings lead to the view that the similar connectivity and gene expression patterns found in adult avian and mammalian pallium may be the result of convergent evolution instead of features inherited from a common stem amniote ancestor [5].

Despite these differences in how the developing pallium is organized, developmentally regulated transcription factors have been used to demonstrate that the dorsal part of the telencephalon is homologous as pallium across vertebrates (Fig. 2). These transcription factors mostly have been studied in the brains of birds and mammals [6], but several also have been studied in reptiles [3,7]. The T-box transcription factor 2 (Tbr2) appears to be expressed in the pallial SVZ of both developing chicks and mice, whereas as Tbr1 is expressed in more peripheral parts of the pallium lateral to the ventricle. In these peripheral parts, Tbr1 is lower in the later developing avian arcopallium and mammalian



**Evolution of the Pallium in Birds and Reptiles. Figure 3** Comparable organization of embryonic telencephalon of reptiles (a), birds (b), and mammals (c and d) highlighting the ventricular zone (VZ) and the subventricular zone (SVZ). Shown are frontal views of the right hemisphere; medial is left, dorsal is up. A positive correlation exists between the presence and size of the SVZ and the size of the adjacent pallial regions. Labels outside of the telencephalons are the presumed adult regions to which these embryonic regions gives rise. These and related findings were used to propose that the amygdala (and adjacent claustrum) of mammals is homologous to the DVR of reptiles and birds and that the six-layered cortex of mammals is homologous to the dorsal cortex of reptiles and hyperpallium of birds. The LGE and MGE in rodents give rise to the striatal and pallidal neuron types, respectively; in primates, the LGE and MGE are fused to form the GE. Abbreviations: DVR, dorsal ventricular ridge; GE, ganglionic eminence; LGE, lateral ganglionic eminence; MGE, medial ganglionic eminence; P, pallium; SP, subpallium. Figure modified from [3]; the medial part of the bird telencephalon is more vertically orientated than that shown, as in other species.



**Evolution of the Pallium in Birds and Reptiles. Figure 4** Examples of type I and type II reptile pallis. Shown are frontal sectons with mirror-image drawings through the telencephalon of a type I lizard (a, the gecko) and a type II lizard (b, the black tegu). Note the differences in the pallium, the ADVR, of each. Type I species have a high density of cells clustered near the ventricle surface. Abbreviations: ADVR, anterior dorsal ventricular ridge; DC, dorsal cortex; DMC, dorsal medial cortex; LC, lareral cortex; MC, medial cortex; S, septum; STR-P, Striatal-pallidal region. Figure from [9, figs.19–21] and used with permission.

pallial amygdala. The empty spiracles 1 (Emx1) homeobox transcription factor is expressed in dorsal pallial regions during development in chick, turtles, and mice, but appears to be absent in the later stages of embryonic avian nidopallium, mammalian claustrum, and parts of reptile pallium. The paired box 6 (Pax6) transcription factor is expressed along the entire developing pallial VZ in birds, reptiles, and mammals, but it is also differentially expressed in other forebrain areas among these groups. These findings have led some investigators to conclude that the avian arcopallium or parts of the avian arcopallium and a similar posterior pallial region in reptiles is homologous to the mammalian pallial amygdala, and that the avian nidopallium and parts of the mesopallium are homologous to mammalian claustrum, if not to other parts of the pallial amygdala [6,7]. I call this the nuclear-to-claustrum/amygdala hypothesis [1], which is described in further detail at the end of this essay.

## Adult Organization

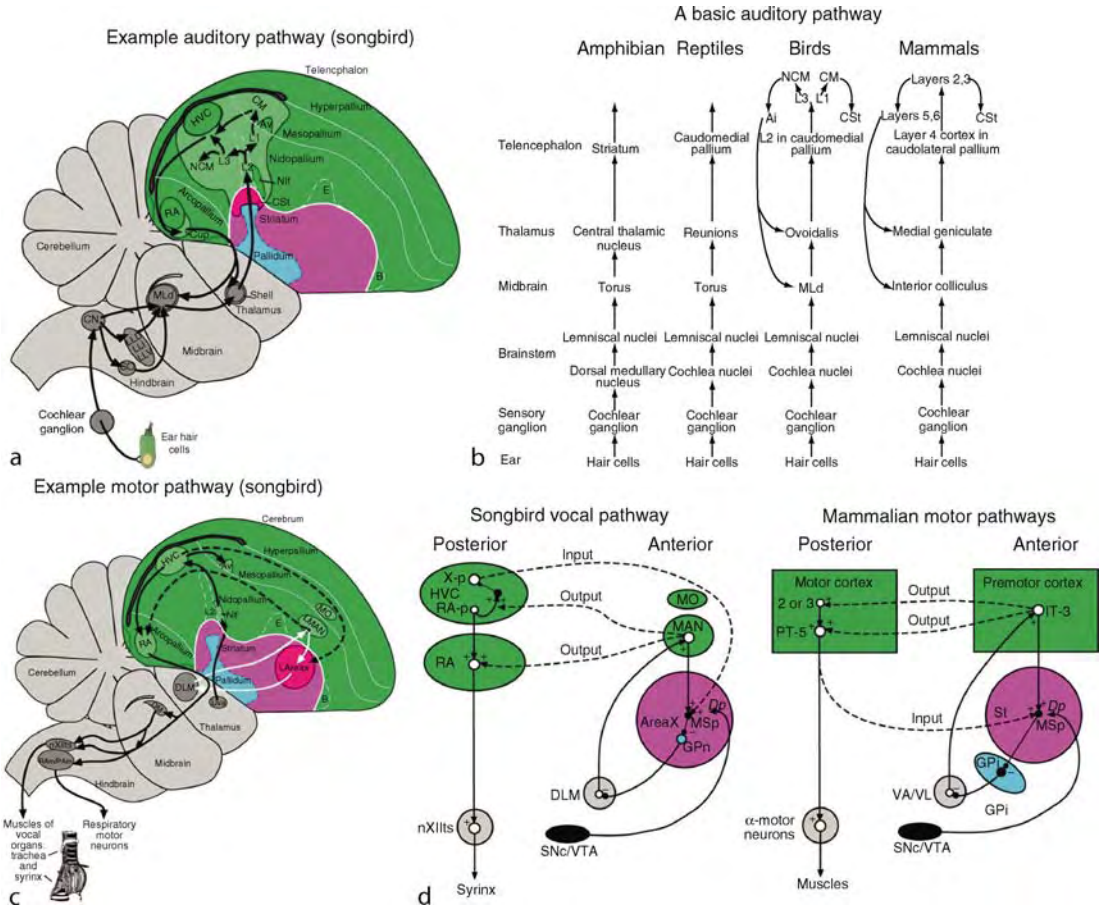
The organization of the adult avian pallium has been well studied and that of reptiles somewhat studied. Based upon Nissl staining patterns of embryonic and adult brains, Ulinksi and others defined a general organization of the bird and reptile pallia [4]. This includes a dorsal part, called the dorsal cortex in reptiles and the Wulst or hyperpallium in birds, and a lateroventral part called the dorsal ventricular ridge (DVR) that grows into the lateral ventricle (Fig. 1a and 1b). In birds the ventricular space between the DVR and hyperpallium is fused during development; in reptiles, the DVR and dorsal cortex remain separate into adulthood (Fig. 1a and b). Ulinski further subdivided the DVR into anterior (ADVR) and posterior (PDVR) parts (Fig. 1a). He then defined two types of ADVR: type I, which consists of concentrically organized neurons with a higher density nearer the lateral ventricle, as found in turtles, the tuatara (the rhynchocephalian *Sphenodon*), and some lizards (such as the gecko; Fig. 4a); and type II, which consists of more uniformly distributed neurons, as found in birds, crocodiles, snakes, and other lizards (such as black tegu; Fig. 4b). As a result, the type II pallium is thought to have been derived multiple times independently (see ►Evolution, of the Brain: in Reptiles).

Which pallial subdivisions constitute the ADVR, PDVR, and dorsal cortex in birds is not clear, although it is often reported as clearly defined. For reptiles, detailed subdivision definitions have not yet been clearly delineated for any species, due in part to more diffuse Nissl staining of boundaries relative to birds [6]. Thus we do not yet know which pallial subdivisions in birds truly constitute presumably homologous subdivisions in reptiles. Approximate comparisons, however, have been given. One view holds that the homologue of the reptilian dorsal cortex is the highly differentiated avian hyperpallium (including the hyperpallium apicale [HA], intercalated hyperpallium apicale [IHA], and hyperpallium densocellulare [HD]), that the homologue of the reptilian ADVR is the avian mesopallium and nidopallium, and that the homologue of the reptilian PDVR is the avian arcopallium [1,4]. However, this view may be too simplistic [4]. Comparative gene expression studies indicate that crocodiles like birds have a mesopallium [11], but that in both the mesopallium may consists of dorsal and ventral parts above and below the ventricle, as described further below. Differences certainly exist between birds and some reptiles. For example, snakes and lizards have a relatively unique feature in the medial part of their PDVR called the nucleus sphericus, which is involved in accessory olfactory bulb function and is not found avians, crocodilians, or turtles [4,9]; nucleus sphericus is thought to be the homologue of portions of mammalian pallial amygdala nuclei (basal lateral amygdala and lateral amygdala) that receives input from the accessory olfactory bulb. Additional studies are needed to determine further similarities and differences in pallial organization between birds and reptiles, especially with the advent of the new avian brain nomenclature [1,2].

## Connectivity: Sensory and Motor Pathways

Comparative analyses of sensory pathways in birds and various reptile species indicate that all have sensory pathways that reach the pallium [4,9]. These consist of at least two visual pathways, two somatosensory pathways, and one or possibly two auditory pathways. Two different types of sensory pathways have been defined as either collothamalic (sensory input serially connecting to midbrain to thalamus to pallium) or lemnothalamic (sensory input skipping midbrain serially connecting thalamus to pallium).

The auditory pathway is collothamalic, where in birds, crocodiles, turtles, and lizards, a midbrain auditory nucleus projects to the thalamic auditory nucleus, which in turn projects to a defined cell population in the caudomedial pallium (Fig. 5a and b). The exact location of this cell population differs across species of mammals, but it also differs across species of birds [12], where the subsequent connectivity has been well studied [13]. This pallial, thalamo-recipient cell population in birds is called field L2, which then projects to surrounding caudomedial nidopallium (NCM), which in turn projects to the caudomedial mesopallium (CM, in the ventral mesopallium). The surrounding nidopallium also has a descending auditory pathway to the arcopallium and thence to the surrounding shell regions of the thalamic and midbrain auditory nuclei. This descending auditory system is similar in connectivity to a descending auditory pathway found in mammals. The collothalamic visual pathway has a similar organization as the auditory pathway, as found in birds, crocodiles, turtles, and lizard,



**Evolution of the Pallium in Birds and Reptiles. Figure 5** Example sensory (auditory) and motor (vocal) pathways in songbirds, in comparison with other vertebrates. (a) Auditory pathway in the songbird showing ascending and descending input. (b) Similar auditory pathways, but sometimes with different nomenclature used for individual nuclei, can be found for all amniotes examined. Only a sub-pathway through the cochlea and lateral leminiscal nuclei are shown. Once in the telencephalon, parallels can be found in cell type connectivity, although the pallial organizations are different and projections in amphibians are mostly to the striatum. (c) Vocal pathway of songbirds consisting of the vocal motor pathway (*black arrows*), the vocal pallial-basal-ganglia-thalamic loop (*white arrows*), and the connections between the two (*dashed arrows*). (d and e) Comparisons of cell types and connectivity of the vocal pathway in songbirds and forebrain motor pathways in mammals. Also shown is dopaminergic input from the SNc/VTA. with the projection field of all suaropsids tested located more anteriorly within the nidopallium adjacent or near to the striatum; the specific pallial, thalamo-recipient target is called the entopallium in birds (Fig. 6a). A pseudo-collothalamic somatosensory pathway exists in birds, from the trigeminal sensory nucleus, innervated by the upper neck and face. The ascending trigeminal somatosensory pathway in birds does not involve a

**Evolution of the Pallium in Birds and Reptiles. Figure 6** One-to-one homology hypotheses between avian and mammalian brains in the context of the new avian brain nomenclature. (a) An example of a nuclear-to-layered hypothesis. Connectivity of collothalamic and lemnothalamic visual pathways in avian (*left*) and mammalian (*right*) brains are shown. The hypothesis illustrated is a combination of Karten [18] and Medina and Reiner [5]. (b) An example of a nuclear-to-claustrum/amygdala nuclei hypothesis. The hypothesis illustrated is that of Puelles et al. [6]. In both hypotheses, color-coding indicates proposed homologies between birds and mammals, but the relationship of the newly named mesopallium needs further study and clarification. Abbreviations: *I–VI* cortical layers I–VI; *B* basorostralis; *Cl-d* claustrum, dorsal part; *Cl-v* claustrum, ventral part; *DP* dorsal pallium; *E* entopallium; *GLd* dorsal lateral geniculate nucleus; *HA* hyperpallium apicale; *HD* hyperpallium densocellulare; *Hp* hippocampus; *IHA* interstitial hyperpallium apicale; *L2* field L2; *LP* lateral pallium; *MD* dorsal mesopallium; *MP* medial pallium; *MV* ventral mesopallium; *OB* olfactory bulb; *Pul* pulvinar nucleus; *Rt* nucleus rotundus; *Sc* superior colliculus; *TeO* optic tectum; *Tn* nucleus taenia; *VP* ventral pallium. Figure updated from Jarvis et al. [1].

connection through the midbrain or dorsal thalamus. But like collothalamic pathways, its pallial target, basorostralis, is within the nidopallium (Fig. 5a). The connectivity from basorostralis is similar thereafter to the collothamalic auditory and visual pathways. In contrast, in mammals, the trigeminal somatosensory pathway for the face and neck regions is clearly lemnothalamic; its connections in reptiles are unknown.

The lemnothalamic visual pathway projects directly from a thalamic nucleus to the posterior part of the IHA lamina within the Wulst in birds (Fig. 6a) and to the outer layer of the dorsal cortex as well to an adjacent lateral region called the pallial thickening in turtles. After reaching the dorsal telencephalon, there are significant differences in intra-pallial connectivity between birds and turtles, suggesting that they evolved divergent pallial connectivity for the lemnothalamic visual pathway [5]. A lemnothalamic somatosensory pathway projects from the body receptors to the dorsal column nuclei to the somatosensory thalamus to the anterior IHA within

the Wulst in birds, and to part of the dorsal cortex in turtles and lizards. Very little is known for intra-pallial sensory pathway connectivity in reptiles, and thus further comparisons with birds will have to await further studies. Ulinksi [4] proposed, however, that type II ADVRs in reptiles (like in birds) have more discrete sensory projections into the pallium than type I ADVRs, which have more diffuse projections that radiate out from a central recipient zone. Thus, there could be several types of sensory pathway organization in the reptile pallium.

As for the motor pathways of the pallium, very little is known for birds and reptiles. A pyramidal tract-like pathway from the anterior HA has been identified in birds, but it is suggested to possibly be a modulatory feedback projection to somatosensory nuclei of the spinal cord [14]. The best known sauropsid motor pathway is the songbird vocal pathway. This pathway consists of two sub-pathways: (i) a posterior vocal motor pathway that connects a series of nuclei in the ventral mesopallium, nidopallium, and arcopallium, which then projects to the vocal motor neurons of the medulla that control the syrinx; and (ii) an anterior vocal pathway that forms a pallial-basal-ganglia thalamic loop through the anterior nidopallium (and possibly ventral mesopallium) to the anterior striatum to anterior dorsal thalamus and back to the anterior nidopallium (Fig. 6c) [1]. This pathway is used for vocal learning of songs. A similar vocal pathway is found in the forebrain of parrots, and similar connectivity is found adjacent to the vocal nuclei in songbirds [15]. These and many other findings have lead to the theory that the vocal learning systems may be motor pathways that evolved out of pre-existing non-vocal motor pathway in birds [12,16] (Feenders et al. unpublished observations). The songbird arcopallium adjacent to the arcopallial vocal nucleus projects to medullary reticular premotor neurons that in other avian orders have been shown to control wing and leg movements [17].

The above findings suggest that birds inherited their existing auditory, visual, and somatosensory pathways from their reptilian ancestor. A similar, but not identical auditory pathway exist in amphibians (Fig. 6b) [9]; a major difference is that the thalamic nuclei project heavily to the striatum, and only weakly to the medial pallium. This medial pallium region is thought to be the homologue of the mammalian hippocampus, but it could also include homologues of sensory areas (►Evolution of the Auditory System in Anamniotes). This suggests that sauropsids may have inherited a rudimentary form of their forebrain auditory pathway from their common stem amniote ancestor. As for the visual pathways, differences between birds and reptiles in the pallial connectivity of the lemnothalamic visual pathway suggest that they diverged after the split of birds from their common reptilian ancestor. As for the motor pathways, the posterior vocal pathways of avian vocal learners have been noted to be similar to descending motor pathways of mammals, and the anterior vocal pathway is similar to motor cortico-basal-ganglia-thalamic loops of mammals (Fig. 6d) [12], indicating possible inheritance from the stem amniote ancestor. It has been recently said that reptiles lack such loops (►Evolution, of the Brain: At the Reptile-Bird Transition), but Ulinski discovered their existence in turtles and lizards [4] before they were popularly studied in mammals. Therefore, if Ulinski is correct, the presence of such forebrain loops in reptiles, birds, and mammals indicate that they may have been inherited from their common stem amniote ancestor.

Harvey Karten noted that the sensory pathways to the pallium in birds share similarities with sensory pathways in mammals, and based upon these findings he and others proposed a hypothesis on the cellular homologies in pallial neuron types of birds with mammals (Fig. 5a) [5,18]. This hypothesis states that the primary thalamic recipient zones in bird pallium is homologous to layer IV neurons of primary auditory, visual, and somatosensory cortices; the second order neurons in the surrounding nidopallium are homologous to layers II and III; the third order neurons of the arcopallium that also send descending projections out of the telencephalon is homologous to layer V. I call this the nuclear-to-layered hypothesis [1], which is described in further detail at the end of this essay.

## Molecular Profiles

Not many studies have compared molecular gene expression profiles of adult pallia in their fully differentiated forms between birds and reptiles. We compared the expression of the fork-head transcription factors FoxP1 and FoxP2 in adult birds and crocodiles [11]. FoxP2 is implicated in spoken language function in humans and in vocal learning in birds, and it is highly expressed in the striatum of both birds and mammals. We found similarly enriched FoxP2 expression in the striatum of crocodiles. FoxP1 is also expressed in the striatum in birds and mammals, but is further enriched in the avian mesopallium and mammalian cortical layer VI neurons. In crocodiles, FoxP1 expression shows very similar profiles, including enrichment in a pallial region similar to the avian ventral and dorsal mesopallium, with the ventral part below the lateral ventricle and the dorsal part above it. These findings suggest that mesopallium was inherited in birds from a common reptilian archosaur ancestor with at least crocodiles and that pallial organization of archosaurs may be very similar, although difficult to detect in the crocodile brain with Nissl staining. They also support an idea that the dorsal cortex and the ADVR may be continuous structures 6, where the lateral ventricle is not a functional boundary between brain subdivisions. Further gene expression studies are necessary to test these ideas and to determine the

similarities and differences in the organization of avian, crocodilian, and other reptilian pallia.

## Function

The connectivity findings are supported by electrophysiology and lesion studies in birds and reptiles, and activity-dependent gene expression studies in birds. They show that there are auditory processing neurons in the caudal pallium, visual processing neurons in anterior and dorsal pallium regions of the two visual pathways, and somatosensory processing neurons in anterior and dorsal pallium regions of the two somatosensory pathways [4,9,12] (Feenders et al. unpublished observations). It is not yet clear whether these pathways in birds and reptiles process their sensory modality-specific information in the same manner. As for possible motor pathways, stimulation of the arcopallium in birds can induce crouching or running movements [4]. Stimulation of ADVR regions in reptiles leads to modulation of movements. However, lesions of ADVR in reptiles and anterior nidopallium in birds indicate that these regions are not essential for the generation of movement. These types of studies parallel the more detailed findings on the songbird vocal pathway, where lesions of the posterior vocal pathway nuclei show that they are necessary for the production of learned song, whereas the lesions of the anterior vocal pathway nuclei show that they are not necessary for song production but are necessary for song learning and the generation of variability in song production [12]. Further experiments are necessary to define non-vocal motor pathways of the pallium in birds and reptiles.

## Evolution Hypotheses on Homologies with Mammals

Based upon comparative neurobiology studies, modern hypotheses on avian (as well as reptilian) brain homologies with mammals fall into two categories that I named nuclear-to-layered and nuclear-to-claustrum/amgydala hypotheses (Fig. 5) [1]. These hypotheses are sometimes presented as final in the literature, but each has it strengths and weaknesses, and thus each needs further testing. Both hypotheses agree on pallial regions that are widely recognized to be homologous among birds, reptiles, mammals and other vertebrates: the hippocampus, olfactory cortex, and olfactory bulb – brain regions covered in other essays (see ►Evolution, of the Hippocampus; ►Martínez-Marcos and Halpern, Evolution, of Olfactory and Vomeronasal Systems). They disagree, however, on homologies of other pallial regions. To appreciate these disagreements, it is useful to consider general organization principles that appear to be unique to each vertebrate group. The avian hyperpallium possesses a more semi-layered organization not found in reptile dorsal cortex to date and thus might have evolved complexity more recently than the mammalian six-layered cortex, since birds evolved well after mammals [by ~50–100 million years (Fig. 2)]. The DVR, with its nuclear organization, is found only in birds and reptiles and thus may have evolved after sauropsids split from stem amniotes. The six-layered cortex is a pallial organization found only in mammals (monotremes, marsupials, and placentals), and thus it was presumably inherited from their common therapsid ancestor over 200 million years ago (Fig. 2). As all non-mammalian therapsids are now extinct, it is difficult to trace from stem amniotes to mammals the evolutionary history of mammalian pallial organization - layered, nuclear, or otherwise. Thus, the reptilian nuclear pallial organization cannot be assumed to represent the ancestral condition for mammals, as it is for birds. The evidence suggests that in contrast to conserved striatal and pallidal domains, there are fewer constraints on how the pallium can be organized [1].

### *Nuclear-to-Layered Hypotheses*

First proposed by Karten [18], this hypothesis states that the common ancestor of birds, reptiles, and mammals possessed a nuclear pallium that was transformed into a layered pallium early in the mammalian lineage, maintaining connectivity of the ancestral nuclear network. In this regard, he argued that the avian pallium is divided into three sets of serially connected types of neurons – thalamo-recipient neurons (Field L2, entopallium, and basorostralis), pallio-pallial neurons (other parts of nidopallium) and extra-telencephalic projection neurons (arcopallium), with cell types and interconnectivity similar to those of mammalian cortical layers IV, II-III, and V-VI, respectively. Similar arguments were made by others for the avian hyperpallium divisions (Fig. 6a) [5]. Supporting this hypothesis, gene expression studies on adult brains have shown that avian thalamo-recipient nuclear fields (L2, entopallium, basorostralis, and IHA) and the mammalian thalamo-recipient layer IV of cortex selectively express some of the same genes. Avian extra-telencephalic projection neurons (in the arcopallium, but not in the hyperpallium) and mammalian extra-telencephalic projection neurons (layer V neurons of cortex) both selectively express some of the same genes [1]. Thus, although the avian pallium is not organized cytoarchitectonically into layers, its nuclear subdivisions bear marked similarities in connectivity and some molecular profiles to different layers of the mammalian cortex. A weakness of this hypothesis is that developmental neural fate mapping studies have not revealed that the specific neurons precursors that give rise to the different layers of the mammalian six-layered cortex also give rise to the different pallial subdivisions of the avian telencephalon [6]; such studies have also not been able to falsify the hypothesis. Another weakness is that since the avian hyperpallium organization appears to be different than the turtle, it is possible that the hyperpallium

organization is novel instead of inherited from a common ancestor with mammals. Falsifying the nuclear-to-layered hypothesis may require the use of novel gene manipulation and fate mapping tools to determine if precursor nuclear-specific neurons or genes of sauropsids and layer-specific neurons or genes of mammals will be incorporated into each other's palliums in the expected manner according to the hypothesis.

### Nuclear-to-Claustrum/Amygdala Hypotheses

First proposed by Bruce and Neary [19], these hypothesis propose that the DVR represents an elaboration of parts of the mammalian pallial amygdala and claustrum, and that the connectivity that the avian DVR shares with the six-layered cortex evolved independently. This view is based on findings that both the avian DVR and mammalian claustrum-amygdala are nuclear in organization, that both the avian DVR and part of the mammalian pallial amygdala have similar connections, and that both have conserved developmental expression patterns of regulatory genes that play key roles in brain regionalization and morphogenesis. Based on these gene expression patterns, Puelles et al. [6] and Smith-Fernandez et al. [7] proposed that the avian mesopallium and the mammalian dorsal claustrum and basolateral amygdala develop from the lateral pallium and are homologous structures, that the avian nidopallium and the mammalian ventral claustrum and lateral anterior amygdala arose from the ventral pallium and are homologous structures, and that the avian arcopallium and mammalian amygdala consists of pallial and subpallial parts derived from striatal and pallidal cell groups and are homologous to the mammalian amygdala (Fig. 6b). Weaknesses of these hypotheses are that the details vary greatly from author to author, from including only a part of the arcopallium to the entire DVR as the homologue of the mammalian amygdala/claustrum, that there is as yet no clear definition of the amygdala in birds or reptiles, that definitions of the amygdala in mammals varies (e.g. Fig. 6a vs. Fig. 6b.), and that some developmental fate mapping studies have been ambiguous in the context of the new avian brain nomenclature. For example, the expression of Emx1 gene (*I note here*) is restricted to the newly defined embryonic mesopallium and arcopallium, but not hyperpallium and nidopallium, which would then lead to revisions of the proposed homologies between birds and mammals. Falsifying the nuclear-to-claustrum/amygdala hypothesis may also require the same novel tools and experiments as mentioned above for falsifying the nuclear-to-layered hypothesis.

It is possible that both hypotheses are partially correct. The mammalian amygdala and claustrum share many similarities with the six-layered cortex and as such has been proposed to be extensions of the six-layered cortex [20]. If true, then the similarities of pallial regions shared with birds and possibly with reptiles would indicate that either the sauropsid pallium has both six-layered and amygdala/claustrum mammalian homologues that are extensions of each other within each brain subdivision or that the sauropsid and mammalian palliums use a pre-existing neural substrate present in their embryonic forms that then diverged into different pallial organizations in their adult forms but maintain basic principles. These hypotheses are testable.

## Synonyms

Dorsal telencephalic area; Dorsal telencephalon

## Definition

The pallium is the dorsal part of the telencephalic lobes. In the telencephalon of vertebrates two main regions have been distinguished, the olfactory bulbs and the telencephalic lobes. The telencephalic lobes consist of a dorsal region or pallium and a ventral region or subpallium. Cytoarchitecture, histochemistry, hodology (connections) and/or gene expression are currently used for setting the boundaries with the ventral part of the telencephalic lobe (subpallium) and between the various pallial regions.

The term "fishes" applies to living representatives of jawless vertebrates, the Agnathans (Petromyzontids or lampreys and Myxinoids or hagfish) and to various groups of jawed fishes (Gnathostomata) included in the large radiations of Chondrichthyes (cartilaginous fishes) and of Osteichthyes (bony fishes). Cartilaginous fishes include the ratfish (holocephali), and sharks, skates and rays (elasmobranchs). Bony fishes include the Actinopterygians, or ►ray-finned fishes (Cladistia or bichirs, sturgeons, garfish and a large number of modern species, the teleosts) and the Sarcopterygians, which include the ►lobe-finned fishes (the coelacanth *Latimeria* and the lungfishes), living fossils thought to be closely related to primitive land vertebrates, as well as the land vertebrates, amphibians and amniotes. Fig. 1 depicts a simplified schema of phylogeny of fishes and the morphology of their telencephalic lobes.

## Characteristics

### The Pallium in Fishes

The long evolutionary history of fishes has resulted in the pallium being very heterogeneous in appearance in the different lines (Fig. 1). For most groups, relevant information on its development, neurochemistry and connections is scant and knowledge on evolution of the pallium is quite incomplete. Modern studies of the telencephalon are centered on a few species of fishes, mainly teleosts, cartilaginous fishes, lampreys and lungs, Neurogenetic studies support the distinction between pallium and subpallium in fishes based on a gene expression program similar to the one observed in other vertebrates. Thus, in early embryo stages of species as different as lampreys, dogfish, zebrafish, frog, chick and mouse, the pallium and subpallium express similar transcription factors. The *Emx1/3* genes are expressed in the primordium of the pallium, whereas *Dlx-1/2* genes characterize the primordium of the subpallium [1,2]. Further distinction of pallium regions by genetic markers in developing fishes is lacking. In the Future paragraphs will describe some of the characteristics of the pallium of fishes using the phylogenetic schema presented above.

### Agnathans

*Hagfish* The forebrain of adult hagfish is well-differentiated cytoarchitectonically but lacks a well-developed ventricular system, which obscures the location of the pallial–subpallial boundary. The pallium lies over a massive "central prosencephalic complex," a structure unique to hagfishes that some authors have interpreted as medial pallium, striatum or even as thalamus. The pallium consists of a superficial "cortical" mantle of gray matter that is subdivided into

two main cellular strata parallel to the surface (layers 2 and 4) separated by layers of fibers and cells (layers 1, 3 and 5). Many cells of these two cellular strata are bipolar and tripolar, and are arranged perpendicularly to the layers. A heterogeneous distribution of substance P- and enkephalin-positive neurons has been reported in layer 2.There is no clear correspondence between the subdivisions of the hagfish pallium and those of other craniates [3]. The entire pallium of hagfishes receives extensive secondary olfactory projections [3]. Other pallium afferents arise from the contralateral pallium, the dorsal thalamic nuclei, the preoptic region and the

►posterior tubercle. Ascending thalamic and secondary olfactory projections overlap throughout the pallium. Ascending nonolfactory sensory information may reach the pallium via a tectal-thalamic-telencephalic route. The pallium projects to the olfactory bulbs, preoptic region, the dorsal thalamus and the mesencephalic tectum [3].

*Lampreys* The pallium of lampreys consists of lateral and medial parts that differ in development, organization and connections [4]. The lateral pallium makes an early appearance, but the medial pallium is only well-organized in adults. The lateral pallium forms the evaginated lateral hemispheres around the lateral ventricles and is continuous with the olfactory bulbs. The medial pallium lines the impar telencephalic ventricle and extends caudally to the habenular region. The lateral pallium does not have clear laminar organization, and many neurons are multipolar. Some of them are GABAergic, but most are probably glutamatergic. This area is richly innervated by serotonergic fibers and also receives fairly abundant dopaminergic fibers. The medial pallium consists of a dense periventricular cell layer with pear-shaped cells that extend dendrites in a wide lateral region of neuropil and scattered cells. The lateral region shows some GABAergic neurons and abundant serotonergic and cholinergic fibers in superficial regions.

Secondary olfactory projections reach all pallial fields, as in hagfish [4]. The lateral pallium of both hemispheres is interconnected through the habenular commissure and also has reciprocal connections with the olfactory bulbs and striatum. Diencephalic afferents to the lateral pallium are very scarce. Instead, in addition to telencephalic afferents (olfactory bulbs, septum, striatum), the medial pallium receives a substantial input from diencephalic and mesencephalic tegmentum and dorsal isthmus cell groups. The medial pallium projects to the pretectum and optic tectum [4]. The connections of the lateral and medial pallium of lampreys suggest specialization of these regions in olfactory and visual functions, respectively.

Some authors also include in the lamprey pallium the "dorsal pallium" (= subhippocampal lobe), a caudal region located below the medial pallium and the striatum. This cell group mainly projects to the habenula and is comparable to the entopeduncular nucleus of teleosts.

## Cartilaginous Fishes (Chondrichtyes)

The cartilaginous fishes are the sister-group of bony fishes. Some elasmobranchs (primitive sharks, some dogfishes and ratfish) have hollow telencephalic lobes, but in most elasmobranchs (some sharks, skates, rays, guitarfish and electric rays), the reduction of the lateral ventricles and midline fusion of both lobes during development gives rise to massive telencephala with hardly distinguishable boundaries [5]. In the dogfish *Scyliorhinus*, three main pallium regions, medial, dorsal and lateral, are distinguished topographically, without obvious laminar organization.

The cells of the elasmobranch pallium are morphologically and neurochemically heterogeneous. The dorsal pallium is the richest in neuron types, whereas the medial pallium is the most homogeneous. The pallium of dogfishes is characterized by the presence of numerous small GABAergic cells, dopaminergic cells, cholinergic cells and cells expressing leuenkephalin, somatostatin, neuropeptide Y, FMRF-amide and thyrotropin-releasing hormone. Fibers immunoreactive to these neuropeptides and to serotonin and substance P are abundant in the pallium.

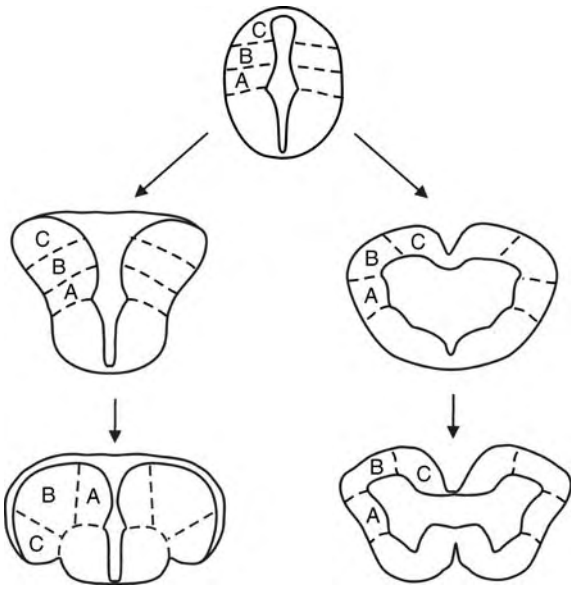
The secondary olfactory tracts in dogfishes project heavily to the pallium and some fibers cross contralaterally in the olfactory commissures. In the spiny dogfish, *Squalus acanthias*, retrogradely labeled cells from the medial pallium were found in the superficial part of the dorsal pallium, the medial pallium, the septal area and in the posterior tubercle and posterior lateral thalamic nucleus. Electrophysiological studies in a guitarfish have mapped the mechanosensory and electrosensory pathways from the lateral line nerves that ascend via the thalamus to the medial region of the pallium.

The massive central nucleus of the pallium of the nurse shark receives afferents from the contralateral central thalamic nucleus, the lateral geniculate nucleus, the ventrolateral optic nucleus, periventricular gray, the ventral mesencephalic tegmentum and the superior raphe nucleus. Experimental studies in sharks reveal that the central nucleus of the pallium is involved in control of visually guided behavior. Telencephalic neurons that project to the optic tectum were observed in the caudal part of the pallium.

## Ray-Finned Fishes (Actinopterygians): Eversion of the Pallium

A developmental feature shared by actinopterygians is the "►eversion" of their telencephalon, in contrast to the evagination of the telencephalon of other vertebrates (Fig. 2). A result of eversion is that the lateral part of the actinopterygian pallium corresponds topologically to the medial pallium of other vertebrates and vice versa [2,5,6]. The degree of eversion varies from basal to ►advanced teleost groups, which can be appreciated by noting the insertion line of the ►choroid plexus.

*Cladistia* In *Polypterus* (Cladistia) the pallium is an externally curved C-shaped lamina, which is poorly organized, consisting of a thin sheet of neurons in a periventricular location and a wide superficial region of neuropil and fibers. The pallium has been subdivided into two primary regions, dorsomedial (P1) and dorsolateral (P2–P3). P1 receives strong olfactory input, whereas P2–P3 receives inputs mainly from the



**Evolution of the Pallium in Fishes. Figure 2**
Schematic drawings showing the eversion process of actinopterygian fishes (on the *left*) versus the evagination process of most vertebrates (on the *right*).

subpallium, and from the nucleus medianus of the posterior tubercle that in turn receives projections from the optic tectum [5]. Evoked potentials have been recorded in the dorsolateral pallium of *Polypterus* in response to light flashes, which supports the existence of visual projections to the pallium via the optic tectum and nucleus medianus.

*Chondrosteans* Studies on the pallium of sturgeons (chondrosteans) are scant. The pallium of the sturgeon *Acipenser* can be subdivided by using cytoarchitectonic criteria, acetylcholinesterase histochemistry and calretinin immunohistochemistry, into four subregions [7], the medial and the dorsal plus lateral zones, a central zone more laterally and the posterior zone caudally. The central zone contains scattered catecholaminergic (dopaminergic) cells and the pallium receives fairly abundant serotonergic fibers. The posterior zone is the main olfactory pallial region, whereas the fibers from the median nucleus of the posterior tubercle, dorsal and ventral thalamus reach mainly to the central zone, suggesting segregation between olfactory and ascending sensory inputs [7]. The medial and the dorsal plus lateral zones of the pallium are also interconnected.

*Teleosts* In teleosts, the most numerous vertebrates in number of species, the organization of the pallium is far more complex than in primitive actinopterygians and varies in the number and extension of subdivisions [5,8,9,10]. Studies on the pallium have been performed in numerous species, including catfishes (channel catfish), cyprinids (goldfish, carp, zebra fish), eel, trout and some percomorphs (*Sebastiscus*, *Poecilia*, *Lepomis, Oreochromis*). In most teleosts, the pallium (dorsal telencephalic area) can be subdivided cytoarchitectonically into medial (Dm), dorsal (Dd), lateral (Dl), posterior (Dp), and central (Dc) regions. Dm can be divided into subzones on the basis of cytoarchitecture, fiber connections and/or calretinin immunoreactivity. Distinction between Dd and Dl and of subregions within Dl is not clear in trout, but in many species Dd is well separated from Dl and Dl is clearly subdivided into dorsal (Dld), ventral (Dlv), and posterior (Dlp) subzones. Dc consists of large multipolar neurons and in many species consists of several differentiated groups. The pallium contains scattered GABAergic neurons and in some species cells immunoreactive to somatostatin and dopamine. Rich innervation by fibers immunoreactive to somatostatin, neuropeptide Y, thyrotropin releasing hormone, gonadotropin releasing hormone and cholecystokinin was reported in some pallial regions of teleosts.

Experimental studies in *Sebastiscus,* trout and goldfish indicate that the regions of the pallium are connected with a number of telencephalic and extratelencephalic centers [9,10]. Studies in trout [9] reveal that Dd + Dl receives afferents from the subpallium and different nuclei of the diencephalon and rhombencephalon and projects to Dc and diencephalic areas. Dm maintains reciprocal connections with the preglomerular nuclei and the mammillary body and also receives afferents from several diencephalic and rhombencephalic nuclei. Dc receives fibers mainly from Dd + Dld, the preoptic nucleus, the ▶preglomerular complex and the torus semicircularis and projects to several extratelencephalic centers. Dp is mainly connected with the olfactory bulbs, subpallium and diencephalic centers and projects to hypothalamic and posterior tubercular regions. Though some pallial connections of trout differ from those reported for *Sebastiscus* and goldfish, together these studies reveal a much richer connectivity of the pallium in teleosts than in other groups of fishes.

Behavioral studies after bilateral lesions of the Dm or Dlv in goldfish indicate that Dm is involved in emotional learning whereas Dlv is involved in spatial learning [6]. These teleost pallial zones are hence functionally similar to the mammalian amygdala and hippocampus respectively, suggesting a general homology with these regions.

## Lobe-Finned Fishes (Sarcopterygians)

Lobe-finned fishes are the sister-group of ray-finned fishes. They include a few "living fossil" species, the lungfishes (Dipnoa) and coelacanths (*Latimeria*: Crossopterygians), which diverged from lines leading to amphibians about 400 million years ago. Lungfishes are the sister group of tetrapods (land vertebrates).

*Lungfishes* The telencephalic hemispheres of the African lungfish (*Protopterus*) are tubular structures

organized around the paired telencephalic ventricles that show a surprising amphibian-like appearance in transverse sections [11]. The dorsal telencephalon (pallium) has been subdivided into lateral, dorsal and medial regions using cytological and immunohistochemical criteria. The dorsal and lateral pallia receive olfactory projections and together may correspond to the olfactory pallium (P1) of *Polypterus* (Cladistia). The medial pallium was found to consist of three immunohistochemically distinct subdivisions, dorsal, intermediate and ventral cell groups, though its correspondence to the medial pallium of land vertebrates is unclear. The dorsomedial telencephalon of *Protopterus* has been interpreted by some authors as a subpallial (septal) structure on the basis of its staining by acetylcholinesterase histochemistry. However, medial parts of the dorsal telencephalon of sturgeon, teleosts and frogs exhibit strong acetylcholinesterase activity, so it is probable that this marker is unreliable for distinguishing pallial from subpallial structures.

*Crossopterygians* The pallium of *Latimeria* is represented by a thickened, solid body covered by a membranous roof resembling the pallium of actinopterygians [5]. The pallium has been subdivided into dorsomedial, ventromedial and lateral on topographical grounds, but correspondence to pallial regions of other vertebrates is not known.

In conclusion, there is no direct line of pallial evolution "from fish to man." The earlier scenario of pallial evolution held that primitive piscine pallia were entirely dominated by secondary olfactory projections. An invasion of dorsal thalamic fibers into the pallium was thought to have occurred in tetrapods, thus giving rise to the sensory pallial areas characteristic of mammals. This scenario however, had to be rejected on the basis of modern comparative data [5].

# Evolution of the Posterior Tuberculum and Preglomerular Nuclear Complex

Philippe Vernier[1], Mario F. Wullimann[2]
[1]Institute of Neurobiology A. Fessard, CNRS, Gif sur Yvette Cedex, France
[2]Department of Biology II–Neurobiology Biocenter, Ludwig-Maximilians-University, Planegg-Martinsried, Germany

## Definition

The posterior tuberculum is part of the ventral area of the caudal diencephalon, arising from the basal plate of the neural tube. It comprises a periventricular area that contains an important contingent of dopaminergic neurons implicated in sensori-motor control. In actinopterygians (ray-finned fishes) and chondrichthyans (cartilaginous fishes), but not in tetrapods (amphibians, reptiles, birds, and mammals), the posterior tuberculum also includes laterally lying, migrated nuclei, which relay sensory inputs to the telencephalon.

## Characteristics

The posterior tuberculum was initially recognized on a cytoarchitectonic basis as a caudobasal division of the diencephalon posterior to the hypothalamus, but

anterior to the area of the medial longitudinal fascicle and named *area* or *pars tuberculi posterioris* by Harry Bergquist in the 1930s, who compared its extent and anatomical complexity in all representative anamniote (fishes and amphibians), and some amniote (reptiles and mammals) vertebrate species (reviewed in [1]). Subsequently, the posterior tuberculum was similarly presented as the basal part of the thalamus (but including also the most posterior part of hypothalamus, the mammillary bodies, plus, explicitely, the migrated preglomerular masses present in teleosts (modern bony fishes, which are the largest clade of the ray-finned fish radiation) [1,2]. In any case, the posterior tuberculum is clearly distinct from the two main alar plate (dorsal part of the neural tube)-derived thalamic divisions (dorsal and ventral) and includes large migrated cell groups that are best developed in teleost fishes. Thus, although the posterior tuberculum was traditionally well recognized in anamniotes, its definition in mammalian or avian brains remained elusive and the notion of a posterior tuberculum is rarely used in amniotes (Fig. 1).

More recently, neurochemical approaches revealed the presence of several populations of dopamine-synthesizing neurons in the periventricular region of the posterior tuberculum in fishes. This observation became the hallmark of the posterior tuberculum. Since many of these dopaminergic neurons project to the ventral telencephalon (striatal component) and likely also to the pallium in anamniotes, they have been proposed to be homologous to at least a part of the substantia nigra/ventral tegmental area of amniotes. The latter, however, are mostly localized in the ventral mesencephalon (reviewed in [3]; see discussion below). Accordingly, the notion of posterior tuberculum is often synonymous of the presence of dopamine neurons in this location in comparative neurosciences [2].

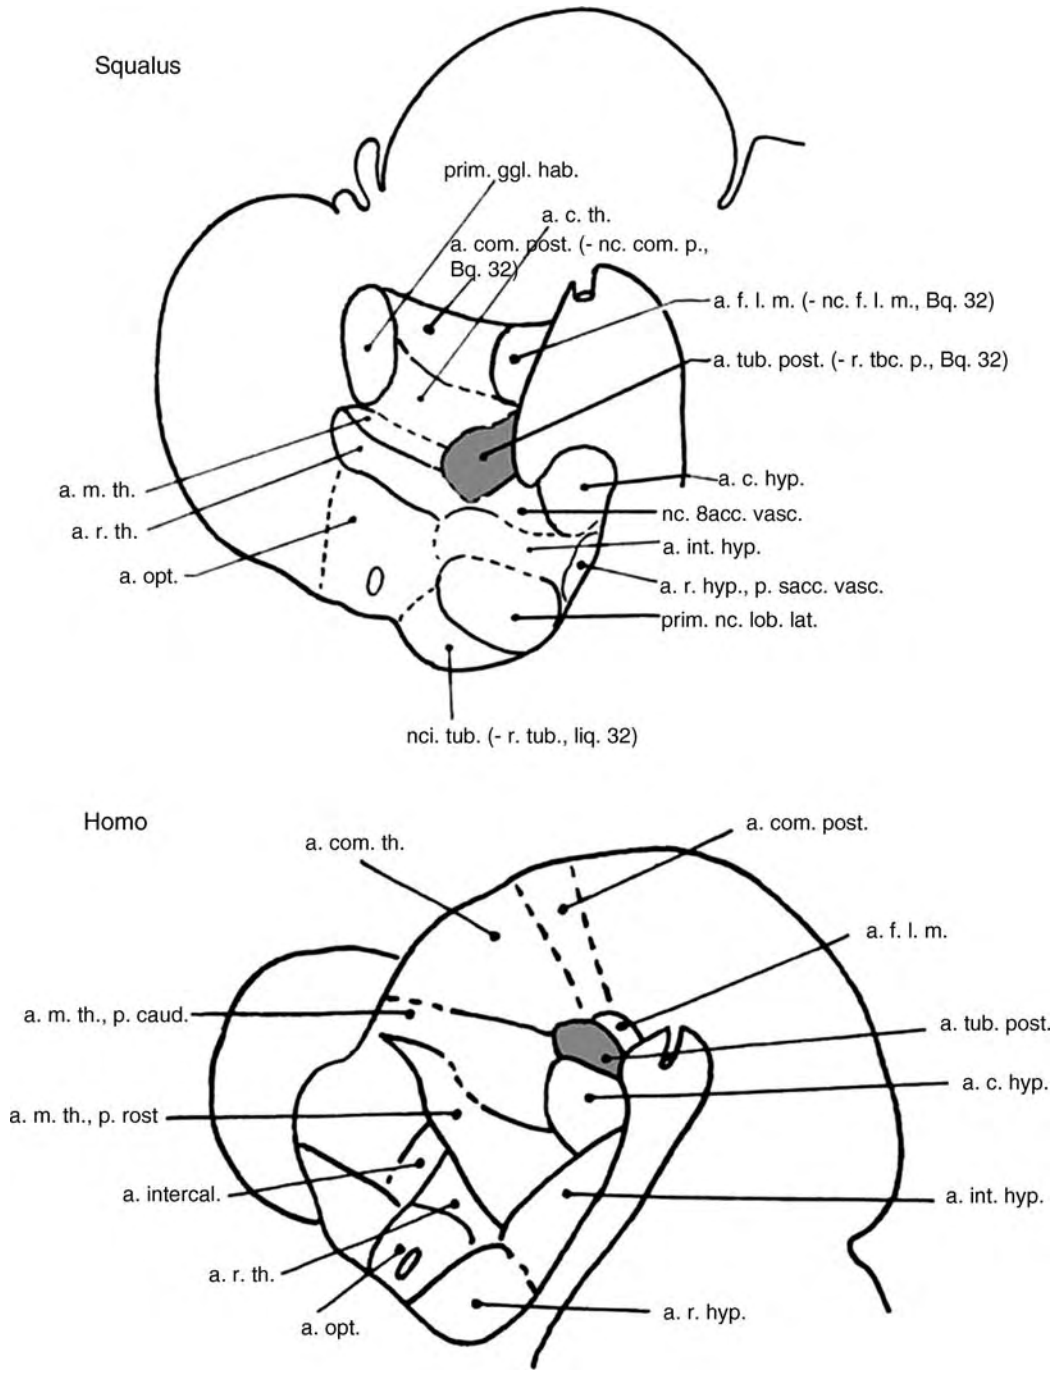
This view has significantly changed during the last twenty years, when the definition of the posterior tuberculum began to take into account the antero-posterior transverse divisions (neuromeres) and dorso-ventral divisions (longitudinal zones or plates) of the brain. These divisions are defined by precise morphogenetic cues, and form the Bauplan (basic design) of the neural tube [4,5]. A clear and more general definition (which extends to amniotes) of the posterior tuberculum can now be proposed on the basis of neuromeres [anteroposterior (rostrocaudal) neural segments] and longitudinal zones. It also helps to integrate embryological, genetic and anatomical observations [4,6]. In this neuromeric view of the neural tube, the posterior tuberculum is defined as the basal plate (ventral part of the neural tube) of prosomeres (forebrain segments) 1 through 3 (the posterior forebrain). These neuromeres share many developemental and anatomical characteristics with each other and with the midbrain tegmentum as well (Fig. 2; see below).

Although the posterior tuberculum has been characterized either on cytoarchitectonical, neurochemical or segmental criteria, these different views are not irreconcilable. In the following section, before examining specific aspects of the posterior tuberculum, we summarize comparative embryological data that shed light on the origin and definition of the posterior tuberculum.

## Developmental Origin of the Posterior Tuberculum

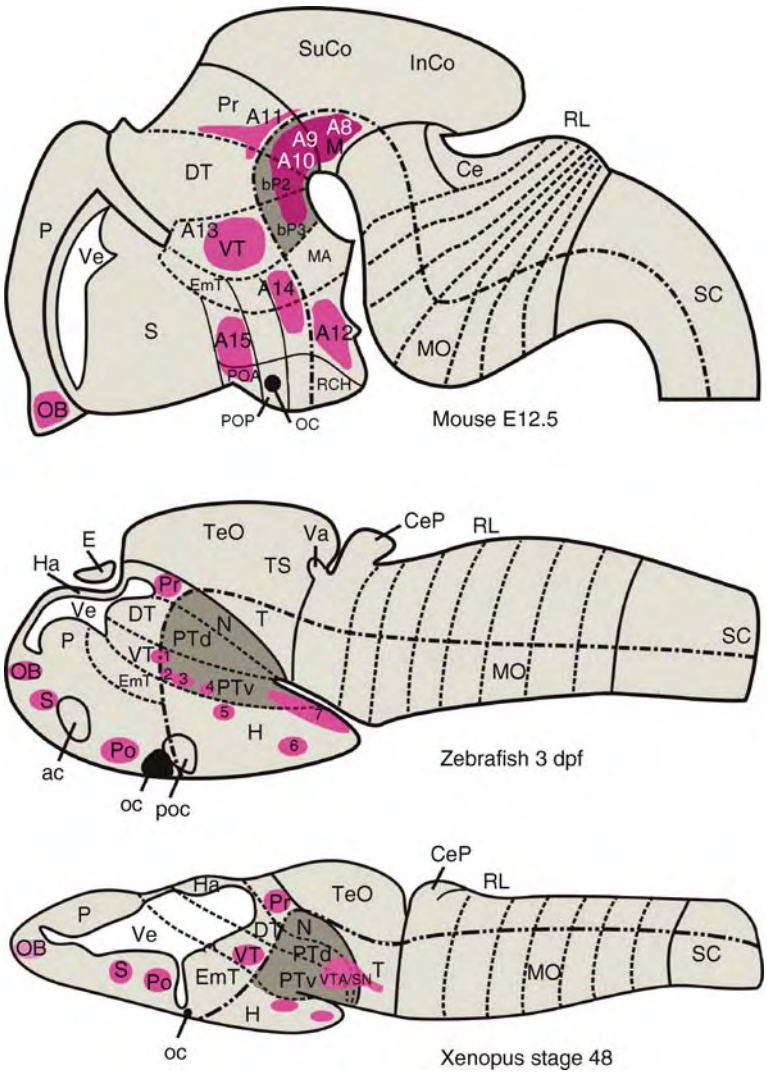
A general consensus asserts that the posterior tuberculum is derived from the basal plate of the posterior part of the diencephalic neural tube. The analyses of proliferation patterns and of expression territories of genes involved in defining (basal) longitudinal zones and in region-specific neurogenesis/differentiation broadly support this assumption. Islands of neural progenitor cells, radial glia and gene expression (the posterior limit of the *Otp* gene, or the anterior limit of *Neurogenin1/2* and *NeuroD* expression, for example) mark the limit between the posterior hypothalamus and the retromammillary area/Forel fields in amniotes, or the hypothalamus and ventral (=anterior) part of the posterior tuberculum in teleosts [4,5]. In the posterobasal diencephalon of zebrafish and rat, clusters of neurogenesis clearly identify three zones in front of the mesencephalic tegmentum, corresponding to the ventral components of p1 (synencephalon), of p2 (parencephalon posterius), and of p3 (parencephalon anterius) [4,5]. Thus, they are respectively ventral to (alar) pretectum, dorsal thalamus and ventral thalamus. In the early prosomeric literature, only the basal p2 is refered to as the posterior tuberculum [4,5], except in anamniotes where the basal components of p2 and p3 are named dorsal and ventral part of the posterior tuberculum [4]. It should be stressed that these prosomeric clusters of neurogenesis are in register at longitudinal levels with the neurogenic clusters of the (basal plate) midbrain tegmentum.

In addition to specific islands of neurogenesis, the basal plate of the caudal diencephalon is characterized by the expression of specific genes involved in different steps of regionalization of the neural tube, neurogenesis or neural differentiation. Several genes such as *Shh* or *axial/hfn3b/foxA2* are expressed in the basal plate portions of the three first prosomeres and the mesencephalon. Other genes have variable anteroposterior expression domains in different vertebrate groups. In mouse, *NeuroD* is abundant in the p2-p3 prosomeres, but at a much lower level in p1 and in the tegmentum mesencephali. *Neurogenin 1/2* is expressed in the three first prosomeres of the basal plate, with a sharp anterior limit towards the posterobasal hypothalamus, and extends into the basal mesencephalon, with a clear-cut posterior limit at the isthmus [10]. Thus, based on neurogenetic patterns and expression of proneural genes, the basal plate of the diencephalon in amniotes



**Evolution of the Posterior Tuberculum and Preglomerular Nuclear Complex. Figure 1** Modified from original figures in a paper by Bergquist, published in 1954, depicting sagittal brain drawings of an embryonic (a) shark (*Squalus acanthias*) and a (b) human embryo. The proposed posterior tuberculum is shaded in grey. Some abbreviations: *a. c. th*., area caudalis thalami; *a. f.l.m*., area fasciculi longitudinalis medialis; *a. tub. post*., area tuberculi posterioris.

and anamniotes can be divided into three different morphogenetic units, which share many commonalities in terms of genetic specification. This is particularly true for the expression of dopaminergic markers in this area. Indeed, the genes coding for tyrosine hydroxylase (TH), or for the dopamine transporter (DAT) are not only expressed in the mesencephalic basal plate but also in the three first prosomeres in mouse, rat, human,



**Evolution of the Posterior Tuberculum and Preglomerular Nuclear Complex. Figure 2** Schematics of brains from mouse (*Mus musculus*) at embryonic day 12,5 (a), zebrafish (*Danio rerio*) at 3 days postfertilization (b), and xenopus (*Xenopus lævis*) at embryonic stage 48 (c) in lateral views showing the distribution of the most important dopamine cell nuclei (in pink). The organization of the dopamine nuclei is interpreted with respect to the neuromeric divisions of the brain. The limits between the antero-posterior neuromeres are marked by interrupted lines, and alar plate (dorsal) and basal plate (ventral) are separated by a doted line, which also indicates the bent aneroposterior axis. For the mouse, the A8-A15 dopamine cell groups correspond to the nomenclature of [3,7]. For the zebrafish, the numbers of the groups of dopamine cells are taken from [8]. For the xenopus, dopamine nuclei are described according to [3,9]. Abbreviations: *ac*, anterior commissure; *bP*, basal part of the prosomere; *Ce*, cerebellum; *CeP*, cerebellar plate; *DT*, dorsal thalamus; *E*, epiphysis; *EmT*, eminentia thalami; *H*, hypothalamus; *Ha*, habenula; *InCo*, inferior colliculus; *MA*, mammillary hypothalamus; *MO*, medulla oblongata, *N*, area of the nucleus of the medial longitudinal fasicle; *OB*, olfactory bulb; *oc*, optic chiasm; *P*, pallium; *poc*, postoptic commissure; *Pr*, pretectum; *PTd*, dorsal posterior tuberculum; *PTv*, ventral posterior tuberculum; *Po*, preoptic area; *POA*, anterior preoptic area; *Pr*, pretectum; *RCH*, retrochiasmatic hypothalamus; *RL*, rhombic lip; *S*, subpallium; *SC*, spinal cord; *SuCo*, superior colliculus; *T*, tegmentum mesencephali; *TeO*, tectum opticum; *Va*, valvula cerebelli; *Ve*, brain ventricle; *VT*, ventral thalamus; *VTA/S*, ventral tegmental area/substantia nigra.

chicken and amphibians [6,7,9,11]. In contrast, the same genes in teleost fishes are expressed in the basal part of p3 only [8,12,13]. Thus, the differentiation of dopaminergic cells is variably occurring in different vertebrates from mesencephalon to posterior tuberculum up to p3. A parsimonious and simple definition of the posterior tuberculum would be that it is the basal plate of the three first prosomeres (Fig. 2).

In teleost fishes, the posterior tuberculum was proposed to include the preglomerular complex and also the lateral torus, which were interpreted as having migrated toward a lateral position within the posterior tuberculum [1,2] and, thus, being derivatives of the posterior tuberculum. More recent developmental data reveal that the early preglomerular complex (named M2; [4]) undergoes ongoing neurogenesis, with proliferative cells likely originating from the periventricular posterior tuberculum. In contrast, the analysis of the concommitant expression of specific developmental genes (*Pax6, Dlx2, NeuroD*) suggests that the preglomerular complex may derive, at least in part, from the alar plate of the diencephalon, and not from the basal plate [4,14]. Thus, the preglomerular complex and the dorsal thalamus in amniotes, which are the major diencephalic sensory relay centers to the pallium in teleosts and amniotes, respectively, may have partly the same embryological origin. If this observation will be further supported by precise fate studies, it will render the organization of diencephalic sensory systems more conserved across vertebrates than originally thought.

## The Periventricular Nuclei and Dopaminergic Neurons of the Posterior Tuberculum

In anamniotes, the posterior tuberculum contains conspicuous neuronal populations synthesizing the modulatory neurotransmitter dopamine. Strong evidence supports that these dopamine cell populations are homologous to the ventral tegmental area/substantia nigra of amniotes. This contention is based on developmental, hodological and neurochemical characters. The differentiation of these neurons depends on a well-conserved gene network induced by the ventral signals Nodal and Shh and by Fgf8 produced at the midbrain-hindbrain boundary. The network comprises genes activated in a sequential manner from committed progenitors to differentiated neurons, namely *Ash1*, *Ngn1/2* and *Lmx1a/b*, then *FoxA2*, *Nurr1/NR4A2*, and finally *En1/2* and *Pitx3*, these latter being required for the maintenance of the phenotype throughout adulthood.

The dopamine neurons of the posterior tuberculum project anteriorly via the medial forebrain bundle to the telencephalon, mostly to the striatum, but also to the pallium, with large variation across the various vertebrate clades. In addition, the dopamine neurons of the posterior tuberculum exhibit, as those of the ventral tegmental area/substantia nigra (VTA/SN), a specific phenotype defined by the presence of a combination of molecules involved in dopamine neurotransmission [7].

These dopamine-synthesizing neurons express TH, the limiting enzyme of catecholamine synthesis, and aromatic amino acid decarboxylase, which transforms L-DOPA into dopamine. They also contain the vesicular monoamine transporter VMAT2 and the membrane dopamine transporter DAT, required to respectively store dopamine into vesicles and to clear dopamine from the extracellular space. Finally, monoamine oxydase, the main degrading enzyme, and the dopamine D2 receptor are also found in a conserved manner in amniotes as well as in teleost fishes [3].

### Jawless Fishes

In agnathans (or cyclostomes, the jawless vertebrates/craniates), the petromyzontids (lampreys) have TH-positive, dopamine-containing cells in the nucleus tuberculi posterioris, which projects anteriorly, mostly to the subpallium (striatum/septum) and occasionally to the pallium [15]. In myxinoids (pacific hagfish), TH-positive neurons are located in the lateral nucleus of the posterior tuberculum, which emits long processes toward the basal telencephalon [16].

### Jawed Fishes

In chondrichthyans (the cartilaginous fishes), the situation differs between holocephalians (chimeras) and elasmobranchs (sharks, skates, and rays). In at least some sharks, two dopamine cell populations lie in the midbrain tegmentum, at the level of the third cranial nerve. The first one, located medially and anterior to the interpeduncular nucleus, is called ventral tegmental area, and the second, scattered around the red nucleus, is named substantia nigra. Both populations display a clear anterior extension into the posterior tuberculum. A very similar situation has been described in rays, with two mesencephalic dopamine cell components, plus posterior tubercular components, and this is probably true for most elasmobranchs. However, in holocephalians, dopamine cells are found in the posterior tuberculum, but not more caudally in the mesencephalic tegmentum, as in agnathans and teleost fishes [17].

### Actinopterygians

In actinopterygians (the large radiation of ray-finned fishes that include the teleost fishes), the periventricular area of the posterior tuberculum exhibits three identifiable components: the nucleus of the posterior tuberculum (TPp), the paraventricular organ (PVO), mainly ependymal cells, which, in anamniotes, exhibit a specific differentiation in continuity with the hypothalamic periventricular wall, and a third nucleus made of larger cells, the nucleus tuberis posterior or posterior tuberal nucleus. These dopaminergic neurons are all housed in the basal third prosomere and do not extend more caudally. It is generally believed that dopaminergic neurons are not present in the mesencephalon, although some evidence exists for the presence of dopamine-containing cells in the tegmentum mesencephali of *Lepisosteus*, a non-teleost actinopterygian fishes (reviewed in [3]). With this possible exception in mind, ray-finned fishes show TH cell groups in

the posterior tuberculum only, where the neurons of the adult ascending dopaminergic system are located. In the bichir, a most basal actinopterygian fish, TH-positive cells have been described in the TPp, and were proposed to project to the dorsal nucleus of the subpallium, a probable homologue of the amniote striatum [3,8]. In teleosts, only TH-positive (small and large) cells of the TPp give rise to ascending projections toward the subpallial area, as demonstrated in the adult zebrafish [8]. In another teleost, the medaka, these posterior tubercular cells express the *Nurr1/NR4A2* gene, which is mandatory for the development and maintenance of mammalian basal midbrain dopaminergic cells [13]. This further substantiates the recognition of the teleostean posterior tubercular dopamine cells as homologous to the VTA/SN of other vertebrates (Fig. 2).

The other populations of TH-positive neurons in teleosts, classified according to their shapes and projections, are located either in liquor-contacting cells of the PVO (or of the more anteriorly located hypothalamus), or in the posterior tuberal nucleus [8]. The cell bodies of dopamine neurons projecting to the spinal cord are also located in the posterior tuberculum. Although it may differ for details, this picture prevails in all the teleosts studied so far (Fig. 2; see [3]).

In lungfishes, which are members of the sarcopterygian radiation, or lobe-finned fishes, that ancestrally gave rise to tetrapods, there is a significant population of TH-positive cells in the mesencephalic tegmentum, comparable to the substantia nigra, which projects to the lateral and medial pallium [2,3].

### *Tetrapods*

In amphibians, as in most fishes, a well-developed posterior tuberculum exists, which hosts dopamine-synthesizing neurons that give rise to ascending projections mostly to the striatum and scarcely to the pallium. This cell group occupies the dorsomedial and ventrolateral portions of the posterior tuberculum, within the three first prosomeres. It extends caudally into the mesencephalon but much less than in amniotes. In all the amphibian groups, the dopaminergic neurons cannot be separated into distinct VTA and substantia nigra populations (Fig. 2). Only in *Siren*, a urodele, TH-positive cells appear much more numerous in the posterior tuberculum than in the tegmentum mesencephali (reviewed in [9]).

In reptiles and birds, dopamine-synthesizing neurons are very numerous in the basal mesencephalon, but also extend into the basal plate of the three first prosomeres. In birds, the VTA lies rostral to the interpeduncular nucleus and medial to the red nucleus. The SN includes cells lateral and posterior to the VTA, and another group similar to the retrorubral population of mammals can be recognized in chick and pigeon. This finding led to a classification as A10, A9, A8 respectively, as in mammals (see below; reviewed in [3]). In lizards, snakes, and turtles, the dopamine neurons of VTA/SN and retrorubral field constitute the largest population of dopamine neurons in the brain [18]. In all these species, TH-positive cells of the mesencephalon extend into the basal diencephalon, homologous to the posterior tuberculum of anamniotes, at least up to the second prosomere (the posterior parencephalon) [3,18].

In mammals, the dopamine neurons of the diencephalo-mesencephalic area have been classified into three groups by Dahlström and Fuxe with histochemical methods (see [3,7]). The retrorubral component (A8) is exclusively located in the mesencephalon, whereas SN (A9) and VTA (A10) extend in a respective lateral and medial position from the mesencephalon to the three first prosomeres [7,11]. Neurons from the A8-A10 area give rise to three main projections pathways, namely meso-striatal, meso-cortical and meso-limbic (Fig. 2). There is no clear distinction of the projections arising from the VTA or the SN, which both contribute to the innervation of striatal or pallial areas, with several species-specific features. (see [7] for review). They also innervate pallidal areas, as well as other nuclei of the basal telencephalon and diencephalon. Dopamine neurons of the VTA/SN are particularly numerous in human, in a proportion that exceeds the regular allometry of brain nuclei. Their degeneration is one of the hallmark of Parkinson's disease and the cause of its most disabling symptoms [3,7].

## The Migrated Nuclei of the Posterior Tuberculum

The posterior tuberculum of ray-finned fishes and cartilaginous fishes exhibits migrated sensory nuclei, the nature and origin of which has been problematic for decades. Difficulty in analyzing these nuclei stems from their variation in size and location among species and from highly confusing terminology. It is now well accepted that these nuclei collectively form the preglomerular nuclear complex in teleosts. These neurons relay sensory information to the telencephalon, mostly from the lateral line and gustatory systems. The lateral torus also has been included into the migrated nuclei of the teleostean posterior tuberculum. A similar situation exists in cartilaginous fishes (see below). These pathways through the migrated nuclei of the posterior tuberculum are similar to the sensory pathways through the dorsal thalamic nuclei of amniotes. However, a direct homology to any known dorsal thalamic nuclei in tetrapods is still difficult to establish, mostly because of the unresolved developmental origin (Fig. 3).

### *Jawless Fishes*

In hagfishes, but apparently not in lampreys, the posterior tuberculum contains a migrated nucleus [16],

the lateral nucleus of the posterior tuberculum which does project to the pallium and, thus, it bears some resemblance to migrated nuclei of the posterior tuberculum of teleosts/chondrichthyans.

### *Jawed Fishes*

In cartilaginous fishes (elasmobranchs), a posterior lateral and central thalamic nucleus, located lateral to the periventricular part of the posterior tuberculum, relay electrosensory and mechanosensory input, respectively, from the lateral lemniscal system to the telencephalon. This contrasts with the other sensory systems, which make synapses in the dorsal thalamus, for relay to the telencephalon [6].

In teleosts, several migrated (preglomerular) nuclei are present in the lateral posterior tuberculum, and they display a large anatomical complexity and interspecific variability. These nuclei provide the major diencephalic input to the pallial zones of the area dorsalis telencephali. Specific sensory preglomerular nuclei exist for the auditory, lateral line mechanosensory, lateral line electrosensory (when present), and the gustatory systems, and for components of the somatosensory and visual systems (Fig. 3); [1,2,6,12,19]).

Ascending inputs from the mechanosensory lateral line reach the torus semicircularis from where they are relayed to the (lateral) preglomerular region. The latter projects in turn both to medial and lateral zones of the teleostean pallium. The electrosensory system of gymnotids and silurids is more complex, with a projection going from the torus semicircularis to a nucleus electrosensorius in the pretectum before reaching the preglomerular complex, from where this input then reaches the pallium. In electrosensory osteoglossomorphs (mormyrids), electrosensation and mechanosensation exhibit significantly different ascending pathways to the preglomerular complex. Electrosensory efferents from the torus semicircularis project to the dorsal part of the preglomerular complex. This area also receives inputs from the dorsal pallium and optic tectum and projects to the cerebellum. Mechanosensory inputs, instead, project from the torus semicircularis to a ventral part of the preglomerular complex, which is probably homologous to the lateral preglomerular nucleus in non-electroreceptive teleosts. Accordingly, this preglomerular nucleus then projects to the pallium. In contrast, acoustic pathways relay mostly through the dorsal thalamus (from where they reach the subpallium), but also in the anterior and lateral nuclei of the preglomerular complex, at least in some teleosts. Auditory inputs from the latter reach the medial and lateral zones of the dorsal pallium.

Gustatory pathways are rather diverse, with a varying degree of complexity among teleosts. Sometimes, the medullary secondary gustatory nucleus projects to preglomerular and hypothalamic nuclei for direct relay to the pallium (mostly the medial zone of the dorsal pallium). In some species, such as goldfish, gustatory diencephalo-telecenphalic pathways are more indirect but also involve the preglomerular area.

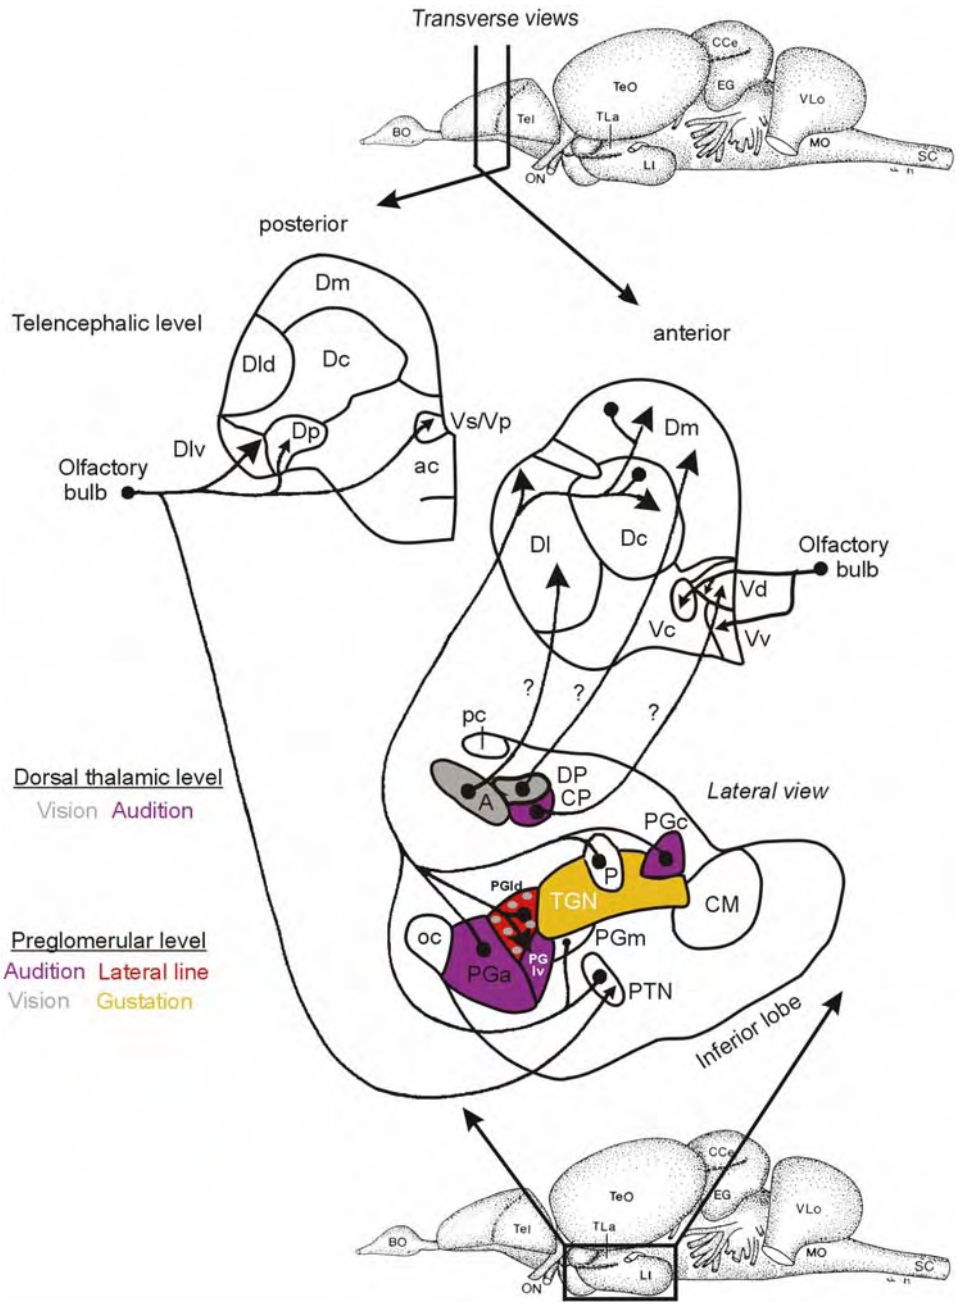
Visual pathways relay partially (tectofugal visual information) through the preglomerular complex in some teleosts. Most visual inputs reach the telencephalon via a direct retino-thalamic and an indirect retino-tecto-thalamic pathway. However, in contrast to amniotes, the major visual telencephalic target in teleosts is the subpallium rather than the pallium.

In certain teleost species, a few other migrated nuclei of the posterior tuberculum are found in the vicinity of the preglomerular complex, the so-called caudal "mammillary body" (although probably not homologous to the mammillary area of mammals), a nucleus subglomerulosus, and a lateral (=posterior) thalamic nucleus.

To conclude, similar to cartilaginous fishes, the predominant diencephalic targets of teleostean ascending sensory projections are in the preglomerular region located in the lateral periphery of the posterior tuberculum rather than in the dorsal thalamus as in amniotes [6,12,19]. Although the homology of sensory pathways between teleosts and tetrapods is not certain in each single case, the functional similarities between the teleostean preglomerular region and the amniote dorsal thalamus are striking: both make up a large proportion of the diencephalon, are subdivided into many nuclei associated with specific sensory systems, and, further, most of them have reciprocal connections with the pallium (Fig. 3).

## Evolutionary Variations of the Posterior Tuberculum

The discussion of the evolution of characteristics of the posterior tuberculum is necessarily based on our current knowledge of the phylogenetic relationships of vertebrates (craniates). (For review see [2,6]). Current embryological data, mostly from teleosts (zebrafish and medaka), amphibians (*Xenopus*) and mammals (mouse and human) support the hypothesis that the posterior tuberculum corresponds to the basal component of the three first (caudal) prosomeres. In addition, in jawed vertebrates, commonalities in neuronal specification exist between the dopaminergic neurons of the posterior tuberculum and of the mesencephalic VTA/SN, which can be considered as derivatives of the same embryological field. Since only posterior tubercular dopaminergic neurons are present in jawless vertebrates/craniates, and only the full extent of dopaminergic neurons from the three first prosomeres to the posterior limit of midbrain tegmentum is observed in amniotes, it could be hypothesized that the localization of the dopaminergic neurons in the posterior tuberculum is the ancestral situation and



**Evolution of the Posterior Tuberculum and Preglomerular Nuclear Complex. Figure 3** Sensory circuits in the brain of the goldfish (*Carassius auratus*). Arrows between preglomerular complex (PG) and pallium (Dl, Dc, Dm) illustrate mechanosensory lateral line inputs (red), auditory inputs, (violet), and visual inputs (gray) originating from the preglomerular complex and the thalamus (audition/vision, which more likely terminate in the subpallium). TGN, P and PGm are gustatory-involved nuclei. Pallial input from PGl is to Dl and Dm, while PGa, PGm and PGc project only to Dm. Exact pallial input terminations from P as well as from PTN, remain tentative. Abbreviations: *A*, anterior nucleus of dorsal thalamus; *ac*, anterior commissure; *BO*, olfactory bub; *CCe*, corpus cerebelli; *CM*, corpus mamillare; *CP*, central posterior nucleus of dorsal thalamus; *Dc, l, m, p*, area dorsalis telencephali, central, lateral, medial, posterior zones; *DP*, dorsal posterior nucleus of dorsal thalamus; *EG*, eminentia granularis; *LI*, lobus inferior; *pc*, posterior commissure; *MO*, medulla oblongata; *oc*, optic chiasm; *ON*, optic nerve; *P*, posterior thalamic nucleus; *PGa, c, l, m*, preglomerular nucleus, anterior, caudal, lateral, medial nucleus; *PTN*, posterior tuberal nucleus; *SC*, spinal cord; *Tel*, telencephalon; *TeO*, tectum opticum; *TGN*, tertiary gustatory nucleus; *TLa*, torus lateralis; *Vc, d, p, s, v*, area ventralis telencephali, centralis, dorsalis, postcommissural, supracommissural, ventral nucleus. Redrawn from [12], including new data from [19].

that, subsequently, associated with the allometric growth of the forebrain (pallium and subpallium), the diencephalo-mesencephalic dopaminergic neurons become more numerous and populate the whole basal plate from p3 to the isthmus. However, since dopaminergic neurons also are present in the midbrain tegmentum of elasmobranchs, lungfishes, and amphibians, in addition to amniotes, it can neither be said that the invasion of the mesencephalon by dopaminergic cells is correlated to the emergence of amniotes nor to the acquisition of terrestrial life. Thus, the multisegmental origin of VTA/SN dopaminergic neurons is a plesiomorphy (evolutionarily basal condition) of jawed vertebrates, and the numerous variations in the details of their connections among species is likely to reflect strong functional adaptation to different life styles.

Regarding the presence and origin of the migrated preglomerular complex in teleosts, it is probably ancestrally present in jawed vertebrates and perhaps in all vertebrates/craniates, based on hodological and embryological evidences [6,12,20]. A comparison of cartilaginous and bony fishes suggests that a dual innervation of the diencephalon (dorsal thalamus/posterior tubercular region) by at least some ascending sensory systems may be the ancestral situation for gnathostomes. Interestingly, in both cartilaginous and bony fishes, hair cell sensory organs of the cochlea and the labyrinth (audition, equilibration) project to the dorsal thalamus. In contrast, the other hair cell sensory organs (mechanoreception, electroreception) project to the posterior tubercular region. Thus, dual sensory pathways may be a gnathostome plesiomorphy. If so, the evolutionary loss of the latter sensory systems in amniotes may directly explain the dominance of the dorsal thalamus as diencephalic sensory relay region in amniotes. For years, the posterior tuberculum was viewed essentially as a fish peculiarity. Rejuvenation of this concept by developmental biology and its extension to the whole craniate/vertebrate phylum promises to shed new light on the important neuronal structures present in this hinge region of the brain.

# Evolution of the Reticular Formation

Paul R. Manger
School of Anatomical Sciences, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, Republic of South Africa

## Definition

The reticular formation encompasses a wide variety of neurons found predominately in the adult derivative of the basal plate of the brainstem but extending to the forebrain. It is involved in the regulation, control and coordination of a variety of neural and neuromuscular processes.

## Characteristics

### Organization of the Reticular Formation

The term reticular formation is used to encompass a large expanse of neurons scattered throughout the central nervous system, from the spinal cord to the forebrain. This distribution makes the definition and delineation of this neural system a difficult task, especially across species, as traditionally, the majority of studies of this formation have been restricted to mammals, with differing terminology used across the various vertebrate classes and no clear homology of this formation in the invertebrate brain. Within the brainstem (the midbrain, pons and medulla oblongata), the reticular formation can be divided into three major rostro-caudally oriented cell columns–the raphe column located either side of the midline, the magnocellular/gigantocellular column located just lateral to the raphe column and the parvocellular column occupying the most lateral position. These columns can be subdivided according to cell size and type and their connectivity with other parts of the brain. The parvocellular or small-celled column tends to be the region that receives axons from sensory systems of the brainstem and spinal cord. The magnocellular/gigantocellular or large-celled column tends to be the region creating the output of the reticular formation, sending axons to the motor neurons of the spinal cord and brainstem or to higher levels of the brain.

The neurons of the reticular formation are mostly characterized by having long straight dendrites (of the ►isodendritic type) and axons that project, often over a large distance in the brain, to other neuronal groups. This neuronal morphology allows the reticular formation to interact with axons traversing the brainstem, whether these are ascending axons from the spinal cord or cranial nerves or are descending axons from more dorsal portions of the brain. The long axons of these neurons often collateralize significantly (except in the lamprey), innervating distant portions of the brain as well as other subdivisions of the reticular formation to allow the subdivisions to act in concert.

A variety of nomenclatures have been applied to the reticular formation and numerous subdivisions either included or excluded from this formation by different authors (see Butler and Hodos [1] for a conciliation of this terminology). Within the diencephalon lies the most rostral portion of the reticular formation, this being the reticular nucleus of the dorsal thalamus. A reticular nucleus associated with the dorsal thalamus (or something similar) appears to be present in most vertebrate classes. Within the diencephalon and brainstem there are many subdivisions of the reticular formation that have been identified across many vertebrate species using immunohistochemical techniques, due to the specific neurotransmitters produced (including noradrenalin, adrenalin, serotonin, acetylcholine, GABA and several others). These neuronal groups are known to be involved in the sleep-wake cycle (see below) and may be the easiest parts with which to determine the evolutionary trajectory of the reticular formation (see below). Many of the immunohistochemically identifiable subdivisions project great distances over the brain and spinal cord. Within the midbrain of most vertebrate species two subdivisions of the reticular formation, the nuclei cuneiformis and subcuneiformis (or mesencephalic division in less complex brains) are commonly found lying dorsal to the substantia nigra within the midbrain tegmentum. Within the pons, the two major components of the reticular formation regularly identified are the nucleus pontis oralis, which lies anterior to the second subdivision, the nucleus pontis caudalis. Neuronal groups within the pons that produce specific neurotransmitters include the noradrenergic locus coeruleus complex, the serotonergic dorsal raphe and the cholinergic pedunculopontine and lateral dorsal tegmental nuclei. Within the medulla oblongata, the three columns of the reticular formation are clearest, with the midline serotonergic raphe nuclei, various subdivisions of the gigantocellular column and the subdivisions of the parvocellular column apparent. These subdivisions are accompanied by the adrenergic neurons of the area postrema. The number and location of the subdivisions of the medullary reticular formation differ across vertebrate species, but there is a great deal of conservation in particular nuclei, which can be recognized across classes.

## Functional Aspects of the Reticular Formation

The functional organization of the reticular formation can be appreciated based on the resultant effects of its two major sets of efferent pathways – the "ascending" pathways that project to the diencephalon and telencephalon and the "descending" pathways that project to the cranial nerve motor nuclei and spinal cord, the ►reticulobulbar and ►reticulospinal pathways respectively. The descending pathways are mainly involved in the regulation, coordination and organization of movement, as well as in the maintenance of muscle tone. Thus the descending pathways act in concert with those parts of the brain that enable rhythmic pattern generation of movements such as respiration, swimming, walking, flying, chewing and, in electric fish, the repetitive discharge of the electric organs. The ascending pathways are involved in processes such as the sleep-wake cycle [and the various phases of this cycle such as arousal, slow wave sleep (SWS) and rapid eye movement sleep (REM)] and attention (the ability to focus upon a particular stimulus while filtering out input from other stimuli). An intriguing example of the differing end effects (or post-synaptic actions) comes from studies of the serotonergic raphe system of the reticular formation. The pontine serotonergic neurons mainly project upon the forebrain and result in inhibition of the post-synaptic neurons (during wake), while the medullary serotonergic neurons mainly project upon the spinal cord and result in excitation of the post-synaptic neurons (the loss of this excitation in REM sleep is partly responsible for the lack of muscle tone in this state). While the majority of research on reticular formation function has been undertaken in mammals, there is good evidence that this system has similar functional roles in non-mammalian amniotes (bird and reptiles) and anamniotes (amphibians and fish), as well as possibly in invertebrates (although, for example, the serotonergic component may be represented by a single neuron). Perhaps the simplest way to encompass the vast variety of functions in which the reticular formation is involved is to consider that the descending pathways are involved in the global coordination and tone of the activities of the musculoskeletal system and the ascending pathways are involved in the global coordination and tone of the neural activity of the forebrain.

The functional roles of the reticular formation in vertebrates were summarized [1] to include:

- the coordination of movements of the head and body by facilitation and inhibition of both voluntary and reflex movements
- alteration of respiration and blood pressure
- serving as a "gate" to block out sensory inputs, including pain
- psychological processes such as arousal and attention
- sleep and dreaming
- regulation of muscle tone

## Immunohistochemically Identifiable Subdivisions and Evolution of the Reticular Formation

In terms of understanding the evolution of the reticular formation, perhaps the parts of this formation that have been studied with the most clarity across species are the immunohistochemically identifiable portions, three of which are the catecholaminergic [2], cholinergic [3] and serotonergic systems [4]. These studies have, for the most part, concentrated on differences between classes of vertebrates and found an increased complexity, in terms of numbers of homologous subdivisions of these systems, increased neuronal numbers and increased branching patterns associated with larger, and ostensibly more complex brains. These studies, however, provide a somewhat limited view of brain evolution, have restricted the analysis of the data to a gradualistic, or neo-Darwinian approach (►gradualistic evolution) and have not forwarded any specific hypotheses regarding the evolution of these systems and of the reticular formation in general. More recently Manger [5], based on earlier observations in various mammals [6,7,8,9,10], proposed that changes in the complexity (the number of homologous nuclei) of these immunohistochemically identifiable neuronal systems might only occur at the genesis of a new mammalian order (►constrained evolution). For example, in both species of monotremes studied, 52 directly homologous subdivisions (and no others) of these systems were found, despite a 3-fold difference in brain size, an over 50 million year divergence and extremely different phenotypes and life histories. It has also been noted that the locus coeruleus of the 1,500 g bottlenose dolphin brain contains fewer subdivisions than the 1 g mouse brain. As a last example, the extreme regression of the visual system in the African common molerat does not lead to a reduction in the number of components of these systems, even those related to the visual system, in comparison to normally sighted rodents [11]. These observations indicate that it is highly likely that at the level of neural organization termed the systems level there may be understandable patterns in the evolution of the reticular formation. This pattern is rather conservative as it appears that changes at the systems level of organization of the reticular formation may only occur during (or be constrained to) the evolutionary events leading to the formation of a new order and not at other times. There are yet to be any substantive evolutionary observations made at other levels of organization of the reticular system; however, it does appear that this system may be one of the most conservative parts of the brain in terms of evolutionary change, at least in vertebrates.

## The Reticular Formation and the Evolution of Sleep and Dreaming

As mentioned above, the reticular formation plays a major role in the regulation and timing of the sleep-wake cycle, including changes in the level of alertness or drowsiness when awake, changes during sleep between the different stages of slow wave sleep (SWS) and changes between slow wave sleep and rapid eye movement sleep (REM). Many of the components of the reticular formation involved in the control of the sleep-wake cycle have been identified immunohistochemically. These components comprise two major neuronal groupings located in the basal forebrain plus hypothalamus (GABAergic, cholinergic, hypocretinergic and histaminergic neurons) and the pontine tegmentum (GABAergic, glutamatergic, noradrenergic, cholinergic and serotonergic neurons) [12]. Their connections include local ones within and between the individual components as well as those with other parts of the brain. How these components relate to the evolution of ►sleep phenomenology is not yet fully understood, however.

Sleep is a vital function for all vertebrates and sleep-like states have been documented for invertebrates, with a sleep-like state being recently reported for jellyfish [13]. There are differences in the way the various vertebrates sleep, particularly in the clear occurrence of REM sleep in mammals and birds but not in reptiles, amphibians or fish. There is also a conservative aspect to sleep evolution, with SWS being found in all classes of vertebrates. One interesting example of sleep evolution is derived from studies of the monotremes, where it has been shown that the forebrain shows classical signs of SWS while the brainstem and body exhibit signs of REM sleep [14,15,16]. These observations fit well with the lack of cholinergic neurons in the anterior hypothalamus of the monotremes [6] and implicate the cholinergic system in the global coordination of brain state, this coordination being split into two parts in the monotremes. This is interesting in a further light regarding the evolution of dreaming. Dreaming is for the most part associated with the desynchronized activity of the forebrain during REM sleep. During SWS dreaming also occurs, but these dreams are very simple dreams and quite different from the intense dreams of REM sleep. As said above, REM sleep does not occur in reptiles and in birds it occurs only in short bursts, but in mammals REM can last for periods of up to 30 mins. In the monotremes, REM sleep occurs in the brainstem but not the forebrain. So do the monotremes dreams? It is likely that they have dreams similar to those that occur in SWS in other mammals (including humans) but that they don't have the intense dreams associated with REM in humans and other mammals. Thus, it might be concluded that dreaming, as a memorable cognitive event, did not evolve until after the monotreme divergence from the remainder of the mammals, and this may be linked to an altered anatomy of the reticular formation in the monotremes.

# Evolution of the Somatosensory System in Mammals

Jon H. Kaas
Department of Psychology, Vanderbilt University, Nashville, TN, USA

## Definition

The somatosensory system comprises multiple ascending pathways that relay information about touch, position sense, nociceptive stimuli (pain) and temperature to various sites in the brainstem, diencephalon and pallium.

## Characteristics

Across vertebrates, the somatosensory system is most elaborated in amniotes, particularly mammals. In addition, the system is variable in complexity, details of organization and function across mammalian taxa. Some of these complexities are discussed here, but the focus is on the basic organization of the mammalian somatosensory system (Fig. 1).

The components of the system that are common to all or most mammals are those that were probably present in the first mammals.

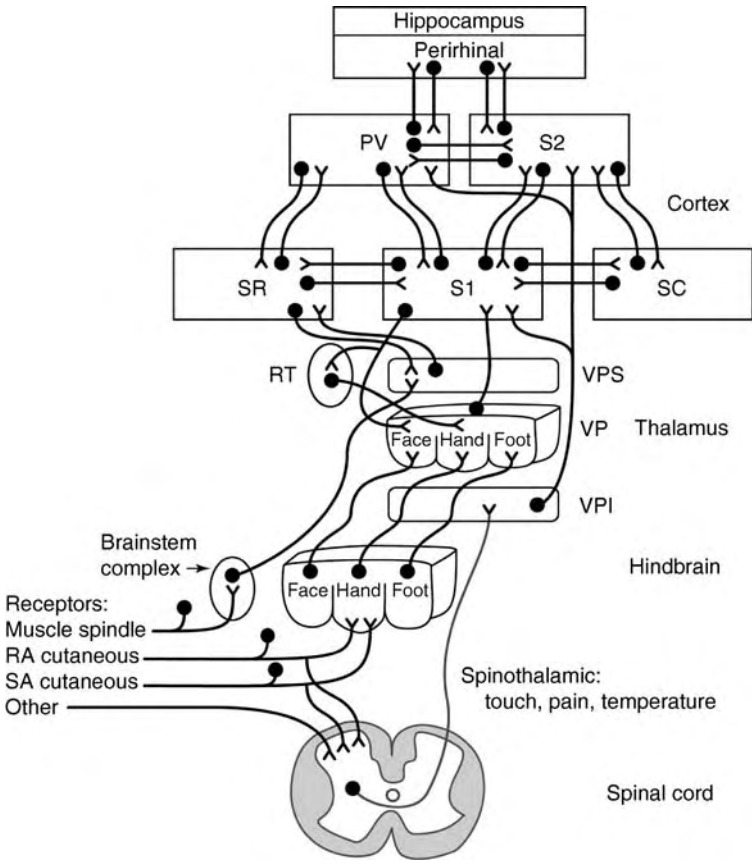
### Somatosensory Receptors

The somatosensory system of mammals is activated by receptors in the skin and in deeper tissues. Most of these receptor types were most likely retained from stem amniote ancestors, including rapidly adapting (RA) and slowly adapting (SA) cutaneous mechanoreceptors mediating touch, muscle spindle and joint receptors for position sense and receptors sensitive to noxious stimuli (pain) and temperature [1]. The interesting difference is that mammals are characterized by having hair and hairs can act as levers so that moving them distorts and activates touch mechanoreceptors in the skin. To take advantage of this characteristic, mammals evolved various types of sensory hairs, often on the face, but also on other parts of the body, to increase sensitivity and to detect objects slightly distant from the body. Thus, cats use mystacial vibrissa to sense the position of prey and guide killing bites and rats use their vibrissa to make a wide range of discriminations of objects near the body. Bats use sensory hairs to guide flight and seals use vibrissa movements due to water flow to find prey. Specialization of receptors has occurred in the non-hairy glabrous skin of mammals as well. Most notably, the glabrous skin of the nose of the star-nosed mole is packed with over 25,000 specialized receptor arrays called Eimer's organs [2]. The aquatic monotreme mammal, the platypus, has evolved electroreceptors in its bill that activate parallel pathways in the somatosensory system [3] and such receptors are also present, although to a lesser extent, on the snout of the other monotreme taxon, the echidna. These and other specializations in the peripheral anatomy of the receptor arrays represent one of the ways in which mammals have varied as they have evolved to adapt to different environmental niches.

### Ascending Somatosensory System Pathways to Midbrain and Thalamus

The receptors activate peripheral nerve afferents that project to second-order neurons in the spinal cord and brainstem. Second-order neurons include those in the dorsal horn of the spinal cord and the hindbrain or brainstem complex of nuclei in the medulla and pons. Some of these second-order neurons access local circuit neurons that mediate reflexes, and others project to a higher target. Some of the second-order neurons project to the cerebellum, providing sensory guidance for adjusting and conducting motor behavior. Others project to the superior colliculus to help direct eye movements to targets of interest and to the zona incerta of the upper brainstem, which projects to other targets including the superior colliculus and even the cerebral cortex to influence the functions of these structures. However, the projections that have been most intensively studied are those to the dorsal thalamus. The rapidly conducting, low threshold cutaneous mechanoreceptors that relay in the hindbrain complex project to the ventroposterior nucleus (VP), a nucleus found in all mammals.

By tradition, two subnuclei have been distinguished as 'nuclei' in VP. The ventroposterior medial subnucleus, VPM, forms the largest target component of VP in most mammals as it receives information carried by branches of the trigeminal nerve from the contralateral face and both ipsilateral and contralateral receptors of the teeth, tongue and other surfaces of the oral cavity. Information from the facial vibrissa and from the receptors of the tongue and teeth guiding food processing [4] are very important for mammals, hence the large size of the VPM portion of VP. The ventroposterior lateral subnucleus, VPL, represents the rest of the contralateral body, mediated through



**Evolution of the Somatosensory System in Mammals. Figure 1** A diagram of the basic organization of the somatosensory system of early mammals. These nuclei and areas are those that have been retained in most extant mammals. Not all of the connections and structures are shown. For example, the posterior nucleus or anterior pulvinar is not included (see text). Processing starts with receptors in the skin, muscles and other deep tissues. Other receptors include those mediating pain and crude touch. Rapidly and slowly adapting receptors (*RA* and *SA*) mediate aspects of touch. The hindbrain, or brainstem, complex (also called the trigeminal-dorsal column complex) in the lower brainstem includes trigeminal, cuneate and gracile subnuclei for the face, forelimb and hindlimb, respectively. Separate nuclei in the complex relay muscle spindle receptor information to the cerebellum (not shown) and thalamus. Terminations in the spinal cord activate neurons that project contralaterally to form the spinothalamic tract. The somatosensory thalamus includes the ventroposterior nucleus (*VP*), the ventroposterior inferior nucleus (*VPI*) that is not recognized in most mammals and the ventroposterior superior nucleus (*VPS*) that is otherwise named or unrecognized in non-primate mammals. The thalamic reticular nucleus of the ventral thalamus receives inputs from *VP* and somatosensory cortex, while having inhibitory neurons that project to *VP*. Primary somatosensory cortex (*S1*), the second somatosensory area (*S2*) and the parietal ventral area (*PV*) are the targets of *VP*. *VPS* projects to the somatosensory rostral belt (*SR*), identified as area 3a in primates, while *VPI* projects broadly to somatosensory cortex. *SC*, the somatosensory caudal belt is in the position of area 1 of primates. For long-term memory, the somatosensory system accesses perirhinal cortex and the hippocampus.

the dorsal column systems. In some mammals such as humans, a large representation of the receptors of the glabrous hand is found, as the hand (forepaw) has become an important tactile surface. Those monkeys with a glabrous surface on a prehensile tail have a larger representation of the tail in VPL. The basic principle is that skin regions with dense arrays of receptors have larger representations in the somatosensory system, including VP. The skin regions that are over-represented are species variable.

Muscle spindle afferents from the body also project to the somatosensory thalamus after relaying in contralateral subnuclei of the medullary complex, but the thalamic target of this relay has not been consistently identified and named. In primates, these proprioceptive inputs terminate in a nucleus on the dorsal (superior) margin of VP that has been called the ventroposterior superior nucleus (VPS) [5,6]. A similar nucleus has been identified in many other mammals, where it has been given different names or considered part of VP. Other second-order neurons in the

spinal cord and spinal divisions of the trigeminal complex project to the contralateral thalamus in and around VP. These projections have many functions and they appear to terminate in more than one nucleus, but these nuclei are usually poorly defined. However, in primates a nucleus with these spinothalamic and medullary inputs just ventral to VP has been defined as the ventroposterior inferior nucleus, VPI.

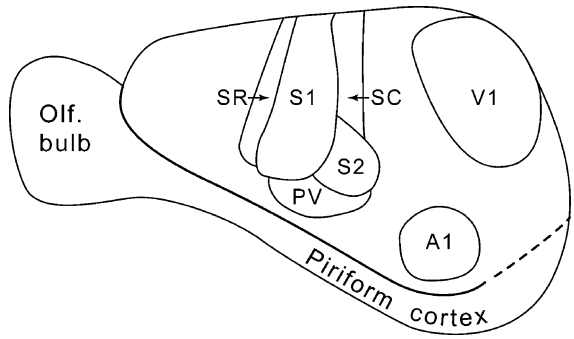
## Somatosensory Cortical Areas

VP relays to primary somatosensory cortex, S1, also termed area 3b in primates [7], as well as to two second-level areas, the second somatosensory area (S2) and the parietal ventral area (PV) [8]. In monkeys and probably other anthropoid primates, the projections to PV and S2 have been lost, while projections to two caudal belt (secondary) areas, termed area 1 and area 2, have been gained [1]. VPS or its homologue projects to the rostral belt between S1 and the motor cortex, termed area 3a in primates and identified as dysgranular cortex in rats. In monkeys, VPS also projects to area 2. Finally, VPI projects broadly to many areas of cortex, but densely to S2 and PV. These VPI projections are thought to modulate ongoing activity.

The thalamic region dorsal and somewhat caudal to VP has been identified as the posterior nucleus (or complex) in some mammals such as rats and as the anterior pulvinar in primates. By position and connections with somatosensory cortex, these regions may contain homologous nuclei, but this remains uncertain. Another nucleus, the somatosensory portion of the reticular nucleus of the ventral thalamus has connections with the somatosensory dorsal thalamus and somatosensory cortex. This nucleus and the anterior pulvinar-posterior nucleus appear to modulate the responses of neurons in somatosensory cortex and VP.

All mammals have a primary somatosensory area S1, adjoining narrow rostral and caudal belts of secondary cortex that have been given various names or ignored, at least S2 and often PV (Fig. 2).

It is uncertain whether PV is missing in some mammals or that the evidence has simply not been collected. Thus, early mammals probably had four or five somatosensory areas [5]. S1 projects to all three to four of the other areas, providing the inputs that drive neurons. There are also feedback connections to S1 and S1 sends feedback to the thalamus. The cortical areas further interconnect with each other to form an interactive network. In most mammals, some of these areas also project to a narrow adjoining strip of posterior parietal cortex that is multisensory. In placental mammals with a primary motor area and one or more premotor areas, areas of somatosensory cortex, especially PV and S2, access motor areas of the frontal lobe. PV and S2 also project to the perirhinal cortex and gain access to the hippocampus and parahippocampal cortex for long-term memory functions.



**Evolution of the Somatosensory System in Mammals. Figure 2** The arrangement of somatosensory areas typical of small-brained mammals with less complex somatosensory systems. The largest area is the primary somatosensory area, *S1*, which is bordered laterally by the second somatosensory area, *S2* and the parietal ventral area, *PV*. The somatosensory rostral (*SR*) and caudal (*SC*) belt areas also border *S1*. Primary auditory (*A1*) and visual (*V1*) areas are shown for reference. *Olf*. bulb, olfactory bulb. The brain is a dorsolateral view of the left cerebral hemisphere.

Other outputs are to the basal ganglia, the superior colliculus, the lower brainstem and the upper spinal cord for motor and sensory functions.

In some mammals with larger, more complex brains, such as cats and primates, a number of other somatosensory areas have been added to the basic five. Anthropoid primates have four areas, organized somatotopically, in anterior parietal cortex, area 3a, 3b (S1 of other mammals), 1 and 2 [9]. In addition, these primates have an uncertain number of areas in and around PV and S2 within the lateral sulcus and a number of areas in a greatly expanded posterior parietal cortex, the caudal half of which is predominantly visual in function and the rostral half of which combines visual and somatosensory information to guide motor behavior via projections to M1 and premotor areas.

In summary, many different somatosensory systems have evolved in mammals. Here, the focus has been on describing a basic framework that applies widely to mammals, while only briefly suggesting the great diversity that has emerged across mammalian taxa. This diversity includes variations in the receptor array, including the evolution of specialized sensory hairs and other sensory organs that instruct the development of the rest of the somatosensory systems so that all components are compatible. The components of the central somatosensory system vary in how they represent receptors, their connections with other structures and their structural organization. The somatosensory systems of mammals vary in number of component nuclei and areas and types of modular organization within these areas and nuclei.

The variable organization of somatosensory systems has allowed mammals to be successful in a great range of environmental niches, including the tactile prey detection system of star-nosed moles, the flight guiding system of bats, the system for detecting aquatic prey in swimming mammals and even the addition of an electroreceptive component in monotremes. Humans can thank the system for the skillful use of the hands in tool manufacture and use that has transformed their way of life.

# Evolution of the Somatosensory System in Nonmammalian Vertebrates

Ann B. Butler
Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

The somatosensory system in both mammals and nonmammals comprises multiple ascending pathways that relay information about touch, position sense, nociceptive stimuli (pain), and temperature to various sites in the brainstem, diencephalon (the more caudal component of the forebrain), and pallium (the more dorsal part of the telencephalon, which is the more rostral component of the forebrain).

## Characteristics

Although the somatosensory system is most elaborated in mammals, at least some of the basic ascending pathways have been identified across most of the other major groups of vertebrates. While in fishes, a substantial amount of exteroceptive sensory information is conveyed to the brain via the lateral line system (see Braun, Evolution, of mechanosensory and electrosensory lateral line systems) that has receptors distributed over head and body regions, ascending spinal, dorsal column, and trigeminal systems are also present and have been studied in some taxa. The trigeminal nerve exhibits a number of diverse specializations across vertebrates, most of which occur in amniotes – from infrared heat sensing in some snakes to electroreception in monotremes to magnetoreception in birds. For a discussion of these adaptations and the anatomy of the system in general in amniotes, see: Manger, Evolution, of the trigeminal sensory system and its specializations.

### Somatosensory System in Fishes

Ascending somatosensory pathways have not been well studied in ray-finned fishes (which include the very large radiation of bony fishes, or teleosts) or cartilaginous fishes (chimaeras and the sharks, skates and rays), so the available information for these taxa is spotty at best [1]. In at least one species of teleost fish, ascending fibers from all levels of the spinal cord project to part of the reticular formation and cerebellum. This pathway has some similarities to the ventral spinocerebellar system of mammals but also several differences. Trigeminal nerve projections have been studied in a relatively basal ray-finned fish, the sturgeon *Acipenser* [2], which has all four of the trigeminal components found in amniotes – principal (medial) (for touch and position sense) and descending (for pain and temperature) sensory nuclei, the motor nucleus (for jaw muscles), and the mesencephalic nucleus (for jaw muscle proprioception). In trout, Walker et al. [3] have found that the trigeminal nerve is involved in magnetoreception: branches of the superficial ophthalmic nerve innervate magnetite-based magnetoreceptor cells located in the olfactory lamellae and are responsive to magnetic field stimuli.

The mesencephalic nucleus of the trigeminal is readily identifiable in most ray-finned fishes, due to the characteristic globular shape of its neuron cell bodies and their constant position along the periventricular cell layers of the optic tectum [1]. This nucleus is extremely large in some fishes, such as the tarpon *Elops*, which is a large fish with powerful jaws, popular with sport fishermen.

More information on the connections of the various somatosensory systems is available in jawless vertebrates [1]. In both hagfishes and lampreys, ascending spinal and dorsal column systems are present. Spinal projections are mainly to the reticular formation, with some fibers reaching as far rostrally as the mesencephalic tegmentum and/or the deep part of the optic tectum, and dorsal funicular fibers also project to sensory, dorsal column nuclei within the medulla. The latter also project to the reticular formation and contain both excitatory and inhibitory cell populations.

The trigeminal system is also present in both hagfishes and lampreys [1]. In the latter, five cell columns receive trigeminal input. Lampreys have nuclei identifiable as homologous to the primary and descending sensory nuclei and the trigeminal motor nucleus of amniotes. Cells within the descending nucleus project to the reticular formation. Consistent with their jawless condition, lampreys lack the tectal-level mesencephalic trigeminal cells found in jawed vertebrates. They may have a homologue of the mesencephalic nucleus in their medulla, and the so-called dorsal cells, or Rohen-Beard cells, which are migrated spinal ganglion cells that lie within the dorsal half of the spinal cord, likewise may be serial homologues of the mesencephalic trigeminal nucleus of other vertebrates.

## Somatosensory System in Amphibians

Dorsal column nuclei are present in amphibians [4]. These nuclei give rise to a medial lemniscus that ascends through the brainstem and projects to sites including the reticular formation, midbrain roof (torus semicircularis and, sparsely in some species, deep layers of the optic tectum), and nuclei within the thalamus [4,5]. A spinothalamic system and a homologue of the mammalian lateral cervical nucleus, which receives ascending spinal inputs and projects to the contralateral thalamus, have also been identified in amphibians [5]. Trigeminal nuclei, similar to those in other vertebrates, include principle and descending sensory nuclei and a trigeminal motor nucleus.

Ascending somatosensory systems may not be relayed through the dorsal thalamus in a manner similar to that in amniotes, however. Westhoff et al. [6] have found that in a toad (*Bombina orientalis*), most somatosensory input to the diencephalon is confined to the ventral thalamus and posterior tuberculum. Within the dorsal thalamus, input is very sparse and appears to be confined to the more caudally lying central thalamic nucleus, rather than to the more rostral part of the thalamus, the latter thought to be homologous as a field to the rostral part of the amniote thalamus, or lemnothalamus [1], that includes the ventral nuclear group. Thus, as Westhoff et al. [6] discuss, amphibians may lack a disynanptic somatosensory pathway to telencephalic pallium via the dorsal thalamus, as they similarly lack a disynaptic, dorsal thalamic visual pathway. Since amphibians also lack any substantive collothalamic pathways to the pallium (relayed through the midbrain roof and then the dorsal thalamus [1], either these pathways are unique to amniotes or have been secondarily lost in amphibians.

## Somatosensory System in Reptiles

In reptiles, only limited information is available on the somatosensory pathways. A projection from the dorsal column nuclei (DCN) to nucleus dorsolateralis anterior (DLA) of the dorsal thalamus has been demonstrated in a lizard [7], but this same study found only a few retrogradely labeled neurons within the cervical spinal cord and only after injections that involved additional dorsal thalamic nuclei. Thus, a spinothalamic system may be essentially absent in lizards. The dorsal column information that reaches DLA is relayed to the dorsal cortex, and reciprocal projections from the cortex to DLA are also present [7]. Since this pathway is not relayed through the midbrain roof, it constitutes a lemnothalamic pathway [1], homologous to the dorsal column-thalamocortical pathway of mammals. The homologue of the ventroposterior nucleus of mammals lies within the reptilian DLA [7].

Reptiles also have a collothalamic somatosensory pathway [1] relayed through the midbrain roof. In crocodiles, this pathway arises from the dorsal column nuclei [8], although from a separate subdivision than that containing the directly thalamic-projecting neurons, and its axons terminate within the deep, somatosensory part optic tectum (the homologue of the mammalian superior colliculus). The somatosensory part of the tectum projects to the medialis complex within the dorsal thalamus, which in turn projects to a restricted part of the dorsal ventricular ridge in the telencephalic pallium [8]. The medialis complex of crocodiles has homologues called by different names in other reptiles – the nucleus medialis posterior and nucleus posterocentralis of lizards, which both also project to the dorsal ventricular ridge [1], and the nucleus caudalis of turtles.

The ascending trigeminal system of reptiles comprises all four components present in other vertebrates – motor, mesencephalic, and two sensory nuclei. Both the descending and the principal sensory trigeminal nuclei give rise to projections to DLA, which relays these inputs to cortex along with those from the dorsal column nuclei [7]. As in mammals, the pathway from the trigeminal nuclei to the dorsal thalamus is bilateral, with the contralateral component predominating.

## Somatosensory System in Birds

In birds, both lemnothalamic and collothalamic somatosensory pathways [1] that arise from the dorsal column

nuclei are present. The former involves a relay through nucleus dorsalis intermedius ventralis anterior (DIVA) of the dorsal thalamus, which projects to the somatosensory part of the Wulst (the anterior part of the hyperpallium apicale) within the telencephalic pallium [9]. The latter pathway is via the deeper layers of the optic tectum, which project to two dorsal thalamic nuclei – the caudal part of nucleus dorsolateralis posterior (cDLP) and nucleus semilunaris parovoidalis – which in turn relay the information to part of the avian dorsal ventricular ridge within the nidopallium intermedium.

Like reptiles, mammals, and anamniotes, birds also have a trigeminal system. However, the ascending projections from the principal sensory trigeminal nucleus are highly unusual. Rather than projecting to a nucleus within the dorsal thalamus, the principal nucleus of V projects directly to a target within the nidopallium of the telencephalon, the nucleus basorostralis pallii (previously called nucleus basalis prosencephali) [10]. This direct pathway is known as the quintofrontal tract.

# Evolution of the Spinal Cord

William Hodos
Department of Psychology, University of Maryland, College Park, MD, USA

## Definition

One of the two major divisions of the central nervous system, the other being the brain. The spinal cord is involved in the integration of sensations from the body region (both internal and external) with somatic motor and visceral motor processes. It also responds to commands from the brain that involve both voluntary and reflex behavior.

## Characteristics

The vertebrate central nervous system is divided into two great regions: the brain, which is involved in using sensory information to affect behavior, and the spinal cord, which controls the musculoskeletal system of the body to move the body through space. Both the brain and spinal cord are also important in the control and regulation of the body's internal organs, also known as the viscera.

## Locomotion

For most animals that live entirely or partly in an aquatic environment, locomotion through the water is by rhythmic, undulatory movements of the body. These movements are augmented by paddling movements of fins or legs and sometimes undulatory movements of fins. Some exceptions to this generalization are aquatic birds, such as ducks and gulls that float on the surface and paddle only with their feet, diving birds that paddle with their wings, and turtles that paddle with their limbs. In contrast, the great majority of land animals (also known as tetrapods, meaning having four legs) move by means of their limbs accompanied by some movements of the trunk [1]. These rhythmic movements, whether of the trunk, fins, or limbs, are controlled by groups of neurons located within the spinal cord called *central pattern generators.* These in turn are controlled by neuronal networks, called *command generators*, that are located within the ►hindbrain and ►midbrain [2–4].

## Reflexes

Another function of the spinal cord is to perform rapid, automatic reactions in response to either external or internal stimuli. These reactions are known as reflexes. External stimuli result in reflex alterations of body posture or location; internal stimuli result in reflexes that affect, heart rate, respiration, digestion, or other visceral functions.

## Spinal Nerves, Roots, and Ganglia

The spinal cord is connected to the internal or external organs that it controls by means of nerves known as spinal nerves. In general, the nerves entering the dorsal portion of the spinal cord carry sensory information from the external or internal environments into the cord. Those exiting on the ventral surface of the cord carry motor commands to operate muscles or internal organs. These entering and exiting nerves are known as spinal roots. In most vertebrates, the spinal roots eventually converge to form a common mixed nerve. A feature of the dorsal root is the dorsal root ganglion, which contains the cell bodies of the incoming sensory neurons. Located on the common sensory-motor spinal nerve root, is another ganglion, which contains the cell bodies of neurons that send their axons to the viscera. These are part of a semi-autonomous visceral regulatory system known as the autonomic nervous system. It is partly a spinal system and partly a hindbrain system [2,5].

In most vertebrates, the spinal cord runs the entire length of the vertebral column, the series of bony rings that form the backbone. The spinal nerves pass between the vertebrae en route to their destinations in muscles or viscera [6]. In some vertebrates, however, such as adult humans, and some fishes, such as the angler fish (*Lophius piscatorius*), the cord does not extend the entire length of the vertebral column. Nevertheless, the spinal nerves continue on to exit between their appropriate vertebrae. This results in the lower levels of the ►spinal column being filled with nerves only and no spinal cord. This shaggy collection of nerves is known as the cauda equina, which is Latin for horse's tail, which it resembles [2,5].

## Organization of the Spinal Cord

The spinal cord is organized into local regions known as spinal segments, each corresponding to a ►vertebra. Each segment is responsible for the reflexes that involve the sensory and motor nerves that enter and exit that segment. The neurons that form these reflex circuits within a single segment are called intrasegmental neurons. In addition, there is a longitudinal organization that coordinates the activities of several adjacent segments, which are known as extrasegmental or intersegmental reflexes. The command generators of the midbrain and hindbrain organize the reflex activities of many spinal segments and are called suprasegmental reflexes.

Some reflexes of the spinal cord involve only two neurons (a sensory and a motor) and a single synapse between them. These are called monosynaptic reflexes. Most reflexes, however, are polysynaptic and involve one or more additional neurons between the sensory and motor neurons.

## Spinal Autonomy

In mammals, the spinal cord is autonomous of the brain for some rhythmic responses, postural reflexes, and some autonomic reflexes, such as those of the gut. However, in non-mammals, the spinal cord has considerably more autonomy. Thus, in non-mammals, the spinal cord tends to carry out many of its postural and locomotor activities independently of the brain. For example, in the event that the brain detects a potential predator, the spinal cord is capable of executing precise and sophisticated escape routines. Likewise, a decapitated bird, such a chicken, in which much of the brain has been removed but the respiratory and cardiac control regions of the hindbrain left intact, is quite capable of maintaining an upright posture and locomotion [2,5].

## Longitudinal Cell Body and Axon Columns of the Spinal Cord

In general, the neuron cell bodies that are present in one segment of the spinal cord are in line with those of adjacent segments [2,5,6]. Thus, these cell bodies form longitudinal columns within the spinal cord. These cells tend to congregate at the core of the spinal cord and are known as the grey matter.

The grey matter has elongated extensions that are known as horns. Those that protrude dorsally are called the dorsal horns, and those that protrude ventrally are the ventral horns. Some species also have lateral horns in certain regions of the cord. In general, the ventral horns contain the cell bodies of the motor neurons and the dorsal horns contain neurons that receive the incoming axons of the sensory neurons. Various types of interneurons are also present that form the neural networks that are the basis of reflexes and coordinated movement of body segments and appendages. An unusual spinal cord component are the electromotor neurons that innervate the ►electric organs in electric fishes, such the weakly electric Mormyrids, which use their electric fields mainly for communication and as a kind of sonar to navigate murky waters, and the strongly electric fishes such as the electric eel, which use their more powerful electric fields to stun prey or for defense [7].

Also present in the spinal cord are the neurons that regulate the various internal organs. The lateral horns, where present, contain the preganglionic cell bodies of the autonomic nervous system. In the thoracic and upper lumbar segments, where lateral horns are present, they contain the cell bodies of the sympathetic part of this system and are called the intermediolateral columns. A lateral horn is also present in the sacral part of the cord, where it contains parasympathetic preganglionic neurons.

Not all neurons lie within the grey matter; a small number of cells occur within the white matter at the periphery of the spinal cord. These cells are called edge

cells or marginal cells and are probably involved in detection of flexion or bending of the spinal cord itself. A canal, the central canal, which contains cerebrospinal fluid, runs through the center of the grey matter [2,5].

The more superficial regions of the cord consist mainly of intersegmental axons and suprasegmental axons of spinal grey matter that ascend and descend within the cord as well as descending axons from the brain. These axon columns are known as the white matter columns. The axon columns also form larger sets, which are called the lateral, ventral, and dorsal white matter columns, or funiculi. Fig. 1 shows a transverse section through the spinal cord of a lamprey. It shows many of the cell and axon columns of the non-tetrapod cord. These are similar in many ways to those of tetrapods.

Some non-tetrapods, however, possess a number of features not found in the tetrapod spinal cord, such as the axons of the giant Mauthner cell and the axons of the Müller cells. The Müller cell bodies are located in the midbrain and hindbrain in jawless fishes and some ray-finned fishes. They control both normal swimming movements and changes in body orientation to acceleration and gravity. Their axons, which are quite large, are located in the ventral white matter columns. The giant Mauthner axon arises from a gigantic, banana-shaped cell body in the medulla. Only one Mauthner cell body is present on each side of the brain. It is present in jawless fishes, ►ray-finned fishes and some amphibians. It plays a crucial role in escape reflexes by bending the body into a C-shape that quickly points it away from the predator to allow the animal to make a swift change in its direction of locomotion [2,5,8].

## Tetrapod Spinal Cords

The transition from the aquatic environment to the land required limbs capable of supporting the animal's weight in response to the pull of gravity and to move the animal across the land. In most tetrapods, additional sensory and motor neurons that serve the limbs are present in two regions of the spinal cord: the caudal part of the cervical region in the neck and the lumbar region in the abdominal area. These neurons are present in addition to those that move the trunk in these levels of the spinal cord and hence cause bulges in the cord known as the cervical and lumbar enlargements.

Fig. 2 shows the cervical and lumbar enlargements (or the lack of them) in several groups of tetrapods that vary in their use of limb and trunk muscles.

Also shown are the major levels of the spinal cord: cervical (neck), thoracic (chest), lumbar (abdominal), and sacral (pelvic). In animals with both well developed trunk muscles and well developed limbs, such as lizards, alligators and mammals, the spinal cord has clearly defined cervical and lumbar enlargemements [2,5,9,10]. In contrast, snakes, which have exceptionally powerful trunk muscles but no limbs, lack these enlargements. Turtles, on the other hand, have powerful limbs, but lack trunk muscles within their shell. Their spinal cords have clearly defined cervical and lumbar enlargements, but are very thin in the thoracic region where it mainly consists of visceral neurons and longitudinal axon columns [11]. Birds that fly have spinal cords similar to turtles because they lack an extensive system of longitudinal axon columns, since there is little need to coordinate the action of the wings and the legs. In flight, the legs are held motionless and close to the body as are the wings on land.

## Evolution of the Spinal Cord

The spinal cord has been a relatively stable region of the central nervous system during vertebrate evolution. The major changes have occurred during the transition from aquatic locomotion with its emphasis on propulsion by body and tail undulation (with some assistance from

From Butler and Hodos [2] and used with permission of John Wiley and Sons.

fins) to rhythmic movements of limbs that support the weight of the body in air [2,5,12]. This shift coincided with changes in local connections within the cord and the enlargement of the grey matter columns in the tetrapod cord along with enlargements in the cervical and lumbar regions, especially in animals with moveable digits on the limbs that can manipulate objects [13]. Another major feature of the tetrapod spinal cord is the development of increased numbers of ascending and descending connections between the brain and levels of the spinal cord [14], particularly in species that manipulate objects with their limb digits.

complement, the hypothalamus, the most rostral portion of the neural tube. The telencephalon represents part of the ancestral craniate (and, thus, anamniote) brain ►Bauplan (morphotype). The craniate telencephalon includes ventrally a subpallial region (medially: septum; laterally: striatum) and dorsally a pallial region. In addition to olfactory bulb input, the pallium receives ascending sensory information in all craniates, with largely separate pallial terminations in all jawed vertebrates (►gnathostomes). While it is likely that a lateral pallium (olfactory cortex homologue) and a medial pallium (hippocampus homologue) arose at the latest with the gnathostomes (and likely are ancestral for craniates), a dorsal pallium may have arisen several times independently in ►chondrichthyans, teleosts and amniotes. A separate pallidal subdivision of the craniate striatal formation may only have evolved with the gnathostomes.

## Characteristics

### Systematics/Species Diversity

For systematic relationships and species diversity of extant craniate fish groups, see Essay: Evolution of the Brain in Fishes by Wullimann and Vernier (including Figs. 1a and b).

Craniates include the agnathan myxinoids (hagfishes) and petromyzontids (lampreys), as well as all gnathostomes ( jawed vertebrates), but the pylogenetic relationships of these three groups is still a matter of debate, with petromyzontids and gnathostomes either constituting the vertebrates, or myxinoids and petromyzontids forming the ►monophyletic cyclostomes [3]. Gnathostomes include three taxa: (i) Chondrichthyans (cartilaginous fishes), including holocephalans (chimaerans), sharks, and batoids (rays and skates); (ii) ►Actinopterygians (ray-finned fishes), including basal groups, i.e., cladistians (bichirs), chondrosteans (sturgeons), ginglymodes (gars) and halecomorphs (bowfin), as well as the more derived teleosts, including three basal taxa, i.e., osteoglossomorphs (arawanas, arapaimas, etc.), elopomorphs (tenpounders, tarpons and eels) and clupeomorphs (herring-like fishes), plus

the more advanced euteleosts, such as ostariophysans (including cypriniforms, characiforms and siluroids) and percomorphs (perches); (iii) ►Sarcopterygians (lobe-finned fishes) include actinistians (coelacanths), dipnoans (lungfishes) and tetrapods, which include (anamniote) amphibians and amniotes. Amphibians (ca. 4,000 extant species) include frogs (anurans), salamanders (caudates, urodeles) and caecilians (gymnophionans, apodans). Thus, unlike amniotes, anamniotes (i.e., all craniates except amniotes) do not comprise all descendants of a hypothetical last common ancestor, because the term, by definition, excludes amniotes. Anamniotes are therefore a paraphyletic group. These systematic relationships are of paramount importance for the discussion of the evolution of telencephalic characteristics in anamniotes [4; and see below].

## Brain Weight-Body Weight Data

For a summary of brain weight-body weight data in anamniotes and amniotes, see Essay: Evolution of the Brain in Fishes by Wullimann and Vernier (including Fig. 2).

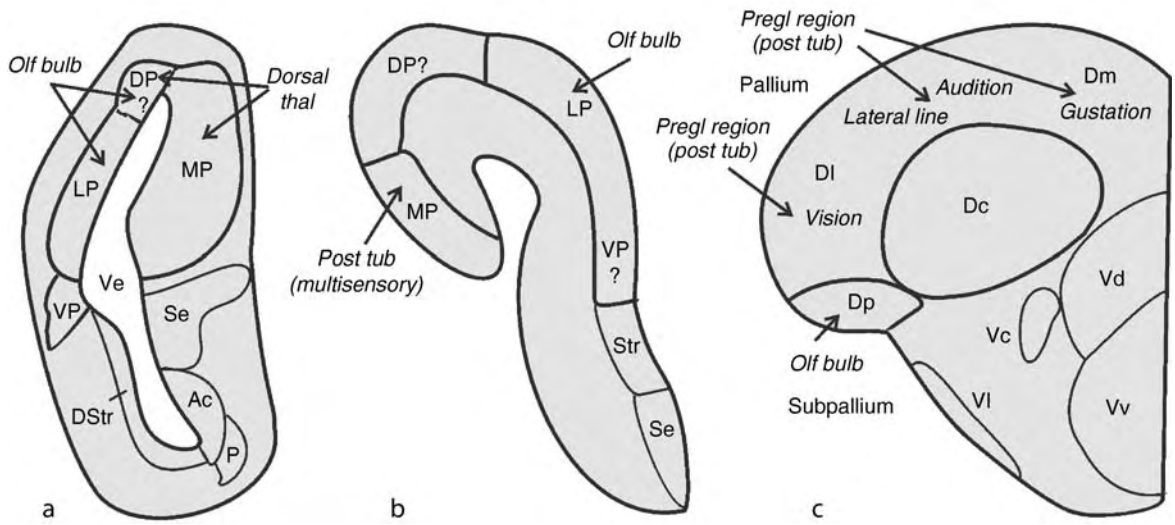
## Phyletic Analysis

For a summary of the comparative (cladistic) method for establishing the evolutionary polarity of brain traits, see Essay: Evolution of the Brain in Fishes by Wullimann and Vernier (including Fig. 1a and b).

## The Telencephalon is Part of a Shared Ancestral Craniate/Vertebrate Brain Morphotype (Bauplan)

Instead of stepwise addition of brain parts at the anterior pole of the neuraxis during evolution, a craniate Bauplan of basic brain parts appears to have been initially present from which novelties arose (see Essay: Evolution of the Brain in Fishes by Wullimann and Vernier; including Fig. 3).

In this Bauplan, the telencephalon occupies the most anterodorsal pole and represents, together with the anteroventrally located hypothalamus (as well as eminentia thalami and preoptic region), the most anterior, prechordal part of the neural tube. The craniate telencephalon includes a pallium (cortex in mammals) and a subpallium (including striatum, pallidum, septum in mammals).



**Evolution of the Telencephalon in Anamniotes. Figure 2** Pallial sensory input and output relationships in amphibians and ray-finned fishes. Sketches of *left* telencephalic hemispheres of: (a) frog. Pallial locations of olfactory bulb and dorsal thalamic inputs are indicated (data from various species) [5,6]. (b) bichir (*Polypterus palmas*). Pallial locations of olfactory bulb and multisensory posterior tubercular inputs are indicated (after [7]). (c) Zebrafish (*Danio rerio*). Pallial locations of olfactory bulb (olf), visual, lateral line mechanosensory, auditory and gustatory inputs (originating in preglomerular nuclei lateral to the posterior tuberculum) as established in various teleost species (for details, see [8,10]). Abbreviations: *Ac* nucleus accumbens; *Dc*, *Dl*, *Dm*, *Dp* central, lateral, medial, posterior zones of area dorsalis telencephali (pallium); *DIL* diffuse nucleus of inferior lobe; *DP* dorsal pallium; *DStr* dorsal striatum; *LP* lateral pallium; *MP* medial pallium; *P* Pallidum; *Se* septum; *Str* striatum; *Vc*, *Vd*, *Vl*, *Vv* central, dorsal, lateral, ventral nuclei of area ventralis telencephali (subpallium); *Ve* ventricle; *VP* ventral pallium.

Figure 3** (after [20]) Complete (*left side*) versus partial pallial eversion model (*right side*) in teleosts and hypothetical relationship of four (medial, dorsal, lateral, ventral) pallial zones in tetrapods to adult teleostean pallial zones. Abbreviations as in Fig. 2.

## Ascending Sensory Pathways Reach Telencephalon in all Craniates

Historically, the smell-brain theory suggested that the fish telencephalon is dominated or even exclusively reached by secondary olfactory input from the olfactory bulb. Thus, a multisensory telencephalon or pallium has been interpreted as a derived amniote or mammalian feature. However, the synaptic relay from diverse primary sensory centers throughout the ascending neuraxis into subpallium and/or pallium in all anamniotes reveals general similarity to the situation in amniotes [4].

## Agnathans

In both the petromyzontid and myxinoid telencephalon, subpallial (striatum/septum) and pallial divisions may be recognized. However, at least in myxinoids (Pacific hagfish; Fig. 1a), the pallium does not appear to exhibit three pallial divisions typical of gnathostomes (i.e., lateral, dorsal and medial pallium; see below), but rather has a homogeneously organized pallial cortex with five distinct neuronal layers throughout [1]. Olfactory bulb input reaches most of the mediolateral extent of the hagfish pallium, but it remains restricted to two pallial layers (P1, P5; Fig. 1a). However, all hagfish pallial layers receive additional dorsal thalamic input [1]. Furthermore, there are reciprocal connections both with the olfactory bulb and, importantly, with the dorsal thalamus. Rather extensive secondary olfactory projections also reach the pallium in petromyzontids (lampreys), but again, these are complemented by dorsal thalamic input to the pallium [9].

Although an outgroup comparison reveals that both agnathan groups have a more olfactory dominated telencephalon or pallium than gnathostome vertebrates, the smell-brain theory is not supported for two reasons. Extant ►agnathans differ much from their ancestors in morphology and life habits that are seemingly very specialized for olfactory orientation, possibly representing adaptive novelties. More importantly, both in lampreys and myxinoids, the telencephalon (including the pallium) is of multisensory, and not of exclusive olfactory nature, as the smell-brain theory would predict.

## Chondrichthyans

Cartilaginous fish display paired evaginated telencephalic hemispheres around a central ventricle with medial, dorsal and lateral pallial divisions located dorsal to the subpallium, which includes (medial) septal and (lateral) striatal components (spiny dogfish: Fig. 1b) as discussed by Glenn Northcutt in the early 1980s. Independent telencephalic enlargement occurs in some batoids and sharks (for original literature, see [2]). For example, galeomorph sharks (smooth dogfish; Fig. 1c, left) display a conspicuous large central nucleus in the dorsal pallium.

### *Sensory Systems in Chondrichthyan Pallium*

Pioneer discoveries by Sven Ebbesson and colleagues in the early 1980s revealed (i) that the galeomorph telencephalon (nurse shark) receives only very restricted secondary olfactory bulb projections to pallial (lateral pallium) and subpallial territories (Fig. 1c, right) and, (ii), that the central pallial nucleus receives substantial contralateral dorsal thalamic input and the lateral dorsal pallium receives ispilateral dorsal thalamic input (unspecified modality). The input to the central pallial nucleus was later recognized as visual, somatosensory and mechanosensory (lateral line) by tract tracing and electrophysiology. Furthermore, the medial pallium of the squalomorph spiny dogfish receives multisensory (vision, electrosense; Fig. 1b, right) dorsal thalamic, as well as posterior tubercular inputs (for original literature, see [2]). These findings falsify the smell-brain theory because they show that the ancestral situation for gnathostome vertebrates already is characterized by ascending pathways of most if not all sensory systems reaching the telencephalon.

### *Sensory Systems in Chondrichthyan Diencephalon*

Apart from the largely unknown gustatory system, most other sensory systems in cartilaginous fishes have been demonstrated to reach the dorsal thalamus, i.e., vision (retinothalamic and retinotectothalamic pathways), lateral line mechanosensation, somatosensation, and probably audition. Electrosensation ascends via the lateral lemniscal system to the lateral posterior tuberculum (as also, additionally, lateral line mechanosensation) and to a hypothalamic nucleus, and both nuclei project to the telencephalon (for original literature, see [2]).

These data in cartilaginous fishes suggest that a dual innervation of the diencephalon (dorsal thalamus/posterior tubercular region) by at least some ascending sensory systems is the ancestral pattern for gnathostomes. Furthermore, it may be a gnathostome plesiomorphy that hair cell sensory organs in the labyrinth (audition, vestibular sense) are represented in the dorsal thalamus and the remaining hair cell sensory organs (mechanoreception, electroreception) are present in the posterior tubercular region. If so, the evolutionary loss of the latter sensory systems in amniotes may directly explain the dominance of the dorsal thalamus as the diencephalic sensory region in amniotes.

## Actinopterygians

The actinopterygian telencephalon is divided into a subpallial ventral telencephalic (septum/striatum) and a pallial dorsal telencephalic area (bichir, Fig. 2b; zebrafish, Fig. 2c). Different from the usual vertebrate location of medial, dorsal and lateral pallia, which results from evagination of bilateral telencephalic hemispheres (e.g., in sharks, Figs. 1b, c and amphibians, Fig. 2a), actinopterygian pallial masses are everted [10], as further discussed below and clearly represent an evolutionarily derived situation among vertebrates. Eversion results in altered topology of pallial masses, best illustrated in basal actinopterygians (bichir; Fig. 2b), where the medial pallium (which receives multisensory posterior tubercular input, but not olfactory bulb input) comes to lie laterally, while the lateral pallium (receiving a dense olfactory bulb input) is medially located. In teleosts, the posterior zone of the dorsal telencephalic area (Dp) is the major recipient of secondary olfactory input and is considered the lateral pallium (or olfactory cortex) homologue. The teleostean pallial lateral zone (Dl) has been described as a visual area, the lateral, central (Dc) and medial (Dm) zones as lateral line mechanosensory, the lateral and medial zones as auditory, the medial and central zones as somatosensory, and the medial zone as gustatory-recipient in various teleost species (for original literature, see [2,4,8,10]).

In teleosts, the synaptic relay of almost all sensory system pathways has been neuronally traced from primary sensory centers into the telencephalon (see above). Although the homology of sensory pathways between teleosts and tetrapods is not certain in each single case, the degree of similarity is nevertheless of great functional and evolutionary interest. Vision reaches the telencephalon via a direct retino-thalamic and an indirect retino-tecto-thalamic pathway. In contrast to amniotes, the major telencephalic target is

the subpallium. However, tectofugal visual information reaches the pallium in certain teleosts via the preglomerular region, a complex of migrated nuclei lateral to the posterior tuberculum. The sensory systems which ascend multisynaptically in the lateral longitudinal fascicle (audition, lateral line mechanoreception and electroreception) to the mesencephalon reach the pallium mostly via nuclei in the preglomerular complex and, possibly, dorsal thalamus (only audition). Gustation in teleosts reaches the pallium via a medullary secondary gustatory nucleus and diencephalic preglomerular (and hypothalamic) nuclei. Finally, teleosts possess direct and indirect spinal ascending somatosensory system reaching the dorsal thalamus and preglomerular region.

Thus, similar to cartilaginous fishes the predominant diencephalic targets of teleostean ascending sensory projections are in the preglomerular region located in the lateral periphery of the posterior tuberculum, not in the dorsal thalamus as in amniotes [2,8]. Specific teleostean sensory preglomerular nuclei exist for the auditory, the lateral line mechanosensory, the electrosensory, the gustatory, the somatosensory, and the visual systems. These preglomerular nuclei have a high degree of cytoarchitectonic differentiation and they - not the dorsal thalamic ones - provide the major diencephalic input to the pallial zones of the area dorsalis telencephali (Fig. 2c). Thus, the functional similarities between the teleostean preglomerular region and the amniote dorsal thalamus are striking: both make up a large proportion of the diencephalon, are subdivided into many nuclei associated with specific sensory systems and, further, most of them have reciprocal connections with the pallium.

## Amphibians

Typically, amphibians have paired evaginated telencephalic hemispheres around a central ventricle and medial, dorsal and lateral pallial divisions have been recognized dorsal to the subpallium, which displays (medial) septal and (lateral) striatal components (frog: Fig. 2a) [5–6]. The olfactory bulb provides heavy input to the lateral pallium, extending also into the dorsal pallium. The medial pallium receives sensory input from the dorsal thalamus (visual, auditory) that also extends into the dorsal pallium. Although ascending sensory input reaches the amphibian posterior tuberculum, its projection to the pallium has not received enough attention, unfortunately. The existence of a separately definable dorsal pallium in amphibians is controversial (see below), although homologies with the mammalian cortex have been evidenced [12,11].

### *Evolutionary Origin of Dorsal Pallium and Ventral Pallium*

A major current debate relates to the ancestral condition of the craniate/vertebrate pallium. Undoubtedly, both lateral (olfactory cortex homologue) and medial pallia (hippocampus homologue) are ancestrally present in gnathostomes, and probably in all craniates, based on hodological and embryological evidences [14–17]. However, the existence of a dorsal pallium [neocortex (isocortex) homologue] has recently again been questioned both in amphibians [5] and basal actinopterygians [7]. If so, dorsal pallial territories (characterized by absence of olfactory input typical for lateral pallium and sensory input functionally separable from that to medial pallium) would have evolved separately in chondrichthyans, teleosts, and amniotes.

Interestingly, embryological approaches have established the existence of a fourth craniate/vertebrate pallial division, the ventral pallium (homologue of parts of the amniote pallial amygdala, endopiriform nuclei and claustrum), which is a genetically and functionally definable histogenetic unit in all tetrapods (and likely in all craniates/vertebrates) [16].

### *Subpallium*

The craniate subpallium has striatal and septal divisions ancestrally. Detailed information recently has been accumulated for the anamniote tetrapod subpallium (e.g., basal ganglia), because homologues of mammalian striatal motor centers (caudatoputamen, nucleus accumbens, pallidum) were identified in amphibians where functional emphasis of basal ganglia is rather on descending motor control than on re-entrant circuits to the pallium (Fig. 2a, [6]). There is also considerable evidence that the dorsal nucleus of the ventral telencephalic area represents both striatum and pallidum in teleosts (Fig. 2c) [8] and that the ventral nucleus represents the septum. Although both striatum and septum appear to exist in chondrichthyans, the exact situation remains elusive because of a lack of functional neuroanatomy and modern developmental work. In contrast, embryological and gene expression data in the ventral telencephalon of lampreys suggest that a pallidal subdivision (in mammals: the derivative of the medial ganglionic eminence) is absent in agnathans and may only originate in gnathostome ancestors [13,15].

## Neurochemical Organization

For a summary of the neurotransmitter/neuromodulatory – i.e. dopamine, noradrenaline, serotonin, histamine, and acetylcholine – systems and their relationship to the telencephalon, see Essay: Evolution of the Brain in Fishes by Wullimann and Vernier, and [2].

## Telencephalic Eversion Versus Evagination

Independent of the problematic ancestral condition of pallial divisions in craniates (see above) is that different modes of telencephalic hemisphere development – eversion in ray-finned fishes versus evagination in all other vertebrates (Figs. 2 and 3) – obscure the comparative interpretation of actinopterygian telencephalic

subdivisions (e.g., subpallial septal and striatal formations, amygdala, or medial, dorsal, lateral and ventral pallial formations seen in tetrapods; as discussed by Mark Braford and Glenn Northcutt in the early 1980s (and see [8,10]). As discussed above, the situation is best grasped in a comparison of basal actinopterygians (bichir; Fig. 2b) with amphibians (frog; Fig. 2a). Also in teleosts, the medial pallium (hippocampus homologue) must be concluded to be dislocated by eversion somewhere to the adult lateral telencephalic periphery. However, the most lateral teleostean pallial division (the posterior zone of area dorsalis, Dp; Fig. 2c) receives the densest secondary olfactory input, typical for the tetrapod lateral pallium (olfactory cortex homologue). Thus, complete topological eversion of the entire teleostean pallium seems doubtful (Fig. 3; left). Recently, a new model of partial pallial eversion (Fig. 3; right) has been suggested [20] where the teleostean Dp is interpreted as a non-everted pallial division, with its main, non-everted portion in the ventrocaudal pallial neural tube wall near the midline (similar to the situation in bichirs; Fig. 2b). A minor anterolateral portion of the teleostean Dp (Fig. 3; lowest right panel) accordingly represents a rostrolaterally dislocated (but also uneverted) portion continous with the more caudally situated main mass of the lateral pallium. Thus, only dorsal and medial – but not lateral and ventral – pallia would be everted.

There is substantial support for the identification of the teleostean medial pallium (hippocampus homolog) directly dorsal to Dp, i.e., a ventral division of the lateral zone of the dorsal telencephalic area (Dlv), and of the teleostean ventral pallium (e.g., pallial amygdala homologue) in the most medioventral part of the medial zone of the dorsal telencephalic area [18,19]. Dlv is involved in learning and memory of spatial maps because focal Dlv lesions in goldfish lead to a specific deficit in place - but not other - tasks, similar to hippocampus lesioned amniotes. In contrast, lesions in the ventromedial Dm in goldfish result in behavioral deficits comparable to amygdala-like lesions observed in amniotes [18], speaking strongly for the identification of the teleostean pallial amygdala in the medioventral Dm. These behavioral data are in accord with the location of medial and ventral pallium predicted by the partial eversion model (Fig. 3). While functional similarity is not necessarily a valid criterion for homology, these functional commonalities of pallial regions in fishes and mammals together with topological correspondences are striking.

Accordingly, the homologue of the tetrapod dorsal pallium (e.g., mammalian neocortex) would then occupy remaining portions of the teleostean dorsal telencephalic area (i.e., most of medial Dl, all of Dd, Dc, and dorsolateral Dm). Comparing the extent of these areas to the rather small dorsal pallium of amphibians, one must conclude that the teleostean situation cannot be ancestral, even if considering possible paedomorphic reduction effects in amphibians. Whether basal actinopterygians show a less elaborated dorsal pallium remains an open question at present [7, and see above]. In any case, the development, functional neuroanatomy and evolution of the large zones likely representing the dorsal pallium of teleosts remain fruitful fields to be investigated.

# Evolution of the Terminal Nerve

Kathleen Whitlock
Department of Molecular Biology & Genetics, Cornell University, Ithaca, NY, USA
Departamento de Neurociencia Facultad de Ciencias, Universidad de Valparaiso, Valparaiso, Chile

## Synonyms

Nervus terminalis

## Definitions

The terminal nerve is one of the three most rostral ►cranial nerves and is characterized by neurons that contain ►gonadotropin releasing-hormone (GnRH). While its modality is not yet completely understood, it may play a role in reproductive behavior.

## Characteristics

This essay on the evolution of the terminal nerve presents as its foundation the premise that understanding the embryonic origin(s) of the terminal nerve provides information about the potential evolutionary origin of this cranial nerve. The terminal nerve is characterized as containing neuroactive peptides including the decapeptide gonadotropin releasing-hormone (GnRH), the presence of which is conserved across vertebrates. Analyses of these GnRH-containing cells of the terminal nerve present two possibilities:

1. The terminal nerve arises from the olfactory placode, a structure that gives rise to the olfactory sensory neurons
2. The terminal nerve arises from the ►cranial neural crest, a group of cells known to give rise to neuroendocrine cells in the vertebrates.

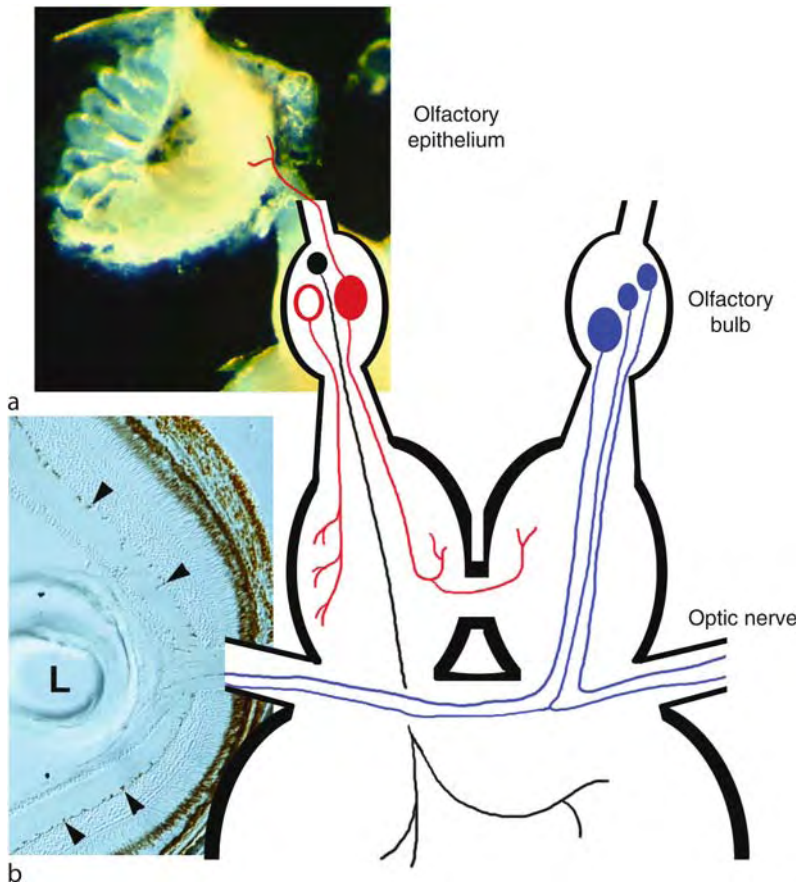
## Structure of the Terminal Nerve

The terminal nerve or nervus terminalis is the last identified of the cranial nerves of the peripheral nervous system in vertebrates. The terminal nerve (TN) is found in all jawed vertebrates including humans, although is axonal projection pattern and cell body location vary widely among the vertebrate animals. The TN is associated with the olfactory nerve, has processes extending into the region of the olfactory epithelium and has ganglia located at various points along its projections that run through the ventral olfactory bulb/telencephalon. The more posterior extent of this ganglionic distribution has been termed the nucleus olfactoretinalis (NOR) in some fishes. The NOR, whose cell bodies are generally located posterior to the junction of the olfactory bulb and the telencephalon, has been considered as a structure distinct from the TN in some analyses. In general, comparative analyses suggest that the NOR is in fact the most posterior part of the TN ganglionic distribution (see for review [1]).

The morphology and distribution of the TN ganglionic cells differs across species. Elasmobranches and teleosts tend to have compact discrete clusters of cells located in the region of the olfactory nerve junction with the olfactory bulbs and at the junction of the olfactory bulbs with the telencephalon. In mammals the TN neurons are more distributed, with less distinct ganglia. The cells of the mammalian TN are often smaller and fusiform-shaped as opposed to the larger round cells observed in the aquatic species. In all animals the cells are predominantly bipolar with one axon process extending toward the peripheral olfactory system and the other one toward the central nervous system.

The axonal projection patterns of the TN vary across vertebrates (Fig. 1). In fishes the TN has a distinct axonal projection to the inner plexiform layer of the retina, a projection that appears also to be present in amphibians [2]. Based on studies in fishes (goldfish), the TN has been shown to have two separate sets of projections, one that extends to the retina but does not have any connections to the olfactory epithelium (Fig. 1, blue) and a second set of projections associated with the olfactory epithelium with extensions in the central nervous system but not to the retina [3] (Fig. 1).

The TN contains neuroactive peptides, such as neuropeptide Y (NPY) and FMRFamide and acetylcholine (as assayed using acetylcholinesterase and choline acetyltransferase markers) [2]. A notable characteristic of the TN is that it contains the neuroendocrine decapeptide



**Evolution of the Terminal Nerve. Figure 1** Diagram depicting the projections of the terminal nerve within the olfactory and visual system. Adapted from Stell et al. [3]. The TN has several types of axonal projections within the olfactory system (*red*), one of which consists of bipolar neurons with axons extending to the olfactory epithelium/mucosa (*red closed circle*). In addition there are projections to the retina (*blue*) and ventral forebrain (*black*). The TN neurons in zebrafish are recognized by an anti-GnRH antibody (LRH13), express *GnRH3* and have axons extending both anteriorly and posteriorly. (a) Olfactory rosette of the adult zebrafish. (b) Section of zebrafish retina depicting GnRH-positive axons and terminals (*arrowheads*) of the TN. *L* = lens of the eye.

gonadotropin-releasing hormone (GnRH). The presence of GnRH (or luteinizing hormone releasing hormone, LHRH) was first described in 1980 in the guinea pig using immunocytochemical methods [4]. This finding allowed for subsequent studies in which GnRH positive cells were identified in a variety of vertebrate species including mammals, fishes and birds [5]. Reptiles contain FMRF positive cells suggesting that they too may have GnRH positive cells in the TN. Through molecular analysis, it has been shown that there are multiple (three) forms of GnRH in vertebrates based on amino acid sequence. In fishes the form of GnRH found in the terminal nerve ("salmon GnRH" or GnRH3) is often distinct from that found in the hypothalamus (see for review [6,7]). This separation of GnRH cell populations does not appear to be generally true for other animals, although the data are clouded by use of cross-reactive antibodies. Until gene expression, using probes specific for the sequence of the GnRH genes, is more carefully analyzed across the vertebrate groups, it is difficult to say with certainty whether the fishes are the only animals showing a unique TN-specific form of GnRH.

## Function of Terminal Nerve

The identification of GnRH positive cells in the TN of gnathostomes provided a valuable tool in the analysis of the function and evolution of the TN. GnRH is a highly conserved neuroendocrine decapeptide that has been identified in all Chordata subphyla – Urochordata, Cephalochordata and Vertebrata – thus suggesting its presence in the ancestral root protochordates. The presence of GnRH positive cells in the TN has been identified in every class of vertebrates except for the silver lamprey [8]. The presence of neurons containing GnRH within the TN suggests a function in reproduction, but this appears to be neuromodulatory and

distinct from the hypothalamic populations of GnRH cells that play a role in release of gonadotropins from the anterior pituitary.

The TN has axonal projections to the olfactory sensory system where the axons terminate near the basement membrane between the lamina propria and olfactory epithelium, although in some cases GnRH positive endings have been observed in the olfactory epithelium [1]. In fishes the TN has axonal projections extending into the retina, of which a subset contain GnRH. The TN has been reported to have functional roles in olfactory and retinal physiology, reproductive function, sexual behavior and interactions with the pineal system, indicating that there is no clear consensus as to the function of the TN.

## Association of Terminal Nerve and Olfactory System

Because the TN ganglionic cells are found in association with the olfactory sensory system, typically embedded in the olfactory nerve, and because some studies propose that the TN arises from the medial olfactory placode, the implicit assumption is that these two nerves are inexorably linked in development and function. The TN is generally present throughout the life of the organism in fishes. In contrast, in mammals the TN is present in all species thus far examined, but it is not uncommon for the TN to be prominent in fetal stages then become less distinct and reduced in the adults. For example, in microsmatic insectivorous bats the TN is present in the early stages of development, but as development proceeds the TN is lost in adults [9]. Interestingly these bats do not have a vomeronasal organ, the part of the olfactory sensory system associated with the TN in mammals.

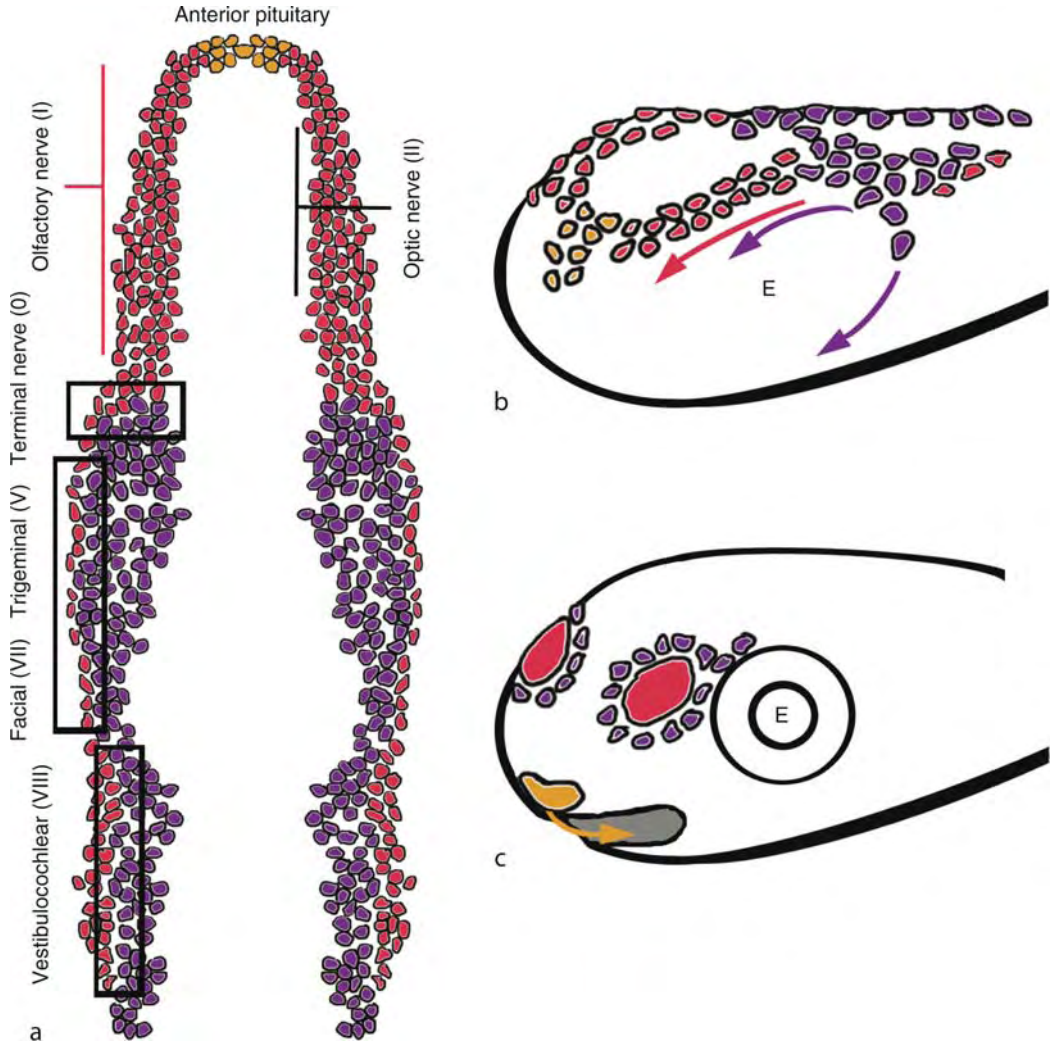
Evidence suggesting that the TN and the olfactory sensory system are not functionally interdependent is gleaned from studies in the toothed whales, whose nares are displaced to the dorsal surface of the head and are anosmatic. The TN in adult odontocetes is large and contains GnRH positive neurons. The developmental association between the TN and the olfactory epithelium has been analyzed in these animals, since their embryos have an olfactory epithelium, a vomeronasal organ and a TN system, although the vomeronasal system is extremely rudimentary. As development proceeds, the olfactory epithelium degenerates as does the vomeronasal epithelium yet the TN remains [10]. The olfactory epithelium actually regresses prior to the appearance of the future terminal nerve ganglion. The retention of the TN in the adult suggests that olfaction is dispensable in whales, but the function of the TN is necessary to the survival of this group of animals. Because the olfactory placode and TN appear to have separable developmental origins (see below), function may in fact be more readily gained or lost in an independent manner.

## Cranial Nerves are Derived from Neural Crest and Sensory Placodes

Ontogeny recapitulates phylogeny in the sense of the general to the specific; thus, the developmental origin of the TN is informative as to its potential evolutionary origin. The cranial nerves of the nonvisual paired sense organs of the head (nose, taste buds, ears, etc.) have their embryonic origins in the thickenings of the neurectoderm (placodes) and in neural crest, as exemplified by the olfactory, vomeronasal, trigeminal, facial, vestibulocochlear, glossopharyngeal and vagal nerves [11]. Shortly after the discovery of the TN, it was suggested that the TN arose from cranial neural crest. This proposal was based on observations that the TN was identifiable while the cranial neural crest vanished on either side of the neuropore and that the appearance of these cells in many sections suggested a neural crest origin in elasmobranches. Observations by Johnston in the early 1900s also noted the close association of the neuropore, developing TN and neural crest and suggested a neural crest origin for the TN (for review see [12]). After the identification of GnRH as a marker for the TN, studies in the developing mouse embryos showed that there are GnRH positive cells associated with the olfactory sensory system, thus supporting the hypothesis that the TN originates in the olfactory placode [13,14]. Thus, the reported close proximity of GnRH-positive cells to the developing olfactory placode and subsequent localization to the TN suggested that the TN arises in part or entirely from the olfactory placode. More recently it was proposed that the ganglionic cells of the TN are of multiple embryonic origins, with the GnRH positive cells proposed to arise from the medial olfactory placode and the catecholaminergic cells from mesencephalic neural crest [11].

Operating on the model that the olfactory placode generates the GnRH containing cells of the TN, a single cell fate map was made in the zebrafish embryo prior to olfactory placode formation and no precursors of GnRH cells (either the TN or hypothalamus) were uncovered [15]. Because neural crest cells contribute to the structural elements of the frontal nasal process by moving anteriorly and surrounding the olfactory placode as it forms (Fig. 2), the possibility that the neural crest contributed to the TN was further explored [16].

The olfactory placode field and pre-migratory neural crest domains are recognizable using gene markers that share a common border (Fig. 2a). Using a combination of dye labeling and single cell lineage tracing, it was demonstrated that GnRH positive cells of the TN originate in cranial neural crest in zebrafish [17]. Subsequently it has been demonstrated that decrement in function of two genes important for neural crest development, *sox10* and *fkd6*, leads to loss of the GnRH cells of the TN as well as those of the midbrain [18]. Thus, the adjacent neural crest and olfactory placode

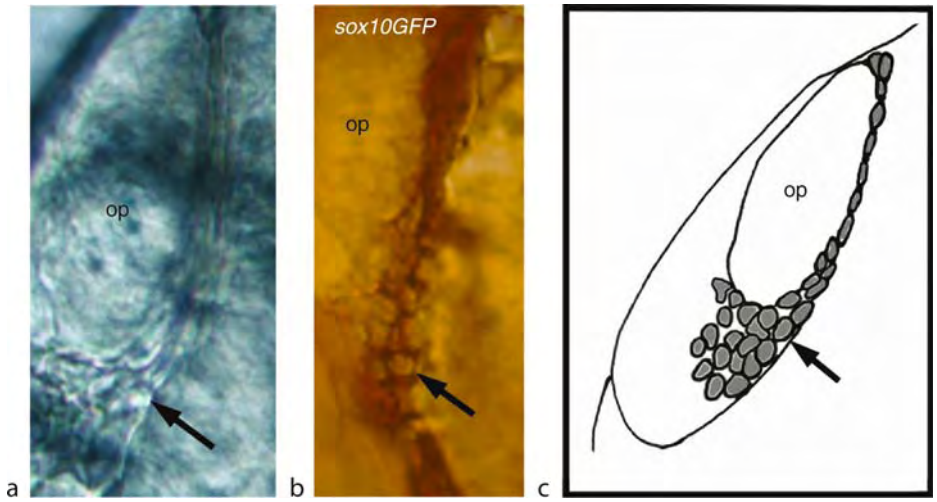


**Evolution of the Terminal Nerve. Figure 2** Cell movements resulting in formation of olfactory placode and TN. (a) Diagrammatic depiction of neural crest (*purple*) and ►sensory placode (*red*) domains in the developing neural plate (dorsal view anterior toward the top of the page). Cranial nerves thought to arise from neural crest and sensory placodes: vestibulocochlear (VIII), facial (VII), trigeminal (V), and terminal (0) [11]. The olfactory nerve arises from the olfactory placode domain, although glia may be neural crest derived, and the optic nerve arises from the neural tube. The TN arises from the most anterior cranial neural crest that interfaces with the olfactory placode domain. These cells will migrate anteriorly resulting in neural crest cells surrounding the newly formed olfactory placode (b, c). *E* = lens of the eye.

domains sort into cranial neural crest- and olfactory placode-derived structures as they migrate anteriorly to form the frontal mass and associated neural tissues. The association of the TN with the forming olfactory placode (Fig. 3) appears to be secondary.

## Conclusions

In examining the evolution of animals, the visual system is a highly conserved sensory structure. Paired eyes have appeared in many different types of animals and the molecular signaling pathways controlling the development of eyes are highly conserved. In contrast, head and neural crest are cell populations that have appeared only once in chordates (for review see [19]). The embryonic origin of the TN, whether partially or wholly derived from neural crest, suggests that it postdates the appearance of eyes in vertebrates. The TN is ontogenetically separable from the olfactory placode both by lineage and by genetic pathways. These findings, coupled with the observations that phylogenetically the TN is not absolutely correlated with the presence or absence of olfactory epithelia across species, suggests an origin independent of, but coordinated with, the appearance of the olfactory placodes.



**Evolution of the Terminal Nerve. Figure 3** Visualization of association of cranial neural crest cells with the olfactory placode in the zebrafish embryo. (a) Olfactory placode (*op*) in living zebrafish embryo. (b) Localization of *sox10*-GFP neural crest marker to cells (*arrow*) associated with the olfactory placode (*op*). (c) Cells proposed to be precursors on TN (*arrow*) located at antero-medial aspect of the olfactory placode.

Because cells of the TN contain GnRH, a neuroendocrine decapeptide and this feature appears to be conserved across vertebrates at least in early development, it can be argued that the ancestral precursor of the TN contained GnRH. The lungfish has a distinct TN that projects to the telencephalon, as well as a second nerve (nervus preopticus) that originates near the nostril and extends to the preoptic area. The lungfish TN does not contain GnRH and the "nervus preopticus does contain GnRH positive cells" [20]. The latter has been called the "posterior root" of the TN. These observations led to the suggestion that the TN may have arisen from the fusion of two separate cranial nerves over evolutionary time.

# Evolution of the Trigeminal Sensory System and its Specializations

Paul R. Manger
School of Anatomical Sciences, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, Republic of South Africa

## Synonyms

Somatosensory trigeminal system; Evolution of trigeminal nerve

## Definition

The ►*trigeminal nerve* or fifth cranial nerve carries sensory information from the head to the brainstem, from whence it is passed to more rostral portions of the brain. In vertebrates several unique sensory systems subserved by the trigeminal nerve have evolved.

## Characteristics

### Basic Structure of the Trigeminal Sensory System

#### *Peripheral Nerve Pathways*

The trigeminal nerve carries sensory information from the cutaneous surface of the head (including the oral cavity) and jaws as well as the muscles of the jaw. As its name suggests, the trigeminal nerve has three main branches, the ophthalmic branch innervating the skin on the anterior part of the head, the maxillary branch that innervates the upper jaw, upper teeth, the roof of the mouth and the upper lip and the mandibular branch that innervates the lower jaw, lower teeth, the floor of the mouth and the lower lip. The trigeminal nerve is large in animals that have a well-developed snout and face, and is significantly expanded in animals that have associated sensory specializations of the face (see below). The three major branches of the trigeminal nerve are found in all vertebrates and are similar in distribution (although they differ in size), but in many of the non-mammalian vertebrates a profundus division of the trigeminal nerve has been identified, which appears to correspond to the ophthalmic division of the mammalian trigeminal nerve [1].

#### *Central Nervous System Pathways of the Trigeminal Nerve*

Within vertebrates the central terminations and pathways of the trigeminal nerve are quite consistent. The three major branches of the trigeminal nerve form synapses with two locations within the central nervous system: (i) the descending or spinal nucleus of the trigeminal nerve, which is found within the somatic afferent column of the lateral medulla oblongata and continues into the dorsal horn of the spinal cord and (ii) the principal nucleus of the trigeminal nerve, which is seen to be a rostral expansion of the lateral somatic afferent column located within the pons. In both these sites there are topographic maps of the various incoming sensory inputs. From these two sites, the sensory information is conveyed to the dorsal thalamus and thence to the somatosensory cortex (of mammals) or the somatosensory pallium of other vertebrates. This pathway is the largest central pathway of the trigeminal nerve. A lesser sized branch of the ascending trigeminal pathway projects to the intermediate gray layer of the superior colliculus in mammals or the optic tectum in other vertebrates. This smaller projection, along with projections from the spinal cord, forms the topographic somatic input to the tectum (see ►*magnetoreception* below). There are two main variations on these pathways.

In birds, the target of the rostrad projection of the principal trigeminal nucleus is not the dorsal thalamus but a group of neurons in the telencephalon called the nucleus basorostralis pallii, which in turn sends axons to the somatosensory pallium. It is unclear whether the nucleus basorostralis pallii is a homologue of the somatosensory dorsal thalamic nucleus of mammals (the ventral posterior medial nucleus, first described in the platypus by Hines [2]). A second unusual morphology of the trigeminal nerve is the mesencephalic nucleus of the trigeminal nerve (or mesencephalic V). This nucleus is found between the commissures of the tectum and the periaqueductal gray matter. The cell bodies are large and readily visible and are in fact ganglionic cell bodies that are embryologically derived from neural crest and have migrated into the central nervous system. In jawed vertebrates, all other neural crest-derived ganglionic cell bodies are located outside the CNS. The neurons of mesencephalic V carry proprioceptive information about the muscles of the jaw, the connective tissue surrounding the teeth and in mammals and amphibians about the extraocular eye muscles. The neurons of this nucleus project upon the trigeminal motor nucleus, thus playing a role in

the opening and closing of the jaw. Interestingly, the mesencephalic V neurons are not found in jawless vertebrates (agnathans), but they may have serially homologous counterparts in the spinal cord of agnathans [1].

## The Various Sensory Modalities of the Trigeminal Nerve

### *Infrared Detection in Snakes*

One of the many unusual sensory systems that have evolved and are associated with the trigeminal nerve is the ability of certain snakes to detect infrared radiation (►Infrared detection) [3]. This sensibility has evolved in two families of snakes, the boids (pythons and boa constrictors) and the crotalids or pit vipers (rattlesnakes, water moccasins, bushmasters, fer-de-lances, etc.). The actual sensory receptor is a pit located on the face of the snake, either as a single pit below the eye (crotalids), or as a row of pits lining the lips (boids). These pits are lined with a sheet of photoreceptors that are sensitive to the infrared radiation (which is out of the visible range of humans) and are supplied by the maxillary branch of the trigeminal nerve. Infrared radiation (IR) is emitted by all objects that have any form of warmth and emissions are especially high from the warm-blooded mammals and birds that form a large part of the snakes' diet. The infrared detectors of the rattlesnake have been shown to be sensitive to differences in temperature of around 0.003°C, which is approximately the heat radiated by a human hand at around 50 cm.

The maxillary nerve fibers that transmit the IR sensory information terminate in a special subdivision of the trigeminal sensory nuclei in the brainstem called the lateral trigeminal nucleus – a subdivision not found in snakes that don't detect IR. The neurons of this nucleus respond to IR sensory information in a manner not dissimilar to the way neurons that process visual information respond to visible light. From here, the IR information is sent to the nucleus reticularis caloris of the reticular formation (again a specialized subdivision only found in IR sensitive snakes) and onto the tectum of the midbrain, where a topographic map is found. Whether IR information is then passed onto the pallium via the dorsal thalamus is presently unknown.

### *Magnetoreception in Fish, Birds and Molerats*

The ability to detect magnetic fields has been described behaviorally in six different vertebrate classes, the most intensively studied models of magnetoreceptive behavior being homing in migratory birds, sea turtles, molerats, newts and salmonid fish [4]. The behavioral responses to magnetic fields and their role in orientation are well understood; in contrast, the biophysical and neurological mechanisms underlying magnetoreception are still poorly understood, although studies using new neurological tools are improving this situation [5]. The primary ►magnetoreceptor is still yet to be definitively identified; however, candidates include photopigments in the retina and pineal gland and magnetite-based magnetoreceptive structures that have been found in the olfactory lamellae of the nose of the trout and the cutis of the upper beak of pigeons. The magnetite-based candidate magnetoreceptors are light independent in action. It has been demonstrated that these putative magnetoreceptors are innervated by the ophthalmic branch of the trigeminal nerve. Thus, one can conclude that the portions of the brain that process magnetic field information derived from these magnetite-based magnetoreceptors must be involved with the trigeminal system.

Electrophysiological recording from neurons of the ophthalmic branch of the trigeminal nerve and the trigeminal ganglion in birds and fish have shown sensitivities to alterations in magnetic fields that would allow them to fix their position with an error of less than a few tens of kilometers [4]. As yet, higher neural centers processing magnetic information have not been identified in birds or fish, even though the trigeminal pathways within the brains of these species are known. In the molerats, the use of inducible transcription factors, such as Jun, Fos and Krox, has provided more detail regarding the central processing of magnetic information and has shown that a discrete sublayer of the superior colliculus plays an important role in orientation to magnetic field alterations [6]. This sublayer of the superior colliculus (specifically the outer sublayer of its intermediate gray layer) is dominated by trigeminal input in other mammals, which makes it likely that the behavioral orientation to magnetic stimuli in molerats is subserved by the trigeminal nerve. These experiments indicated that, like other sensory systems, there is a topographic arrangement or magnetotopic map within the superior colliculus, which may be aligned and integrated with other collicular maps as occurs in most vertebrates. Further experimentation using these techniques is likely to reveal other regions of the brain that process magnetic information. One particularly interesting open question is whether this information is passed on to the thalamo-cortical system, as this may indicate an awareness of changes in the magnetic field and thus bring the magnetosensory system into the realm of cognition, conscious experience and decision making on the basis of magnetic information.

### *Mechanoreception*

The mechanical receptors (►Mechanoreception) supplied by the trigeminal nerve exhibit a great variety of forms, from basic free nerve endings, typical sensory cell type receptor endings and normal hair follicle receptors through specialized ►vibrissae (or whiskers) in mammals and specialized feathers at the base of the bill in birds to the complex array of multiple

E

mechanoreceptors found in the bill-tip organ of several species of birds, the Eimer's organ of insectivores and the push-rod mechanoreceptors of the monotremes. Given that the trigeminal nerve supplies the skin of the face and the oral cavity, the range of mechanoreceptors found in vertebrates is perhaps not surprising, as this is generally the region of the body that is involved in the detection and ingestion of food. Most interestingly, there are a few cases of convergent evolution in the form of the specialized mechanoreceptor complexes that are quite spectacular in nature.

*Vibrissae* or whiskers, which are a specialized hair follicle receptor, are a common feature of the lateral maxillary skin region of the therian (marsupial and placental) mammals. Amongst the therian mammals, those possessing vibrissae with associated central nervous system specialization (see below) include the metatherian possums and gliders and the eutherian rodents [7,8]. The possums, gliders and rodents use the vibrissae to navigate in the darkness and also to investigate objects of interest. One of the more spectacular cases of central nervous system convergent evolution is found in the representation of the vibrissae in the primary somatosensory cortex of these species, which are heavily reliant on vibrissae information. This central morphological similarity is referred to as "barrel" cortex due to the manner in which the cells of the cerebral cortex are clustered. The barrels exhibit two distinct forms, termed hollow and solid [7,8] due to the location of the neuronal bodies in the barrel-shaped formation that occurs in the cerebral cortex. That these barrels occur in several taxa, many of which are distantly related (for example the African porcupine of the eutherian Rodentia and the sugar glider of the metatherian *Diprotodontia*) and in different forms in more closely related taxa (for example the rat has solid barrels with the cells forming a cluster in the middle of a sheath of myelinated axons and the mouse has hollow barrels with a bundle of myelinated axons being surrounded by a shell of neuronal bodies) is an excellent example of convergent or divergent morphology in the central processing of sensory information from similarly specialized peripheral sensory receptors.

►*Mechanoreceptor epidermal rod complexes*, such as bill-tip organs in birds, Eimer's organs in moles and the push-rod mechanoreceptors of the monotremes, provide another example of convergent evolution, as they occur in distantly related taxa but have a very similar form and a similar function, i.e., extremely sensitive somatosensation involved in the location of food. These complexes are found within a column of epidermal cells, forming a rod that traverses the epidermis from the skin surface (the tip of the rod being visible under the dissecting microscope) to the dermis, in the skin of the rhinarium. In mammals there are usually three type of tactile receptors localized within the complex: (i) one to three paciniform or encapsulated receptors that are sensitive to vibration, located deeper in the dermis than the epidermal rod, (ii) Merkel cells (one to twelve) that are slowly adapting light touch sensitive receptors, found within but at the base of the epidermal rod and (iii) a series of vesicle-chain neural processes that traverse the rod from its base to its tip, forming free nerve endings very close to the surface of the skin (the physiology of these vesicle chains is unknown, but it is presumed that they are very sensitive to light tactile stimulation, probably of a shearing nature). Of the mammals possessing these epidermal rod complexes, that of the platypus is perhaps the most complex, typically exhibiting two or three paciniform receptors, up to 12 Merkel cells, and upward of 40 vesicles chains, with a total of around 46,500 of these complexes arranged over the bill [9]. In the birds, a series of Herbst (similar to mammalian paciniform corpuscles) and Grandry (similar to Merkel cells) corpuscles are found in varying number and location throughout the rod, along with terminal cell column receptors and branched nerve endings with terminal cells toward the tip of the rod. The Herbst corpuscles detect vibratory stimuli, the Grandry corpuscles and terminal cell column receptors encode the velocity of the mechanical stimulus and the branched nerve endings the static stimulus components [10]. The central representation of these receptors is also specialized, especially in the primary somatosensory cortex of mammals, where stripes relating to the peripheral location and distribution of these receptors have been recognized (e.g., platypus [11]; star-nosed mole [12]).

### Electroreception in the Monotremes

Perhaps the most intriguing sensory system associated with the trigeminal nerve is the electroreceptive system of the monotremes, first discovered by Scheich and colleagues [13]. In the two species of echidna, the electroreceptive system is not extensively expressed in comparison to that of the platypus [14]. In the platypus, two types of ►*electroreceptor*, one associated with a mucous gland the other with a serous gland, are found within the skin of the bill. The mucous gland electroreceptors are arranged in rostro-caudally oriented stripes along the bill and number in the region of 40,000 per individual platypus, while the serous gland electroreceptors are found most densely along the edges of the bill and number in the region of 13,000 [9]. The striped array of the mucous gland electroreceptors probably underlies the ability of the platypus to detect the origin of an electrical field and move its bill toward this field, as electrical fields decay exponentially as they pass through freshwater [15]. The mucous gland electroreceptor is a complex receptor organ, made up of a ring of up to 16 free nerve endings surrounding the duct of the mucous gland at the dermal–epidermal

junction. Each free nerve ending has a small neural protrusion piercing a layer of tightly joined keratinocytes that surround the epidermal duct of the mucous gland, presumably forming electrical insulation. From each of these neural protrusions there are small side branches that appear to connect (probably through a gap junction) to similar branches from neighboring nerve terminals. This pattern of peripheral interconnectivity probably serves a function in enhancing the signal to noise ratio [16]. The mucous gland electroreceptor is also innervated by several autonomic and C-fibers. The autonomic fibers are found surrounding the mucous gland in the dermis and a series of actin containing keratinocytes that form something akin to a sphincter lie around the upper epidermal portion of the duct [17]. The C-fibers are found traversing the epidermis peripheral to the mucous gland to within a few cells of the skin surface. These C-fibers are probably thermo- or wet-sensitive and appear to initiate an autonomic reflex loop, which when wet initiates secretion by the mucous gland and relaxation of the actin sphincter (which allows the rose-like arrangement of superficial keratinocytes around the duct pore to open). Personal observations of comfortable captive platypus indicate that prior to entering the water they immerse the bill in water for a few seconds, two to three times. This presumably prepares the bill for ►electroreception prior to full immersion and swimming by the platypus, this being somewhat akin to the rubbing of eyes on waking up. Interestingly, the push-rod mechanoreceptors and serous gland electroreceptors display similar actin rings and C-fiber innervation, indicating that both these structures are activated in water. The push-rod mechanoreceptors would have their tips freed up and become more sensitive. Presumably, as the bill dries, the actin sphincters tighten and the glands cease secretion.

This initiation of electroreception in the water and the increased tactile sensitivity in water may play an important role in the detection of food for the platypus. Firstly, the distribution of the mucous gland electroreceptors allows them to act as an antenna, providing the platypus with knowledge of the source of a bioelectric field and thus the direction in which to move the bill to capture the prey. The loosened push-rod mechanoreceptor may be sensitive enough to detect water pressure waves. At a distance of around 10 cm, the water pressure wave generated by the tail-flick of a freshwater shrimp (a natural prey item of the platypus) arrives approximately 5 ms later than the electrical wave created by the muscular contraction [18]. Using this time delay in the arrival of the pressure wave, the platypus will be able to compute the distance from the bill to the source of the bioelectric potential. This synergy between electrical and tactile processing provides the platypus with an accurate 3D locality for its prey item. A nice analogy to this capacity of the platypus was first described by Jack Pettigrew as the "thunder and lightening" hypothesis of platypus prey location [19]. On seeing lightening, the seconds until the arrival of the thunder are counted to gauge the distance of the storm. Pettigrew postulated that the platypus might be doing a similar calculation, only in the range of milliseconds and centimeters, not seconds and kilometers. This processing would take place in the primary somatosensory cortex of the platypus, where a stripe-like arrangement of specialized neurons, responsive to both tactile and electrical stimulation could detail the decay of the electrical field across the bill and the time delay in arrival of the pressure wave.

# Evolution of the Vestibular System

Werner M. Graf
Department of Physiology & Biophysics, Howard University College of Medicine, Washington, DC, USA

## Synonyms

Vestibular system; Labyrinth; Sense of balance; Sense of equilibrium

## Definition

The sense of balance, the vestibular system, is our unknown sense. We recognize its existence only under pathological conditions, such as seasickness, dizziness, vertigo, etc. Among the classical five senses, i.e., vision, taste, smell, touch, hearing, our sense of balance is not mentioned. Quite often, the sense of balance is just considered as an appendix of the auditory sense due to the anatomical unity of cochlea and vestibular apparatus, the so-called inner ear. The inner ear is really a fabulous example of the "engineering" capabilities of nature and evolution being one of the most complex anatomical structures in vertebrate history: in humans, we find two hyper-sensitive hyper-precise sensory organs housed within the space equivalent to that of an aspirin tablet – the auditory sense and the sense of balance. Moreover, under normal life conditions, we are not even aware of the latter's existence. The sense of balance could thus be considered our sixth sense, and its functions are manifold. At least four different and vital functions should be mentioned: (i) postural control and postural stabilization, (ii) reflex movements, (iii) perception of self-movement, and (iv) autonomous control.

## Characteristics

### Anatomy

The inner ear is a bilateral organ. It is located inside the petrosal bone of the temporal bone of the cranium. The balance organ is part of the inner ear and consists of the ►semicircular canals and the ►otoliths (Fig. 1).

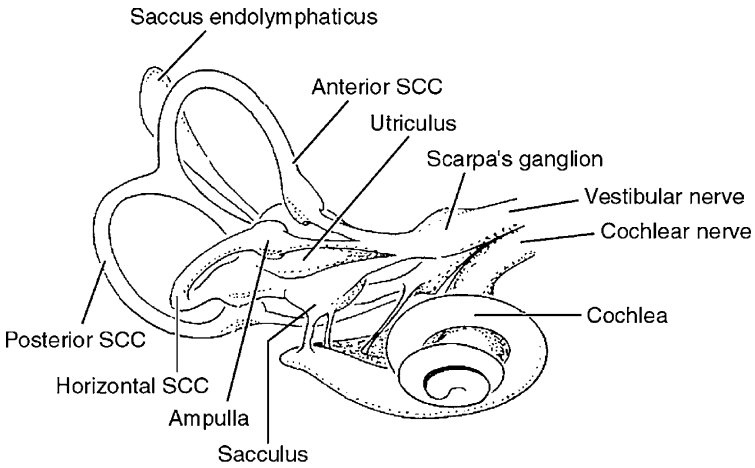
At first sight, the twisted and three-dimensional structure of the inner ear looks quite complicated and has earned the balance organ the name *labyrinth*.

Semicircular canals and otoliths are sense organs, which detect accelerations. The semicircular canals detect angular accelerations (rotations), the otoliths linear accelerations (translations). An example for a ubiquitous and permanent linear acceleration is earth gravity (gravity vector). Under normal living conditions, we rarely spend a thought about gravity, but when gravity becomes absent, the effects can be dramatic, as during space flight under micro-gravity conditions with resulting space motion sickness.

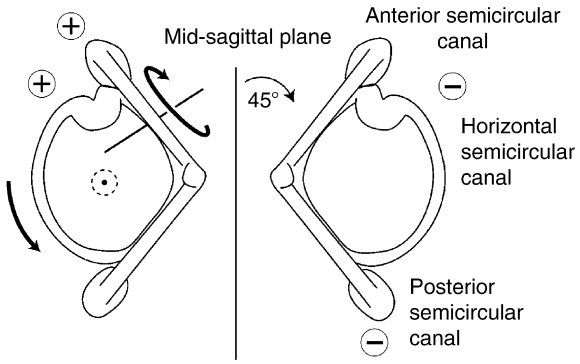
#### *The Semicircular Canals*

The operational mode of the semicircular canals is independent of gravity. The canals are filled with a fluid, the so-called endolymph, which, during a given head movement, causes a so-called endolymph current, which displaces receptor cells inside a specialized area of the canal lumen, the so-called ►ampulla [1]. An important characteristic of the macroscopic anatomy of the semicircular canals is their three-dimensional orientation. The ensemble of the six canals, three on each side forms a physical coordinate system to detect angular accelerations in three-dimensional space. The semicircular canal system on each side of the head consists of a horizontal (lateral) canal, and two vertical canals (one anterior and one posterior canal) (Fig. 2). The horizontal canal is lightly tipped upward (about 30° in humans) at normal head resting posture. The vertical canals are oriented about 45° off the mid-sagittal plane of the head (Fig. 2).

The orientation of the semicircular canals in the head follows three interdependent functional principles: (i) bilateral symmetry: both labyrinths are mirror symmetric; (ii) reciprocal operational mode: during head rotations receptors in a given canal will be excited, while the receptors in the contralateral coplanar canal will be inhibited; so-called push-pull system; (iii) mutual orthogonality of canals: the functional planes of the canals enclose angles of 90°, or close to that value (Fig. 2). The semicircular canal system thus constitutes an intrinsic sensory reference frame system, which provides a blueprint for the spatial coordination of a number of reflex functions and sensory interactions.



**Evolution of the Vestibular System. Figure 1** Anatomy of the organ of the sense of balance. Lateral view of the right human labyrinth in the approximate normal resting position of the head showing the portions of the sense of balance (semicircular canals, SCC, and otoliths) and of the sense of hearing (cochlea).



**Evolution of the Vestibular System. Figure 2** Spatial orientation of an idealized semicircular canal system (top view). Anterior and posterior canals are oriented vertically, horizontal canals are oriented horizontally. The vertical canals are oriented 45° off the midsagittal axis ("diagonal" orientation). Note bilateral symmetry, mutual orthogonality between canals, and the push-pull operational mode illustrated for the right posterior and the left anterior canals, and the right and left horizontal canals. When one canal becomes excited (+), its coplanar counterpart becomes inhibited (−). Canal on-directions are indicated by the directions of the arrows about the canal rotation axes. The combined excitatory and inhibitory responses of all canals during head movements produce a meaningful activity pattern in the afferent nerves and recipient brain nuclei to represent a movement vector in physical space (Figure modified after [2]).

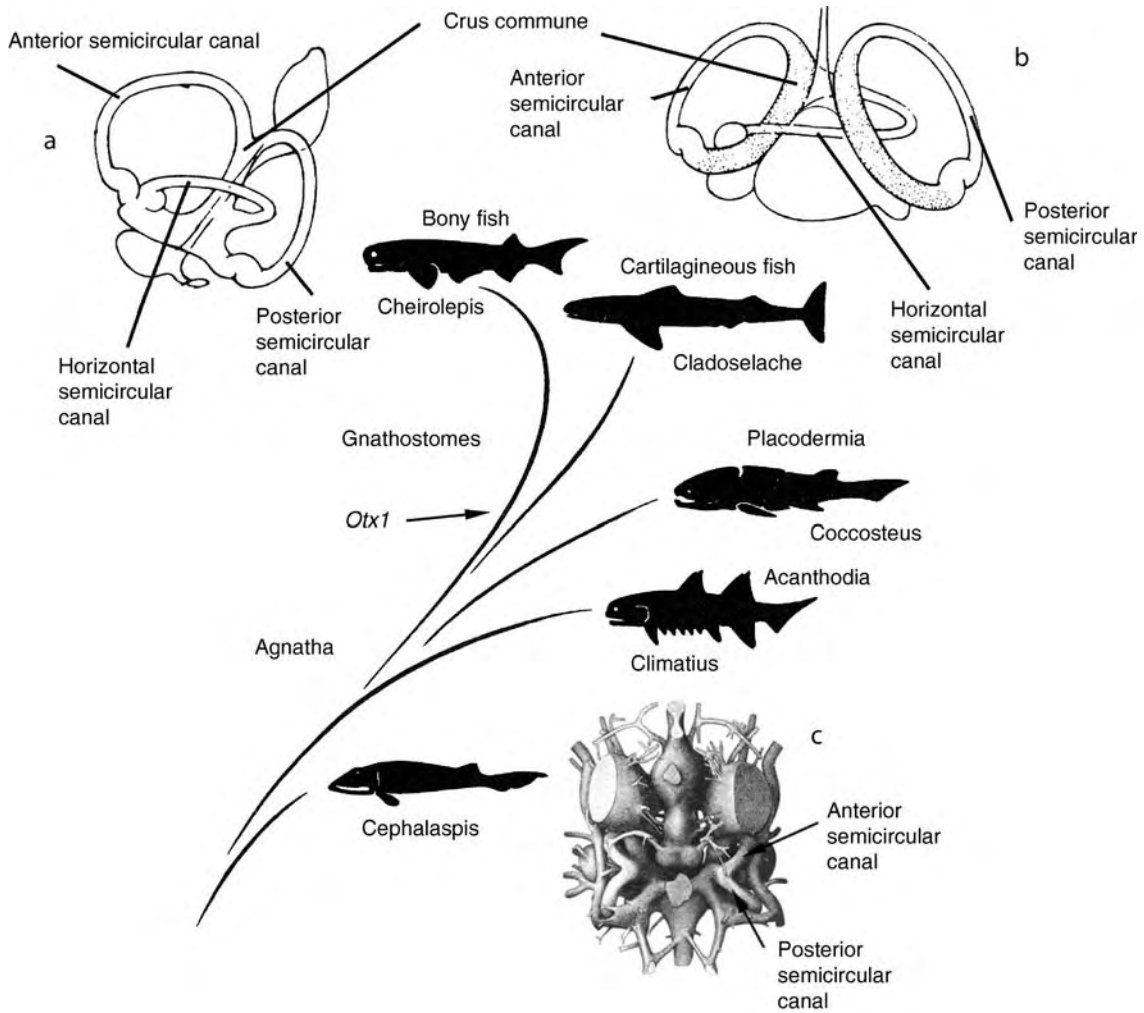
### *The Otoliths*

By contrast to the semicircular canals, the otoliths are receptors that depend on the presence of gravity ("graviceptors"). They detect linear accelerations, and do not function in microgravity. Most ►vertebrates, including humans, posses two otoliths on each side, the horizontal utriculus and the vertical sacculus. At normal resting posture of the head, the utriculus seems to be oriented earth horizontally. The receptor cells of the otoliths are embedded in the so-called otolith membrane, which contains the ►otoconia. During a displacement of the head from normal upright position, the otoconia will slide across the otolith membrane and produce a shear force upon the receptor cells.

## Evolutionary History of the Labyrinth

The phylogenetic origins of the vertebrate labyrinth are not known. The only living proto-chordate, *Amphioxus*, possesses a median eye but no candidate for a homologue of the vestibular apparatus. Furthermore, only fragmentary fossil records exist that testify to the beginning of vertebrate life in Cambrian times, more than 500 million years ago. However, there now seem to be indications from molecular biology data for a common ancestor regarding mechanoreceptor cell evolution between *Drosophila* and vertebrates, i.e., ►hair cells [3]. Although for a long time, the balance organ had been thought to have evolved from the ►lateral line system, recent evidence based on multiple out-group comparison suggests, that the inner ear of vertebrates evolved as a statolithic system before the lateral line system and before semicircular canals appeared.

The fossil record becomes more complete only during the middle of the Paleozoic era, the Devonian period (400–350 million years ago). The first record that demonstrates the existence of semicircular canals comes from jawless vertebrates, agnathan species of the Devonian and Silurian times, the ostracoderms. They possessed vertical but not horizontal canals (Fig. 3).



**Evolution of the Vestibular System. Figure 3** Phylogenetic relationship of early agnathans and gnathostomes (bony fishes, cartilaginous fishes, placoderms, and acanthodians) (modified after [4]), including prototypical vertebrate labyrinth characteristics. (a) Human labyrinth (after [2]). (b) Shark labyrinth, *Chlamydoselachus* (after [2]). (c) Ostracoderm labyrinth without horizontal canals (after [5]). Horizontal semicircular canals appear in bony fishes and cartilaginous fishes coinciding with the appearance of the ►*Otx*1 gene. In bony fishes through humans, the anterior and the posterior canal form a common crus. In cartilaginous fishes there is no common crus between the anterior and the posterior canal. All labyrinths display a similar ("diagonal") orientation of the vertical semicircular canals in the head.

Their vertical canals were oriented in the head as described before [5] (Fig. 2). The ostracoderm labyrinth was similar to the ►semicircular canal system of lampreys, the extant forms of their once-abundant ancestors. The Devonian period also marks the advent of jawed vertebrates (ganthostomes), bony and cartilaginous fishes (osteichthyes and chondrichthyes, respectively; Fig. 3). We know nothing about the labyrinth structure of the immediate ancestors of these newly appeared animals, but their modern successors display a new acquisition: horizontal semicircular canals. Thus, the vertebrate labyrinth now spans all three dimensions of physical space. The circumstances that led to the development of a horizontal semicircular canal system are unknown, but its presence most certainly introduced distinct advantages for the detection of three-dimensional space in comparison to the four canal system in the agnatha. The acquisition of horizontal semicircular canals coincides with the expression of the vertebrate-specific gene ►Otx1. Knock-out mutants who do not express Otx1 do not develop horizontal semicircular canals [6]. One could speculate that the appearance of horizontal semicircular canals, allowing an optimal solution, i.e., best and most

economical high signal-to-noise-ratio, for movement detection in three-dimensional space constituted one prerequisite for the success of vertebrates later on in phylogeny. At any rate, it certainly provided one further advantage.

Interestingly enough, there are two main lines of labyrinthine development in the surviving radiations, namely what we will refer to as the "bony fish/tetrapod line" (Osteichthyes) and the "cartilaginous fish line" (Chondrichthyes) (Fig. 3) (we are using the term "bony fish/tetrapod" in the following to delineate vertebrate species between bony fish and the two living amniote clades, mammals and sauropsids, the latter comprising reptiles and birds). Unfortunately, no fossil record testifies to the labyrinth structures of earlier radiations that became extinct (e.g., acanthodians, placoderms).

In viewing a typical vertebrate labyrinth of the bony fish/tetrapod line, in this case a human labyrinth (Fig. 3a), we observe that it consists of three canals, one anterior, one posterior, and one horizontal canal. Typically for this type of labyrinth, the anterior and the posterior canal form a so-called ►common crus; that is, they share a segment of their circular structure. The typical cartilaginous fish labyrinth, in this case from a shark (Fig. 3b) also possesses anterior, posterior and horizontal canals that display the same orientation in the head as the bony fish/tetrapod labyrinth type. However, there is no common crus between the anterior and the posterior canals. The posterior canal is separate and has a communication with the sacculus, whereas a common crus-like structure is formed between the horizontal and the anterior canals. This particular difference in labyrinth structure between bony fishes and cartilaginous fishes leads to the intriguing question of whether the phylogenesis of horizontal canals was monophyletic or polyphyletic in vertebrates.

## Comparative Anatomy

A great variety of movement and position detectors, so-called ►statocysts are found in vertebrates, and we will introduce only the most pertinent examples here. One type is found in cephalopods that are fast moving – squid and cuttlefish – while a second type is found in the slower moving cephalopods such as octopus. The third type is typified by the semicircular canals of crabs. Their characteristics show convergent evolution with the arrangements found in vertebrates for solving three-dimensional space orientation challenges.

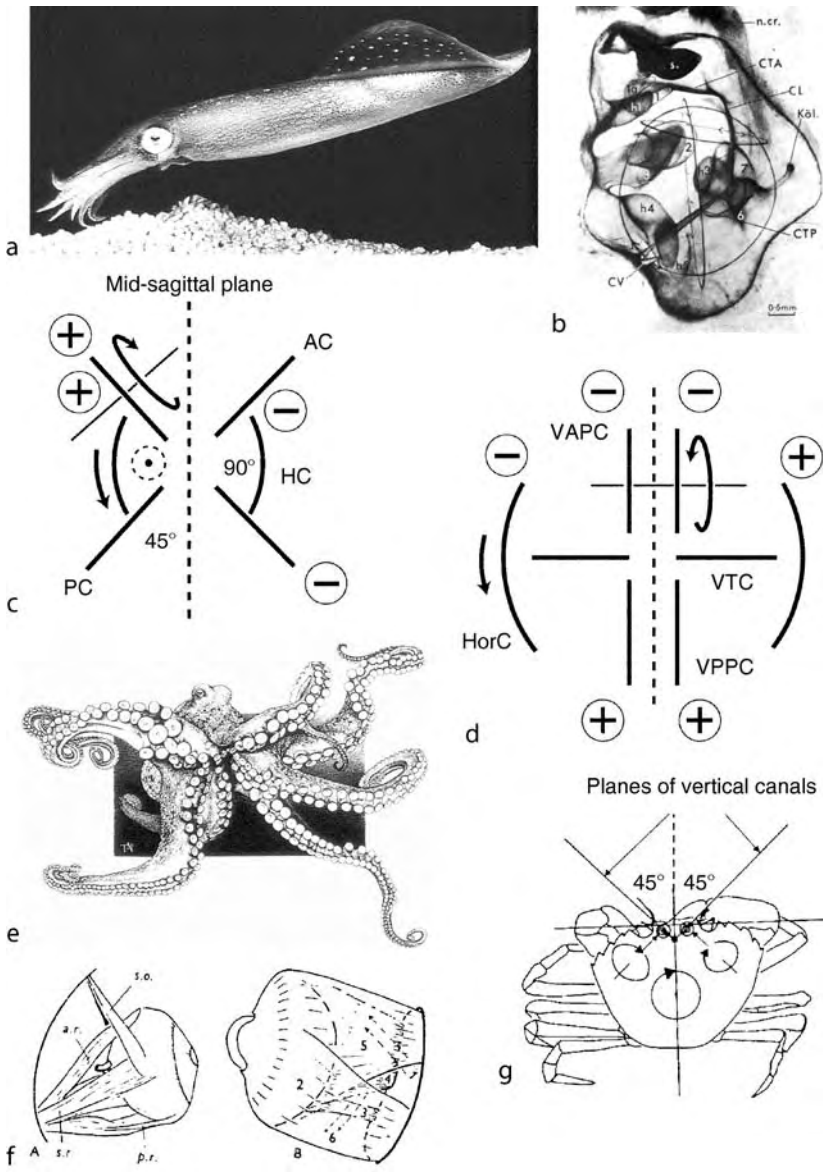
The statocysts of the fast moving squid and cuttlefish (Fig. 4a) include grooves, which, similar to the vertebrate semicircular canals of vertebrates, direct endolymph flow towards a sensory crista with a ►cupula [7].

These invertebrate semicircular canals are oriented in space in a roughly orthogonal three-dimensional planar arrangement (Fig. 4b). Four canals on each side can be distinguished, which are oriented approximately in the main planes of the body (Fig. 4d), in contrast to the vertebrate arrangement (Fig. 4c). Sensory receptors detect movements in the transverse plane of the body, with excitation occurring during ipsilateral upward roll movements, in the longitudinal plane of the body, with receptors detecting pitch-up and pitch-down movements, and in the horizontal plane with receptors being excited during contraversive rotation (Fig. 4d). Some receptors also detect linear accelerations [7]. The squid semicircular canal system can thus monitor three-dimensional angular accelerations just like the idealized vertebrate semicircular canal system with bilateral symmetry, orthogonality and push-pull operational mode. Orthogonality of the semicircular canals would provide an optimal signal-to-noise ratio, but in order to achieve paired orthogonality, the vertical semicircular canals need not necessarily be arranged in the familiar diagonal fashion. The one (and only) alternative arrangement is pairs in coronal, parasagittal and horizontal planes as shown in Fig. 4d. The squid/cuttlefish semicircular canal system could thus be termed a "principal axes" system, in contrast to the "diagonal" vertebrate arrangement.

In the octopus (Fig. 4e), the sensory receptor organ on each side consists of nine subsections, and is divided into three main planes which are approximately orthogonal to each other. The arrangement of the subsections suggests an angular acceleration detection system similar to that of vertebrates. Interestingly, the extraocular muscle arrangement of the octopus resembles closely that of lateral-eyed vertebrates [8] (Fig. 4f).

The third type of "semicircular canal" system introduced here in invertebrates of interest is found in crabs (Fig. 4g), which possess one horizontal and one vertical toroid structure on each side. Depending on the species, these "toroids" can either be open or can form a closed canal system [9]. In freely moving crabs, the horizontal canals are held earth horizontally, and since the horizontal and the vertical canals are close to orthogonal, the vertical canals are nearly vertical. Each vertical canal lies at an angle of 45° to the midsagittal plane in a configuration comparable to that of the anterior semicircular canals in vertebrates. Although there is only one vertical canal on each side, each one responds preferentially to movements about orthogonal axes, and thus the canals of crabs are collectively capable of accurately transducing three-dimensional angular accelerations [9].

Comparison of vertebrate and invertebrate solutions about how to "build" movement detection systems shows a remarkable uniformity to an idealized three-dimensional geometry of optimal decomposition of all given rotation vectors. The semicircular canal systems of vertebrate and invertebrates are thus prime examples of convergent evolution.



**Evolution of the Vestibular System. Figure 4** Convergent evolution of movement detection systems. (a) Photo of a squid. The animal propulses itself rapidly backwards by ejection of a jet of water. (b) Retouched photograph of a squid statocyst indicating the orientations of the toroid planes [from [7]]. (c) Comparison of the "diagonal" vertebrate semicircular canal system, and the "principal axes" system of squids (d) The squid system also fulfills the three criteria of orthogonality, bilateral symmetry, and push-pull operational mode. However, instead of six canals, it has eight toroid structures, and the on-directions of the sensory receptors are just about opposite to that of vertebrates. Nevertheless, the squid movement detection system functions according to the same operational principles as the vertebrate semicircular canal system). (e) Drawing of an octopus. Despite its seemingly amorphous body structure, the octopus possesses a well-defined three-dimensional movement detection system similar to vertebrates. (f) Comparison of the extraocular muscles in a shark, left, and in the octopus, right. Note similar "diagonal" spatial arrangement in the two animals [from [8]]. (g) Spatial arrangement of the semicircular canal system in crabs. Although there are only four canals in crabs, the vertical canals are oriented just like the anterior canals of vertebrates, as are the horizontal canals (after [9]).

## Ontogeny and Phylogeny of the Labyrinth

The vertebrate labyrinth develops from an enlargement of the ectoderm, the ►otic placode, which invaginates to form the so-called ►otocyst [10]. A number of genes and induction molecules play a role for the complicated morphogenesis of the labyrinth. There are genes that are necessary for the differentiation of various organ- and system developments and others that

are labyrinth-specific. Many genes work in parallel or are redundant. Gene duplication, or multiplication of genes during the progress of evolution has to be taken into consideration as well [3]. The differentiation of the main structures of the labyrinth is guided by independent genes, which will be introduced below.

Although many vertebrate genes are ►homologous with *Drosophila* genes, the vertebrate labyrinth is a development of chordates and without precedent in other animal groups. Flies do not possess balance organs *per se*, but rely on relative movement of body parts (►halteres) to orient in gravity. Homologies with other animal groups seem to be restricted to the development of receptor cells, which transform mechanical stimuli into electrical impulses (mechano-electrical transduction). The receptors of the labyrinth are important examples for the general question of the origin of mechano-electrical transduction at the level of receptor cells. For many years, it was believed by evolutionary biologists that the labyrinth was derived from the ►neuromast cells of the lateral line organ of aquatic vertebrates. Meanwhile, however, functional interrelations between the pressure receptors of the nematode *C. elegans* and the sensory bristle receptors and proprioceptors of the fruit fly *Drosophila* on one hand and vertebrate hair cells on the other have been described [3]. The description of a mechano-electrical transduction channel in *Drosophila* and *C. elegans* points to an early development of a mechano-electrical receptor in evolution. The original receptors might have consisted of a ►cilia-like structure including support cells. Thus, receptor cells seem to have been an important evolutionary component for the development of the sense of balance of vertebrates, but it was not the structure *per se* that led to the macroscopic expression of ►analogous sense organs. Interestingly, inner ear hair cells develop without involvement and influence of the neural crest, which normally guides the development of most of the sensory neurons of the peripheral nervous system of chordates.

The actual morphogenesis of the ear is governed by numerous genes, which also play a role in the development of lungs, kidneys and extremities. Embryogenesis and morphogenesis occur during particular periods in ontogenesis, when certain genes are switched on or off, and when certain organs and characteristics are being developed. The development of sense organs is embedded into the general process of structurization and position specification. In this process, proneural genes will be activated, which are determining the precursors of the elements of sensory organs, such as support cells, glia, and portions of the actual sensory cells. Two mechano-sensory bHLH genes (basic helix-loop-helix) are expressed in the ear, *Neurogenin 1* (*ngn1*) and *mammalian atonal homologue 1* (*Math1*). In insects, *atonal* (*ato*) is important, whose vertebrate homologue *Math1* is indispensable for the development of hair cells. Knock-out mutants without *Math1* develop support cells and primary neurons, but no hair cells. For the development of primary neurons, another bHLH homologue is required, i.e., *ngn1*, one of three so-called neurogenin genes.

For further labyrinth development, the so-called FGF and FGFR genes play an indispensable role (FGF, fibroblast growth factor; FGFR, tyrosine kinase receptor family). In particular, FGF19 seems to be a fundamental element for the induction of ear development in chickens, and which is activated together with *Wnt8c*. The interplay between FGFs and FGF-receptors in vertebrates seems to induce the budding out of the growth zones of lungs, extremities and of the ear placode. With regard to inner ear development, the receptor FGFR-2(IIIb) is essential for the development of the semicircular canals, the endolymphatic duct and the cochlea.Besides the FGF genes, BMP, Pax, POU and zinc-finger genes were shown to be present in the ear. POU4f3 knock-out mutants form a labyrinth with hair cells that are later lost. Missing the Pax2 gene results in an ear without cochlea, however, with semicircular canals and otoliths [6,17].

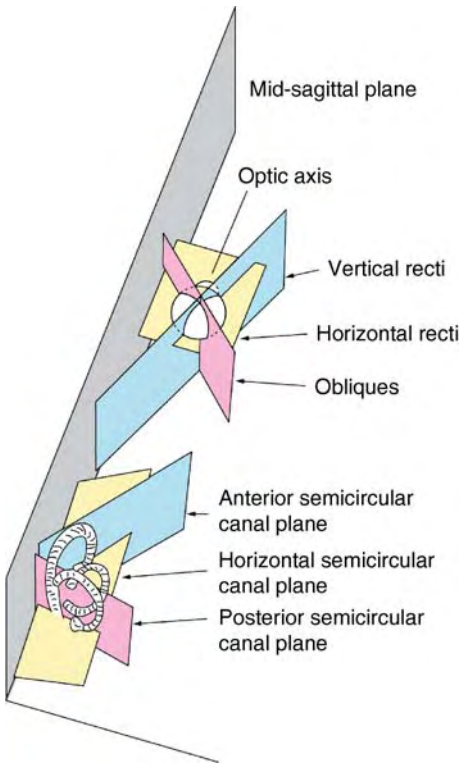
While all thus mentioned genes have been shown to exist in insects, some vertebrate-specific genes are noteworthy, such as the above-mentioned *Otx1*, which regulates the development of the horizontal semicircular canals (Fig. 3). Vertebrates without horizontal canals do not express this gene in the ear.

## The Extraocular Muscle Apparatus

The extraocular muscle apparatus can be considered as a prime example for the efficiency of biological systems. The spatial orientation of the extraocular muscles, in particular, illustrates in an almost ideal fashion, how evolution solved a complicated problem of sensory-motor transformation.

The six extraocular muscles move the eye in a reference frame that corresponds to the spatial geometry of the vestibular semicircular canals, i.e., the typical diagonal, 45° off the midsagittal plane orientation of vertical canals, is reflected in the pulling direction of the vertical eye muscles (Fig. 5).

The vertical eye muscles are superior rectus (SR), inferior rectus (IR), superior oblique (SO) and inferior oblique (IO); the horizontal eye muscles are lateral rectus (LR) and medial rectus (MR). These anatomical designations give the impression of a distinct separation between “straight” and “oblique” eye muscles. In the true sense of the word, only lateral rectus and medial rectus are “straight” eye muscles, whereas all vertical eye muscles, including superior rectus and inferior rectus, are in reality “oblique” muscles. The illustrated example drawing of the human vestibulo-ocular system (Fig. 5) demonstrates this fact very clearly.



**Evolution of the Vestibular System. Figure 5**
Three-dimensional orientation of semicircular canal planes and extraocular muscle pulling directions in man. Note alignment of certain eye muscle pulling directions with particular canal planes, forming an intrinsic reference frame system.

## Vestibular Output and Postural Control

Some of the earliest motor control systems of vertebrates are the tecto-spinal and the vestibulo-spinal pathways. Tecto-spinal connections underlie visually based orienting and control mechanisms. Vestibulo-spinal pathways essentially provide tonic postural and balance control. This function can be impressively demonstrated following ablation of one entire labyrinth (►hemilabyrinthectomy), or components there of [11,12]). In essence, the horizontal semicircular canals provide the straight-ahead direction of the head, whereas the utricles assure the upright posture of the entire head-neck ensemble in the midsagittal plane, at least in birds and mammals. The sacculi seem to play a similar role regarding lateral tilt displacements of the head [12]. In this context, we have to mention the fact that mammals in general possess a vertical cervical vertebral column, regardless of bipedal or quadrupedal locomotion. The transition to bipedalism from quadrupedalism in mammals thus requires bringing the thoracic vertebral column into an upright position and modifications at the cervico-thoracic junction and the lumbar level but not within the cervical vertebral column or the atlanto-occipital articulation.

## The "New Wave" of Vestibular Interest

The intriguing geometry and three-dimensionality of the vertebrate labyrinth has fascinated scientists since the beginning of modern science, i.e., Antonio Scarpa in 1789, and numerous comparative studies have dealt with the expression of labyrinthine structures in basically almost all known vertebrates. While all these studies used invasive methods to visualize ear structures, modern imaging methods have now opened a way to study them non-invasively in living tissue, and also fossilized heads have become accessible to large-scale investigations. These possibilities led to a number of interesting morphological discoveries that added to the vast data set already available.

In general, there were no surprises regarding the spatial orientation of the semicircular canals. These followed the familiar pattern (see Fig. 2) [13]. A number of authors also sought to make use of their new investigative tool to re-interpret the functional context of vestibular system by putting it into the sole context of locomotion [13,14]. These authors argued that the dimensional morphology of the semicircular canals gave an indication about the locomotor capabilities of their owners. Thus, conclusions were drawn as to the point of effective bipedalism in certain hominids [13] or the agility of Neanderthal man [14]. We had argued against such interpretations based on a number of known facts and characteristics of the vestibular system [15]. In essence, the former authors had based their arguments largely on the size differences in the circumference of semicircular canals within one species and across different species. However, canal fluid dynamics affecting sensitivity are also largely governed by the lumen of the canal, i.e., its cross-section. Furthermore, to base locomotor activities solely on peripheral morphology means ignoring any well known adaptive mechanisms at the receptor level, ion channel dynamics, and above all, the vast apparatus of the neuronal processing machinery that make use of vestibular signals from the brainstem and cerebellum to the cortex. Focusing on locomotion alone also ignores all the other important and vital functions subserved by the vestibular system, notably compensatory eye movements and perceptual mechanisms. Without compensatory eye movements, in particular, we would not be able to have unblurred vision during any movement. In addition, during active movements, a number of postural reflexes become suppressed, which is reflected in elimination or attenuation of vestibular movement signals in the vestibular nuclei. Arguments about vestibular canal size have even been forwarded to explain the behavior of cetaceans and pterosaurs,

proposing a link between apparent extreme aquatic and aerial acrobatic capabilities of these animals, respectively. Although these arguments received wide acclaim in the popularized science literature, the "vestibular" argument again did not take into consideration all aspects of vestibular function or the entirety of a biological system. Against the aerial capabilities of pterosaurs could be brought forward, for instance, the size and shape of their cerebellum given the fact that the cerebellum plays an eminent role in motor coordination. Pterosaur cerebella resemble closely that of certain bats [16], and bats are not the very best flyers. As we have seen, postural control, locomotion and eye movements are closely related to vestibular output, and there is a lot more to consider than meets the eye at first glance.

## Summary and Conclusions

The semicircular canals of the labyrinth of vertebrates provide one way of motion detection in three-dimensional space. The fully developed form of the vertebrate labyrinth consists of six semicircular canals, three on each side of the head, whose spatial arrangement (vertical canals are placed diagonally in the head, horizontal canals are oriented earth horizontally) follows three interconnected principles: (i) bilateral symmetry, (ii) mutual orthogonality, (iii) push-pull operational mode. Motor systems related to the vestibular reflexes such as the extraocular muscles, or the neck muscles, share the same geometrical framework. This framework is also reflected in the anatomical networks mediating compensatory eye- and head movements, linking each of the semicircular canals to a particular set of extraocular muscles (so-called principal ►vestibulo-ocular reflex connections to yoke muscles) and to particular head-neck muscles. These connections are identical across species throughout evolution.

The particular spatial arrangement of the vertical semicircular canals is already present in fossil ostracoderms, who, however, lacked horizontal canals. The fully developed vertebrate labyrinth with its six semicircular canals displays distinct differences that are obvious when comparing different taxa (e.g., elasmobranchs vs. other vertebrates). Whereas the common crus of the semicircular canals in teleosts through mammals is formed between the anterior and the posterior semicircular canal, it occurs between the anterior and the horizontal canal in elasmobranchs. However, despite this morphological difference, these two vertebrate labyrinth prototypes constitute a functionally identical solution. A similar analysis holds for certain invertebrate species (squid, octopus, crab), which display an even wider variety in the physical expression of movement detection systems when compared to vertebrates. Although the physical expressions of motion detection systems differ in the animal kingdom, the functional solutions (providing the best signal-to-noise ratio) with adherence to bilateral symmetry, mutual orthogonality and push-pull operational mode are identical. Furthermore, this functional principle is reflected in the intrinsic organization of related motor systems.

The evolution of the sense of balance of vertebrates and analogous systems in invertebrates suggest a number of important features of brain operations. We also observe conserved vestibulo-motor organizations and circuitry in vertebrates after the development of one optimal solution, when arrangements have been preserved throughout subsequent vertebrate history. In contrast to the many different morphological types of eyes, for instance, only two basic types of three-dimensional movement detectors have been retained, the "diagonal" ones of vertebrates, octopus, and crabs, and the "principal axes" ones of squids and cuttle fish. Each one of the two possibilities constitutes an ideal physical solution, with optimal signal-to-noise ratio. The early appearance of a viable and up-to-date conserved vertebrate vestibular system, in tandem with systems of similar geometry in certain invertebrates may suggest that close to ideal physical solutions developed early in vertebrate history.

## Synonyms

V1, primary visual cortex, also referred to as striate cortex or Brodmann's area 17; V2, secondary visual cortex; LGN when used without classifier dorsal or ventral usually means dorsal LGN; Neocortex, Isocortex

## Definition

The visual system of mammals consists of a complex interconnected network of subcortical and cortical areas that are considered "visual" because cells in these areas respond to input from the ►retina. All mammals share a similar retinal organization. The output cells (►ganglion cells) of the retina send axons to the brain. These ►retinal ganglion cells are specialized to convey different aspects of the visual scene, such as object detail or motion, to a number of subcortical target areas and to provide each of these areas with a map of visual space. Most of the subcortical targets of the retina can be found in all mammals. Mammals also have a number of cortical visual areas, some of which can also be identified in all mammals. However, variation exists in the detailed organization of subcortical targets and in the number of cortical visual areas across mammals. Evolution has progressed independently in different mammalian lines by addition and deletion of characteristics at all levels of the visual system.

## Characteristics

Studying the evolution of visual structures within the brain poses more challenges than studying the evolution of other structures such as wings or hooves because soft tissue does not fossilize. Skulls may be preserved, or sediments may solidify within a brain case forming an ►endocast, but these give only a general idea of the size and shape of the brain. While useful, this information provides few clues to the internal organization of brain structures, which is more relevant than mere size, especially where the visual system is concerned.

The main tool we have to infer the evolutionary relationships of visual brain structures and their organization is comparison of the brains of modern species using a cladistic approach, that is, by comparing brains of closely and distantly related species [1,2]. A ►clade is a group of all organisms at any phylogenetic level that share a common ancestor, such that all members of the clade are more closely related to each other than to any organisms not in the clade. Mammals, carnivores, and felines are examples of clades. A characteristic present in all members of a clade can be assumed to have been present in the last common ancestor of the clade, i.e., to be ►homologous. If a characteristic is present in only some, but not all, members of two distantly related clades, the possibility must be considered that the characteristic arose independently in each clade by ►homplasy (parallel evolution). Since unrelated animals can adapt to the same niche, especially one that places particular demands on the visual system (becoming ►nocturnal, or ►arboreal, etc.), their brains may show similar evolutionary changes. In making these determinations, we follow the principle of parsimony, the minimization of the number of gains or losses of a characteristic in a hypothetical evolutionary scenario.

It is noteworthy that, due to incomplete data on brain organization across taxa, these determinations are often based on data from a limited number of carefully chosen species.

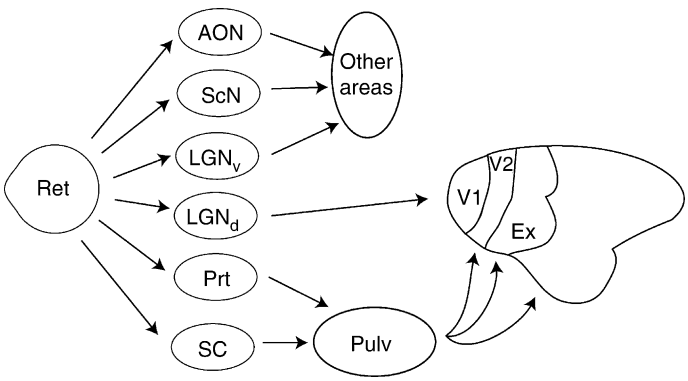
In order to chart evolutionary changes in the brain with a cladistic approach, it is necessary to have valid clades. Molecular genetics helps define the phylogenetic trees used to infer evolutionary changes [3,4]. Molecular ►phylogeny classifies extant mammals into six superorders: Monotremes (e.g., the duck-billed platypus and echidna), Marsupials (e.g., the kangaroo and opossum), and, among the eutherians, Afrotheria (e.g., the aardvark, elephant and manatee), Xenartha (e.g., the armadillo, anteater and sloth), Laurasiatheria (e.g., insectivores, carnivores, and ungulates), and Euarchontoglires (e.g., primates, treeshrews, and rodents). Knowledge of these relationships, in conjunction with comparative information on brain structure and function, enables the determination of which characteristics of the visual system are present across many groups, and therefore, which were likely to be present in the earliest mammals or were present only in certain groups and therefore likely were derived independently during the course of evolution.

## Cross-Species Comparisons at Successive Levels of the Visual System

The visual system of all mammals has the same basic structures (Fig. 1).

The retina sends axons to a number of subcortical targets, which include: (i) the ►suprachiasmatic nucleus of the hypothalamus, (ii) the ventral lateral geniculate nucleus (pregeniculate nucleus of primates) of the ventral ►thalamus, (iii) the dorsal ►lateral geniculate nucleus (LGN) of the dorsal thalamus, (iv) the pretectum and ►superior colliculus of the ►midbrain and (v) the accessory optic nuclei of the midbrain and ►hindbrain. Each of these nuclei receives axons from a specialized subset of retinal ganglion cells and has a network of connections with different areas of the brain. The retinal axons also project to their subcortical targets in an orderly manner so that each target area has a map of the visual world. Many of these subcortical retinal targets have homologues in non-mammals, such as the optic tectum of non-mammals, which is homologous with the superior colliculus of mammals [5]. The LGN is important in mammals as it provides the most direct pathway for retinal signals to reach the cortex. With minor exceptions none of the other subcortical targets of the retina sends axons directly to the cortex. In all mammals the LGN sends axons to the primary visual cortex (also called V1, striate cortex or area 17) located in the occipital lobe. V1, in turn, sends axons to several ►extrastriate cortical areas located in regions that tend to lie in more anterior zones of the cortex. These extrastriate areas, located in occipital, temporal and parietal areas, are connected, directly or indirectly, to the ►frontal cortex and ►hippocampus, allowing integration of visual information with other aspects of behavior.

**Retina.** The neural organization of the retina is similar across all vertebrates and contains at least five main cell types organized into layers. Light activates the receptors, rods and ►cones. Rods are specialized for night vision and cones for daylight vision, and where two or more cone types are present, color vision. From the receptors neural signals are processed through the retinal network before leaving the retina for the brain via the axons of retinal ganglion cells. In mammals, the proportion of rods to cones and number of cone types



**Evolution of the Visual System in Mammals – Comparative Evolutionary Aspects across Orders. Figure 1** The retina (Ret) forwards information (via axons of retinal ganglion cells) to several subcortical structures including the accessory optic nuclei (AON), suprachiasmatic nucleus (ScN), the ventral lateral geniculate nucleus (LGNv), also called the pregeniculate in primates, the pretectal (Prt) nuclei, the dorsal lateral geniculate nucleus (LGNd), and the superior colliculus (SC). Of these structures only the LGNd has direct access to the visual cortex projecting to V1 in all mammals, and V2 in some mammals, such as carnivores. SC and Prt project to pulvinar (Pulv), which in turn projects to variety of subcortical and cortical structures including exstrastriate visual cortex. The remaining subcortical nuclei project to a diverse array of brain areas.

varies across different species based primarily on visual niche, not phylogeny. Photopigment genetics suggests that ►opsins in all vertebrates are homologous, and that the primitive condition was four opsins. Ancestral mammals were ►dichromats; they lost two of their four ancestral pigments, possibly during a nocturnal bottleneck, leaving the short and medium wavelength opsins. Some extant nocturnal mammals (e.g., bush babies, owl monkeys, kinkajous) and some aquatic mammals (e.g., sea lions) have more recently and independently lost the short wavelength opsin. ►Old World primates and some ►New World primates have independently become ►tricromats, by duplication and divergence of the genes for the medium wavelength opsin in Old World Primates, and by a sex-linked polymorphism in the New World primates and some prosimians, such that only females, with two X chromosomes, have the potential for trichromatic color vision. All other mammals are thought to be dichromats [3,6; but see 7].

One of the main elaborations of visual processing in mammals is the expansion of areas devoted to vision at the cortical level and the parallel processing streams to visual cortex that begin in the retina from classes of retinal ganglion cells with different physiological responses and projections [1,4,8]. These classes of ganglion cells include cells that convey information about visual detail (higher spatial frequencies) and respond in a more sustained manner to the continued presence of an appropriate visual stimulus, cells that respond transiently to visual stimuli and respond well to high temporal frequencies (fast movement), and cells with slowly conducting axons and heterogenous response properties. In carnivores such as cats and ferrets, these classes correspond to the X, Y, and W neuron classes, respectively. In primates, they correspond to the ►parvocellular (P), ►magnocellular (M), and ►koniocellular neuron (K) classes [9,10]. Similar retinal ganglion cell triads are present in ►tree shrews, squirrels, rats, and rabbits, and are suggested from less complete studies in other species. Considering that physiologically and anatomically distinct classes of ganglion cells have been described in reptiles and birds [5], as well as all mammals so far examined, it seems likely that the presence of parallel retinal streams is a primitive condition in mammals; however, it is not completely clear how, or even if, the parallel streams in different mammals are homologous.

In carnivores and primates, the two groups for which we have the most data, both the cat's Y pathway and the primate's M pathway originate from the largest retinal ganglion cells with wide dendritic arbours and fast-conducting axons, while the cat's X and the primate's P pathways originate from smaller retinal ganglion cells, with small dendritic arbours and more slowly-conducting axons. The W and K retinal ganglion cells both have small cell bodies, thin but extensive dendrites, and the thinnest, and most slowly conducting axons in the optic tract [9].

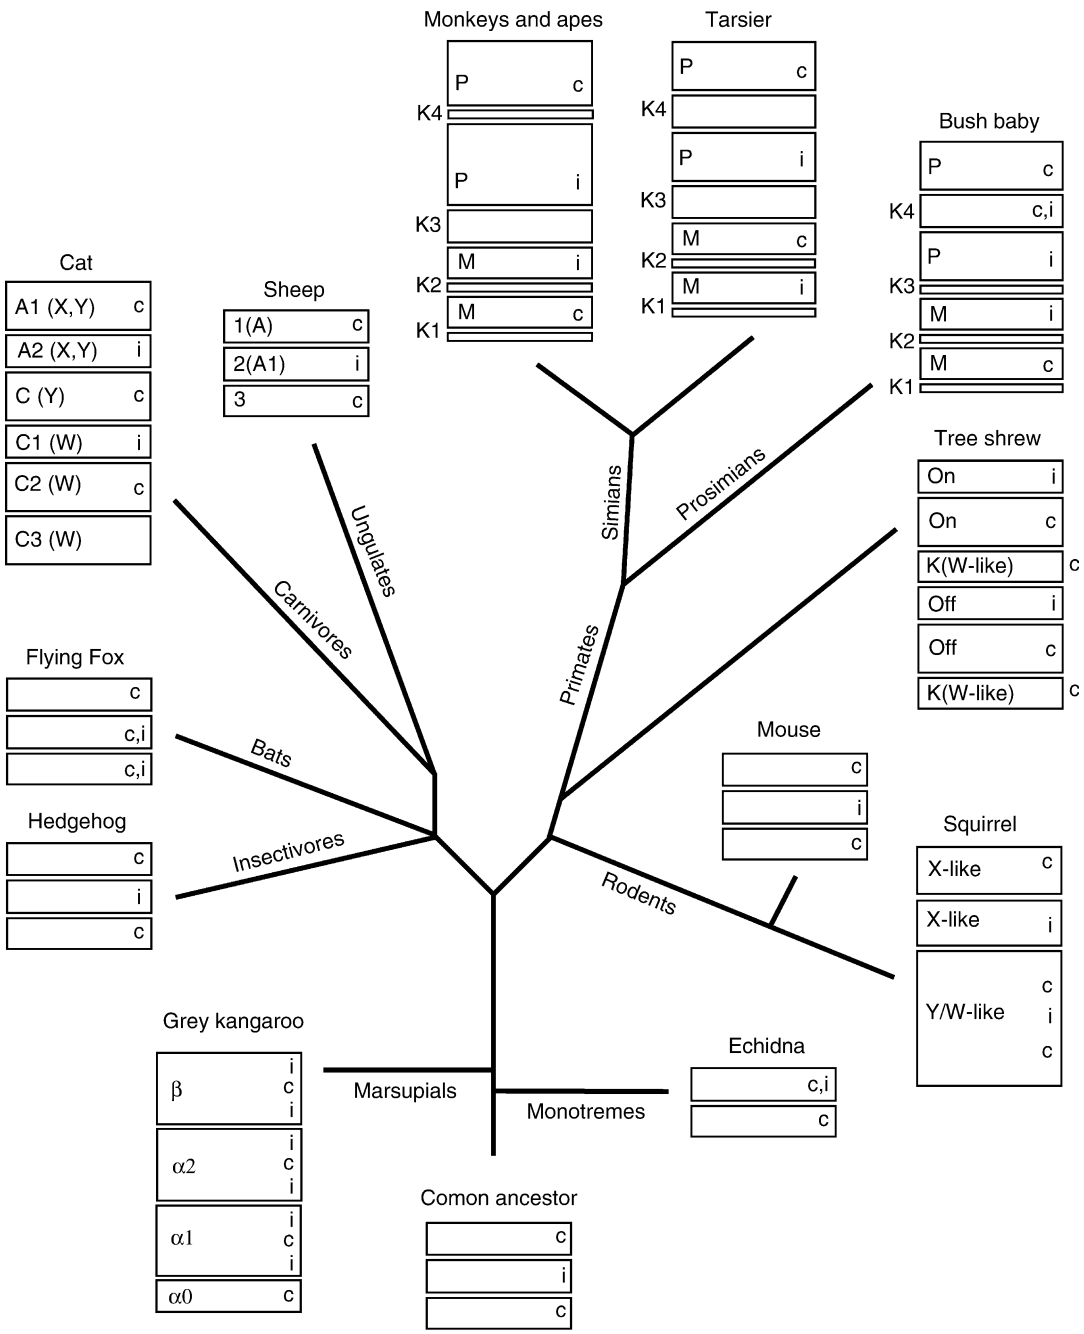
Physiologically, both Y cells and M cells have larger receptive fields, lower preferred spatial frequencies, higher preferred temporal frequencies, and higher contrast sensitivities than their X/P counterparts. Because of these similarities, it has been proposed that M and P cells are homologous to Y and X cells, respectively [3,6]. An alternative hypothesis, based partially on the fact that P cells have ►chromatic opponency while X cells do not, is that cat X and Y cells correspond to subgroups of M cells, and that the P pathway is primate-specific. As mentioned previously, however, many primates including some prosimian primates are dichromats and lack long-wave length cones. Their P cells, like cat X cells, lack chromatic opponency suggesting that chromatic opponency evolved in the P pathway of some primates and not others. Chromatic oponency, however, does appear to exist in a subset of W and K cells in all mammals where this has been examined.

**Retino-Recipient Nuclei.** As previously noted, the retina projects to many central targets, which are conserved in vertebrate evolution. The relative development of retinal targets differs in mammals. In non-mammals, the optic tectum appears to be the main target of the retina, whereas in mammals the retinal input to the superior colliculus is either balanced by input to the LGN as in tree shrews, or dominated by input to the LGN as in primates [5]. Also, in non-mammals retinal input is almost completely crossed; the right eye sends axons to the left hemisphere whereas the left eye sends axons to the right hemisphere. Binocular combination is achieved in some non-mammals either via pathways to the telencephalon or optic tectum that do not appear to exist in mammals.

In mammals, the LGN has undergone a wide array of structural changes in different mammalian lineages, due to segregation of retinal afferents of different functional class and eye specificity (Fig. 2).

The simplest plan of LGN lamination, which is found in at least some of mammals, is basically three layered, with two layers receiving inputs from the contralateral eye (crossed input) sandwiching a single layer receiving ipsilateral eye (uncrossed) input. The size of the ipsilateral LGN layer varies with the position of the eyes in the head of the mammals and therefore, in proportion to the amount of binocular overlap between the eyes, being positively cryptic in laterally-eyed rats and fully formed in binocular cats. These layers can also be subdivided in various ways in different species [3,4,6].

In even the simplest LGNs, there is some segregation according to fiber type. The most external layer (nearest the optic tract) is always enriched in input from retinal ganglion cells with thin axons (W or K cells in cats and primates, respectively) whereas the other layers tend to



**Evolution of the Visual System in Mammals – Comparative Evolutionary Aspects across Orders. Figure 2** As with the primary and secondary cortical visual areas, there is a common theme governing the pattern of retinal input to the LGNd. In the presumed common ancestor the cells of the LGNd can be divided into layers based on their retinal input. In the presumed common ancestor there were three layers, two of which received crossed input from the contralateral (c) retina and one of which received uncrossed input from the ipsilateral (i) retina. This basic three layer plan underwent expansion during evolution, with the addition of more layers. In addition to layers devoted to each eye, some species also have LGNd layers that receive input from functionally distinct retinal ganglion cell classes such as the parvocellular (P), magnocellular (M) and koniocellular (K) cells in primates or the X, Y, and W or ON and OFF cells in some non-primates. For instance while most primates acquired the basic two P, and two M layers separated by variable numbers of K layers, their close relative the tree shrew has subdivisions into ON and OFF layers instead. Some animal groups, like primates, demonstrate clear separation of eye specific layers while, others, like rodents, can have extensive mixing of the inputs from both eyes. Only major subdivisions of LGNd are shown. Ungulates, carnivores, and to some extent bats, have an additional LGNd subdivision, the medial interlaminar nucleus (MIN).

get input from retinal ganglion cells that are more rapidly conducting (X, Y or P, M). Further segregation according to fiber type appears to have occurred in parallel in different mammalian lines. The LGN of carnivores and ungulates, for instance, consists of two main layers, A (contralateral) and A1 (ipsilateral), receiving X and Y cell input, and layer C, subdivided into large (Y) and several small (W) cell sublayers. In primates, the segregation of different functional classes is most complete, with separate M (external) and P (internal) layers for each eye, and K layers between or ventral to each of the P and M layers.

The P layers in the representation of the central visual field split into four layers in many primates, and up to six in some humans. A general rule is that larger LGNs have more layers, and not all layers need correspond to a unique combination of eye and functional class. In this light, it is interesting to note that some marsupials have evolved laminated LGNs independently of eutherian mammals, and large diurnal kangaroos have more layers in their LGN than their smaller relatives.

Although the position and number of K/W layers is rather variable, geniculate projections of K/W retinal ganglion cells in all mammals are to small-celled layers that are either next to the optic tract or intercalated between the main layers. Neurochemically, these small-celled layers have been identified in many species using antibodies to the calcium binding protein calbindin [3,6].

Interestingly, the tree shrew has a unique LGN organization, with 2 layers containing W-like cells, and 4 layers segregated by both eye input and contrast sign (ON center vs OFF center). Projections from sustained and transient retinal ganglion cells do not appear to segregate into different LGN layers. The tree shrew thus appears to have an LGN with many derived characteristics not shared with its primate sister group. This example reminds us that considerable evolutionary variation exists among mammals even in the primary target nuclei of the retina.

The midbrain targets of the retina, the superior colliculus and the pretectum, are also conserved in vertebrate evolution, and their inputs and outputs in mammals are similar to other vertebrates [5]. Supporting the hypothesis that W and K ganglion cells are homologous in primates is the fact that subclasses of these cells project to the superior colliculus in many mammals. In turn, the superior colliculus sends axons to layers of the LGN that receive K/W cell input in a variety of mammals.

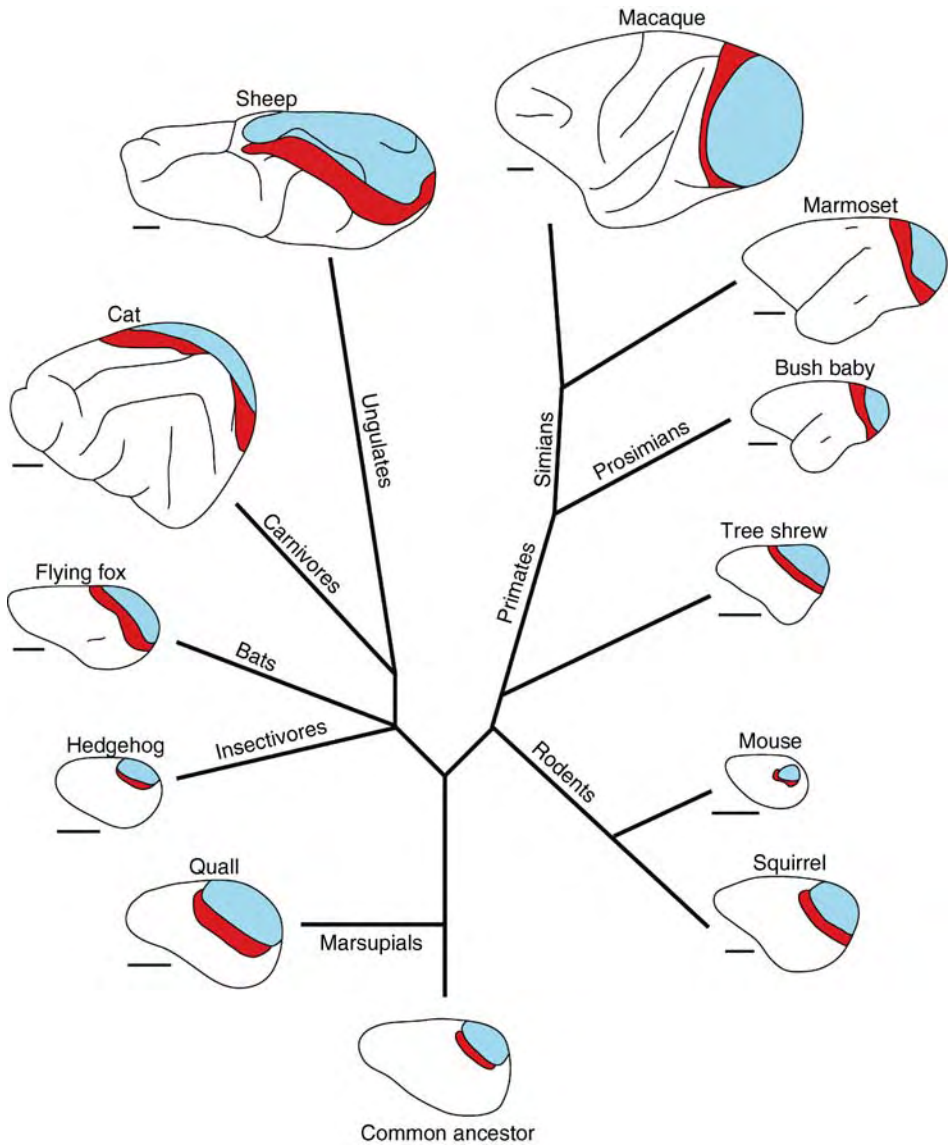
In all vertebrates, the superior colliculus also projects to dorsal thalamic nuclei that receive no or minor input from the retina (►collothalamic nuclei, as opposed to the ►lemnothalamic nuclei, such as the LGN, which receive direct projections from ascending sensory pathways) [5]. These collothalamic nuclei, unlike the LGN, project to extrastriate visual areas of cortex instead of V1. They also receive projections from V1 (at least in the placental mammals that have been examined), providing an indirect pathway to extrastriate cortex. Subdivisions of these nuclei appear to have arisen independently in different mammalian lines, and there is no straightforward way to homologize between them, e.g., the various subdivisions of the lateral posterior nuclei in cats and the components of the pulvinar in primates.

As to the other nuclei, each can be recognized in a variety of mammals. Thus, the suprachiasmatic nucleus, which appears to be important for circadian rhythms in mammals, has been recognized in a variety of mammals. Many of the pretectal nuclei such at the nucleus of the optic tract can be identified in a variety of mammals, but the relative development of others varies greatly across mammals. The same holds true for the ventral lateral geniculate nucleus which is as large as the dorsal LGN in many mammals but almost non-existent in primates.

**Primary Visual Cortex.** In all mammals V1 can be recognized by its projection from the LGN, its position on the caudal pole of the cortex, its single inverted map of visual space, and its distinctive architecture [3,6,11,12] (Fig. 3).

Birds and reptiles also have an area in the telencephalon that receives input from the visual thalamus, the dorsal cortex, which has been proposed to be homologous to mammalian isocortex [5]. Dorsal cortex has a simple three-layered structure, while six layers can be recognized in the isocortex of all mammals, including marsupials, suggesting that the six-layered organization originated very early in mammalian evolution. Although dolphins and whales lack a granular layer 4, it is suggested here that this may be a secondary reduction in neuronal packing density of neurons as an adaptation to limited oxygen availability during long dives.

Projections of the different cell classes in the LGN onto the visual cortex are similar in all mammals so far examined, with X/P and Y/M cells terminating in layer 4, and W/K cells terminating in layers 1 and 3. There is a trend towards a sublaminar segregation within layer 4, with Y/M cells tending to project to the upper portion of layer 4, and X/P cells tending to project to the lower portion of layer 4 [3,6]. This segregation pattern is most obvious in primates. Also, as at the level of the LGN, the segregation of ocular and functional inputs is most obvious in primates although relatively few mammals have been examined. Outputs of primary visual cortex are also similar across mammals, with layer 3 providing most of the outputs to extrastriate cortex, layer 5 projecting to the superior colliculus, layer 6 projecting to the LGN, and both 5 and 6 projecting to other visual thalamic nuclei. Although isocortex has six layers across mammals and is presumed to be homologous, sublamination within the



**Evolution of the Visual System in Mammals – Comparative Evolutionary Aspects across Orders. Figure 3** There is a clear commonality in the organization of cortical visual pathways in mammals. The primary visual area (V1, area 17, striate cortex) marked in blue is always located at the posterior aspect of occipital lobe. Its relative size and exact location depend on how "visual" the particular animal is. There is a tendency for primary visual cortex to be pushed toward posterior and medial aspect of the hemispheres as the relative size of the brain increases. Next to primary visual cortex lies the secondary visual area (V2, area 18) marked in red. Further anterior lie various extrastriate visual areas; no general consensus exists, however, concerning which extrastriate areas are present in which animals and how homologous areas are to each other. (Modified with permission from Rosa and Krubitzer, TINS 22(6) 1999) Scale bars = 5mm.

different layers has evolved independently in different lines of descent, as for example, the sublayers of layer 3 in primates and squirrels.

Visual cortex in many mammals is marked by a ►columnar organization of response properties and anatomical connectivity. How these columnar systems are related in different mammals is unclear. Segregation of inputs driven by the two eyes creates ocular dominance (OD) columns, which are found, to a lesser or greater extent, in most mammals with substantial binocular overlap. It is likely that OD columns evolved independently in different mammalian lines as they evolved frontal vision. In primates, some New World monkeys lack OD columns, raising the possibility that Old and New World primates evolved OD columns independently, but recent work indicates that New

World species formerly thought lacking OD columns have them, albeit variable and poorly segregated, so OD columns need only have evolved once in primates. It seems likely that ocular segregation evolved independently in several lines of mammalian decent given that close relatives of primates, tree shrews, show a laminar, not a columnar segregation of ocular inputs to V1. Selectivity for stimulus orientation is another feature organized into columns in some mammals (e.g., carnivores, primates and tree shrews) but not in others (e.g., rodents and lagomorphs). Similar to LGN lamination, there is the possibility that increasing cortex area may lead to increased segregation into columns, independent of any contribution of columns to cortical processing. Counter to this argument is the fact that in squirrels V1 is equal in size to V1 in tree shrews yet does not show a columnar pattern for orientation suggesting that perhaps other factors besides size drive the development of this form of organization.

In some carnivores (cats) and primates, the metabolic enzyme cytochrome oxidase (CO) marks "blobs" of high activity in layer 3 that correspond to input zones of W/K LGN terminals, and also to segregation of projection neurons to extrastriate areas [3,6,9]. If blobs in cats and primates are homologous, they should exist in the Laurasiatherian relatives of cats and the Euarchontogliresian relatives of primates. Although blobs have been seen in ferrets, they have not been seen in tree shrews or rodents, and it is currently more parsimonious to conclude that blobs in carnivores and primates are a parallel homoplasy. Since blobs were more difficult to demonstrate in cats than in primates [9], it is possible that a cryptic columnar segregation of inputs and outputs may exist in other mammals, homologous to CO blobs, even if not readily visualized by CO content.

**Extrastriate Cortex.** Beyond V1, visual information is analyzed by a variety of different cortical areas, and it is unclear to what extent these extrastriate areas are homologous across species. Fossil evidence indicates that brain size and, hence, cortical area increased independently in different mammalian groups. Early mammals likely had few extrastriate areas; thus, few extrastriate areas can be common to all extant mammals.

Nearly all mammals have a narrow secondary visual area, V2, that wraps around V1 laterally and receives direct input from V1 [8,11] (Fig. 3). In rats and mice, it has been suggested that V1 is instead bordered by multiple small retinotopically defined areas, with perhaps the largest of these being homologous to V2 in other mammals. It has also been suggested that these small areas are actually modules within a single V2. Alternatively, a *bona fide* V2, narrow and easily overlooked, may be interspersed between V1 and these areas. In carnivores, V2 is a primary visual area, receiving as strong an input from the LGN as does V1, and having a granular layer 4. Either the invasion of V2 by LGN axons induced a V1-like cytoarchitecture, or carnivore V2 is not homologous to V2 in other mammals. In the latter case, V2 may represent a duplication and divergence of V1, with laterally adjacent area V3 being the V2 homologue. It is not yet known if related Lauasiatherian groups such as ungulates have a carnivore-like V2 or a primate-like V2.

Beyond V2, extrastriate cortex in large, highly visual mammals such as cats and primates has expanded independently in evolution, with more than 10 extrastriate areas in cats and potentially over 30 in Old World primates. Even within primates, it is difficult to compare visual areas [4,13], and solid evidence in all studied primates exists for only three homologous areas, V1, V2, and the middle temporal area (MT), although it appears that smaller primates may have less extrastriate areas than larger ones. Likewise in carnivores, cats may have more visual areas than smaller brained ferrets.

In primates, it has been proposed that extrastriate areas can be divided into two streams for visual information processing, a dorsal stream to the parietal lobe involved in spatial vision, and a ventral stream to the temporal lobe involving object vision. Hierarchical chains of connections can be traced through multiple visual areas for each of these streams [3,4,6,10]. For the dorsal steam, V1 and V2 project to MT, which projects to parietal areas adjacent to and interconnected with premotor areas important for visually guided behaviors. For the ventral stream, V1 and V2 project through other intermediate areas, eventually reaching temporal cortex adjacent to and interconnected with perirhinal cortex and hippocampus, important for object recognition and encoding visual memories. Connectional, physiological, and behavioral evidence in cats suggests a similar functional specialization of dorsal and temporal visual areas, and similar specialization has been claimed for the multiple extrastriate areas of rodents as well [3,9]. Dorsal and ventral streams may be present in all mammals, as the targets of these streams, motor cortex and hippocampus, are present in all mammals. In this scenario, V1/V2 in early mammals would have direct projections to only a few areas that, in turn connected to motor cortex and to perirhinal cortex/hippocampus. Independently in different lines of descent, additional extrastriate areas for each stream would be inserted laterally to V2, more parietally (closer to motor cortex) for dorsal stream areas, and more temporal (closer to hippocampus) for ventral stream areas.

## Summary

Early mammals shared a similar retinal organization with specialized retinal ganglion cells sending axons in parallel to several subcortical targets with segregation

and differentiation of these pathways evolving separately in different evolutionary lines but with each target maintaining a map of visual space.

Early mammals had an LGN with projections to a 6 layered primary visual cortex. These mammals likely also had at least two types of LGN cells that projected in parallel to cortex. Orientation and ocular dominance columns likely evolved independently in different lines.

Early mammals had little extrastriate cortex and few extrastriate areas, which increased in size and number separately in different lines. A basic distinction between dorsal (motor-related) and ventral (hippocampal-related) processing was likely present in early mammals.

# Evolution of the Visual System in Amphibians

Ursula Dicke, Gerhard Roth
Brain Research Institute, University of Bremen, Bremen, Germany

E

## Definition

The amphibian visual system like that of other vertebrates is anatomically organized into two ascending visual pathways, namely the retino-thalamo-telencephalic and the retino-tecto-thalamo-telencephalic pathways. In contrast to the situation in mammals, the dorsal thalamus does not contain a visual relay nucleus that receives direct retinal input and projects monsynaptically to the cortex. Primary and topographically organized visual areas are likewise absent in the pallium of amphibians. The thalamic and telencephalic centers involved in visual processing exert a modulatory rather than a primary sensory role. An additional pathway, the retino-tectal-pretectal system, processes localization and recognition of objects and depth perception and controls visual behavior. Visual processing takes place in essentially the same way as in amniotes; it is based on population coding and occurs in a parallel-distributed fashion simultaneously and subsequently by interaction with several visual centers.

## Characteristics

### The Retina and Functional Anatomy of Retinal Ganglion Cells

The amphibian retina shows a five-layered structure typical of the vertebrate eye. The outer and inner nuclear layer and the layer of retinal ganglion cells (RGC) are separated by two fiber layers, viz. the outer plexiform layer and the much thicker inner plexiform layer. These two layers are the main sites of synaptic contacts between retinal cells, i.e. photoreceptors, amacrine cells, bipolar cells, horizontal cells and ganglion cells [1]. The outer nuclear layer contains the inner segments of the photoreceptors (rods, cones and double-cones) and their nuclei. Amphibians have no specialized intraretinal structures like the fovea of primates or birds. In some frog species, a streak of high cell density exists in the RGC layer along the nasotemporal meridian of the retina. Three major classes of RGCs exist in amphibians. ►Small-field cells respond either to moving or non-moving objects and require relatively high visual contrast; subclasses differ in color sensitivity and in responses to light “On/Off”. This cell type is comparable to X-cells in cats and to P-cells in primates. ►Medium-field cells respond to small changes in contrast and small dislocations of edges and

thus to movement; these cells correspond to Y-cells in cats and M cells in primates. ►Large-field cells respond well to large objects and to changes in illumination in larger parts of the visual field [for an extended overview see 2]. The axons of RGC form bundles and the majority of them cross in the optic chiasm.

The projections of RGCs are topographically organized and reach targets in the contralateral diencephalon and mesencephalon. Four thalamic neuropils are formed by their terminals: the neuropil of Bellonci (NB), the corpus geniculatum thalamicum (CGT), the nucleus preopticus, and the posterior thalamic neuropil, which is divided into a laterally situated pretectal neuropil and a medially situated uncinate field [3,4]. In the mesencephalon, the superficial fiber layer and part of the deeper fiber layers of the tectum receive extensive visual afferents forming three to four laminae [5,6]. Another terminal site of retinal afferents is the ►basal optic neuropil situated in the tegmentum. Axons of RGCs often form multiple terminal structures in the tectum and in the thalamic neuropils.

## The Tectum Mesencephali as the Main Visual Center

In amphibians, as in all anamniote vertebrates, in reptiles and partly in birds, the tectum is the major brain center for integrating visual perception and visuomotor functions. In the amphibian tectum, localization and recognition of objects and depth perception takes place. Three separate retino-tectal subsystems for object recognition exist, which process information about (i) size and shape, (ii) velocity and movement pattern and (iii) changes in ambient illumination. These kinds of information are processed at the level of different types of retinal ganglion cells and tectal neurons in close interaction with neurons in other visual centers (Fig. 1).

The tectum has substantial reciprocal connections with the ventral thalamus, the ►pretectum, the dorsal tegmental nucleus, the ►nucleus isthmi [see ►Evolution, of Nucleus Isthmi] and the middle reticular nucleus of the medulla. Transmitter-specific input originates from the cholinergic nucleus isthmi and from cholinergic tectal cells (only in salamanders), the serotonergic nucleus raphe and serotonergic tectal cells (only in frogs) or from the glycinergic middle reticular nucleus of the medulla (in salamanders), which modulate retino-tectal transmission and/or postsynaptic tectal processing [7–10].

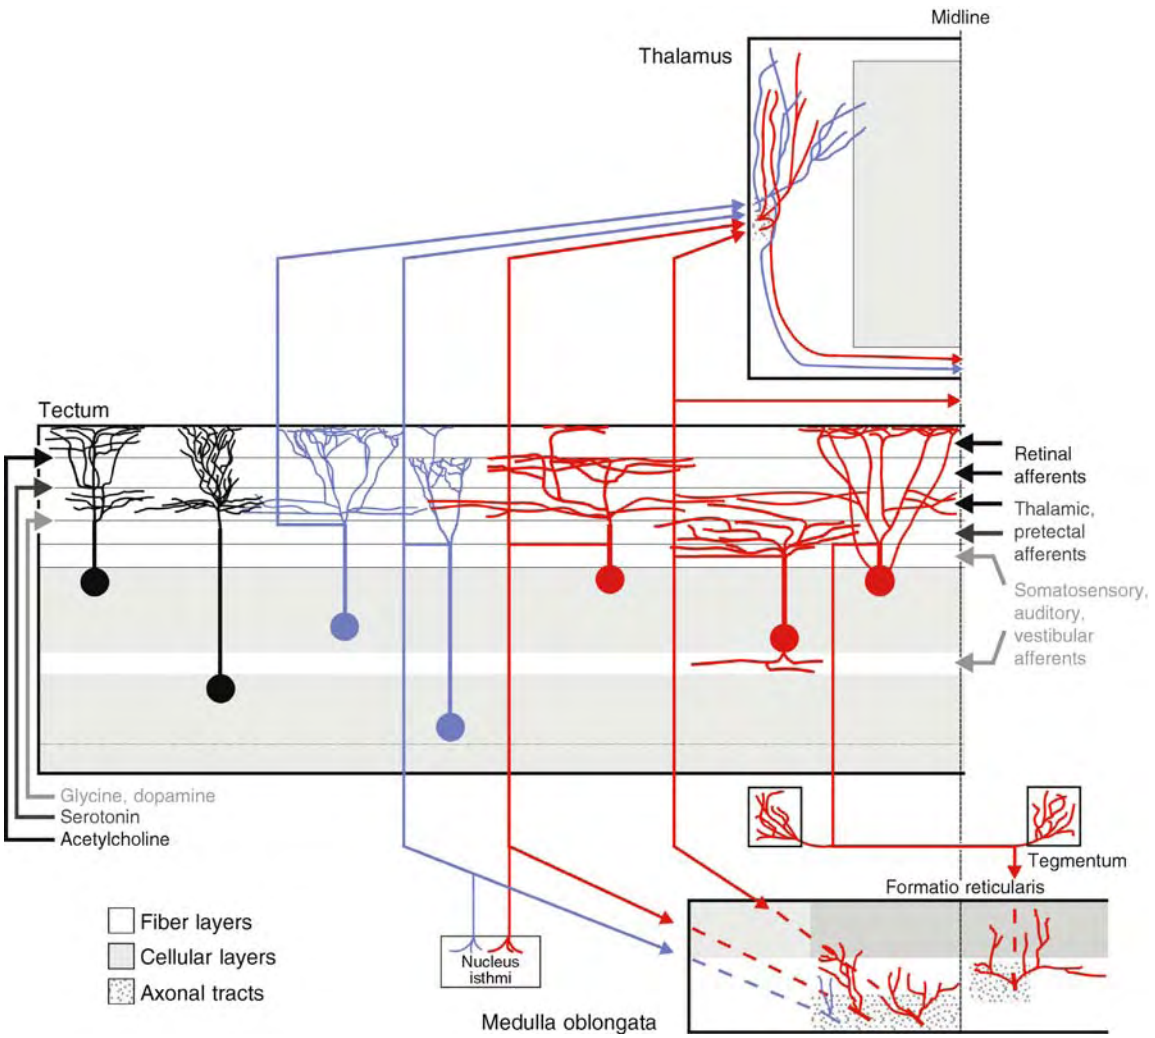
Nine layers are distinguished in the tectum of frogs, while the tectum of salamanders consists only of a periventricular cellular layer and a superficial white matter with only few migrated neurons. During ontogeny, tectal cells originate in the periventricular germinal zone and then migrate toward the surface. In salamanders, this late ontogenetic migration process is either strongly reduced or completely abolished due to secondary simplification as a consequence of ►paedomorphosis [11], while the functional organization of the tectum is essentially the same in frogs and in salamanders [12–14]. The salamander tectum contains on average 100,000 cells and this number is 2–17 times larger in frogs. Glutamate is found in the majority of tectal neurons. However, cells containing only GABA comprise at least one-third of the total population of neurons. The bulk of tectal neurons represent local interneurons and only roughly 5% are projection neurons. Separate tectal pathways descend to premotor and motor centers in the brainstem and cervical spinal cord that are involved in the guidance of visual behavior.

At least four types of neurons with medium- or large-sized dendritic arbors located in different tectal layers give rise to one crossed descending tract and several uncrossed descending tracts. The descending fibers of the different tracts form distinct terminal fields in the tegmentum and/or the medulla. The descending projectional system of the amphibian tectum corresponds to that found in other vertebrates as regards neuronal types and projection sites. Ascending tectal pathways run bilaterally to the dorsal and ventral thalamus, which in turn are connected with telencephalic associative (pallial) and limbic centers (amygdala and septum) and the striato-pallidum. These ascending pathways are formed by small-field tectal neurons with only ascending projections, as well as by two types of wide-field neurons with ascending and descending projections. The former neurons constitute the majority of ascending tectal projection neurons; they give rise to a retinotopic tectal projection to the thalamus. In contrast, the latter two types of neurons appear to give rise to a non-retinotopic tectal projection to the thalamus. Accordingly, in amphibians the ascending pathways may be divided into two functional systems, viz. a retinotopically organized one and a non-retinotopically organized one. This is comparable to the situation found in reptiles and birds.

Unlike other jawed vertebrates, the amphibian tectum includes no saccadic system, because eye movements do not exist in adult amphibians. This is probably due to a secondary loss, because eye movements are present during ontogeny of amphibians with aquatic or semi-aquatic life styles. In addition, directionally selective neurons are absent in the amphibian tectum, in contrast to their presence in all amniotes.

## The Visual Thalamus

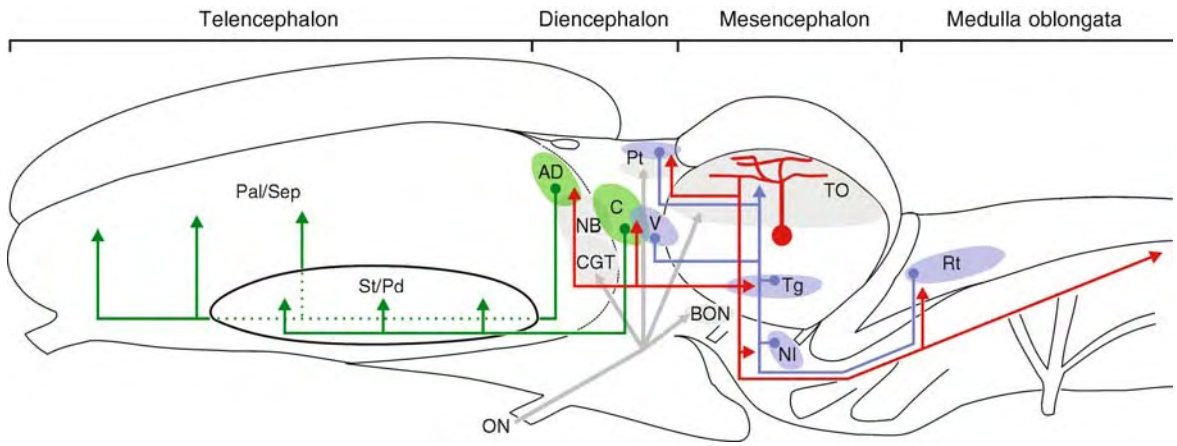
Visual afferents to the thalamus include primary afferents from the optic nerve and secondary afferents from the tectum. The optic tract forms two neuropils in the thalamus, i.e. the neuropil of Bellonci (NB) and the corpus geniculatum thalamicum (CGT), which occupy most of the lateral region of the thalamus. Afferents from



**Evolution of the Visual System in Amphibians. Figure 1** Summary diagram of the tectum and its layers, afferent input and types of tectal neurons. Local interneurons are drawn in black, small-field and large-field projection neurons are drawn in blue and red, respectively. Only ascending projections to the thalamus and descending projections to the tegmentum and medulla oblongata are shown.

the tectum terminate in the medial portion of the neuropil area. Thalamic neurons with only descending projections have dendritic trees that arborize in restricted parts of retinal afferents, while those with only ascending projections to telencephalic targets have dendritic trees that do not, or not substantially, contact retinal afferents. With electrical stimulation of the optic nerve, neurons in the ventral thalamus exhibit mostly excitatory responses at short latencies and thus appear to be mono- or oligo-synaptically driven by retinal afferents, while those of the dorsal thalamus respond with inhibition or excitation at long latencies and are regarded as poly-synaptically driven by retinal afferents [15,16].

A remarkable difference between amphibians and mammals is the absence in the dorsal thalamus of amphibians of a visual relay nucleus that receives direct retinal input and projects mono-synaptically to the cortex. Another difference is the absence from the pallium of amphibians of primary and topographically organized visual areas such as are present in the striate cortex of mammals. Birds possess two visual pathways, viz. a retinotopically organized pathway from the retina to the nucleus geniculatus lateralis pars dorsalis, which in turn projects to the visual Wulst of the hyperpallium and is comparable to the retino-thalamo-cortical pathway in mammals and a non-retinotopically organized pathway from the tectum via the thalamic nucleus rotundus to the entopallium (formerly ectostriatum), the homology of which in mammals is currently a subject of debate [see Evolution, of the Telencephalon: in



**Evolution of the Visual System in Amphibians. Figure 2** Schematic diagram of the visual pathways in the amphibian brain. An outline of the salamander brain is shown. Gray lines denote the optic nerve (*ON*), gray areas refer to the terminal fields of the axons of retinal ganglion cells in the neuropil Bellonci (*NB*) and corpus geniculatum thalamicum (*CGT*) inside the thalamus, the pretectum (*Pt*), the basal optic neuropil (*BON*) inside the tegmentum, and within the layers of the tectum (*TO*). A schematized tectal neuron and the efferent pathways of tectal cells are drawn in red; axons run to the ventral and dorsal thalamus, pretectum, tegmentum, isthmic region, reticular medullar zone and cervical spinal cord. Feedback connections (blue lines) exist between tectum and ventral thalamus (*V*), *Pt*, dorsal tegmental nucleus (*Tg*), nucleus isthmi (*NI*) and reticular nuclei (*Rt*). Ascending pathways (green lines) extend from the central dorsal thalamic nucleus (*C*) to the striato-pallidum (*St/Pd*), and from the anterior dorsal thalamic nucleus (*AD*) to the amygdala, pallium and septum (*Pal/Sep*). Descending projections from the telencephalon to the thalamus, tegmentum and medulla are omitted for the sake of clarity.

Amniotes and Evolution, of the Forebrain: Embryological Development]. The situation in turtles and squamates is somewhat intermediate, because although on the one hand a lateral geniculate nucleus exists, receives direct retinal input and projects both to the dorsal cortex and the pallial thickening, on the other hand, in neither area are retinotopically arranged visual areas found [17].

## Functional and Comparative Aspects

The major visual system differences that exist between amphibians on the one hand and mammals and birds on the other can be summarized as follows: (i) in amphibians, visual object recognition and visual guidance of behavior is mostly exerted by the retino-tecto-pretectal system, (ii) a unimodal visual thalamo-telencephalic system characteristic of mammals and birds is absent in amphibians and poorly developed in reptiles, (iii) the visual pallial area in amphibians is not topographically organized and (iv) in amphibians, thalamic and telencephalic centers appear to exert a modulatory but no primary sensory role.

On the basis of tract tracing and intracellular and extracellular recording experiments, it appears that besides the above mentioned differences, the amphibian visual system is organized in essentially the same way as that of amniotes in the sense that object recognition is based on population coding and occurs in a parallel distributed fashion simultaneously and subsequently at several to many visual centers [18,19]. Interaction and modulation between these centers occurs to a large extent, because they are interconnected by several feedback loops and top-down influences are most likely (Fig. 2).

This pattern of interaction is supported by a complex chemoarchitecture [20–21]. At least three major streams of information converge at premotor and motor levels in order to elicit the various steps of visually guided behavior: (i) information about properties of the object perceived concerning size, contrast, color, shape, velocity, movement pattern etc. and (ii) information about the precise location of that object. Pathways (i) and (ii) need to interact in order to fully identify visual objects including their absolute size. Additionally, information about the level of motivation, most probably coming from limbic telencephalic regions (amygdala, nucleus accumbens/ventral striato-pallidum) and the hypothalamus, affects the behavior.

# Evolution of the Visual System in Fishes

Shaun P. Collin
Sensory Neurobiology Group, School of Biomedical Sciences, The University of Queensland, Brisbane, QLD, Australia

## Synonyms

Fishes; Visual systems

## Definition

The evolution of the visual system can be defined as the series of changes in the structure and function of the eye and visual input to the brain that has occurred as a result of selection pressures over a relatively long time period. The visual system of fishes comprises the optical apparatus (cornea, iris and lens), the neural retina (converting an optical image into an electrical image) and the optic nerve (conveying visual information to the brain). Primitive fishes are either jawless (Agnatha) or jawed (Elasmobranchii and Osteichthyes) and are remarkably diverse, occupying a large range of aquatic environments.

## Characteristics

The extant jawless fishes (hagfishes and lampreys) represent the earliest stage in vertebrate evolution. Lamprey-like animals are represented in fossil deposits dating back approximately 540 million years. The jawed fishes (cartilaginous and bony) evolved approximately 400 million years ago and occupy a diverse range of habitats and lifestyles. At present, about 25,000 species within almost 500 families and 60 orders of fishes exist (85 jawless, 850 cartilaginous sharks, skates, rays and chimaeras and 24,000 bony fishes). However, the visual systems of only a small percentage of these species have been examined. Many of their ocular features have been shown to be under environmental, rather than phylogenetic, selection pressures.

### The Eye

#### *The Evolution of the Eye in Fish*

The single-chambered chordate eye appears to have evolved not long after the Cambrian explosion, a period

in evolutionary history that generated many of the animal phyla in existence today. The evolution of an image-forming eye in conodont animals provided spatial vision and the opportunity for predation, a strong selection pressure that was to greatly influence eye design. The vertebrate retina is derived from the neural epithelium of the central nervous system, while the lens is derived from an invagination of the epidermal epithelium. The evolution of the eye from a region of photosensitive skin to an eyecup with retinal elements and a lens is considered to have taken less than 400,000 generations or less than half a million years [1]. Given the enormous range of visual environments occupied by various species of fish, it is therefore not surprising that their eyes have evolved a plethora of mechanisms to increase sensitivity and/or spatial resolution. The size and position of the eyes within the head and the extent of the ►visual field also varies and governs visual behavior.

### The Cornea

The cornea is the first optical interface in the eye and acts as a protective goggle predominantly comprising collagen fibers (stroma) interposed between an epithelium and an endothelium. The fish cornea confers little if any refractive power due to the comparable refractive indices of the cornea and the surrounding aquatic media. In early fishes, the cornea was split into dermal (continuous with the skin) and scleral (continuous with the eyecup) components, which, in some amphibious or burrowing species, allows the underlying globe to move freely. The evolution of the dermal cornea or secondary spectacle is thought to streamline the head and, in benthic species, protects the eye from abrasion. Colored pigments within the cornea (and lens) also act as short wavelength absorbing filters to minimize chromatic aberration and to tune the light reaching the retinal photoreceptors. These intraocular filters have been described in the corneas of agnathans and in cartilaginous and bony fishes. In some pelagic species of bony fishes, a fusion of horizontal or vertical eyelids has resulted in an intraconjunctival space (termed a tertiary spectacle by Walls [2]). In agnathans and elasmobranchs, ►sutural fibers inhibit the corneal stroma from swelling in response to low temperatures and changes in osmotic pressure associated with moving between salt water and freshwater.

Multilayered stacks of materials (such as connective tissue, modified ►rough endoplasmic reticulum, collagen fibrils and cytoplasmic plates) with different refractive indices are common inclusions in bony fishes (Osteichthyes) and produce iridescence [3]. The result of constructive interference, the wavelength and intensity of the reflected iridescence depends upon the thickness, spacing and the angle of incidence of the light on the cornea. Iridescence may reduce intraocular flare produced by bright down welling light, act as a birefringent filter and provide camouflage for the pupil. Given the diversity of iridescent structures, its appearance may represent convergent evolution.

### The Lens

In water, and in the absence of any corneal refraction, the refractive power of the fish eye lies solely with the lens. In order to reduce the focal length and improve the quality of the image focused on the retina, a lens with a small radius of curvature is required. Therefore, the fish lens is generally spherical (Figs. 1, 2).

However, this presents the optical problem of spherical aberration. This type of aberration is produced by light rays refracting (bending) too much at the spherical surface of the lens, thereby not bringing all rays to a single focus and producing a blurred image. In order to overcome spherical aberration, and in contrast to terrestrial lenses, the fish lens has a graded refractive index from the lens center to the periphery. The result is that the lens periphery bends the light less and all rays are brought to a single focus on the neural retina. The graded refractive index is lacking in young sea lampreys, which exhibit positive spherical aberration until they mature.

Some species of fishes have evolved mechanisms to alter the refractive power of either the lens or cornea or both. In amphibious fishes (e.g. mudskippers and flying fish), the cornea has become flattened to compensate for the increase in corneal power in air. The sandlance, a minute bony fish with independent turret-like eyes, has evolved a highly refractive corneal lenticle with increased power (balanced by a flattened lens with decreased power) in water (Fig. 2). This unique optical design moves the nodal point of the eye forward, thereby providing new information about a prey object's location against a background, without translations of the head or body [4]. The four-eyed fish is able to see in both air and in water by sitting at the water's surface with the dorsal half of the eye out of the water facing upwards and the ventral half of the eye submerged and facing downwards. Clear vision in both aerial and aquatic axes is accomplished simultaneously with a lens that has different radii of curvature (Fig. 2).

Unfortunately for biological lenses, short wavelengths of light are refracted more than long wavelengths of light (chromatic aberration). This results in blue light focusing closer to the lens than red light. However, interruptions to the otherwise smooth refractive index gradients of the lens in lampreys, lungfish and teleosts bring the focal length of the light spectrum back to a single focus on the retina. These multifocal lenses allow the incident light to be focused on a single layer of retinal photoreceptors, thereby optimizing the capture of light by multiple cone types involved in mediating color vision [5].

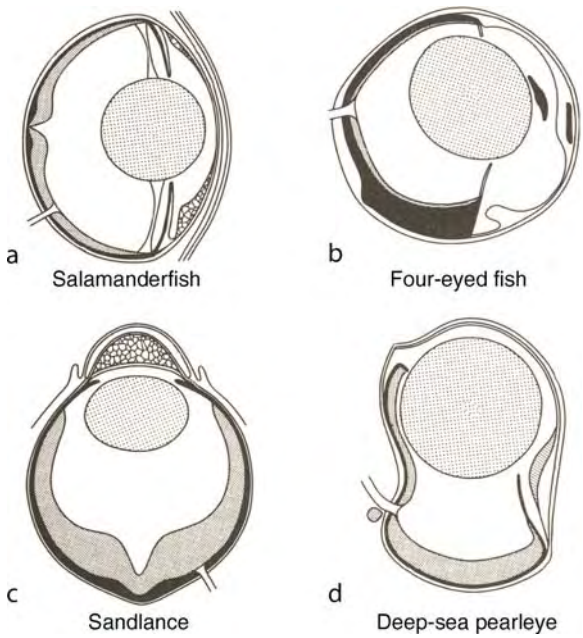
The size of the pupillary aperture can improve the level of spherical aberration by reducing the number of rays passing through the lens periphery. The shape and size of the pupil varies across fishes from a circular to a U- or W-shaped with multiple apertures to a slit. Lampreys possess little, if any, active movement of the iris, while most elasmobranchs elicit rapid changes in pupil shape in response to ambient light levels. Teleosts predominantly do not possess pupillary movements, although some benthic catfishes use the constricted pupil to camouflage their eyes [6].

### Accommodatory Apparatus

With a spherical shape of fixed focal length, the fish lens must be physically moved back and forward to focus on near and far objects within the visual field. Accommodatory mechanisms have been subject to appreciable selection pressure in fishes and vary across many of the groups [7]. Many hagfishes do not possess a lens. However, in other agnathans (the lampreys), a cornealis muscle lying in the head next to the eye is thought to retract the cornea and thereby the closely apposed lens towards the retina during accommodation. However, stimulation of the cornealis muscle does not elicit lens movement in some species of lampreys and other static forms of accommodation i.e. a multifocal lens and a variable distance between the photoreceptor plane and the lens center, may provide a focused image on the retina (Fig. 1). In lampreys, some batoid elasmobranchs and developing teleosts, the eyes are not symmetrical, the dorsal retina sitting closer to the lens than the ventral retina. This "ramped retina" allows both near and far objects to be focused on the retina simultaneously (Fig. 1). Cartilaginous fishes and bony fishes possess a protractor and a retractor lentis muscle, respectively. These intraocular lens muscles within the ventral papillae of the ciliary body move the spherical lens anteriorly (towards the cornea accommodating for near objects) and posteriorly (toward the retina accommodating for distant objects). Two species of teleost, the sandlance and the deep-sea pearleye, possess corneal accommodation, where a striated cornealis muscle flattens the corneal curvature thereby retracting the lens towards the retina.

### The Retina and Photoreception

With the exception of the hagfish retina, which appears undifferentiated, the retina of both primitive and advanced fishes possesses all of the major retinal neurons found in other vertebrates. These include photoreceptors, horizontal, bipolar, amacrine and ganglion cells, which are arranged into three nuclear layers



**Evolution of the Visual System in Fishes. Figure 2** Schematic eyes of a range of teleost fishes. a The salamanderfish, *Lepidogalaxias salamandroides*. b The four-eyed fish, *Anableps anableps*. c The sandlance, *Limnichthyes fasciatus*. d The deep-sea pearleye, *Scopelarchus michaelsarsi*. Note the diverse range of corneal, lenticular and retinal specializations [adapted from 21].

and two plexiform (synaptic) layers. In lampreys, most (75%) of the ganglion cells lie within the inner nuclear layer. Axons of these "ectopic" ganglion cells join those lying within the ganglion cell layer to exit the retina at the boundary of the inner nuclear and inner plexiform layers at the optic nerve head, effectively negating the blind spot [8]. In elasmobranchs and teleosts, most of the ganglion cells lie within the ganglion cell layer, with a small proportion "displaced" to the inner nuclear layer. Their axons traverse the retina within the nerve fiber layer abutting the inner limiting membrane. A great deal of work still remains to be done on the evolution of the inner retina in fishes, but it appears that lampreys possess a population of biplexiform ganglion cells that make direct connections with the photoreceptors and inner nuclear layer cells.

The photoreceptors within the outer retina of a range of extant species of fishes have received more attention. Their visual pigments phototransduce light energy into electrical impulses that trigger a cascade of enzymatic reactions that amplify the signal and ultimately change the rate of neurotransmitter release from their synaptic terminals. The signals are conveyed to the ganglion cells via bipolar interneurons. The visual pigments comprise a chromophore based on either vitamin $A_1$ (rhodopsin) or $A_2$ (porphyropsin) covalently bonded to an opsin protein, comprised of seven transmembrane alpha helices embedded within the outer segment discs. The amino acid sequence of the opsin protein and the type of ►chromophore used in fishes determines the spectral sensitivity/tuning of the visual pigment and therefore the range of wavelengths to which each species is sensitive. Rods mediate dim light (scotopic) vision and cones mediate bright light (photopic) vision. In jawed vertebrates, rod visual pigments are classified as Rh1, while cone visual pigments fall into four classes (long wavelength-sensitive or LWS, ultraviolet-sensitive or SWS1, blue wavelength-sensitive or SWS2 and medium wavelength sensitive or Rh2). Cones may be also characterized on size and whether they are single or double (although triple and quadruple cones have also been described). Single cones can be divided into at least four classes based on size and the class of visual pigment. Double cones are closely apposed cones that are morphologically distinct (with principal and accessory components) or indistinct (twin cones). The presence of more than one cone type, each with a different (but overlapping) spectral sensitivity, provides the basis for color vision.

While hagfishes, possess at least two photoreceptor types, lampreys possess up to five morphologically distinct photoreceptor types, all of which possess cone-like characteristics and contain a different visual pigment (LWS, SWS1, SWS2, RhA and RhB), providing the basis for pentachromatic vision [9]. Three of these opsin genes are orthologous to the visual pigment classes of gnathostomatous (jawed) vertebrates but the other two (RhA and RhB) have evolved by an independent gene duplication event, which occurred within the agnathan lineage. Given the absence of the Rh1 opsin gene within the agnathan lineage, scotopic vision may have evolved exclusively within the gnathostomatous lineage prior to the evolution of the cartilaginous fishes. The functional characterization of rods and cones requires further examination in the early vertebrates at both the physiological and the biochemical levels. Multiple cone types have been retained within the cartilaginous (3 cone types) [10], dipnoan (4 cone types) [11], early ray-finned (3 cone types) [12] and teleostean (up to 7 cone types) [13] fishes. Therefore, it appears that all vertebrate classes possess the potential for color vision, although this has not yet been confirmed behaviorally in the non-actinopterygian fishes. The comoran coelacanth appears to have lost the SWS1, SWS2 and LWS opsin genes and retained the Rh1 and Rh2 opsin genes that are tuned to detect the full spectrum of light available at the depth it inhabits (200 m) [14].

### Spectral Filters

Filtering mechanisms in fishes are common and typically comprise the accumulation of short wavelength-absorbing pigment within the ocular media

(cornea, lens and vitreous humor) [15] and within the inner regions of some photoreceptor types (myoidal pigment and oil droplets). These spectral filters narrow the absorption spectrum of the visual pigment housed in the outer segment of the photoreceptors, shift the peak absorption of the visual pigment towards longer wavelengths and decrease the absorption efficiency. Accumulations of yellow myoidal pigment exist in lampreys, the Australian lungfish and in reptiles. Oil droplets exist in the lobe-finned (lungfish and coelacanth) [11] and early ray-finned (sturgeon and paddlefish) [12] fishes and may be red or colorless. Oil droplets allow the discrimination of more colors under bright light conditions. Intracellular structures resembling oil droplets lie within the photoreceptor inner segments in a single species of lamprey and some teleostean cyprinids. Termed ellipsosomes based on their elliptical shape, these structures are of mitochondrial origin and may either contain a heme pigment, thereby acting as a spectral filter (cyprinids) or lack any light-absorbing pigment and may act as an intracellular focusing device.

### *Tapeta*

A mirror or tapetum located behind the retina for increasing sensitivity by reflecting light back onto the photoreceptors is an early invention in vertebrate evolution. Of the 33 species of lampreys described, a single species (*Mordacia mordax*) possesses a mixture of reflective needles and pigment granules within the retinal pigment epithelium, which elicits a yellow eye shine. Retinal tapeta have been also described in garfishes and several species of teleosts. These comprise spheres containing astaxanthin, phenolic compounds or lipids packed into a hexagonal array within the confines of the retinal pigment epithelial cell membrane. All these spheres are reflective and elicit a colored reflex produced by diffuse scattering. Choroidal tapeta, typically with guanine as the reflector, are found in cartilaginous fishes (sharks, skates, rays and ratfishes), Polypteriformes (bichirs), Ginglymodi (gars), Acipenseridae (sturgeons), Dipnoi (lungfishes), the coelacanth and a few nocturnal ray-finned fishes. In cartilaginous fishes, the choroidal tapetum is occlusable, masking the mirrored surface with pigment granules in bright light.

Another way of increasing sensitivity to a range of ambient light conditions is to differentially place the rod photoreceptors adapted for dim light vision closer to the incident light (at the outer limiting membrane). Under these conditions, the cone photoreceptors migrate towards the back of the retina. The opposite occurs in bright light, where the cones adopt a position at the outer limiting membrane and the rods are masked by the migration of the melanosomes within the retinal pigment epithelium. In teleosts, not all photoreceptor types undergo photomechanical movements. There appears to be a trade-off between the level of photomechanical retinomotor movements (inherently slow) and the evolution of more rapid pupillary movements. In evolutionary terms, pupillary and retinomotor movements appear to be most developed within the elasmobranchs and teleosts, respectively.

In contrast to optimizing sensitivity with either retinomotor movements or a tapetum, many fishes are specialized for acute vision, sampling a particular part of their visual field with high ►spatial resolving power. The lamprey retina is specialized for acute vision, where both the photoreceptor and ganglion cell densities increase to form an area centralis in the central retina [8]. All of the fishes examined thus far, irrespective of their phylogenetic origins, possess some form of retinal specialization, which may be in the form of a concentric increase in cell density (area centralis) or an elongated increase in cell density across the retinal meridian (horizontal streak). Environmental cues and the symmetry of each species' perceived world play a large role in the topography of retinal cells rather than any phylogenetic relationships. The first appearance of a retinal invagination or foveal pit in predatory fishes appears to be in the euteleosts, i.e. in the seahorse and the sandlance (Fig. 2).

## Central Visual Pathways

The optical image formed by the visual apparatus is transformed into an electrical image by the retina, which is conveyed to the visual centers of the brain via the optic nerve. The optic nerve comprises the axons of the retinal ganglion cells and ►efferent fibers. In lampreys, the optic nerve is avascular and contains an ependymal core and unmyelinated axons. However, typically, the axons of gnathostomatous (jawed) fishes are myelinated and form fascicles or bundles subdivided by astroglia. The optic nerves from the left and right eyes cross (decussate) at the optic chiasm crossing as separate nerves (most teleosts) or where one optic nerve is interlaced with the other (cartilaginous fishes and a few teleosts). In most fishes, contralateral and ipsilateral projections from the eyes terminate in the suprachiasmatic nucleus, the posterior parvocellular preoptic nucleus, the anterior nucleus of the thalamus, the pretectal nuclei and the optic tectum. In all species examined, retinal input to the optic tectum is retinotopic and is restricted to the stratum opticum (SO), the stratum fibrosum et griseum superficiale (SFGS), the stratum griseum centrale (SGC) and the junction between the stratum album centrale (SAC) and the stratum periventriculare (SPV), although some phylogenetic variation exists.

### *Laterality*

Ipsilateral (non-decussating) input to the visual centers of the brain is thought to be an inherent component of

the visual pathway in all vertebrates, including hagfishes and lampreys. However, the relationship between ipsilaterally projecting ganglion cells and the extent of the binocular visual field is not well understood in early fishes. The optic tracts in both hagfishes and lampreys project bilaterally to the preoptic, thalamic and pretectal nuclei and terminate in the mesencephalic optic tectum [16]. In garfishes, the mediorostral and ventrolateral regions of the optic tectum receive ipsilateral input from the retina and subtend the dorsal and ventral binocular fields, respectively [17]. Discrete ipsilateral input to the entire optic tectum is found in the Australian lungfish and juvenile teleosts suggesting that there may be phylogenetic differences in binocular partitioning (when compared to most modern teleosts). Ipsilateral input via the intertectal and posterior commissures does not appear to occur in all non-actinopterygian fishes and appears to have evolved independently many times [25].

### Ascending Pathways to the Telencephalon

Visual information is relayed to the telencephalon through several different routes in various fishes [18]. While little is known about the ascending pathways in agnathans, these pathways have been studied in both cartilaginous and bony fishes. In some sharks and in skates, the retina projects to the nucleus anterior in the rostral thalamus, which in turn projects to part of the pallium. The retina also projects to the optic tectum, which in turn projects to a more caudal part of the dorsal thalamus, the dorsal posterior nucleus, which also projects to the pallium and additionally robustly to part of the subpallium. More detailed information is needed on these two pathways in cartilaginous fishes and their respective terminal fields within the pallium. In ray-finned fishes, the nucleus anterior within the rostral part of the dorsal thalamus likewise receives retinal input, but whether it projects to part of the pallium or not remains controversial. Ray-finned fishes do have an ascending tectal-dorsal thalamic-pallial pathway, via the dorsal posterior nucleus and this pathway terminates predominantly in the medial part of the pallial region (which compares topographically to the lateral pallium of most other vertebrates due to the developmental process of eversion [see ►Evolution: of the Pallium Fishes]).

### Pretectal Elaboration in Ray-finned Fishes

The pretectum reaches a high degree of elaboration in ray-finned fishes, particularly among teleosts [18]. In all fishes, three zones from superficial to deep can be recognized in this region — superficial, intermediate and periventricular. In all teleosts, generally comparable nuclei are present in the latter two zones, but marked variation occurs in the degree of elaboration of the superficial zone. In three of the four major teleost radiations (osteoglossomorphs, elopomorphs and clupeomorphs) the superficial zone comprises the parvocellular superficial pretectal nucleus (PSp), the magnocellular superficial pretectal nucleus (PSm), the nucleus corticalis (NC) and a posterior pretectal nucleus (PO). The PO attains a very large size in some taxa, such as some osteoglossomorphs. In teleosts, PSp, PSm, and NC are present, but instead of a single additional nucleus (PO), two different nuclei are present; the intermediate superficial pretectal nucleus (PSi) and the nucleus glomerulosus (NG). Based on connections, location and other indications, these two nuclei appear to have differentiated out of the same field that gives rise only to PO in other teleosts. NG is a highly elaborate nucleus with neuronal clusters and afferent fibers forming a ring of glomeruli around its periphery. These nuclei are involved in what may be a feeding circuit. Visual input from the retina is relayed through PSp to either PO or, in euteleosts, to PSi and then to NG. PO and NG both project to the inferior lobe of the hypothalamus, which may be involved in controlling motor aspects of feeding.

### The Nucleus Rostrolateralis of Ray-finned Fishes

An additional apparently unique feature of ray-finned fishes is the presence of a nucleus in the rostral and lateral part of the diencephalon, which is thus named the nucleus rostrolateralis. This receives visual inputs, a modest input from the retina and a robust projection from the optic tectum [18]. The nucleus does not appear to project to the telencephalon but rather may be involved with more caudal, tegmental visual pathways. The nucleus is striking for its very widespread but sporadic phylogenetic distribution, having been found in clusters of several closely related species within several taxa (from gars to some euteleosts to date), which themselves are very distantly related, but being absent from the phylogenetically intermediate species that have been examined. Remarkably, in the four-eyed fish, *Anableps*, each half of the diencephalon contains two rostrolateral nuclei, one for each half of the retina, for the visual space in and out of the water from each eye.

Efferents within the optic nerve of ray-finned fishes form the centrifugal system. Neurons located in the olfactoretinalis nucleus, located at the junction of the telencephalon and the olfactory bulb, the pretectal nuclear complex, the dorsomedial optic nucleus and the optic tectum project directly to the retina and synapse upon dopaminergic interplexiform cells located within the inner nuclear layer. In both lampreys and hagfishes, two tegmental cell groups (the reticular mesencephalic area and the nucleus M5 of Schober) give rise to centrifugal fibers and, as in teleosts, also make contact with bipolar, horizontal and ganglion cells. The centrifugal system responds to chemical cues such as sex pheromones and regulates visually mediated sexual

and reproductive behavior in addition to altering ganglion cell responses to color contrast.

## Adaptations

Extant eyes are extremely variable and reflect a high degree of evolutionary change. Although restricted within the confines of the vertebrate camera-type eye design, the evolution of the visual system is regulated by the light environment, the ecological niche occupied by each species and their visual demands for survival. The proportion of rods and cones and their retinal distribution is determined largely by ambient light intensity and spectral composition (dictated by the amount of attenuation and absorption throughout the water column), which play an important role in the spectral sensitivity and tuning of the photoreceptor visual pigments [19]. Some teleost species have a labile mechanism for varying spectral sensitivity, with many cichlids possessing up to seven opsin genes in response to the behavioral demands of feeding and reproductive success [13]. The duplex nature of the retina and the visual demands of predation and predator avoidance also affect retinal processing and ultimately behavioral outcomes. It appears that the visual system can respond very rapidly to evolutionary changes in lifestyle [1]. The selective pressure on the phenotype of the retinal photoreceptors for example can be measured by examining the rates of synonymous (no effect on the encoded proteins) and non-synonymous (affects the protein) nucleotide substitution of the opsin genes [20]. In this way, a measure of the regulation of the molecular evolutionary clock may be gained at least over comparable time frames where a fossil record is available or where data is available for other vertebrate phylogenies.

Evolutionary and developmental changes in the visual system of fishes has ensured that each species is adapted to their often changing environment. Avoiding predation, successfully feeding and finding reproductive partners is ultimately the function of the visual system. Although in concert with a battery of other senses, vision remains a crucial modality for survival in an aquatic environment. The diverse range of adaptive specializations and the high degree of developmental plasticity reflects intense selection pressure to maintain and optimize visual sampling within a range of environments [27].

# Evolution of the Visual System in Reptiles and Birds

Toru Shimizu[1], Tadd B. Patton[1], Gabrielle Szafranski[1], Ann B. Butler[2]
[1]Department of Psychology, University of South Florida, Tampa, Florida, USA
[2]Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

Reptiles and birds (sauropsids) depend heavily on the sense of vision to detect danger, find food, defend territory, and select a mate, and vision is of course essential for birds to fly in the air. Sauropsids have well-developed eyes, midbrains, and forebrains for visual processing. Among sauropsids, many avian species have excellent visual abilities, including color vision, visual acuity, motion perception, and visual memory.

## Characteristics

### Reptilian Eye

*Features:* As in other vertebrates including birds, the eyes of reptiles consist of an outer, fibrous and tough layer of sclera, a vascular layer called the choroid, and an inner, thin pigment epithelium that is applied to the outer surface of the neural retina. The choroid supplies oxygen and nutrition to the retina of many reptiles, but in lizards and to a lesser extent in snakes, an additional cone-shaped structure is present that supplements this function [1]. This structure is called the conus papillaris [2] and is homologous to the pecten of birds, which is discussed below.

The sclera is also somewhat specialized in reptiles. In most taxa, it includes cartilaginous elements, and, in its anterior region, it contains about 14 scleral ossicles that form a ring around the cornea. These bones are also present in birds, as discussed further below, but they are absent in extant crocodiles and snakes.

The scleral ossicles are involved in the process of accommodation of the eye in those reptiles that possess them [1]. For accommodation to occur, the lens must become rounder, i.e., assume a shape that gives it greater depth from front to back. Rather than acting to relax the tension on the lens ligaments as occurs in mammals, allowing the lens to assume a more spherical shape, the ciliary muscles in reptiles contract in such a way as to press the ciliary body against the sides of the lens, causing it to lengthen from front to back. Also, as the lens pushes against the rim of the cornea, the scleral ossicles assist in maintaining the pressure supplied by the ciliary body. As discussed below, the latter mechanism is greatly augmented in some diving birds.

*Visual Fields:* In most reptiles – crocodiles, land tortoises, and most diurnal lizards – the eyes are laterally placed on the head, resulting in mostly monocular visual fields with only a small region of binocular overlap. In contrast, some freshwater turtles and snakes have a more extensive binocular overlap, up to 30° or more [1]. Chameleons (such as *Chamaeleo vulgaris*) have the exceptional ability to independently move their eyes, such that the eyes can swivel up to about 180° in the horizontal plane and up to about 90° in the vertical plane. At times, a chameleon may have each eye directed laterally for monocular vision to each side, while at other times one eye may be directed forward and the other backward. For a wide field of binocular vision, both eyes may be directed forward [1].

*Retina:* Reptiles have a variety of specializations with regard to the retina, depending upon their particular niche or other factors [1]. Retinas that contain both rods and cones occur in many reptiles, including some turtles, crocodiles, and the tuatara (the rhynchocephalian *Sphenodon*). Diurnal lizards, however, lack rods. Unusual for lizards, anoles (which are iguanids) have two foveas in each eye rather than just one. In contrast, nocturnal lizards, such as geckos, have retinal receptor cells that resemble rods, which (as in some other taxa) may actually be a derived form of cone cell. The retina of snakes reflects their convoluted evolutionary history of a period of assuming a fossorial niche and then subsequently

reemerging to a surface niche. The retinas of snakes exhibit marked variations in their rod and cone types.

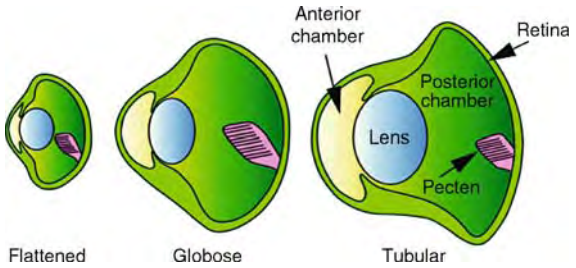
## Avian Eye

*Features:* A striking feature of the avian eye is the presence of the ▶pecten. It is a comb-like, pigmented, and highly vascularized structure, standing in the posterior chamber of the eye, and is much more elaborate in its size and development than the similar cone-shaped structure, the conus papillaris, in lizards and snakes. Although various possible functions of the pecten have been suggested, evidence indicates that it is probably involved in the nutrition of the internal parts of the eye. In the avian eye, unlike the human eyes, there are no surface retinal blood vessels. Instead, the vascularized tissue of the pecten may serve as an agitator to propel nutrients and oxygen into the retina [3].

Although the overall design of the avian eye is similar to those of other vertebrates, there are some important differences. As in reptiles, the avian sclera is specialized in terms of the presence of the scleral ossicles, with particular specializations of these elements having occurred in some species of shore birds [see 6]. Some shore birds, including herring gulls, pelicans, and some species of ducks, lack specialization of their scleral ossicles, and therefore have reduced ability to accommodate under water. Other birds, including cormorants, merganser ducks, and guillemots, have specialized scleral ossicles and ciliary muscles that provide accommodation of the lens when under water as well as in air, allowing them to dive to pursue and catch fish and other prey under water without the benefit of goggles. These species have exceptionally large ciliary muscles and heavily ossified scleral elements that form a rigid ring around the cornea. When diving, the ciliary muscles compress and hold the lens against the scleral ring, causing its front portion to partially herniate through the ring and become almost spherical in shape, thus allowing excellent vision under water. Penguins have a similar adaptation.

Another major distinguishing characteristic of the avian eye is its huge size relative to the brain and head. Human eyes occupy about 5% of the cranial volume, whereas the eyes of birds usually occupy over 50% [4]. Indeed, the largest eyes of all land animals belong to the ostrich, whose eyes are approximately 5 cm in diameter, compared to human eyes that are about 2.5 cm in diameter. The large eye-size can be advantageous for visual acuity, which is a measure of the ability to see fine details. The larger the eyes, the longer the focal length (the distance between the lens and retina), so that images projected on to the retina are magnified for the detection of details.

The overall shape of the eye varies widely among avian species. There are at least three types of eye shape: flattened, globose, and tubular [5] (Fig. 1). The eyes of many birds with not-so-sharp vision (e.g., quail, chickens) are of the flattened type. The short focal length of the flattened eye is not ideal to see details, but it can provide a wide field of vision, which may be essential to detect approaching predators. Birds of prey with sharp vision (e.g., hawks, eagles) have the globose-type of eyes with a similar length and width. The longer focal length of a globose shape helps to produce a larger retinal image, which is presumably important to find small prey. Nocturnal birds (e.g., owls) have the tubular type of eyes, which include exceptionally large pupils relative to the focal length. The characteristics of tubular eyes enable nocturnal birds to gather a maximum amount of light in a dark environment.



**Evolution of the Visual System in Reptiles and Birds. Figure 1** Schematic images of the three types of avian eyes, which are categorized based on shape: flattened (swan), globose (eagle), and tubular (owl). Adapted from [6].

*Visual Fields:* In most birds, as in reptiles, the eyes are placed on the bilateral sides of the head, enabling a large monocular visual field but a small binocular field. Without moving their heads, pigeons can see over 300° in the lateral fields, and American woodcocks can survey 360° [4]. The large visual field may be critical for birds that need to be vigilant for approaching predators. On the other hand, the lateral placement of the eyes appears to sacrifice binocular vision, which is important for adequate depth perception. However, many birds have excellent eye movements and can transiently increase binocular overlap by convergence. They also have extremely flexible, fast-turning necks and can easily turn their heads with great speed without repositioning their bodies. Many predatory or nocturnal birds (e.g., owls) have eyes that are placed more frontally. They are less concerned about approaching predators, resulting in selection for smaller monocular fields and a relatively larger binocular field.

*Retina:* The basic anatomical circuitry and constituent neurons in the avian retina are similar to those of other vertebrates. However, the avian retina is characterized by its thickness due to a high cell density and connectivity within the retina [5]. This indicates that a significant amount of visual information is processed at

the level of the retina before reaching the brain. As in humans, birds have cone receptor cells for color vision and rod receptor cells for night vision. Humans have approximately 200,000 cones per square millimeter in the fovea whereas small sunbirds have about 380,000 cells per square millimeter [7]. The peak density of rods is about 180,000 rods per square millimeter in humans whereas nocturnal oilbirds have a million cells per square millimeter [8].

Photoreceptor cells are not distributed evenly within the avian retina. Some areas have more photoreceptor, as well as bipolar and ganglion cells, which serve to enhance acuity in the certain sectors of the visual field. Most birds with lateral eyes have two areas of high cell density in the retina: one in the central area and the other in the more temporal area. The central retina is presumably important for monocular vision in the lateral visual fields, whereas the temporal retina is used for binocular vision in the frontal visual field. In contrast, birds with frontal eyes, such as owls, have a single retinal area with a high cell density, which may assist binocular viewing of objects in the frontal field. The single area of high cell density in nocturnal birds may be important for collecting the maximum amount of light in an environment with a low light level [3].

## Visual Pathways in Reptiles

*Midbrain:* The decussation of the optic nerve in reptiles is almost but not entirely complete [9]. The optic tracts project to sites in the diencephalon and midbrain, within the latter principally to the optic tectum [See: Evolution, of the Optic Tectum: in Amniotes]. The reptilian optic tectum is well developed and highly laminated. Retinal fibers terminate in the superficial layers of the tectum [10]. The optic tectum gives rise to several sets of efferent pathways, including descending projections to the brainstem, a major ascending projection that principally targets a large, centrally located nucleus in the dorsal thalamus, nucleus rotundus, and a projection to two nuclei within the nearby isthmal region: nucleus isthmi [See: Evolution, of Nucleus Isthmi], which contains cholinergic neurons and projects reciprocally back to the optic tectum, and the isthmo-optic nucleus [10]. The latter projects centrifugally to the retina and is present in crocodiles, turtles, and, to a lesser degree in lizards, but is apparently absent in snakes [11].

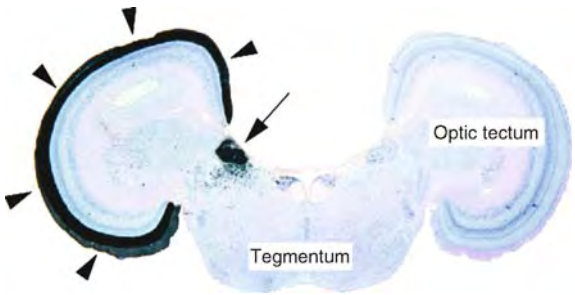
*Forebrain:* As noted above, one of the major targets of the optic tectum is nucleus rotundus. This dorsal thalamic nucleus [See: Evolution, of the Dorsal Thalamus] projects to the visual part of a large structure in the telencephalon called the dorsal ventricular ridge (DVR) [See: Evolution, of the Telencephalon: in Amniotes]. The anatomy of the DVR varies substantially across reptiles [12]. In turtles, the rhynchocephalian *Sphenodon*, and some lizards, it consists of a cell plate, often formed by a series of clumps, or clusters, of the neuron cell bodies, with a more central portion that is mostly neuropil. In other lizards and in snakes and crocodiles, as well as in birds, the DVR is larger and consists of many neurons that are migrated away from the ventricular surface to form various nuclear groups. This pathway – from the retina to the optic tectum to nucleus rotundus to the visual part of the DVR – is sometimes referred to as a collothalamic pathway, due to its substantial relay through the midbrain roof [see 6]. Like in birds, the tectorotundal projection in reptiles is bilateral, and the projection from nucleus rotundus to the DVR is entirely ipsilateral.

A second major visual nucleus of the dorsal thalamus is the dorsal lateral geniculate nucleus (DLGN), as identified by Kenigfest et al. [13]. This nucleus receives its predominant input directly from the retina and projects to a part of the dorsal cortex. In turtles, this projection is to the dorsal cortex itself, referred to in this taxon as the general cortex, while in lizards it is to a rostral portion of the dorsal cortex called the pallial thickening. This cortical, pallial target of the DLGN across all reptiles is thought to be homologous to the visual part of the Wulst in birds and to the primary visual cortex – the striate cortex – of mammals. This thalamofugal pathway is sometimes referred to as a lemnothalamic pathway, in regard to the predominantly direct (or "ribbon-like") input from the retina to the thalamus rather than by relay through the midbrain roof [see 6]. It should be noted that the geniculopallial pathway in reptiles is entirely ipsilateral, in contrast to the situation in birds as discussed below.

*Variations in the Visual System of Snakes:* Just as is the case for their rod and cone types, as discussed above, snakes exhibit variation in their visual thalamus. Several studies have investigated the major visual pathways in snakes, particularly the tectofugal, or collothalamic, pathway [12,14–17], and some interesting variation has been found in their visual thalamic nuclei in comparison to other reptiles. In at least some species such as the water snake *Natrix*, the DLGN is substantially larger than nucleus rotundus, which is dramatically small in relation to all other dorsal thalamic nuclei and in comparison to its dominant thalamic presence in other reptiles and in birds [6,18]. This observation supports the hypothesis of Walls [5] that snakes evolved from an ancestral line of fossorial lizards, in which the eyes and the entire visual system were markedly reduced. As their descendants resumed a surface habitat, the visual sense again became important, but the lemnothalamic portion of it was favored by selective pressures and re-enlarged. In line with this hypothesis, it is of particular interest to note that in the water snake *Natrix*, in which nucleus rotundus is markedly reduced, the optic tectum projects robustly to the DLGN [6] – a highly unusual shift in the collothalamic pathway from the tectum to the primary lemnothalamic nucleus.

## Visual Pathways in Birds

*Midbrain:* In all birds, as in reptiles, visual information from the retina is sent almost exclusively, but not completely, to the contralateral hemispheres. Although several structures in the midbrain and forebrain receive retinal output, the major target among them is the optic tectum of the midbrain [19,20] (Fig. 2). The avian optic tectum is a large, round-shaped structure protruding laterally, visible between the cerebrum and cerebellum. It is highly laminated, with the superficial layers receiving retinotopically-organized input and the deeper layers giving rise to tectal efferents. As in reptiles, these efferents are categorized into at least three groups based on the targets. The tectum sends a descending projection to motor-related nuclei in the brainstem and the spinal cord to control skeletal movements. The tectum also sends a major ascending projection (tectofugal or collothalamic pathway) to the nucleus rotundus, which is the largest cell group in the avian dorsal thalamus. Finally, the optic tectum sends a projection to several nuclei within the nearby isthmal region. One of these projections is to a small midbrain nucleus called the isthmo-optic nucleus adjacent to the tectum [21]. This nucleus is a part of the feedback loop that sends a projection to the retina. The feedback system from the brain to the retina is not unique to birds, but is found in many other vertebrates. Although the exact role in birds has not been clarified, the feedback system has been suggested to be associated with the selective attention mechanism. The optic tectum also has reciprocal connections with three other isthmal nuclei, rather than with just one such nucleus as in reptiles – the parvocellular, magnocellular, and semilunar isthmal nuclei. Two of the latter nuclei, the parvocellular and semilunar, contain cholinergic neurons, as does the nucleus isthmi of reptiles, while the magnocellular contains GABAergic neurons.



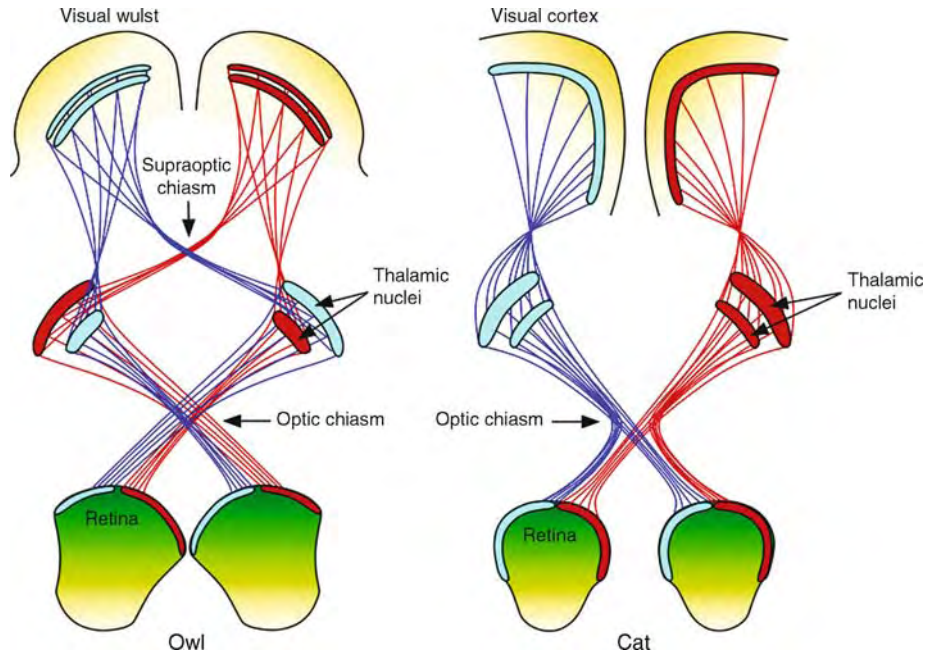
**Evolution of the Visual System in Reptiles and Birds.**
**Figure 2** Transverse section of the pigeon midbrain, consisting of the large optic tectum and tegmentum. Dark staining in the left brain indicates labeling after the tract-tracing chemical cholera toxin was injected into the right eye. Such labeling is visible in the surface layers of the left optic tectum (arrow heads), where the retinal fibers primarily terminate. Also labeled is a region adjacent to the tectum (arrow), where a group of neurons (the isthmo-optic nucleus) sends a projection to the contralateral retina.

*Forebrain:* In the thalamus of birds, as in reptiles, two nuclei are directly associated with visual information processing, one of which is the nucleus rotundus of the tectofugal, or collothalamic, pathway. In birds, the various subdivisions of the extremely large DVR are most frequently referred to as the mesopallium, nidopallium, and arcopallium [22,23]. The telencephalic target of nucleus rotundus is a specific subdivision of the nidopallium, called the entopallium [22,23]. The entopallium in turn sends direct and indirect projections to multiple cerebral structures, including the avian equivalents of the basal ganglia and the prefrontal cortex. The mammalian homologues of the nucleus rotundus and entopallium are still unclear, although possible candidates include part of the pulvinar for the nucleus rotundus and part of the extrastriate cortex, claustrum, or amygdala for the entopallium [20].

The other major thalamic cell group associated with visual processing is the principal optic thalamic nucleus (OPT), which is considered to be the avian equivalent of the dorsal lateral geniculate nucleus of mammals and the nucleus of the same name in reptiles [10,19]. As is true for mammals and reptiles, the avian OPT receives direct retinal input and sends a projection to the cerebrum for further processing. The target of the OPT projection is called the visual ►Wulst (the German word for "bump"), or visual hyperpallium, and is located in the mediodorsal cerebrum. The visual Wulst is presumably a homologue of the mammalian primary visual cortex. This retina-thalamus-Wulst route is called the thalamofugal or lemnothalamic pathway and is comparable to the retina-geniculate-visual cortex pathway in mammals.

In birds with frontal eyes (e.g., owls), the visual Wulst plays a critical role for binocular integration of the large binocular field [24]. These birds have a well-developed OPT and visual Wulst compared to those with laterally located eyes. In order to accomplish binocular integration, other animals with frontal eyes (e.g., cats) have a partial ►optic decussation so that each brain hemisphere receives information from both ipsilateral and contralateral eyes (Fig. 3). In contrast, birds have an almost complete decussation from the retina to OPT, and thus OPT in each hemisphere receives information only from the contralateral eye. However, the visual Wulst can still perform binocular processing because OPT of each hemisphere sends bilateral projections to the Wulst and therefore necessary information from the ipsilateral eye can re-cross to reach the Wulst.

In birds with lateral eyes, especially pigeons, many lesion studies have been conducted to investigate lesion effects on various visual discrimination tasks. The



**Evolution of the Visual System in Reptiles and Birds. Figure 3** Schematic representation of visual pathways in owls and cats. In both animals, the cerebrum can accomplish binocular integration by receiving visual information from the temporal retina of the ipsilateral eye and the nasal retina of the contralateral eye. However, the pathway organizations from the retina to the cerebrum are different between the two animals. In cats (right), binocular convergence occurs at the thalamic level due to partial decussation from the retina at the optic chiasm. In owls (left), binocular convergence does not occur at the thalamic level due to an almost complete optic decussation. Instead, thalamic fibers representing the ipsilateral eye re-cross in the supraoptic chiasm. Adapted from [3].

results suggest that lesions in the tectofugal pathway, more so than lesions in the thalamofugal pathway (the avian equivalent of the geniculo-visual cortex pathway), cause serious deficits in the discrimination of brightness, pattern, and color [25]. This contrasts to the observation that the geniculo-visual cortex pathway in humans is a major visual processing system, lesions in which cause severe effects on conscious vision. The functional significance of the avian tectofugal pathway corresponds to the well-developed and differentiated organization of the avian tectum and its subsequent visual centers in the forebrain.

## The Exceptional Visual Capabilities of Birds

*Color Vision:* Colorful ornaments in their plumage indicate that many birds have excellent color vision, as do humans. However, avian color perception may be quite different from human color perception [26]. Birds have at least four kinds of cone photopigments, instead of the three primary-color system found in humans. Three of the avian pigments can detect the wavelength ranges seen by humans. The additional photopigment in birds is sensitive to ultraviolet or near ultraviolet light, which humans and other primates are not able to perceive. This ultraviolet sensitivity may be useful for detecting optical markers on plants during foraging, as well as recognizing sexual ornaments during mate selection [27].

*Visual Acuity:* ►Raptors, such as falcons and eagles, have extremely keen vision which is most likely necessary for successful foraging. For instance, the visual acuity of American kestrels (46 cycles/degree, 28) is quite superior to that of normal human observers (30 cycles/degree). To accomplish the high visual acuity, raptor eyes are globose-shaped with a long focal length and have a very high density of photoreceptors in the retina. In contrast, other birds, such as ground-feeding quail with more flattened eyes, have poorer vision (6.8 cycles/degree, 29) than do humans.

Visual acuity also varies depending on the specific visual field. For example, raptors have better vision in the lower visual fields [4] and must tilt their heads to view objects in higher visual fields. Ground-feeding birds are near-sighted for the lower frontal visual field, which enables them to see close objects on the ground. They are also far-sighted for lateral vision, which

enables them to see possible predators far in the lateral visual fields.

*Motion Perception:* Flying birds, which are among the fastest moving animals, can detect motion much better than can humans. Birds have the excellent ability to resolve quickly changing images. In pigeons, the temporal resolution threshold can reach up to 100 Hz [30], compared to about 60 Hz by humans. This superb motion sensitivity is partly attributable to the high density of photoreceptors and complex connections within the retina. In addition, the midbrain and forebrain contain many neurons sensitive to moving stimuli. Some neurons of the nucleus rotundus are particularly intriguing in that they selectively detect approaching objects on a collision course. This looming detection ability is essential for flying birds in order to avoid obstacles before imminent collision while flying.

*Visual Cognition:* Field observations and laboratory studies have demonstrated that birds have excellent cognitive ability associated with vision [31]. New Caledonian crows use twigs to fetch insects hiding in trees; in fact, the crows will actually trim the twigs to make hooks that improve their efficiency. During the fall, Clark's nutcrackers hide tens of thousands of seeds in thousands of locations. Months later, they can retrieve the seeds to survive the winter. In laboratories, pigeons have repeatedly demonstrated their ability to learn the categories of numerous pictures of both natural objects (e.g., person, flower) and man-made objects (e.g., alphabet, car). The African grey parrot, Alex, learned to name the color, shape, and size of more than 100 objects using English words [32].

[2]Department of Biological Sciences, Simon Fraser University, Burnaby, BC, Canada

## Synonyms

V1; Primary visual cortex; also referred to as striate cortex or Brodmann's area 17

## Definition

Visual information is transmitted from the retina through the thalamus to cortex via parallel anatomical and functional pathways. One of the controversies surrounding existence of these parallel pathways is whether color is transmitted via an independent pathway and, if so, which pathway.

## Characteristics

All mammals with good vision have retinal ganglion cells that are specialized to encode different aspects of the visual scene. In well-studied mammals, such as cats and some primates, it has been shown that specific classes of retinal ganglion cells send information in parallel to separate classes of cells in the ►lateral geniculate nucleus (LGN) of the ►thalamus. The LGN is critical for vision in mammals because all visual information from the ►retina that is utilized for conscious visual perception passes through this nucleus. LGN cells can also be divided into cell classes based on physiology and morphology. Different LGN cell classes receive input from different classes of retinal ganglion cells and send signals via parallel channels to the ►primary visual cortex, also called V1, striate cortex or area 17. Although there is general agreement that parallel visual pathways from retina to cortex (via LGN) exist in mammals, there is considerable controversy over the homology and function of these pathways. In this chapter we argue that recent research on the evolution of color vision can provide potential insights into both the homology and function of parallel visual pathways in primates.

### Color Channels

Color plays an important role in the perception of objects in many mammals. The ability to see color derives from the ability to compare wavelengths. Retinal ganglion cells, which can distinguish between wavelength signals they receive from different retinal receptors (cones) via the ►bipolar cells of the retina, can "see" color and can then transmit this message to the brain. Most mammals, including many primates, are ►dichromatic, meaning that they have only two types of cones in the retina, a ►cone sensitive to the shorter (S, blue) visible wavelengths of light and another sensitive to either midrange (M, green) wavelengths or longer (L, red) wavelengths. Early vertebrates are thought to have had four opsin types, L, M, S and ultraviolet (UV). Early mammals lost one of the UV and S opsins, and one of the L and M opsins [1,2]. Regardless, it is generally agreed that early mammals had S cones [3]. It has been proposed, therefore, that the earliest color pathway in mammals compared S cones with M/L cones to create the ability to distinguish blue from green or yellow [4]. In non-primates, such as ground squirrels, it has been proposed that specific retinal ganglion cells code for color [5]. In cats also, S and M cones are compared only in one class of ganglion cell, the W cell, to provide the basis of color vision in this species [6]. In primates the situation concerning the evolution of color vision is complicated by the proposal that ancestral primates were nocturnal [7–9]. Since some present day nocturnal prosimians are monochromatic and have only a single M cone it has been proposed that this was the condition of primate ancestors [7,8,10]. Regardless of whether the earliest primates were nocturnal, it is likely that they already had an S cone gene since all extant primates examined appear to have this gene including those primates that are nocturnal [4,8]. Whether this gene is functional in nocturnal primates is a separate issue, given that nocturnal members of other mammalian

orders have also been shown to lack S opsins even when the S opsin gene is present in the ancestor [4]. Additionally, it is clear that a number of diurnal prosimians have color vision and at least two cone types [8] (Fig. 1).

As mentioned, most existing primates are dichromats and have only two cone types like cats and ground squirrels. There are, however, primates that have three cone types. In Old World simian primates such as ourselves and macaque monkeys, gene duplication on the X chromosome has led to trichromacy with both L and M cone genes represented on single X chromosomes. In New World simians and some prosimian lorises and lemurs, the X chromosome has only one M cone gene but gene polymorphism in some members of these primate groups has allowed females with two X chromosomes to develop trichromacy. Since males have only one X chromosome, all the male members of the latter primate groups are dichromats like cats and ground squirrels.

## Parallel Pathway Function

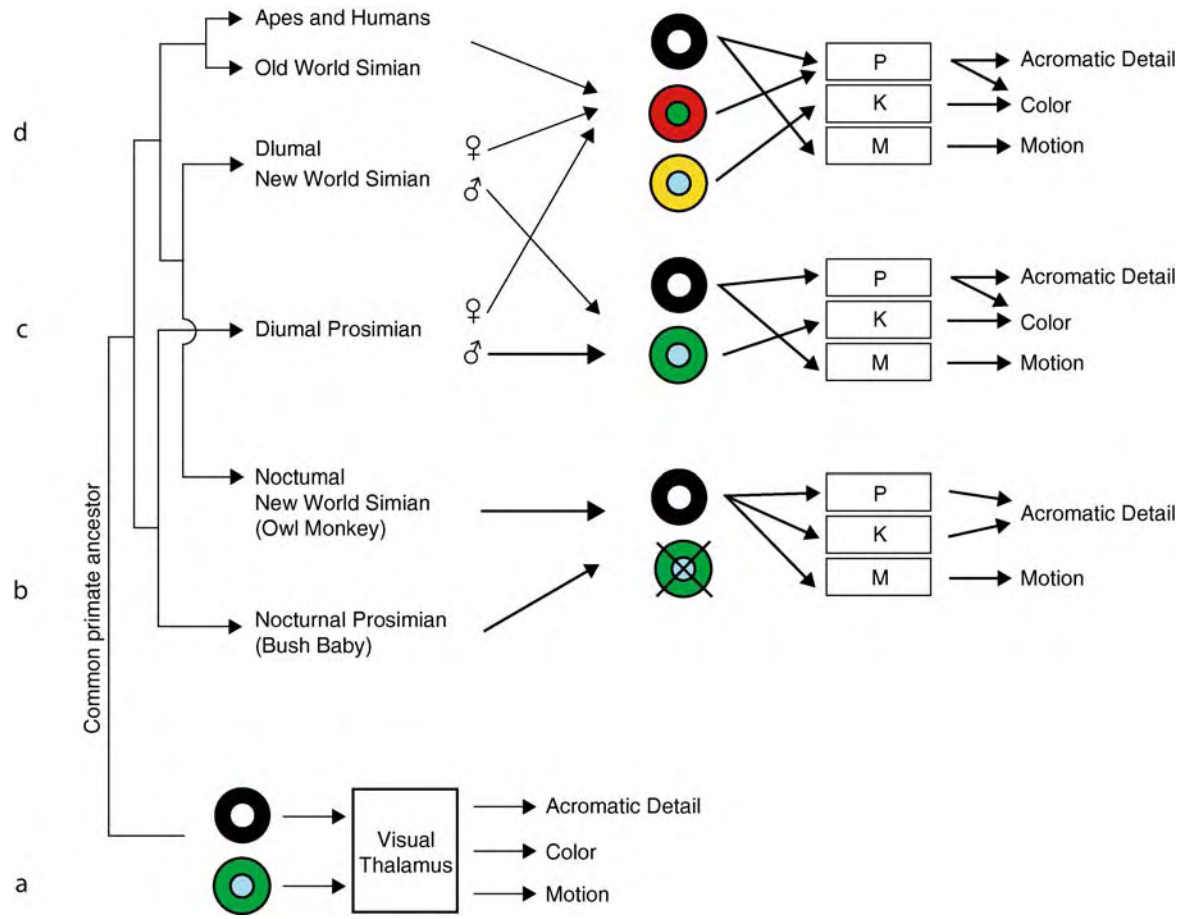
Although most primates are dichromatic, macaque monkeys, which are trichromats, have generally been used as models of primate visual system functional organization. In fact, most textbooks diagram the visual system based on work in macaque monkeys. These diagrams generally show two pathways extending from retina to cortex via the LGN, namely, the magnocellular and parvocellular pathways. In all studied primates these magnocellular and parvocellular pathways originate in the retina in separate classes of ganglion cells, the parasol and midget ganglion cells, respectively. These parasol and midget ganglion cells send axons to magnocellular and ►parvocellular cells of the LGN, that, in turn, project to separate sublayers of the primary visual cortex, V1 [11]. Based in part on the physiological properties of parasol and midget ganglion cells in macaque monkeys and the fact that V1 cells send axonal output to two hierarchies of ►extrastriate cortical visual areas concerned with either motion (or action) or object identification, it has been proposed that the magnocellular pathway is important for motion vision while the parvocellular pathway is essential for form and color vision. This view is supported by evidence in macaque monkeys showing that most magnocellular LGN cells respond transiently and are sensitive to high temporal frequencies (fast motion) while some parvocellular cells show red/green color selectivity and are sensitive to higher spatial frequencies (i.e. detail) [12].

Here is the problem. In well-studied mammals such as dichromatic cats, the cells in the LGN that are most likely to carry information relevant to detail vision, namely X cells, are color blind. This does not mean that they lack cone input, but simply that they do not receive input from two classes of cones arranged in an opponent fashion, either center surround (e.g. S center, M surround) or sign of contrast (e.g. S on, M off). In most other respects, X cells in cats respond in ways that are similar to parvocellular cells in macaque monkeys; they have small receptive fields, respond in a sustained manner to the presence of an appropriate stimulus and outnumber other cell classes at the level of the LGN [12]. The color blindness of X cells in cats has led some to propose that the parvocellular pathway from retina to cortex in primates is not homologous to the X cell pathway of cats. Instead, it has been proposed that the parvocellular pathway evolved either as a specialization of primate vision or from a W-like cell pathway simply because W cells in cats are the only cells that could support color vision in this species since they receive opponent input from S and M cones [13]. This scenario seems unlikely for the following reasons. First, in New World ►trichromatic female marmosets all red/green color selective cells are parvocellular cells [14]. In dichromatic males of the same species all parvocellular cells are color blind (Fig. 1). Nevertheless, parvocellular cells in all studied primates have higher acuity, on average, for luminance defined gratings than ►magnocellular cells [12], suggesting that the parvocellular pathway evolved first to represent detail and secondarily came to represent color in some primates. Second, in both marmosets and macaque monkeys, S cones send their information via a separate ►retinal ganglion cell pathway to some koniocellular LGN cells [15 for review]. These ►koniocellular cells also can receive opposing input from other existing cones to create a separate blue/yellow or blue/green color channel. Koniocellular cells share other (non color) physiological and morphological characteristics with cat W cells [16, 17, see also above] suggesting that some koniocellular and W cells could represent part of a homologous pathway. It is noteworthy that even in distant relatives of primates, ►tree shrews, there are LGN cells that resemble primate koniocellular and cat W cells anatomically and physiologically [18]. Whether such LGN cells in tree shrews uniquely carry signals from S cones or provide the substrate for color vision in this dichromatic species is unknown. In ground squirrels, S cones also appear to project via dedicated retinal channels where they are combined in different ways that suggest that they support three vision channels, a koniocellular or W-like color channel, a channel devoted to luminance where two cones are mixed just as is the case for magnocellular LGN cells in primates and a channel that receives input only from single M-cones just as parvocellular LGN cells do in dichromatic primates and X cells do in cats [5].

## The S Cone Pathway in Primates

As we have seen above, the evolution of color vision in mammals can provide additional clues as to the basic

E



**Evolution of the Visual System in Mammals – Color Vision and the Function of Parallel Visual Pathways in Primates. Figure 1** Evolution in primates of parallel pathways for color, achromatic detail and motion vision. The white disc on a black background represents retinal ganglion cell types without chromatic opponency. The blue disk on a green background represents retinal circuitry, present in the last common primate ancestor and maintained in all diurnal primates, creating retinal ganglion cells with short wavelength sensitive centers and medium wavelength sensitive surrounds. The pale blue disk on a green background with a cross through it represents the loss of the short wavelength sensitive cone type in some nocturnal prosimians and in the owl monkey. The green disk on a red background and blue disk on a yellow background represent the color opponent channels made possible in Old World primates by duplication and divergence and in female New World primates by polymorphism of the gene on the X chromosome for the medium wavelength sensitive opsin. Note that for each channel shown there is also an opposing channel not shown in this diagram (e.g. black disc on a white background) "*M*", "*P*", and "*K*" represent, respectively, the magnocellular, parvocellular and koniocellular layers of the lateral geniculate nucleus. See text for details.

functions of parallel visual pathways in primates. By the same token differences in the color vision pathways of extant primates can provide clues about ancestry. The fact that S cone genes exist in all studied primates and are of ancient origin [3] and that all primates have at least one other functional gene for either M or L cones argues strongly for a diurnal origin for primates [see also 8] rather than a nocturnal bottle neck, especially considering the fact that the closest living relatives of primates, tree shrews (*Tupaiidea*) are also diurnal.

S cone pathways in primates also show interesting differences that argue for the idea that the parallel pathways supporting color vision in apes and monkeys may have diverged early in evolution from their prosimian ancestry. In macaque monkeys, recent work suggests that the main layer receiving S cone input from the LGN in V1 is cortical layer IIIBβ (IVA of Brodmann) [19]. Since thalamic axons project to layer IIIBβ in many diurnal simians but not in the prosimian bush baby or in apes (chimpanzee) or in man, this pathway appears to be a specialization of some primates and not others [20]. These findings indicate that apes and man may have diverged from a primate ancestor where the koniocellular pathway carrying S cone input

did not innervate layer IIIBβ. These findings support the hypothesis that components of the K pathway could have either been lost in the evolution of apes and man or that their common ancestor showed a parallel pathway organization more like that of present day prosimians where the thalamus does not project to layer IIIBβ.

## Summary

The evolution of color vision genes and pathways in mammals argues that the primate parvocellular and magnocellular pathways evolved to support detail vision and motion vision, respectively not color vision. Evidence indicates that color vision is supported mainly by the koniocellular pathway in primates and by a similar W-like pathway in dichromatic mammals.

# Evolution of the Wulst

J. M. Wild
Department of Anatomy, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

## Synonyms

Eminentia sagittalis

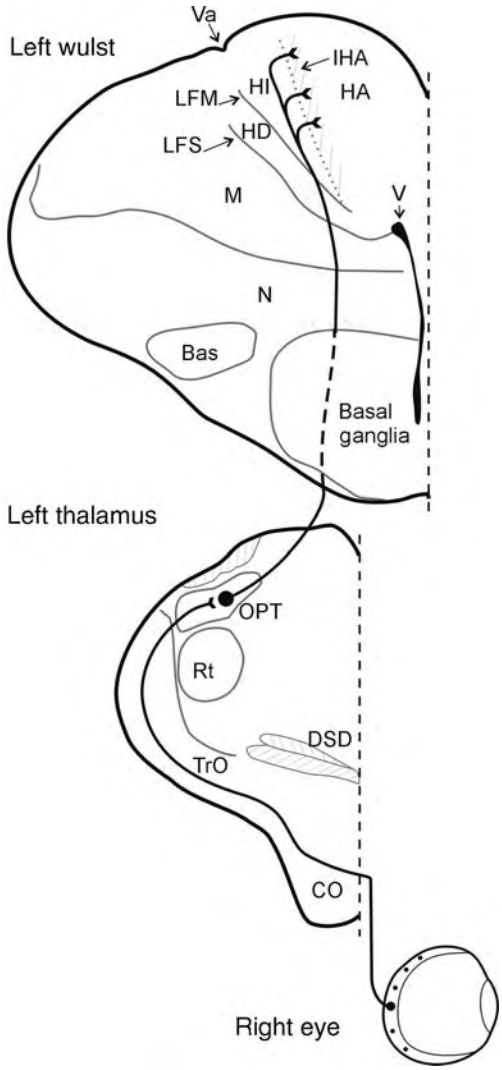
## Definition

The Wulst is a part of the ►telencephalic pallium in birds that forms an elevated protuberance on the dorsomedial surface of the cerebral hemisphere. It has caudal and rostral divisions that are in receipt of ascending visual and somatosensory information respectively. The rostral division also gives rise to a motor tract that closely resembles the ►pyramidal tract of mammals.

## Characteristics

### Anatomy and Connections of the Wulst

The Wulst is a bulge or swelling on the dorsomedial aspect of the brains of birds. It is bounded laterally by a groove called the vallecula (Fig. 1), in which runs a prominent blood vessel. The vallecula extends from the frontal pole of the brain, a variable distance posteriorly in different species, indicating that the Wulst itself varies in extent accordingly. The largest, posterior part of the Wulst forms the end station of the thalamofugal visual system, one of two major visual projection systems in the avian brain (Fig. 1).



**Evolution of the Wulst. Figure 1** The avian thalamofugal visual system, as represented in a pigeon. Abbreviations: *Bas* nucleus basorostralis pallii; *CO* optic chiasm; *DSD* dorsal supra-optic decussation; *OPT* principal optic nuclei; *HA* hyperpallium apicale; *HD* hyperpallium densocellulare; *HI* hyperpallium intercalatum; *IHA* interstitial nucleus of the hyperpallium apicale; *LFM* supreme frontal lamina; *LFS* superior frontal lamina; *M* mesopallium; *N* nidopallium; *Rt* nucleus rotundus; *TrO* optic tract; *V* lateral ventricle; *Va* vallecula.

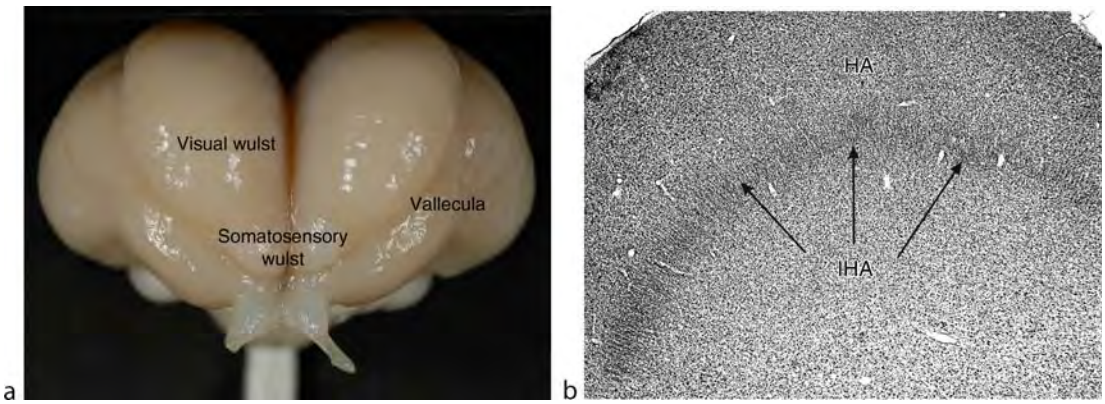
The visual Wulst receives its thalamofugal input from the various subnuclei of the principal optic nuclear complex (OPT) of the dorsal thalamus, one or more of which are considered the avian equivalent of the mammalian dorsal lateral geniculate nucleus (dLGN). Unlike the dLGN, however, the OPT in birds receives its input directly from retinal ganglion cells solely in the contralateral eye. This does not mean that the Wulst receives input only from the contralateral eye, for depending on the species, some OPT cells project ipsilaterally to the Wulst, some project contralaterally (via the supra-optic decussation) and possibly a few project bilaterally. There is a double decussation in the avian thalamofugal visual system, a complete decussation at the optic chiasm and a partial decussation of OPT fibers projecting to the Wulst.

The size of the Wulst is greatest and its internal differentiation most distinctive in those predatory species with frontally placed eyes such as owls and in those species with the largest eye size to brain size ratio, e.g. the emu. In the barn and burrowing owls for instance, the Wulst forms a massive bulge on the dorsum of the brain (Fig. 2a), made up of a number of neuronal layers arranged concentrically from the pial surface dorsally to the mesopallium ventrally [1] (Fig. 2b).

These layers, sometimes referred to as pseudolayers [2] are unlike those of mammalian neocortex – although they are together considered homologous to them – in that there are fewer of them (four vs. six), they are generated from different regions of the ventricular zone during embryogenesis, they are generally thicker, they lack pyramidal neurons and as far as is known they lack the interlaminar connections of the type afforded by the radially organized dendritic trees of mammalian neocortical neurons. In owls the hyperpallium apicale (HA) [3] forms the thickest and most superficial layer, then comes a bilayer making up the interstitial HA (IHA) and then a layer of dispersed cells, the intercalated hyperpallium (HI), separated from the underlying densocellular hyperpallium (HD) by the supreme frontal lamina (LFM). In turn, the HD is separated from the ►mesopallium by the superior frontal lamina (LFS). Analogously to the dLGN input to layer IV of mammalian visual cortex, the OPT input terminates most densely in the granule cell layer IHA, with other inputs terminating in HD. The laminar-specific terminations from individual OPT nuclei however, remain to be elucidated.

In contrast to the concentric organization of the Wulst laminae in owls, the Wulst laminae in columbiformes (e.g. pigeons) and passerines (e.g. finches) tend to be arranged diagonally on a dorsolateral to ventromedial axis, especially rostrally, with the result that the whole Wulst forms a wedge shaped structure having its wide base at the surface of the brain and its narrow apex ventromedially, where it converges on the dorsal tip of the lateral ventricle (Fig. 1).

Although the Wulst is largely a visual structure, its most rostral portion is somatosensory in nature, this being exemplified again in the barn owl, in which the representation of the claw is confined to a specialized small bulge anterior to the much larger bulge of the visual Wulst [4] (Fig. 2a). In pigeons and finches the IHA and to a lesser extent HA of the somatosensory Wulst receives its thalamic input from



**Evolution of the Wulst. Figure 2** (a) Frontal view of the brain of a barn owl. (b) frontal section though the visual Wulst of a barn owl showing the hyperstriatum apicale (*HA*) and the interstitial nucleus of the hyperpallium apicale (*IHA*), which receives the bulk of the thalamic afferents [1].

the nucleus dorsalis intermedius ventralis anterior (DIVA), which in turn receives its input predominantly from the contralateral dorsal column nuclei [5]. No auditory projections to the Wulst have been identified anatomically.

Another thalamic input to the more medial HD of the Wulst arises from the dorsomedial anterior thalamic nucleus [1]. This input is likely to be limbic in nature, in view of the fact that the HD projects to the hippocampal formation [6].

The greater part of the output from the Wulst arises from the HA, which receives much of its input from other Wulst lamina, the IHA in particular. From the visual Wulst, axons of HA cells exit primarily in three directions, ventrolaterally to the frontal ►nidopallium, ventromedially to the basal ganglia and medially into the so-called septomesencephalic tract (TSM). This tract (TSM) courses ventrally adjacent to the midline and exits the telencephalon to supply a host of visual structures in the di- and mes-encephalon, including the OPT, the ventral lateral geniculate nucleus, the pretectal nuclei, the retinorecipient layers of the optic tectum and accessory optic and isthmo-optic nuclei [1,6,7]. These extratelencephalic projections are in general remarkably similar to those of the striate cortex in mammals. Within the ►telencephalon of the burrowing owl, Wulst fibers were also traced to the ►perientopallium, thereby potentially linking the thalamofugal and tectofugal visual pathways. Such a link in other avian species however, has yet to be defined unequivocally.

From the HA of the rostral somatosensory Wulst arises an avian equivalent of the mammalian pyramidal tract, which exits the telencephalon via the basal branch of TSM and terminates in the medial spiriform nucleus (which then projects to the cerebellum), the red nucleus and throughout extensive regions of the rhombencephalic lateral reticular formation. In the medulla it targets the dorsal column and external cuneate nuclei bilaterally and terminates in lamina IV of the dorsal horn of upper cervical spinal cord segments contralaterally [8]. Like the mammalian ►pyramidal tract, the avian "pyramidal tract" can therefore control sensory input and motor output, the latter predominantly via the red nucleus, which projects to all levels of the spinal cord and to the cerebellum.

## Physiological Properties of the Wulst

A thorough analysis of the visual properties of Wulst neurons in owls shows a remarkable similarity to those of striate cortical neurons in mammals; the visuotopic representation of space within the Wulst is also similar, with the vertical meridian represented at the lateral edge, adjacent to the vallecula [9]. IHA neurons are monocular and have concentrically organized receptive fields, whereas more dorsally located cells tend to be binocular and more closely resemble those in the mammalian extrastriate area 18, with increasingly stringent requirements for stimulus orientation, movement and binocular disparity – which suggested to Jack Pettigrew [9] that the visual Wulst of owls might be analogous to both striate and extrastriate areas of cats and monkeys. However, because of the very different strategies of optic decussation in birds and mammals, the total absence of pyramidal neurons in the avian Wulst and the anatomically and functionally differentiated nature of the owl Wulst compared with that of other avian species, Pettigrew was of the opinion that the owl Wulst and mammalian striate cortex are not homologous as visual structures, i.e. are not likely to be derived from a neural antecedent possessed by an ancestor common to both birds and mammals. Instead, he thought that the similarity of owl Wulst and mammalian striate cortex was more likely to be an example of convergent evolution, possibly reflecting a unique solution to the problem of stereopsis. This opinion contrasts with the more generally accepted view that the Wulst in birds is

probably derived from the same simple cortical structure in stem amniotes that gave rise to the superior part of the neocortex in mammals, which includes the target of dLGN projections.

The retinotopic and receptive field organization of the Wulst in other species such as chickens and pigeons, which have eyes placed on the side of the head instead of in front, may be quite different from that in owls [e.g. 10]. In these and other non-raptorial species there is generally a small and variable degree of binocular overlap, so that the inputs to the two eyes are largely independent, except when the eyes converge, e.g. during pecking. Even so, the OPT (in the pigeon) receives its strictly contralateral input from ganglion cells only in that part of the retina that looks laterally into the monocular visual field [11]. This implies that binocular fusion is not a significant function of the Wulst in this and other species with laterally placed eyes (compared with the geniculostriate system of mammals). How such birds cope behaviorally with the input from completely different parts of the visual world to the largely separate sides of the thalamofugal system is an interesting question for which there is as yet no satisfactory answer.

Given the undisputed visual nature of the greater part of the Wulst, it might be expected that lesions in this structure would cause severe visual deficits. Surprisingly, this is not always the case, as is evidenced by the results of many studies using color, brightness or pattern discriminations, although reversal learning tasks tend to be more affected. One suspects that the visual Wulst has functions that remain to be discovered. If the Wulst is analogous as well as homologous to the striate cortex of mammals, then as Harvey Karten has suggested it might be suspected that a major function of the Wulst is the control of certain kinds of eye movements, probably via the projections to the optic tectum and its descending projections to the brainstem [cf 12]. The effects of lesions of the somatosensory Wulst have not been assessed.

►Action Potential

## Excitation-Contraction Coupling

A. Russell Tupling
Department of Kinesiology, University of Waterloo, Waterloo, ON, Canada

### Synonyms

E-C coupling; voltage-dependent calcium release

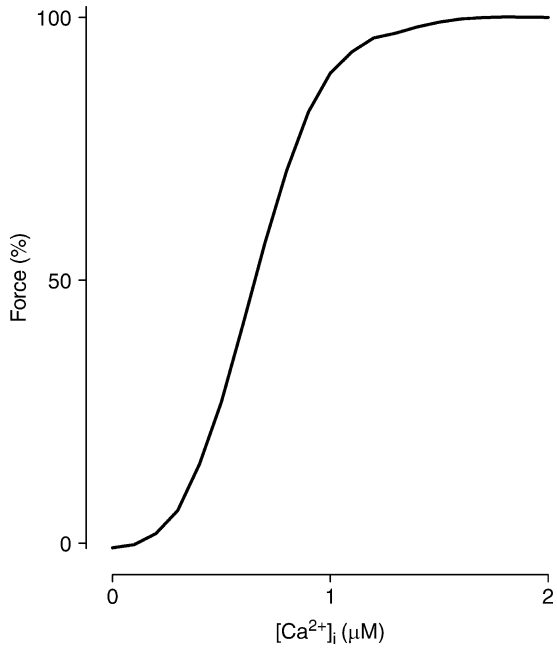
### Definition

The series of events linking depolarization of the sarcolemma and t-tubule membrane to the release of messenger calcium ($Ca^{2+}$) from the sarcoplasmic reticulum (SR), resulting in muscle contraction [1].

### Characteristics

Quantitative Description: Force production in muscle primarily depends on the level of intracellular free [$Ca^{2+}$] ($[Ca^{2+}]_i$) achieved in excitation-contraction (E-C) coupling. The steady-state relationship between force and $[Ca^{2+}]_i$ is shown in Fig. 1.

Within a single motor unit or single muscle fiber, the major factor that determines the $[Ca^{2+}]_i$ achieved in E-C coupling, and thus force, is motor unit firing frequency or stimulation frequency (see accompanying essay on the force-frequency relation of this Encyclopedia). At low stimulation frequencies (i.e. 1–20 Hz), there is sufficient time between successive action potentials for $Ca^{2+}$ to be taken back up into the SR by the sarco(endo) plasmic reticulum $Ca^{2+}$-ATPase (SERCA) or $Ca^{2+}$ pump, which limits the amount of $[Ca^{2+}]_i$ and force that can be achieved (i.e. unfused tetanus). At high stimulation frequencies (i.e. 50–100 Hz for human muscle; 100–200 Hz for rodent muscle), maximum or saturating $[Ca^{2+}]_i$ and maximum force (i.e. fused tetanus) are achieved because there is not enough time between successive action potentials for any appreciable SR $Ca^{2+}$ uptake to occur. The important role of SR $Ca^{2+}$ uptake in determining the $[Ca^{2+}]_i$ achieved in E-C coupling can be illustrated with the following two examples: (i) The



**Excitation-Contraction Coupling. Figure 1** The steady-state force-$[Ca^{2+}]_i$ relationship. The resting $[Ca^{2+}]_i$ in skeletal muscle is approximately 100 nM, which is largely determined by the activity of the SR $Ca^{2+}$ pump. During high-frequency stimulation, $[Ca^{2+}]_i$ reaches ~1–10 μM, which maximally activates the contractile apparatus resulting in a fused tetanic contraction [2]. At low stimulation frequencies, force falls on the steep part of the relationship, meaning that small changes in $[Ca^{2+}]_i$ will result in a marked change in force. This relationship is fit by the Hill equation, which describes the cooperative nature of $Ca^{2+}$ activation [2].

stimulation frequency required to obtain a fused tetanic contraction is significantly lower in slow-twitch (Type I) muscle (i.e. 100 Hz for mouse soleus) compared with fast-twitch (Type II) muscle (i.e. >150 Hz for mouse extensor digitorum longus), due to a slower $Ca^{2+}$ uptake rate in slow-twitch muscle (A.R. Tupling, unpublished observations); (ii) Pharmacologic block of SR $Ca^{2+}$ uptake results in higher $[Ca^{2+}]_i$ and force at low stimulation frequencies [2].

Higher Level Structures: The SR is a membranous structure in all muscle cells that closely and completely surrounds each myofibril forming part of the pathway of E-C coupling. In skeletal muscle, the SR is segmented and the segments are defined by their association with the t-tubules, which are continuous with the sarcolemmal membrane and run across the muscle fiber at the ends of the A-band regions of each sarcomere. Discrete junctional domains of the SR (terminal cisternae) appose either side of a t-tubule segment forming a triad. Communication between the t-tubule membrane and SR terminal cisternae membrane occurs at specific structures called calcium release units (CRUs) [1]. These structures contain two major proteins identified as key elements in E-C coupling, namely dihydropyridine receptors (DHPRs), located in the t-tubule and ryanodine receptors (RyRs) or $Ca^{2+}$ release channels located in the junctional SR membrane. The latter are visible as "feet" in electron micrographs from thin section [1]. The junctional domains of SR and t-tubular membranes are separated from each other by nonjunctional domains of the sarcolemma and SR membranes. The major protein located in the non-junctional SR is the $Ca^{2+}$ pump.

## Lower Level Components

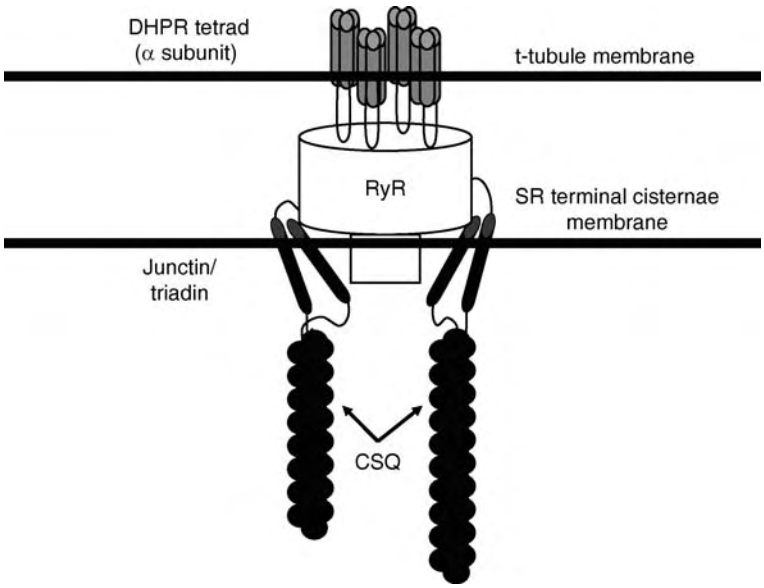
DHPR – In skeletal muscle, the DHPR (L-type $Ca^{2+}$ channel) consists of five protein subunits: α1, α2, β, γ, and δ [3]. This protein complex is responsible for the L-type $Ca^{2+}$ current and serves as the voltage sensor for E-C coupling. Being the principal functional DHPR subunit, the α1 subunit of 170 kDa, which contains the $Ca^{2+}$ pore, is the receptor for $Ca^{2+}$ antagonists (i.e. $Ca^{2+}$ channel blockers) and also functions as the voltage sensor which regulates opening of the channel in response to changes in the electrical potential across the cell membrane, permitting $Ca^{2+}$ entry from extracellular spaces. The α1 subunit contains four homologous transmembrane domains and the loop linking domains II and III interacts closely with the RyR of the SR [3]. The other subunits have regulatory functions.

RyR – The predominant RyR isoform expressed in skeletal muscle is RyR1. RyRs are extremely large homotetrameric proteins consisting of identical subunits of 565 kDa. Isolated RyR1, viewed by electron microscopy, is seen to be composed of four equal subunits, with the hydrophobic parts of the subunits forming a membrane-spanning base plate, and the more hydrophilic segments forming a cytoplasmic domain which bridges the 12 nm gap between the t-tubular and SR membranes [4]. The opening of RyRs is modulated by two RyR binding proteins, namely the FK506 binding protein (FKBP12) and calmodulin [4].

Calsequestrin (CSQ) – CSQ, a relatively low-affinity $Ca^{2+}$-storage protein capable of binding and releasing large quantities of $Ca^{2+}$ rapidly, which is located within the lumen of the SR terminal cisternae. CSQ binds about 40–50 $Ca^{2+}$ ions with a binding constant of about 1 mM under physiological conditions [4]. With $Ca^{2+}$ bound, CSQ polymerizes, forming linear ribbon-like structures that are associated with RyR1 through a supramolecular complex that involves CSQ binding to the lemenal domains of triadin and/or junctin (Fig. 2) [4].

This network of interacting proteins assures that high concentrations of $Ca^{2+}$ are stored very near to the site of $Ca^{2+}$ release.

Structural Regulation: In skeletal muscle, DHPRs are grouped into tetrads, or clusters of four DHPRs, which form ordered arrays in the t-tubular membrane. DHPR



**Excitation-Contraction Coupling. Figure 2** Schematic model demonstrating the location and interaction between key proteins involved in E-C coupling. The DHPRs are grouped into tetrads in the t-tubule membrane, and the α1 subunit II-III loop of each DHPR interacts closely with one of the four underlying RyR subunits located in the SR terminal cisternae membrane [3]. CSQ is a $Ca^{2+}$-binding protein located in the lumen of the SR that polymerizes upon binding $Ca^{2+}$, and is associated with the RyR through a supramolecular complex that involves CSQ binding to the lemenal domains of triadin and/or junctin [4]. During E-C coupling, the DHPR II-III loop allosterically activates the underlying RyR to open and release $Ca^{2+}$. Conformational changes in CSQ also occur during E-C coupling, suggesting that DHPR-induced conformational changes in RyRs are transmitted to CSQ, probably through triadin and/or junctin, and that the conformational changes in CSQ are likely involved in regulating $Ca^{2+}$ release [5].

tetrads face ordered arrays of RyRs in such a way that each of the four DHPRs composing a tetrad appears to be linked (α1 subunit II-III loop) to one of the four underlying RyR subunits. Every other RyR in the array is associated with a DHPR tetrad [1]. This distinct morphology of CRUs in skeletal muscle forms the structural basis underlying the so-called "mechanical" hypothesis of E-C coupling for skeletal muscle. This hypothesis proposes that DHPRs sense membrane depolarization and affect calcium release from the SR by a direct molecular interaction [1].

Until recently, it was believed that RyRs adjacent to a DHPR-linked RyR were probably activated by the $Ca^{2+}$ released by the DHPR-linked RyR through a $Ca^{2+}$-induced $Ca^{2+}$ release mechanism [6]. However, new evidence suggests that a functional grouping of RyRs, DHPRs and other junctional SR proteins (triadin, junctin, CSQ) may act in concert to release $Ca^{2+}$ during E-C coupling. This functional grouping of CRUs is referred to as a couplon [7]. In skeletal muscle, a triad contains two couplons, one on either side of the t-tubule, which act independently of each other. Therefore, a new model suggests that adjacent RyRs within a couplon are mechanically linked, and that the linked RyRs open and close simultaneously during E-C coupling [6].

Higher Level Processes: In the relaxed muscle, RyRs are closed and a potential difference is generated across the t-tubular membrane (positive outside; negative inside) by the $Na^+$-$K^+$-ATPase [3]. The entry of $Na^+$ following stimulatory events at the neuromuscular junction initiates a muscle action potential that travels along the sarcolemma and enters the t-tubular system (see accompanying essay on the neuromuscular junction of this Encyclopedia). The electrical signal is transmitted from the t-tubules to the SR terminal cisternae, which causes $Ca^{2+}$ release from the SR. $Ca^{2+}$ released into the cytoplasm binds to troponin C, resulting in a conformational change that alters the interactions between tropomyosin and the contractile machinery allowing actin and myosin to interact, leading to muscle contraction.

Lower Level Processes: Signal transmission between the t-tubule membrane and the SR terminal cisternae membrane during E-C coupling occurs through a direct molecular interaction between the DHPR located in the t-tubule and the RyR located in the SR terminal cisternae. Depolarization of the t-tubules is thought to destabilize positively charged transmembrane helices in the α1 subunit of the DHPR, causing them to shift in the lipid bilayer and move toward the more negative

exterior [3]. As a result of this conformational change in the DHPR, the DHPR II-III loop allosterically activates the underlying RyR to open and release $Ca^{2+}$. Conformational changes in CSQ also occur during E-C coupling, after t-tubule depolarization and before $Ca^{2+}$ release from the SR, suggesting that the E-C coupling signal is transmitted to CSQ and that it is somehow involved in regulating $Ca^{2+}$ release [5]. These conformational changes probably lead to release of $Ca^{2+}$ ions from CSQ, which raises the lumenal free $Ca^{2+}$ concentration, thus increasing the driving flux ($Ca^{2+}$ gradient) for rapid $Ca^{2+}$ release. However, another model has been proposed where CSQ acts as a $Ca^{2+}$ wire that conducts $Ca^{2+}$ into the $Ca^{2+}$ release channel during E-C coupling [4]. Thus, $Ca^{2+}$ diffusion from CSQ to the RyR would involve surface diffusion, which is a more rapid process than diffusion through liquid [4].

Process Regulation: The $Ca^{2+}$ release process during E-C coupling is a DHPR-mediated process; however, this process is modulated by various cytoplasmic (and SR lumenal) ligands such as ATP, $Mg^{2+}$ and $Ca^{2+}$. Significant insights into the regulation of E-C coupling in skeletal muscle have transpired from experiments using the mechanically skinned fiber preparation [8]. As these fibers retain the normal voltage-dependent E-C coupling mechanism, and because the intracellular environment can be easily manipulated in these fibers, it is possible to investigate which factors influence normal E-C coupling and which do not. From these experiments, it was found that ATP has to be bound to the RyRs for them to be activated by DHPRs [8]. Presumably, ATP binds to a regulatory site on the RyR and stimulates depolarization-induced $Ca^{2+}$ release [8]. It is known that a glycogenolytic complex, consisting of glycogen and several metabolic enzymes from glycolysis, is associated with the terminal cisternae membrane and is capable of synthesizing ATP [9]. This metabolic complex may serve as a source of local ATP within the triad membrane region that is important for the regulation of E-C coupling.

Cytoplasmic $Mg^{2+}$ is also an important regulator of RyRs in muscle. $Mg^{2+}$ acts as a $Ca^{2+}$ release antagonist even at physiological resting free [$Mg^{2+}$] (1 mM) and has a dual inhibitory effect: (i) $Mg^{2+}$ binding to a low-affinity $Ca^{2+}/Mg^{2+}$-inhibition site in RyRs inhibits channel opening, and (ii) $Mg^{2+}$ binding to a high-affinity $Ca^{2+}$-activation site in RyRs not only prevents $Ca^{2+}$ activation of the channel but also directly inhibits channel opening [8]. Therefore, DHPR activation of RyRs during E-C coupling must overcome the inhibitory effect of $Mg^{2+}$ on RyRs at rest, given that RyRs are near maximally activated during action potential stimulation [8]. It is proposed that allosteric activation of RyRs by DHPRs, resulting in a conformational change in RyRs, reduces RyR affinity for $Mg^{2+}$ at both the $Ca^{2+}$-activation site and the low-affinity $Ca^{2+}/Mg^{2+}$ site [8]. Removing a resting inhibition of RyRs by $Mg^{2+}$ would allow cytoplasmic ATP to activate the channel and the released $Ca^{2+}$ would also be able to reinforce this activation [8]. The regulatory role of cytoplasmic factors in E-C coupling is particularly relevant to the basis of muscle fatigue under some conditions.

Function: The primary function of muscle is to do mechanical work. It is well known that repetitive muscle contraction unavoidably results in a progressive decline in mechanical performance known simply as fatigue (see accompanying essay on muscle fatigue of this Encyclopedia). The mechanistic basis of fatigue is complex and likely involves multiple etiologies, however; it is increasingly apparent that intense or continuous muscle contraction leads to alterations in E-C coupling processes, resulting in lower activating intracellular free $Ca^{2+}$ levels and reduced force [2]. Experiments with mechanically skinned fibers have shown that changes in the level of specific substances in the cellular environment that mimic changes seen in fatigued muscle, directly impair muscle contractility either by altering the regulation of E-C coupling or by altering the physical interaction between DHPRs and RyRs [8].

Two factors that play a role in the regulation of E-C coupling that are likely to be important in muscle fatigue in some circumstances are: (i) a decrease in cytoplasmic [ATP] in the vicinity of the RyRs in the triad membrane compartment, and (ii) the associated increase in free [$Mg^{2+}$] since the hydrolysis products of ATP, namely ADP and AMP, have a far lower affinity for $Mg^{2+}$ than ATP [8]. With intense muscle activity, [ATP] can drop to <1 mM ([ATP] is ~6 mM at rest) and free [$Mg^{2+}$] can increase more than twofold in mammalian fast-twitch fibers [8]. Decreasing [ATP] and increasing [$Mg^{2+}$] to these levels inhibits voltage-dependent $Ca^{2+}$ release in mechanically skinned fibers, and this is exacerbated by increases in ADP and AMP [8]. Under some conditions such as low-frequency fatigue, long-term interruption of the coupling between DHPRs and RyRs can occur. Under these conditions, it appears that elevated cytoplasmic [$Ca^{2+}$] for prolonged periods could be responsible for the E-C coupling failure due to physical disruption of the triad junction [8].

Pathology: Malignant hyperthermia (MH) and central core disease (CCD) are inherited diseases of E-C coupling. MH susceptible individuals undergo an uncontrollable skeletal muscle hypermetabolism when exposed to potent inhalational anesthetics or depolarizing skeletal muscle relaxants due to excessive release of $Ca^{2+}$ from the SR into the cytoplasm, thereby triggering sustained muscle contracture [10]. The incidence of MH during anesthesia is about 1 in 15,000 children and

about 1 in 50,000–100,000 adults [10]. The clinical symptoms of MH include muscle rigidity, tachycardia, hyperkalemia, hypoxia, lactic acidosis and eventually fever. If not treated immediately with the $Ca^{2+}$ release inhibitor dantrolene, the patient may die within minutes from ventricular fibrillation, within hours from pulmonary edema or within days from post anoxic neurological damage or renal failure [10]. More than 50 different mutations in the *RYR1* gene have so far been associated with MH, and abnormalities of the α1 subunit of the DHPR are also linked to MH [10].

Closely related to MH is CCD, which is a rare skeletal muscle myopathy that is characterized by hypotonia, delayed motor development and muscle weakness [10]. Diagnosis of CCD is based on histological examination, which shows the lack of oxidative enzymes in the central regions (cores) of skeletal muscle cells and electron microscopic analysis reveals unstructured myofibrils and enlarged, but less well structured, SR and t-tubular systems [10]. It is hypothesized that cytoplasmic $Ca^{2+}$ overload due to a mutation in RyR1 is responsible for the mitochondrial damage that would lead to a reduction in ATP production. The decreased metabolic activity might therefore be the underlying cause of the muscle weakness observed in CCD [10].

## Synonyms

Pre-motor interneurons; glutamatergic interneurons; network interneurons

## Definition

Rhythmic ►motor patterns are generated by networks of neurons within the CNS, these networks are referred to as ►central pattern generators (CPGs). They consist of populations of neurons that produce a motor output underlying a specific motor behavior such as locomotion, respiration, or mastication. The locomotor CPG is located in the spinal cord, and can generate the basic locomotor pattern that consists of alternation of ►excitation and ►inhibition.

The spinal CPG is a functional entity that can generate and sustain rhythmic locomotor patterns in the absence of descending and sensory inputs [1–3]. Normally, however, the activity of the spinal locomotor CPG is initiated by descending excitatory inputs

from the brainstem [2–4]. Also, the ongoing locomotor pattern can be adjusted to environmental demands via movement-related sensory feedback [2].

The locomotor CPG contains an intrinsic source of excitation that is composed of excitatory CPG interneurons. These interneurons are an essential component of the locomotor network. They provide the phasic synaptic excitatory drive to motoneurons that in turn produce the appropriate sequence of muscle contractions allowing the animal to swim, walk or fly. In addition, they also provide excitation to inhibitory CPG interneurons responsible for the alternation of activity in antagonistic motoneurons.

The excitatory CPG interneurons use glutamate as their synaptic transmitter, which is stored in their presynaptic terminals. The electrical activity of the excitatory CPG interneurons releases glutamate from their terminals, which diffuses in the synaptic region and activates glutamatergic receptors located on the postsynaptic target neurons (motoneurons and CPG interneurons). Activation of ►ionotropic receptors by glutamate leads to the depolarization of the membrane potential of the postsynaptic neurons. These synaptic potentials are mediated by activation of AMPA and NMDA receptors, and produce the phasic excitatory drive occurring during each locomotor cycle in motoneurons and interneurons. Release of glutamate from excitatory CPG interneurons also activates ►metabotropic ►receptors (modulatory receptors) that underlie modulatory actions at the short and long time scales.

To be considered as CPG neurons (1) the excitatory interneurons need to be activated first during the locomotor cycle enabling them to drive the activity of other locomotor CPG neurons; (2) they should project ipsilaterally direct or indirect synaptic connections with motoneurons and CPG interneurons (excitatory and inhibitory), and (3) they should receive synaptic inputs from the command centers responsible for the initiation of locomotor activity, and sensory afferents to adjust the locomotor pattern to the environment.

## Characteristics

### Quantitative Description

Excitatory CPG interneurons can be characterized by: (1) their ipsilateral axonal projections, (2) monosynaptic connections with motoneurons and other ►network interneurons, and (3) their glutamatergic synaptic transmission.

The first indications for the existence of excitatory CPG interneurons were derived from the existence of depolarizing synaptic potentials in motoneurons in the lamprey and tadpole spinal cord. These excitatory potentials have their source within the spinal cord, and are due to activation of interneurons in the same segment or adjacent segments. Following these observations, it was possible to characterize excitatory CPG interneurons using paired intracellular recordings. Excitatory CPG interneurons in the lamprey and tadpole spinal cord make monosynaptic connections with motoneurons and inhibitory interneurons responsible for left/right alternations. They also provide mutual excitation to one another. Stimulation of presynaptic excitatory interneurons elicits monosynaptic excitatory potentials in motoneurons or other network interneurons that are mediated by activation of NMDA and AMPA receptors [5,6]. Ipsilateral excitatory interneurons have also been identified in the mammalian spinal cord, but their role in locomotion has not yet been determined [7,8].

### Higher Level Structures

Locomotor activity is initiated by descending inputs from command centers in the brain. Stimulation of specific regions in the brainstem (mesencephalic locomotor region, MLR) or diencephalon (diencephalic locomotor region, DLR) can elicit coordinated locomotor patterns through an action mediated by reticulospinal neurons [4,9]. These regions are conserved in all vertebrates. To be able to trigger the activity of the spinal locomotor CPG, signals from the command centers need to activate the excitatory CPG interneurons. Indeed, the available data from lamprey shows that excitatory CPG interneurons receive monosynaptic excitatory inputs from reticulospinal neurons located in the different areas in the brainstem. Once these interneurons are activated they in turn excite motoneurons and inhibitory interneurons, and thereby a rhythmic locomotor pattern is generated. The inputs from the command centers not only trigger the activity of the spinal locomotor CPG, but they also regulate the level of activity resulting in changes in the frequency of the locomotor rhythm. The descending control of the activity of the excitatory CPG interneurons plays an important role in regulating the activity of the locomotor CPG, and thus enables the CPG to integrate influences from different parts of the CNS.

### Lower Level Structures

In the lamprey and tadpole CPG, the excitatory CPG interneurons provide synaptic inputs to each other via excitation within the pool of interneurons. Here they represent the first level of processing within the locomotor CPG that result in rhythmic activity. In addition, excitatory interneurons provide the excitatory drive to inhibitory interneurons, which project to the contralateral side and inhibit excitatory interneurons on the opposite side of the spinal cord ensuring left/right alternation of locomotor activity. Finally, excitatory CPG interneurons provide excitation to motoneurons that receive excitatory inputs from several excitatory interneurons that cause action potentials, which lead to muscle contraction. As the mammalian CPG has not been characterized in detail, no data from mammals is available.

The excitatory CPG interneurons are not only essential for the generation of a coordinated locomotor pattern, they are also important for the precise recruitment of different types of motoneurons. In the lamprey spinal cord, the analysis of synaptic connections between excitatory interneurons and motoneurons has shown that each motoneuron receives excitation from a small proportion of interneurons. In this preparation, stimulation of a single excitatory interneuron can elicit activity in the ventral root, but it is unable to produce a sustained rhythm. The excitatory CPG interneurons are likely to be subdivided into groups, which may enable different motor functions. For example, motoneurons responsible for movement around different joints (hip, knee and ankle) may be controlled by separate groups of excitatory interneurons [1].

## Structural Regulation

The activity of excitatory CPG interneurons is triggered by descending inputs from command centers. To account for the full locomotory repertoire, the spinal CPG also has to integrate sensory feedback generated by the movements being performed. These effects are mediated via synaptic connections between sensory afferents and interneurons within the locomotor CPG. By modulating the activity of excitatory CPG interneurons, sensory feedback can affect the overall locomotor pattern.

Overall, excitatory CPG interneurons are a pivotal player within the spinal locomotor network. They provide the intrinsic excitatory drive in the spinal cord and act as an integrating entity to adapt the ongoing locomotor rhythm to central commands and peripheral changes in the environment.

## Lower Level Processing

In the spinal locomotor network, excitatory CPG interneurons provide excitation to ipsilateral motoneurons and interneurons. The characteristic alternation of activity is ensured by inhibitory CPG interneurons that project to the contralateral side and inhibit both motoneurons and interneurons. As the basic locomotor pattern is dependent on synaptic interactions involving excitation and inhibition, the question was raised regarding the extent to which the excitation alone is able to produce rhythmic locomotor activity. To address this, experiments have been done in which the reciprocal inhibitory synaptic transmission is disrupted either pharmacologically or by a surgical approach. Thus, locomotor activity can be induced in vitro with left/right alternation, and flexor-extensor activity is blocked by blocking inhibitory synaptic transmission by adding an antagonist of glycine receptors. When the glycinergic reciprocal inhibition is blocked, the locomotor pattern switches from the characteristic alternation of left/right root activity to synchronous bursting. Although synchronous, the rhythmic pattern of ventral root activity is not abolished by the glycine receptor antagonist. Moreover, the section of the spinal cord along the midline does not interrupt the rhythm. This rhythmicity does not depend on inhibitory synaptic transmission within each hemi spinal cord, because ventral root bursting continued to occur even when inhibition is blocked.

Each hemi-segment is thus able to independently generate rhythmic motor activity in the absence of inhibitory transmission. This suggests that the excitatory CPG interneurons on each side of the spinal cord form a neural network through excitatory interactions that is responsible for the basic motor activity. These interneurons make mutual excitatory connections with each other and form the kernel of the locomotor CPG. When the excitatory CPG interneurons are activated they synchronize their firing and drive the motoneurons. Their activity is terminated by mechanisms independent of active synaptic inhibition. These may include intrinsic membrane properties, such as activation or inactivation of specific ion channels that hyperpolarize the membrane potential of excitatory CPG interneurons and stop their firing.

In mammals, genetic manipulations promoting abnormal projections of excitatory CPG interneurons to the contralateral spinal cord, that otherwise do not occur in normal conditions, resulted in a synchronous activation of left and right sides [10]. In these mice, instead of alternating limb movements, a rabbit-gait with a hopping pattern develops. The cellular analysis in the isolated spinal cord showed abnormal axonal projections from excitatory CPG interneurons to the contralateral side. The crossed excitation thus dominates over inhibition, explaining the synchronous activation of both sides of the spinal cord. The normal locomotor pattern with alternating left/right activity could be restored experimentally by increasing inhibitory transmission or decreasing crossing excitation.

In conclusion, excitatory CPG interneurons seem to form the basic network in each side of the spinal cord and generate rhythmic motor activity via excitatory synaptic interactions. The two sides are connected to each other mainly via crossing inhibitory interneurons that are responsible for left/right alternation, which is characteristic for the locomotor movements from lower vertebrates to primates, including humans.

## Process Regulation

The firing frequency of excitatory CPG interneurons and their transmitter release can be modulated by various modulatory receptors that act on a slow timescale [11,12]. The postsynaptic modulation affects the electrical processing of these interneurons by changing specific conductances. The presynaptic modulation is mediated by receptors located on the axonal terminals of these interneurons that, when activated, can regulate

the amount of transmitter released and thus the response in the target neurons. During locomotor activity, synaptic transmission from excitatory CPG interneurons is phasically modulated via presynaptic inhibition. In addition, there are a number of modulatory receptors that change the frequency of the locomotor rhythm by acting on cellular and synaptic processing in excitatory CPG interneurons. Due to their central role in locomotor pattern generation, the excitatory CPG interneurons represent a critical target for modulatory inputs that trigger, maintain and regulate the locomotor behavior.

### Function

Based on the results for the lamprey and tadpole spinal cord, it can be suggested that the excitatory CPG interneurons represent the first order interneurons within the spinal locomotor network. They are important for starting the activity of the locomotor network and drive the motoneurons and inhibitory CPG interneurons. They also integrate sensory and descending inputs from descending commands allowing adaptation of the ongoing motor activity. The organization and synaptic processing of excitatory interneurons in mammalian spinal cord remains to be determined.

### Therapy

The excitatory CPG interneurons are the only source of excitation inherent to the spinal locomotor network. Understanding the mechanisms used by these interneurons to generate locomotor rhythm will allow the designing of novel pharmacological therapies and rehabilitation strategies, which may help to restore locomotor and postural function following spinal cord injury or disease affecting the spinal network.

## Excitatory GABA

►Chloride Homeostasis and Development

## Excitatory Postsynaptic Potential (EPSP)

### Definition

Depolarization of the postsynaptic membrane potential by the action of a synaptically released neurotransmitter. Usually reflects release from a population of presynaptic fibers but it can be evoked by a single presynaptic fiber.

►Synaptic Transmission: Model Systems

## Excitatory Synapse

### Definition

The synapse exhibits the feature that presynaptic stimulation increases the excitability of a postsynaptic cell. At excitatory synapses, transmitter binds to the postsynaptic receptors, allows cations to enter the cell, and drives the membrane potential toward the threshold.

►Synaptic Transmission: Model Systems

## Excitotoxic Lesions

### Definition

Excitotoxins are analogues of glutamate that bind to glutamate receptors and cause unregulated influx of calcium into neurons, killing them. Different excitotoxins bind to the various different glutamate receptors – which excitotoxin will be most effective in a given brain area will depend upon the prevalence of different glutamate receptor types there. The value of excitotoxins is that, because glutamate receptors are found on the somatic not axonal portions of neurons, they make lesions of neurons while sparing fibers of passage in the region of effect.

►Mesopontine Tegmentum

## Excitotoxicity

### Definition

Neurodegeneration caused by over-activation of excitatory neurotransmitter-gated ion-channels (such as the glutamate-gated NMDA receptor), which then permits lethal levels of ions to enter the cell.

## Executive Attention

### Definition

Executive attention is a part of the attentional control system. Many models of executive attention assume a set of schemas with goals and actions that can be executed without interference of executive attention. Executive attention interferes with ongoing activity of these schemas, when the schemas fail to reach the goal, errors are made, preset responses have to be inhibited. If two or more tasks have to be executed at the same time, executive attention is also involved. Executive attention is thought to have a limited capacity and be coordinated by neurons in the cingulate gyrus and dorsolateral prefrontal cortex.

►Attention

## Exercise

### Definition

Exercise can be defined as physical activity that is a planned, structured movement of the body designed to enhance physical fitness. Regimented or purposeful exercise consists of a program that includes 20–60 min of activity at least 3–5 days a week. Some examples of this type of activity include walking, running, cycling, or swimming. For athletes, exercise training programs are sport-specific and are considered according to intensity and volume. Scientists investigated "acute" or "chronic" exercise effects. Exercise may be classified in one of two categories, anaerobic and aerobic, depending on where energy is derived from. There is a distinct difference between the two, and specific training techniques are used to enhance both. Anaerobic exercise does not require oxygen for energy. This is due to the intensity and duration of anaerobic events, which typically are high intensity and last only a few seconds to a minute or two. These activities range from a tennis serve to an 800-m run. Aerobic exercise does require oxygen for energy. This is observed during exercise that is less intense but of longer duration. This energy system is primarily used during events lasting longer than several minutes, such as a 2-mile run or the Tour de France bicycle race or prolonged running races. The potential does exist that one can use both systems, as in soccer, where a match requires 90 min of continual activity with short intense bursts of effort.

►Autonomic Function and Exercise
►Stress Effects During Intense Training on Cellular Immunity

## Exocyst Complex

### Definition

A large protein complex (e.g. single copies of eight different subunits) required for polarized exocytosis, likely functioning at the stages of vesicle targeting/tethering.

►Synaptic Proteins and Regulated Exocytosis

# Exocytosis

Masami Takahashi, Teruo Abe
Department of Cellular Neurobiology, Brain Research Institute, Niigata University, Niigata, Japan

## Definition

A process in which the membrane of a membrane vesicle fuses with the plasma membrane, resulting in secretion of the vesicle content to the cell exterior. In this process, the lipids in the two membranes mix with each other, eventually forming a single membrane. The content of the vesicle varies from cell to cell: small organic molecules, peptides, proteins and other molecules. These secreted molecules could be used for communicating with other cells or could just be unwanted or harmful materials. From yeast to human, most, if not all, cells are capable of exocytosis, demonstrating that the process is important for the cell. Importantly, recent studies have shown that exocytosis is involved in the insertion of plasma membrane proteins.

## Characteristics

### Quantitative Description

Small synaptic vesicles fuse with the plasma membrane and release their contents (neurotransmitters) in less than 1 ms of the arrival of an action potential at the nerve terminal. ►Synaptic vesicle (SV) exocytosis is triggered by $Ca^{2+}$-influx through voltage-sensitive Ca channels [1]. A major part of the above time is spent for Ca channel opening.

### Higher Level Structures

Nerve terminal.

### Lower Level Components

SVs, presynaptic membrane, active zone.

### Higher Level Processes

Synaptic transmission.

### Lower Level Processes

Exocytosis consists of four steps: ►docking, ►priming, fusion and recycling [1].

#### *Docking*

SVs must first be attached to the plasma membrane (docking). The molecular mechanism of this docking is unknown. Since SVs are only attached to the plasma membrane at the active zone, some component(s) of the active zone must be involved in docking. However, such component(s) have not yet been identified. The cytosolic protein nSec1/Munc18-, which binds to ►syntaxin 1 seems to contribute to synaptic vesicle docking, as docked SVs are decreased in mice lacking the protein. In many CNS synapses, less than 10 SVs are docked per active zone, and only 0 to a few SVs are released at a time.

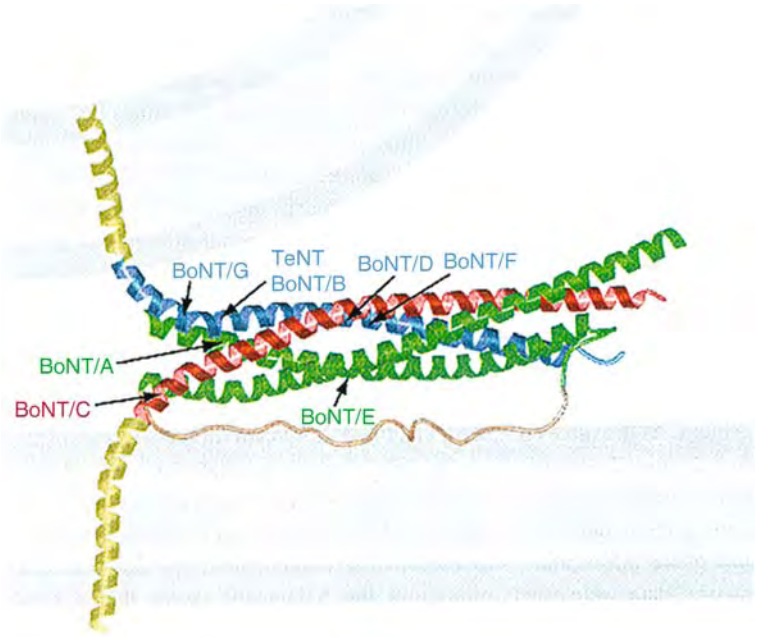
#### *Priming*

Docked SVs are not immediately available for exocytosis. They need to be activated to become fusion-competent. This process is called priming. Although the mechanism of priming is not clarified, it possibly involves conformational changes of ►SNARE proteins (syntaxin 1, ►SNAP-25 and VAMP/synaptobrevin, referred to as VAMP hereafter) that are directly involved in synaptic vesicle exocytosis. In the closed conformation, N-terminal autoinhibitory domain masks the region consisting of about 70 amino acid residues (SNARE motif) adjacent to the transmembrane segment at the C-terminal. SNARE motifs are critical to SNARE complex formation and subsequent ►membrane fusion. The cytosolic protein nSec1/Munc18-1 is proposed to keep syntaxin 1 in this closed conformation, preventing complex formation between syntaxin 1 and the other two SNARE proteins [2]. The closed conformation can be converted to the open conformation by the active zone protein Munc13-1 by exposing the SNARE motif, enabling syntaxin 1 to interact with SNARE motifs of SNAP-25 and VAMP. The complex of syntaxin/SNAP-25/VAMP in the molar ratio of 1:1:1, called the ternary or core complex, plays a pivotal role in membrane fusion.

#### *Fusion*

One SNARE motif from each of syntaxin 1 and VAMP, and two motifs from SNAP-25 form a parallel four-bundle helix (trans-SNARE complex) [3] (Fig. 1).

It is generally postulated that helix bundle formation starts from the N-terminal regions, extending toward the C-termini of the three proteins like a zipper. This zipper-like, very stable structure pulls the SV membrane and the plasma membrane together, eventually leading to membrane fusion. In the presence of the cytoplasmic domain of ►synaptotagmin 1 (a $Ca^{2+}$-binding protein in the SV membrane), liposomes containing syntaxin 1/SNAP-25, and those containing VAMP fuse with each other in a $Ca^{2+}$-dependent manner, suggesting that these proteins represent minimal machinery for membrane fusion in $Ca^{2+}$-triggered SV exocytosis [4,5]. However, it cannot be excluded that some other protein(s) also participate in the fusion reaction in vivo. The small cytosolic protein ►complexin (synaphin) that binds to the SNARE complex promotes membrane fusion, possibly by stabilizing or oligomerizing it. Very recent studies indicate that SVs in the CNS synapses exhibit at



**Exocytosis. Figure 1** A model of ternary complex of SNARE proteins at the synapse. SNARE motifs are shown in *blue* (synaptobrevin/VAMP), *red* (syntaxin 1) and *green* (SNAP-25). Lipid bilayers of synaptic vesicle membrane (*above*) and presynaptic terminal plasma membrane (*below*) are depicted in *gray*. The sites cleaved by botulinum neurotoxin (BoNT, type A to G) and tetanus toxin (TeNT) are also shown. These neurotoxins are $Zn^{2+}$-metalloproteases that potently inhibit neurotransmitter release by specifically cleaving the SNARE proteins. Reproduced from [3] with permission.

least two types of exocytosis: full fusion and kiss-and-run [6,7]. In the latter, a small tube-like structure (►fusion pore with a diameter of 1–2 nm) temporarily forms between a SV and the plasma membrane. This aqueous fusion pore subsequently closes and SVs go back to the cytoplasm without fully collapsing into the plasma membrane. Although the fusion pore is rather small, they are sufficient to allow intravesicular small components (e.g. neurotransmitters like glutamate, GABA, norepinephrine, epinephrine, acetylcholine etc.) to leave SVs. Whether these fusion pores contain proteins in addition to lipids is not established. The kiss-and-run mechanism has a definite advantage of very rapid recycling of SVs.

### $Ca^{2+}$-Triggering of Release

Depolarization of the nerve terminal opens voltage-sensitive Ca channels. In many synapses, $Ca^{2+}$ influx through P/Q- and/or N-type Ca channels are responsible for instantaneous rise of $Ca^{2+}$ concentration around the active zone that triggers SV exocytosis. $Ca^{2+}$ concentrations required for triggering neurotransmitter release vary from synapse to synapse in the range of 1 μM to tens of μM. How do calcium ions trigger SV exocytosis? Synaptotagmin 1 (synaptotagmin 2 in some synapses) acts as a major Ca sensor in the release process in the brain [8]. Synaptotagmin 1 binds SNARE complexes in a $Ca^{2+}$-dependent manner. C2A and C2B domains of the protein bind three and two calcium ions, respectively. Low $Ca^{2+}$ affinities of the C2 domains dramatically increase when they bind phospholipids, roughly matching those required for SV exocytosis. However, the $Ca^{2+}$-dependent binding of synaptotagmin 1 to SNARE complex may not be essential for triggering SV exocytosis, because strontium ions that do not facilitate SNARE complex binding of synaptotagmin 1 can trigger SV exocytosis [8]. None of the $Ca^{2+}$-dependence of synaptotagmin functions including membrane insertion, oligomerization and SNARE binding exactly matches that of the neurotransmitter release rate [9]. Thus, the mechanism of synaptotagmin 1 action leading to SV exocytosis remains unclear.

### Recycling

#### Function

After exocytosis, the cytosolic proteins ►NSF (N-ethylmaleimide-sensitive factor) and ►alpha-snap (alpha-soluble NSF attachment protein) bind to the cis-SNARE complex, and dissociate each SNARE protein

for reuse. In this reaction, ATPase activity of NSF is required. Exocytosed SVs are recovered by endocytosis. At least three mechanisms of SV endocytosis exist: very rapid endocytosis without endosomal intermediate, and clathrin-coated pathway with or without endosomal intermediate. SVs become refilled with neurotransmitter molecules by vesicular transporters, and regenerated SVs can be used again.

Function: SV exocytosis releases neurotransmitters towards postsynaptic receptors, thereby transmitting information to the postsynaptic cell. Thus, it links presynaptic action potentials to postsynaptic neurotransmitter receptors by means of chemical substances.

### *Advantages of Exocytosis*

Two types of secretion by exocytosis occur in the cell: constitutive and regulated. The former takes place constantly, and the latter is triggered only when a specific external or internal stimulus is given. Neurotransmitter release from the nerve terminal is an example of regulated secretion. It is triggered by the influx of external $Ca^{2+}$. Membrane vesicles to be exocytosed contain large amounts of specific, physiologically active substances. Trapped in membrane vesicles, these substances are protected from modifications by cell components. Thus, membrane vesicles to be exocytosed could serve as safe reservoirs for such substances. Since many membrane vesicles that contain the same substances usually exist in a cell and are released by exocytosis, the cell can liberate a large amount of such substances in a very short time, especially in regulated exocytosis. Thus, exocytosis could quickly achieve a high external concentration of such substances, facilitating rapid reaction(s) in target cells.

### *Intracellular Membrane Vesicle Transport*

Membrane proteins are transported in small membrane vesicles from their site of synthesis to the place where they function. For instance, plasma membrane proteins are usually transported from endoplasmic reticulum to Golgi apparatus to plasma membrane. At each of these compartments, a part of membrane containing a set of particular plasma membrane proteins buds from the membrane and form vesicles. These vesicles are transported to the next compartment, and fuse with its membrane, transferring the proteins to the compartment. This fusion, though a purely intracellular event independent of $Ca^{2+}$, takes place in a very similar manner as that between an intracellular vesicle with the plasma membrane. In fact, NSF, snaps and SNARE proteins were identified as components of transport systems in the studies on intracellular membrane transport [10]. In other words, SV exocytosis can be regarded as a specific form of intracellular membrane transport. Many isoforms of syntaxin and VAMP exist, and one of these isoforms acts in each transport route. However, only SNAP-23 exists as an isoform of SNAP-25. Combinations of these SNARE proteins seem to specify the transport route.

### *Pathology*

In Lambert-Eaton myasthenic syndrome (LEMS), antibodies against P/Q-type Ca channels of the motor nerve terminal are produced. These antibodies decrease $Ca^{2+}$ -influx, resulting in impaired neurotransmitter (acetylcholine) release. LEMS is often associated with small cell lung cancer.

## Experience with Natural Images as a Basis for Vision

Dale Purves
Center for Cognitive Neuroscience and Department of Neurobiology, Duke University, Durham, NC, USA

E

### Definition

The phrase "natural images" refers to ►images projected onto the ►retina by light reflected from objects in typical visual environments.

### Characteristics

#### Defining the Problem

Despite much effort over the last century, visual perception is not understood in either psychological or neurobiological terms. Most thinking about this issue has been predicated on the seemingly obvious intuition that the ►visual system detects, represents and reports the physical features of stimuli and their sources in the world.

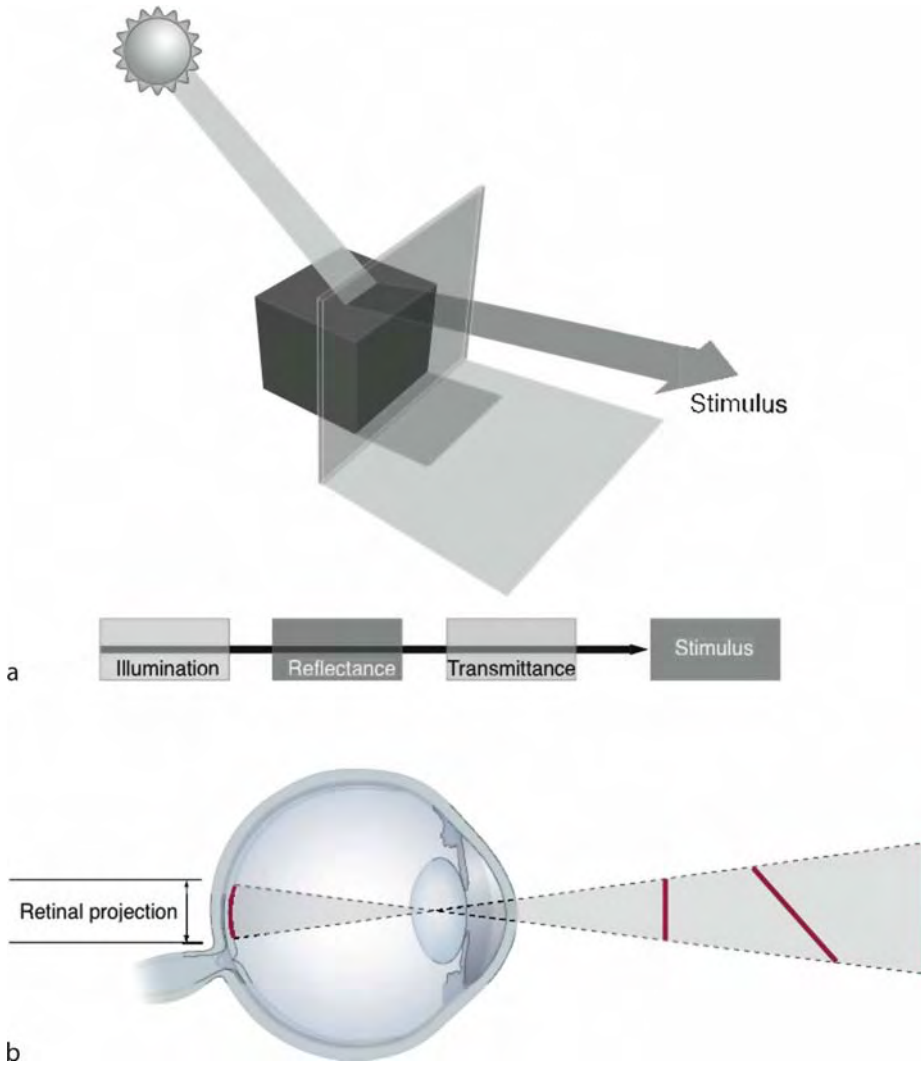
However, a growing body of evidence suggests that ►visual percepts may be generated in a quite different way. The alternative concept is that visual percepts depend on and ultimately represent accumulated ►empirical experience with light stimuli arising from natural scenes rather than the physical characteristics of the stimuli or their sources as such. The basis of this perspective is the inevitable ambiguity of information in retinal images, and the fundamental challenge presented by this "inverse optics problem" (Fig. 1).

Historically, exploring vision in terms of ►feature detection has used simple stimuli presented to anesthetized cats or monkeys in the laboratory while recording the electrophysiological responses of single neurons at different levels of the visual system. In contrast, exploring vision in empirical terms has depended on reports of what human subjects actually see, using analyses of natural images to predict perceptual functions. The purpose of this article is to compare and contrast these approaches to explaining vision, which must eventually be brought together if vision is to be understood.

#### Vision Explained in Terms of Feature Detection

The classical studies of David Hubel and Torsten Wiesel begun in the late 1950s and proceeding through the early 1980s showed that neurons in the primary visual pathway (which includes the retina, ►lateral geniculate nucleus of the ►thalamus and the ►primary visual cortex in the ►occipital lobe) respond selectively to stimuli with particular characteristics [2]. These neuronal properties define each cell's ►*receptive field*.

Investigators have now studied the receptive field characteristics of visual neurons at different levels of the visual system in a variety of species, focusing on non-human primates such as rhesus monkeys. Neurons in the primary and higher order visual cortices of such animals respond selectively to stimulus orientation, direction of movement, speed of movement, spectral characteristics and ►binocular disparity. Moreover, some neurons in visual cortical areas in the ►temporal lobe respond selectively to more complex stimulus characteristics such as shape and texture, and even to patterns associated with specific objects such as faces. These studies have all reinforced the idea that the primary function of visual neurons is to detect and represent stimulus features in retinal images.



**Experience with Natural Images as a Basis for Vision. Figure 1** A fundamental problem in biological vision is the necessarily uncertain relationship between the information in the images that fall on the retina and their real-world sources. (a) Conflation of the factors that determine the amount and spectral quality of light falling on the retina. Illumination depends on the properties of a source like the sun; the reflectance of objects depends on their physical composition; and transmittance depends on the amount and quality of the atmosphere intervening between an object and the observer (as well as between the source of illumination and the illuminated objects). These basic factors that together determine the luminance and spectral distribution of any stimulus at the eye cannot be disentangled by analysis of the retinal image as such. (b) The problem is much the same in the perception of geometry, since the spatial properties of three-dimensional objects are also conflated when the light reflected from them is projected onto a plane. The diagram shows that the same retinal projection can be generated by objects of different sizes at different distances from the observer, and in different orientations. Again, there is no logical way to disentangle these factors by analysis of the retinal image [1].

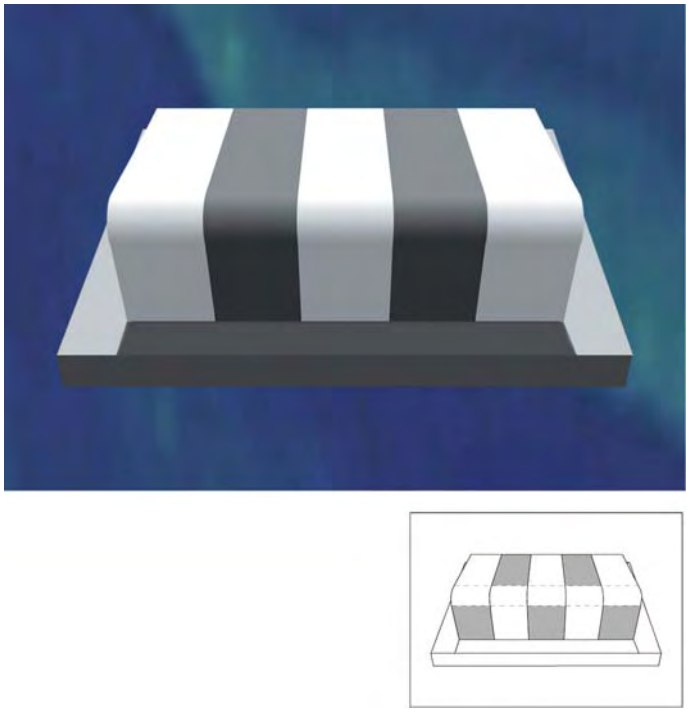
## Vision Explained in Terms of Filters

A somewhat different and not mutually exclusive approach to understanding receptive field properties is based on the idea that visual neurons act as filters. This line of thought was initiated by Fergus Campbell and John Robson in the late 1960s and is predicated on Fourier's theorem [3]. This theorem shows that any continuous periodic function can be decomposed into a set of sinusoids and that the original function can be reconstructed from this set. ►Fourier analysis had been used to explain how the basilar membrane of the inner ear extracts frequency components from complex sound signals, and, as Campbell and Robson recognized, the same idea can be applied to images. Any image can be decomposed into a set of sinusoidal gratings with different spatial frequencies, and by reversing the process the image can be reconstructed from this spectrum.

This conception of neuronal function seemed promising in that it explained some otherwise puzzling psychophysical findings and suggested how the visual system might actually analyze complex natural images. For example, when human observers are presented with image patterns of alternating dark and light stripes, the minimal level of ►contrast between the stripes required to detect the pattern varies according to the spatial frequency of the stripes, defining the so-called "contrast sensitivity function." In this framework, the function would arise from the different contrast sensitivities of these filters. Visual neurons would thus encode the spatial frequency of the area of the image falling within their receptive fields, operating as Fourier analyzers. This result, together with evidence that cells in the primary visual cortex are tuned to different spatial frequencies, supported the idea that the local spatial frequency analyzers (filters) are important in visual processing. This conception has been extended to moving stimuli by the further suggestion that motion selective neurons function as spatio-temporal filters, thus analyzing the frequency structure of the retinal stimulus over time as well as space.

## Vision Explained in Terms of Past Experience with Natural Images

Despite these advances, explaining visual percepts in terms of receptive field properties has been frustrated by the persistent inability to relate the electrophysiological responses of visual neurons to the range and peculiarity of the psychophysical functions that have been established over the years. An example is the odd way humans perceive the lightness of a surface or the brightness of a light source, which has repeatedly found to be dependent on the detailed context of the surface or source being examined. As shown in Fig. 2, this



**Experience with Natural Images as a Basis for Vision. Figure 2** The dependence of visual perception on the contextual relationships in scenes. Although the indicated patches in the inset are physically identical, a dramatic perceptual difference between them is generated by empirical information in the scene [4].

dependence can make the same gray surface in a stimulus look either nearly black or nearly white. Although some specific lightness or brightness effects can be explained on an ad hoc basis, there has been no consensus about how such perceptual phenomena in general are linked to the receptive field properties of neurons at the various processing stations of the visual system.

Given this impasse, another approach to rationalizing visual percepts has focused on the challenge of the quandary illustrated in Fig. 1, and the possible ways the visual system could relate natural images to their real-world sources as a means of contending with the inverse problem [1,4,5]. In this framework the concept of vision as detecting and representing image features is abandoned in favor of the idea that the connectivity of the visual system has evolved to link images, their sources and visually guided responses on a wholly empirical basis. The supposition is that the percept elicited by any particular stimulus parameter (e.g., the lightness or brightness elicited by the luminance of a stimulus; see Fig. 2) corresponds to the relative frequency of occurrence of the relevant stimulus parameter (e.g., the luminance of any part of a natural scene) in relation to all other instances of that parameter experienced in the past.

Thus the lightness perceived in response to the luminance of a surface in a visual scene would be determined by how often the specific luminance had occurred relative to all the other luminance values experienced in that context. Visual percepts are thus conceived as statistical constructs that have no direct correspondence to the possible real-world sources of a stimulus; they are subjective sensations that link visual stimuli to the empirical significance of their sources according to the success or failure of visually guided behavior in the past.

A number of neurobiological observations suggest that visual circuitry could indeed be subserving this sort of empirical strategy as a way of contending with the inverse problem [6,7,8,9]. For example, enhanced responses to contrast boundaries as well as color responses are correlated with the basis functions of efficient statistical representations of natural images. Moreover, some anatomical characteristics of the primary visual cortex, e.g., preferential horizontal connections between neurons tuned to similar orientations, are also consistent with the incorporation of natural image-source statistics. Recent evidence suggests that neurons involved in decision making in other brain regions also operate probabilistically [10].

### Implications

The challenge of the inverse problem presents visual systems with a daunting problem: humans or other highly visual animals must extract behaviorally useful information from images whose sources can't be known directly. This quandary implies that biological visual systems must take advantage of the empirical links between the inherently ambiguous images and their possible generative sources in the real world. In this view, this empirical information is gradually accumulated in the structure and function of evolving visual system circuitry as a result of the benefits of successful visually guided behavior. As a result, patterns of light on the retina activate circuitry that, over the millennia, has come to represent biologically useful constructs elicited as reflex responses to stimuli. The experimental support for this way of understanding vision is simply its ability to predict anomalous percepts of brightness, color, form and motion that have been difficult to explain in any other way. If this concept of vision is correct, then the detailed structure and function of visual system circuitry gleaned over the last half-century – i.e., the receptive field properties of visual neurons – will need to be rationalized in terms of this framework, which appears to be demanded by the challenge of the inverse problem.

### Definition

►Experimental Autoimmune Encephalomyelitis (EAE)

## Experimental Autoimmune Encephalomyelitis (EAE)

### Definition

Experimental autoimmune encephalomyelitis (EAE) is a widely used animal model of the human demyelinating disease multiple sclerosis (MS). EAE is generally induced in rodents or primates by either immunization with myelin antigens [e.g., myelin oligodendrocyte glycoprotein (MOG), proteolipidic protein (PLP), myelin basic protein (MBP), etc.] in adjuvant (active induction) or adoptive transfer of myelin-specific T cells (passive induction), resulting in inflammatory infiltrates, demyelination and axonal loss in the central nervous system (CNS). Induction of EAE typically results in ascending flaccid paralysis of limbs with inflammation and tissue damage primarily targeting the spinal cord.

## Explanation (Deductive-Nomological, Mereological, Reductive)

Michael Esfeld
Department of Philosophy, University of Lausanne, Lausanne Switzerland

### Definition

An explanation seeks to enable us to understand a given phenomenon by indicating its cause or by tracing it back to some general structure or pattern. The standard conception of explanation used to be the ►deductive-nomological model of covering laws. According to that conception, a given phenomenon is explained by deducing its description from a law plus a description of the particular circumstances in which the phenomenon in question occurs. The main conceptions today are explanation by referring to the ►relevant causal factors that bring about the phenomenon in question as well as ►unificationism: a phenomenon is explained by integrating its description into a general pattern of argument. Overall ►unification is achieved by reducing the number of independently acceptable hypotheses or argument patterns that one needs to explain the phenomena in the world.

A widespread idea how to explain phenomena and how to achieve the unification of descriptions at different levels is ►mereological explanation: the behavior of a system as a whole is explained by the intrinsic properties of its parts. Mereological explanation is a special case of ►reductive explanation: according to the ►classical conception of reduction, a theory of a higher level is reduced to a more fundamental theory by translating its concepts into the concepts of the more fundamental theory and then deducing its laws from the laws of the more fundamental theory. The multiple realization of higher level properties is the main objection to that conception. ►Functional reduction takes into account multiple realization by providing for a case by case reductive explanation of a higher level property by reference to the arrangement of lower level properties that realizes the higher level property in question on a given occasion.

### Description of the theory

#### Deductive-Nomological Explanation

The deductive-nomological model used to be the standard conception of explanation: one explains a phenomenon by deducing the description of the phenomenon from a law and a description of the particular circumstances in which the phenomenon in question occurs. This model has been developed within the context of the philosophy of science of logical empiricism, notably by Carl Gustav Hempel (1905–2001) ([1], Chap. 12, Sect. 2). It takes the following form:

$C_1, C_2, ..., C_k$ Statements describing particular conditions

$L_1, L_2, ..., L_k$ Statements of laws of nature

$E$ Statements describing the phenomenon to be explained (the explanandum)

The law statements are of universal application. They do not contain any terms referring to individuals. In order to derive from them a description of individual phenomena, a description referring to a particular situation is necessary. One may envisage applying the

deductive-nomological model to the law statements themselves, thus seeking to explain phenomenological laws, such as the one in the example mentioned above, by more general laws; it is, however, questionable whether the deductive-nomological model permits in general an explanation of the laws themselves (compare [1], Chap. 10, p 273 note 33).

## Problems of the Deductive-Nomological Model

The deductive-nomological model faces a number of problems.

1. First, it presupposes a clear distinction between statements of laws and statements of accidental regularities. Consider the following example:

(a) This thing is a cube of gold (Au).
(b) All cubes of gold (Au) have a diameter of less than hundred meters.
(c) This thing has a diameter of less than hundred meters.

The fact that the thing in question is made of gold does not explain its size. The deductive-nomological model of explanation cannot distinguish between statements of laws and statements of accidental regularities (such as the one about the diameter of gold cubes), for the logical form of both these types of statements is the same. It therefore simply has to presuppose that a distinction between statements of laws and statements of accidental regularities is available that does not reside in the logical form of these statements.

2. Even if the second premise of the mentioned-example were a law, the problem would not have been solved. For the law to be explanatory it has to be relevant to the phenomenon that is to be explained without stating anything that is not relevant. Consider the following example:

(a) This stick is partially submerged in water.
(b) All sticks partially submerged in water look bent.
(c) This stick looks bent.

Suppose that on a given occasion, a stick is partially submerged in water that has been blessed by a priest. Adding this fact contributes nothing to the explanation, but fits the deductive-nomological model:

(a) This stick is partially submerged in a container of water blessed by a priest.
(b) All sticks partially submerged in water blessed by a priest look bent.
(c) This stick looks bent.

3. Moreover, explanation is asymmetric. If *A* explains *B*, *B* cannot explain *A*. However, the deductive-nomologicalmodel does not satisfy this condition. Consider the following example: a flagpole of a certain height casts a shadow of a certain length. Given the position of the sun and laws about the rectilinear propagation of light, the height of the flagpole explains the length of the shadow. However, given the position of the sun, the relevant laws and the length of the shadow, we can also deduce the height of the flagpole. But the length of the shadow does not explain the height of the flagpole.

In view of these problems the deductive-nomological model is accepted as a starting point, but all sides agree that changes to this model are called for.

## Corrections of the Deductive-Nomological Model

There are three main types of changes suggested in the contemporary literature that may supersede the deductive-nomological model:

1. ►*Causal explanation*: an explanation has to mention the causally relevant factors that bring about the phenomenon to be explained, and only these factors [2]. For instance, in the examples mentioned above, the height of the flagpole causes the shadow, but the shadow does not cause the height of the flagpole, and the fact that a priest blessed the water is causally irrelevant to the stick looking bent. In what way this conception of causally relevant factors is worked out depends on the view that one takes in the metaphysics of causation. If one regards causation as being tied to laws, the causal conception of explanation can be seen as an amendment of the deductive-nomological model: the covering law has to be a causal law that refers to the causally relevant factors that produce the phenomenon that is to be explained.
2. *Unification*: the ultimate aim of explanation is unification. A phenomenon is explained by integrating its description into a general pattern of argument. For instance, Newton's three laws of motion and his universal law of gravitation explain a lot of phenomena, including the laws of earlier theories such as Kepler's, by showing how they fit into one general pattern. Thus, explanation by unification can be conceived as reducing the number of acceptable argument patterns ([3], Sect. 4). Explanation by unification is also conceived as reducing the number of independent phenomena that we have to accept as ultimate ([4], pp 14–15). Since these argument patterns involve laws, the view of explanation by unification can be seen as an improvement of the deductive-nomological model: the laws that figure in an explanation have to be such that they permit a unification.

Explanation by citing the causally relevant factors and explanation by unification capture salient features of explanation, but it is not the case that all explanations are causal or that all explanations proceed by unification. However, if it turns out to be possible to bring these two approaches together (as suggested by [2], Chap. 4), this may lead to a satisfactory theory of explanation.

3. ►*Pragmatic explanation*: any explanation is relative to the context in which the phenomenon that is to be explained occurs, including the interest and the knowledge of those who call for the explanation ([5], Chap. 5).

   This third position in the current literature takes the objections to the deductive-nomological model to suggest that the search for a general scheme of explanation is futile. It thus stands in opposition to the two other mentioned positions.

## Mereological Explanation

According to a widespread view, we understand a complex system by considering the things which are its parts taken separately. This is mereological explanation (derived from the Latin word "meros," that is to say, "part"). This conception can be traced back at least to Thomas Hobbes, notably the preface to *De cive* (1642).

The idea is that (i) by considering the parts taken separately, that is, by considering their intrinsic properties, we can understand the way in which the parts interact and that (ii) if we understand the way in which the parts interact, we can understand the properties of the whole. This idea presupposes that (i) the relations among the parts supervene on their intrinsic properties and that (ii) the properties of the whole supervene on the relations among the parts and their intrinsic properties.

Both these presuppositions are called into question in contemporary philosophy of science. As regards the first presupposition, it is evident that the properties of the whole depend on the spatial arrangement of the parts, but the spatial arrangement of the parts does not supervene on their intrinsic properties. Furthermore, it is questionable whether causal relations supervene on intrinsic properties (this depends on whether these relations can be traced back to dispositions and whether dispositions are – or supervene on – intrinsic properties). Moreover, our current most fundamental physical theory, quantum theory, is widely received as showing that the fundamental properties of physical systems are not intrinsic properties, but consist in certain relations, namely the relations of quantum entanglement.

As regards the second presupposition, a number of properties of a complex system depend not only on the properties of the parts, but also on the environment of the system. For instance, the biological property of fitness of an organism crucially depends on the environment. Two organisms that are alike internally can differ in fitness because they live in different environments. For these reasons, mereological explanation in the narrow sense that can be traced back to Hobbes is not a viable option.

## Reductive Explanation

Mereological explanation is a kind of reductive explanation. But the notion of reductive explanation is wider than the mentioned one of mereological explanation. It is not committed to the view of basic properties that are intrinsic properties. Reductive explanation concerns in the first place the relation between the concepts of different theories. The ultimate aim is to achieve theory unification. There is a theory $T_1$ that explains one class of phenomena and we wonder how this theory is related to another theory $T_2$ that explains a wider range of phenomena. $T_2$ hence is a more fundamental theory that covers the domain of $T_1$ as a special case. In the last resort, $T_2$ is a fundamental and universal theory of physics. According to the classical conception of theory reduction ([6], Chap. 11), we reduce $T_1$ to $T_2$ by (i) constructing biconditional links between the concepts of $T_1$ and concepts of $T_2$ and by (ii) deducing the laws of $T_1$ from the laws of $T_2$. In order to gain biconditioned links, bridge principles are needed that establish an identity of extension between the concepts of $T_1$ and concepts that can be defined within $T_2$.

The main objection to this conception is that no such identity of extension can be achieved due to the multiple realization of higher level properties. Higher level properties – such as biological properties, neurophysiological properties, psychological properties – typically are functional properties, that is, properties which are defined by the characteristic causes and effects of their instantiations. Functional properties admit of multiple realization. That is to say, one and the same functional property can be implemented by arrangements that are composed in different manners of – in the last resort – instantiations of fundamental physical properties. Thus, for instance, the same type of gene can be realized by different sequences of bases in the DNA (or the RNA), a mental property such as pain may be realized by neural states of type $N$ in humans, but it is realized in a different way in octopuses, etc. [7].

Nonetheless, there is a conception of reductive explanation available that accommodates multiple realization, namely functional reduction [8]. It is in principle possible to identify in each case the realizer of a given instantiation of a functional property. That realizer may include the environment of the system. The way in which the parts of the realizer interact explains how there can be an instantiation of a certain functional property, explaining how there can be the cause and effects that characterize the functional property in question. This is a reductive explanation without an overall theory reduction.

However, on that basics, attempts have been made in recent years to develop functional reduction into a fully-fledged theory reduction. (i) The stream known as

new wave reductionism seeks to construct for each higher-level theory of a special science several physical theories that wap the special science theory in question for a particular domain or species; consequently, the higher-level theory can be replaced by these physical theories [9]. Furthermore, (ii) one can seek to make the higher-level functional concepts more precise so that functional sub-types are gained that are no longer multiply realizable; the aim there is to get to a conservative theory reduction by means of biconditional links [10]. In any case, explanation by theory reduction against the background of functionalism is one of the central topics of the curreat discussion.

# Explanatory Gap

Michael Pauen
Institut für Philosophie, Humboldt-Universität zu Berlin, Berlin, Germany

## Synonyms

Hard problem of consciousness

## Definitions

The "explanatory gap" [1] opens up between scientific explanations of neural processes on the one hand and conscious experience on the other, such that it is impossible, in principle, to account for the very existence and the specific quality of the latter in terms of the former. It is an ►*epistemic* problem that does not concern the relation between mental and neural processes themselves but, rather, the relation between ►*knowledge* concerning mental processes and *knowledge* concerning neural processes. Therefore, an explanatory gap may exist even if mental states are in fact physical states.

## Description of the theory

It seems intuitively highly plausible that the specific quality of mental experience, like the way it is to feel a pain or to have a sensation of red, cannot be accounted for in terms of knowledge about neural activity. The problem does not result from the imperfection of current neuroscience. Rather, it is a problem for neuroscientific knowledge in general. It would persist, even if we knew everything that can be known with respect to neurobiology.

The underlying intuition has already been articulated in ancient philosophy, it can be found in Leibniz's Monadology and later in the work of the nineteenth century German physiologist Emil Du Bois-Reymond.

The recent discussion in the philosophy of mind has focused on two questions: (i) Can the underlying intuition be transformed into an intelligible claim and, if so, (ii) is it possible to reconstruct this claim as the conclusion of a sound argument? One of the basic difficulties that such an argument has to overcome is that it must hold, no matter how far scientific progress will reach in some distant future.

(i) It is now widely accepted that the central question is, whether a reductive explanation of mental properties in terms of general laws concerning the underlying physical properties can be given [2]. Reductive explanations account for the higher level properties of a system in terms of lower level laws that refer to the elements of the system. Thus, the freezing of water can be reductively explained in terms of general microphysical laws concerning $H_2O$-molecules. Reductive explanations of this sort face a general difficulty: They often try to account for higher-level properties which play no role in the lower-level laws they appeal to. As a consequence, so called "bridge laws" are needed in order to link the higher-level properties in the explanandum to the lower-level laws in the explanans.

Consequently, reductive explanations consist of two steps [2]. In the first step, the higher level property in the explanandum has to be linked by a bridge law to some lower level property that figures in the explanans. In a

second step, an explanation for the lower-level property in question has to be provided.

Bridge laws must not be empirical correlations because such correlations call for an explanation themselves, so the problem would only be transferred. What is needed is a conceptual connection between higher- and lower-level properties in a neutral language that applies to both levels of description. Given that causes and effects play a central role on all levels of scientific description, a so called "functional" account of the higher level property in terms of its typical causes and effects appears as the most promising candidate for such a bridge law [2]. So the functional description, say, of the freezing of water might mention that freezing is an effect of temperatures below 0°C, that it makes water less penetrable, that it prevents water from adapting to the walls of a receptacle it might be in etc. This list is certainly only the beginning of what might be a full blown functional account of "freezing," but we have no reason to believe that such an account is impossible, in principle. Given such an account, any lower level property, say of $H_2O$-molecules, that meets the functional criteria in question would have to be counted as a case of freezing.

In order to take the second step, the property in question would have to be explained with reference to some lower-level laws. Since such explanations are daily business in science, this step should raise no particular philosophical problems. The functional account would then provide the bridge law that links the higher-level property to be explained with the lower-level laws that figure in the explanation. This would complete the reductive explanation of the higher level property.

The answer to the first question regarding the central claim of the explanatory gap argument should therefore be clear: According to this claim, it is impossible, in principle, to provide a reductive explanation for the qualitative features of mental properties.

(ii) But what would be a sound argument in support of this claim? According to the above considerations, reductive explanations require bridge laws, and bridge laws, in turn, call for a functional account of the higher-level properties to be explained. If it can be demonstrated that certain mental properties cannot be captured by such a functional account, then this would result in an argument to the effect that these properties cannot be reductively explained. Given that this would be a purely conceptual argument which does not depend on the deficits of current scientific knowledge, the argument would seem to be unaffected by scientific progress.

Many proponents of the Explanatory Gap argument have argued that this is true for the qualitative or phenomenal character of mental states, the so called "qualia." According to their view, it is impossible, in principle, to give a functional account of these qualia, that is, of the way it is like to have a pain feeling or a red experience [1–5].

The evidence for this claim comes from a number of well known thought experiments which appeal to our conceptual intuitions with respect to phenomenal properties. Typically, these experiments demonstrate that the phenomenal aspects of mental states can be dissociated completely from their functional aspects. It is therefore impossible, in principle, to account for the phenomenal character in functional terms.

So, according to the "inverted spectrum" thought-experiment, it is conceptually possible that a physically and functionally identical twin of a person with normal color-vision has an inverted color experience, such that the inversion-twin has a green experience when she looks at a ripe tomato and a red experience when she looks at a cucumber. Note that these differences will in no way affect the inversion-twin's behavior, not even with respect to color-discrimination: The twin, after all, has learned to describe the color of ripe tomatoes as "red" and the color of cucumbers as "green." So given that there is no functional difference whatsoever that would allow us to discriminate between the person with normal-vision and the inversion-twin, it seems to follow that it is impossible, in principle, to capture the respective phenomenal experience in functional terms.

In a similar vein, it has been argued that the physical-functional twin of a conscious person may be a "zombie" who has no conscious experience at all. Given that there is no functional difference by definition between the conscious person and her zombie-twin, this would support the intuition that mental properties cannot be accounted for by functional properties.

It should be kept in mind that these thought experiments are only intended to explore our conceptual intuitions. Nobody believes, of course, in the existence of zombies and inversion twins. The claim is only that our phenomenal concepts are such that they permit these dissociations and therefore cannot be captured in functional terms.

Given that a functional account is required by a reductive explanation, it could be concluded that such an explanation is possible, no matter how far scientific progress might go.

## Conclusions

While it is almost uncontroversial that the failure of a reductive explanation of phenomenal properties would pose a problem for ▶physicalism [1,3], it is unclear how severe the consequences might be. Nagel and particularly Levine concede that the problem might render physicalism less plausible, still they insist that this does not force us to reject it. This is so because physicalism makes a *metaphysical* claim about the entities that exist in our world. The explanatory gap argument, by

contrast, makes an *epistemic* claim about certain failures of the theories that try to explain those entities. Given that our theories or their conceptual framework may happen to be inadequate for whatever reasons, the failure of low level theories to account for high level properties would not permit the conclusion that the high level properties are no physical properties – provided, of course, that we have independent reasons to accept physicalism.

Other authors, however, argue that the problem leads to a rejection of physicalism. According to Jackson's ►knowledge-argument [4], physical knowledge does not comprise phenomenal properties. That is why Jackson thought that they cannot be physical properties. Another line of reasoning attacks the physicalist assumption that mental entities are identical with certain physical entities. As it has been demonstrated by Kripke, identity claims like the claim of psychophysical identity that employ rigid designators are either *necessarily* true or false. Given that the dissociation thought experiments show that psychophysical identity claims are not necessarily true, so the argument continues, they must be false and physicalism has to be given up.

### Objections

Several objections have been brought forward against the explanatory gap argument. According to the most radical objection, no such problem exists, to begin with. This may be so, because the existence of ►qualia is denied so that there is nothing left to be explained [6]. Those who accept the existence of qualia have tried to show that the alleged problem is based on a confusion that can be dissolved as soon as we understand an important implication of identity claims [7]: These claims need justification but there is no need and not even a possibility for explanation – how should we explain why something is itself? Others claim that the whole problem is based on an fallacious "argument from ignorance" that fails to account for future scientific developments. These developments might provide us with those explanations that now seem impossible [8]. Another line of attack tries to undermine the dissociation thought experiments. If psychophysical dissociations are possible, then they can affect any individual. However, given that the abilities to remember and recognize are certainly functional features, variations of phenomenal properties in the absence of any variation of functional features would make no difference to our memory. It would follow that we would be unable to remember and recognize those variations, no matter how often they occur. Apart from leading to absurd consequences, this would clearly undermine any knowledge with respect to phenomenal properties. But how could we ask for an explanation of properties that we have no knowledge of? [9] Finally, it is controversial whether reductive explanations of high-level properties really are a standard in science. If they are not, then nothing really follows from our inability to provide reductive explanations for phenomenal properties [10].

## Explicit Memory

### Definition

Explicit memory refers to a memory with conscious recollection for specific facts and episodes. Difference between explicit or implicit memory depends on consciousness when retrieving information from the storage. Information examined by formal test of recall or recognition belongs to explicit memory. Explicit memory is synonymous with declarative memory.

►Long-Term Memory
►Recognition Memory

## Exploratory Behavior

### Definition

A constellation of behaviors that are expressed in a novel environment or when features of a familiar

environment are rearranged or otherwise changed. In a novel environment an animal will rear frequently, navigate around the boundaries and spend time near objects.

►Spatial Learning/Memory

## Exportin

### Definition

Exportin is a class of molecules involved in transporting molecules, in particular mRNA, out of the nucleus.

## Express Saccades

### Definition

A saccade elicited by the appearance of a new target after a distinctively shorter time (≈ 100 ms) than regular saccades (>150 ms) and yet having approximately normal accuracy. Their frequency of occurrence is idiosyncratic but mostly quite low in standard situations (current target disappearing upon presentation of new one) but can be primed by a gap period (current target off about 200 ms before new target appears) and by reduced uncertainty about target location. The study of express saccades supports the notion that an important, and time consuming, step among the processes leading to the generation of a new saccade is the release of attention and fixation from their current focus.

►Oculomotor Control
►Saccade, Saccadic Eye Movement

## Expression Profiling

### Definition

Expression profiling using microarrays the complement of genes expressed in a specific tissue or cell type can be compared between samples that differ by some critical variable (e.g. age, drug treatment, disease state, loss or gain of a gene's function).

## Extended Amygdala

George F. Alheid
Department of Physiology, Northwestern University, Feinberg School of Medicine, Chicago, IL, USA

### Definition

The extended amygdala describes a large ►basal forebrain macrostructure encompassing a contiguous but heterogeneous collection in excess of 16 interconnected and functionally related neuronal aggregates, or subnuclei, extending from the centromedial amygdala to the bed nucleus of the stria terminalis. It is important to note that the definition of the extended amygdala does not encompass the large lateral-basolateral complex of the amygdala nor the superficial cortical amygdaloid nuclei, although the extended amygdala is one of the most important recipients of afferent input from these structures.

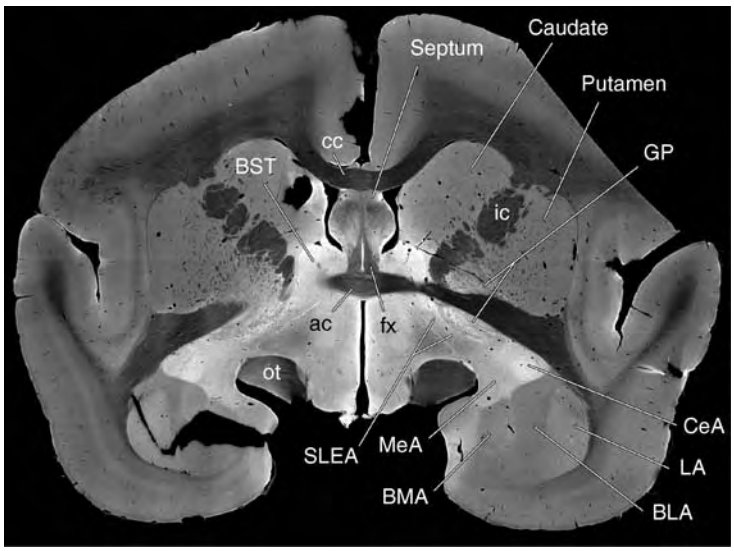
### Characteristics

#### Historical

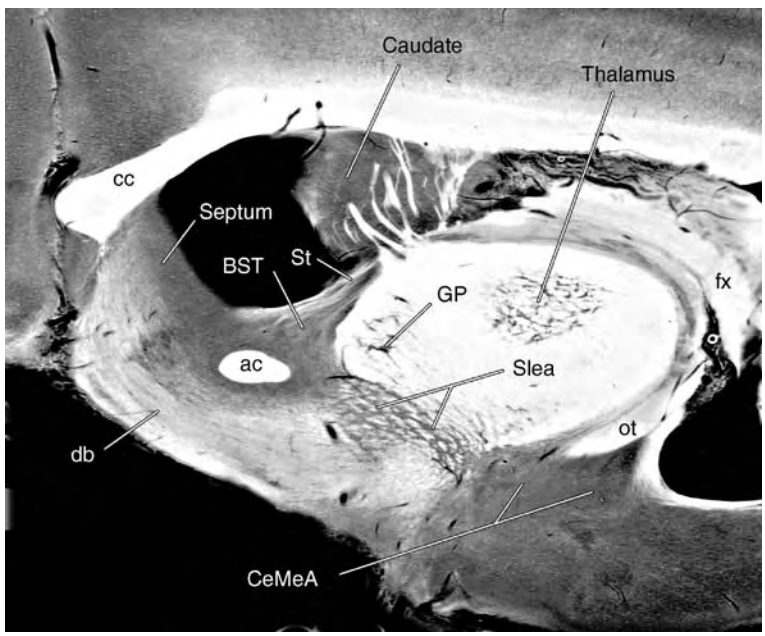
On the basis of comparative and embryological studies (including human embryos) J. B. Johnston [1] proposed in 1923 that the centromedial amygdala, the bed nucleus of the stria terminalis, and neurons accompanying the stria terminalis formed a continuum in the basal forebrain of mammals, that was homologous to neurons accompanying the lateral forebrain longitudinal association bundle he observed in embryos and non-mammalian vertebrates. Embedded within Johnston's extensive treatise on the comparative anatomy of the amygdala and basal forebrain, this proposal did not persist in the anatomical literature, but was later revived and extended by de Olmos and colleagues in the 1980s. In addition to neurons accompanying the stria terminalis, the latter authors asserted that interconnecting neurons below the globus pallidus should be included as part of this lateral forebrain continuum, conceptualized as an "extension" of the central and medial amygdala into the basal forebrain [2], or alternatively as the "extended amygdala" [3].

#### Functional Neuroanatomy

The central and medial nuclei of the amygdala lie just below the caudate putamen and globus pallidus (together the lenticular nuclei) in the medial part of the temporal lobe of mammals (Fig. 1). Rostrally, the borders of the central and medial amygdaloid nuclei are indistinct, and they merge dorsomedially with corridors of neurons in the "sublenticular" area that in turn merge with ventrolateral portions of the bed nucleus of the stria terminals (Figs. 1 and 2). Neurons related to the amygdala accompany the stria terminalis as clusters, or interrupted columns of cells (the supracapsular bed nucleus of the



**Extended Amygdala. Figure 1** Extended amygdala in the primate brain. Depicted is a direct photographic print of a coronal section from the brain of a tamarin monkey that has been stained for secretoneurin (white areas). In rodents and humans this peptide is highly expressed in the region of the extended amygdala and serves to graphically depict its extent. Note the continuous field of secretoneurin immunoreactivity between the bed nucleus of the stria terminalis and central and medial amygdala.



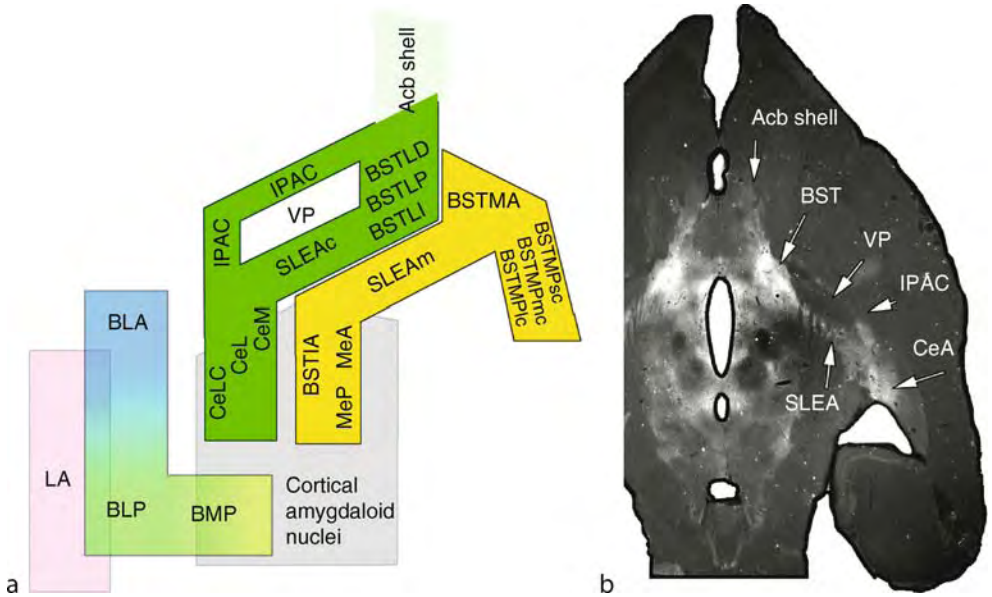
**Extended Amygdala. Figure 2** Extended amygdala in the rat brain. This figure is a direct photographic print of an unstained section of a rat brain cut parallel to the main rostrocaual plane of the extended amygdala. Note the distorted circle formed by the bed nucleus of the stria terminalis (BST), the sublenticular extended amygdala (SLEA), the centromedial amygdala (CeMeA) and the arcing fibers of the stria terminalis (st).

stria terminalis). An additional corridor of amygdala-like neurons accompany the posterior limb of the anterior commissure (the interstitial nucleus of the posterior limb of the anterior commissure; "IPAC") as it courses rostromedially from the amygdala. IPAC crosses the rostral face of the ventral pallidum (i.e. across the caudal surface of the nucleus accumbens), and eventually merges with lateral portions of the bed nucleus of the

stria terminalis. In primates, and particularly in the human brain where the ventral pallidum is represented by a more dispersed archipelago of neurons (when compared with non-primate mammalian species) it is not clear that a separate column of cells representing the primate homologue of IPAC exists.

## Two major Groups of Subnuclei, Medial and Central make up the Extended Amygdala

1. The medial nucleus of the amygdala is contiguous with the medial part of the bed nucleus of the stria terminalis via neurons scattered within the medial part of stria terminalis (medial supracapsular bed nucleus of the stria terminalis), and by neurons traversing a caudal and ventral corridor in the sublenticular area. These regions are collectively termed the "*medial division of extended amygdala*" (Fig. 3a) and are particularly characterized by reciprocal connections with medial hypothalamic nuclei. Most of the structures composing the medial division of extended amygdala have been implicated in aspects of social and reproductive behaviors. These include mediation of reproductive behaviors (including parenting), of related psychoendocrine responses, and intra- and inter-specific aggression.
2. The "*central division of extended amygdala*" (Fig. 3b) takes its name from the central amygdaloid nucleus, its largest and most characteristic component. The central nucleus of the amygdala is contiguous with the lateral part of the bed nucleus of the stria terminalis via neuronal corridors in anterior and dorsal portions of the sublenticular area and via IPAC. The central extended amygdala has robust, generally reciprocal connections with hypothalamus (particularly lateral hypothalamus), mesencephalic tegmentum, dorsolateral pons and medulla. It targets potential premotor areas such as in the lateral pontine and medullary reticular formations as well as in more complex sensory-motor regions such as the periaqueductal gray, parabrachial complex, and the nucleus of the solitary tract. Theoretically important targets of the central extended amygdala include the dopamine cells in the ventral tegmentum of the mesencephalon, as well as serotonergic and



**Extended Amygdala. Figure 3** Elements of extended amygdala. The Schematic horizontal diagram of the rat extended amygdala in 2A outlines the central (green) and medial divisions (yellow) of extended amygdala. The central division surrounds the ventral pallidum which is distinct histochemically and connectionally from the central division of extended amgydala. The definition of extended amygdala *does not* include the lateral amygdaloid nucleus (pink) basolateral (blue-green) complex, or the superficial cortical amygdaloid nuclei (gray). 2B is a direct photographic print of a horizontal section of the rat brain immunolabeled for the peptide angiotensin II. This peptide is prominent in both subdivisions of extended amygdala, but not the ventral pallidum or striatum, with the exception being the most caudal portions of shell of nucleus accumbens. Note the prominent amygdala related band (SLEA) caudomedial to ventral pallidum traversing the sublenticular region between the centromedial amygdala and the bed nucleus of the stria terminalis. Although it is not evident in this view, it should be noted that IPAC is also continuous across the rostral face of ventral pallidum and joins the ventrolateral quadrant of the lateral bed nucleus of the stria terminalis. (Modified from Alheid (2003) [4], with permission from Blackwell Publishing).

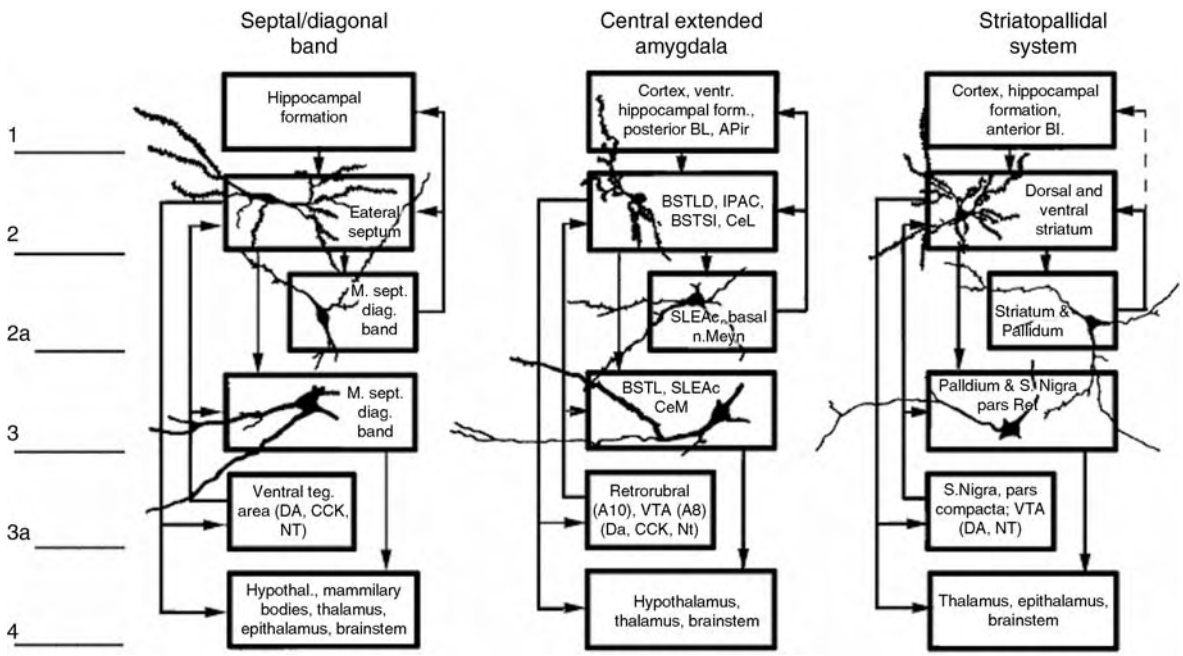
noradrenergic neurons in the pons. Behavioral data has implicated central extended amygdala neurons in the motor, endocrine, and autonomic responses conditioned to stimuli associated with fear, anxiety, and unavoidable stress. Mediation of positive emotional/motivational stimuli or the rewarding impact of drugs of abuse has also been associated with modulation of dopamine or GABA neurotransmitters in the central division of the extended amygdala. As a consequence, it is included as a focus of research aimed at understanding the biological substrates of drug abuse.

## Extended Amygdala and Nucleus Accumbens

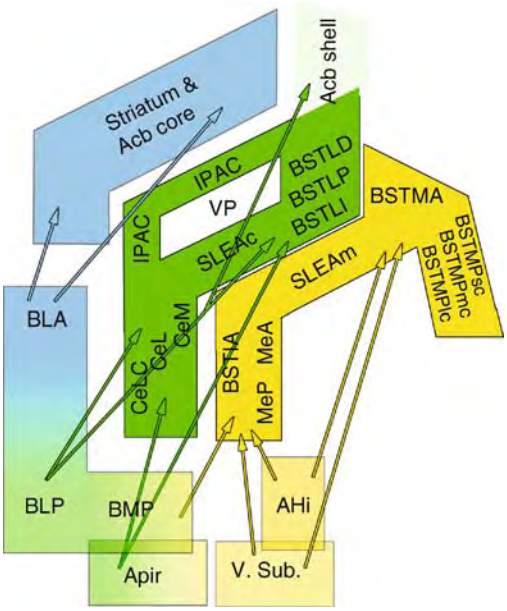
Just rostral to extended amygdala, the "shell" area of nucleus accumbens has been the main focus for studies on structures mediating the central rewards and the rewarding effects of drugs of abuse. It has been suggested that caudal portions of the accumbens shell region might represent transitional areas with extended amygdala where neurons from both structures are incompletely separated. Recent evidence has, in fact, indicated that some neurons scattered in caudal parts of the accumbens appear to derive developmentally from a "caudal ganglionic eminence" in the lateral forebrain of the embryo which also gives rise to the lateral bed nucleus of the stria terminalis and central nucleus of the amygdala [5]. On the other hand, various studies, particularly those by Zahm and coworkers (e.g., [6]), have amply demonstrated the particularly striatal nature of the shell of the accumbens, including its caudal portions. It is, therefore, not accurate to treat the accumbens shell as simply the rostral most portion of extended amygdala.

## Parallel Processing in Basal Forebrain

It has been argued that much of the forebrain may be understood as parallel anatomical corridors through the basal ganglia (striatum and globus pallidus) that process efferents of functionally unique cortical zones [3]. In some respects the organization characterizing the cortico-striato-pallidal system may be used to model relations in nearly the entire basal forebrain (Fig. 4), including extended amygdala, and even the medially



**Extended Amygdala. Figure 4** Basal forebrain columns. Three major cortical-subcortical corridors in basal forebrain (i.e. hippocampal septal-diagonal-band; central extended amygdala; cortico-striato-pallidal). Note that comparable processing steps are not depicted for the medial extended amygdala but such a scheme might be attempted. Basically, in all three systems shown, glutaminergic (level 1) cortical neurons and cortical-like amygdala neurons project to GABAergic medium sized spiny neurons (level 2). These in turn project to projection neurons with long slender dendrites (leptodendritic) (level 3) in the diagonal band nuclei, in central extended amygdala, but also to downstream targets such as the ventral tegmental dopamine neurons (level 3A). The leptodendritic neurons provide a massive output to (level 4) hypothalamus, thalamus, and brainstem. Large leptodendritic interneurons (level 2A) receive input from medium spiny neurons and from thalamus, but more rarely from cortex. To varying degrees these provide feedback locally to medium spiny neurons, but also back to cortical areas that were the original source of the input to the medium spiny neurons. (From Alheid (2003) [4], with permission from Blackwell Publishing).



**Extended Amygdala. Figure 5** Multiple corridors in the projections of the basolateral amygdala to extended amygdala and striatum. In the rat, anterior basolateral amygdala selectively targets striatum and posterior basolateral amygdala projects to extended amygdala. Cortical-like excitatory projections from anterior or posterior segments of the basolateral amygdala more or less exclusively target separate parts of the forebrain, the striatum or central division of extended amygdala respectively. To some extent, the projection from posterior basolateral amygdala to the extended amygdala is mirrored by afferents from lateral portions of the amygdalopiriform area. A similarly focused input to medial extended amygdala originates from basomedial, amygdalohippocampal, and ventral subicular projections and to some degree form. *ac* anterior commissure; *Acb Shell* shell region of the nucleus accumbens; *AHi* amygdalohippocampal transition area; *APir* amygdalopiriform transition area; *BLA* anterior basolateral amygdaloid nucleus; *BLP* posterior basolateral amygdaloid nucleus; *BMP* posterior basomedial amygdaloid nucleus; *BST* bed nucleus of the stria terminalis; *BSTIA* intraamygdaloid bed nucleus of the stria terminalis; *BSTLD* dorsolateral part of the lateral BST; *BSTLI* intermediate part of the lateral BST; *BSTLP* posterior part of the lateral BST; *BSTMA* medial anterior part of the medial BST; *BSTMPlc* large-celled lateral column of the medial posterior part of the BST; *BSTMPme* medium-celled intermediate column of the medial posterior part of the BST; *BSTMPsc* small-celled medial column of the medial posterior part of the BST; *cc* corpus callosum; *CeA* central amygdaloid nucleus; *CeLC* lateral capsular part of CeA; *CeL* lateral CeA; *CeM* medial part of CeA; *CeMeA* centromedial amgydala; *CCK* choleycystokinin; *DA* dopamine; *db* diagonal band; *fx* fornix; *GP* globus pallidus; *ic* internal capsule; *IPAC* interstitial nucleus of the posterior limb of the anterior commissure; *La* lateral amygdaloid nucleus; *M. adjacent hippocampal-septal system. In each forebrain corridor, glutaminergic pyramidal neurons in a cortical area (Level I, Fig. 4) target GABAergic medium sized spiny neurons in the basal forebrain (Level II) and these, in turn, send axon terminals to sparsely spiny GABAergic output neurons such as those found in pallidal areas. Additional elements that appear to be represented in all basal forebrain systems include large cholinergic and non-cholinergic (e.g. somatostatin) neurons providing either intrinsic (in striatum) or cortical feedback (septum/diagonal band and extended amygdala. Mesencephalic dopamine neurons also appear to be reciprocally connected with most basal forebrain regions in a loose topographical fashion.

## Parallel Projections from Basolateral Amygdala to Extended Amygdala and Basal Ganglia

A major source of afferents to the extended amygdala is the basolateral amygdala, a cortical-like structure with glutamatergic pyramidal neurons, but little evidence of a layered structure. The basolateral amygdala has been implicated both in conditioned fear (as an efferent relay from the lateral nucleus of the amygdala) and in the rewarding effects of drugs of abuse. In the context of parallel processing in basal forebrain, it is significant that the small-celled part of the basolateral amygdala (posterior part in the rat nomenclature) projects mainly to extended amygdala and to the shell area of nucleus accumbens, while the large-celled part of the basolateral amygdala (anterior part in the rat) projects mainly to striatum and to the core of nucleus accumbens, but not to extended amygdala (Fig. 5). As yet, few functional studies have capitalized on this distinction. In one set of experiments comparing chemical inactivation of anterior vs. posterior basolateral amygdala in the rat, the reinstatement of behavioral responses normally rewarded by cocaine administration was blocked by lidocaine deactivation of the posterior basolateral amygdala, when test injections of cocaine itself was the cue. On the other hand, reinstatement of drug rewarded behaviors was dependant on ongoing activity in anterior basolateral amygdala when reinstatement was prompted by environmental cues rather than by the drug itself [7]. These observations are consistent with

mediation by the extended amygdala and shell of the accumbens of the physiological consequences of natural rewards, including behavioral arousal, while the striatum and core of the accumbens appear to be more important in mediating the adaptive behavioral procedures elicited by learned cues signaling the availability of rewards.

In the final analysis, any gross generalization about the functional impact of the extended amygdala is qualified by the complex collection of subnuclei that compose its major divisions. These multiple subnuclei with their distinctive cortical and subcortical afferents, including their afferents from the remaining cortical-like nuclei of the amygdala proper, bespeak a substantial number of differentiated functional-anatomical systems accessing a broad range of neuroendocrine, autonomic, and somatomotor responses. This underscores the importance of the ongoing behavioral and physiological analyses that recognize the specific functional attributes of the many individual components of the amygdala, extended amygdala and basal forebrain in general.

## Definition

"Externalism" is used in different philosophical disciplines. In the philosophy of action, externalism refers to the view that there are objective reasons for action that are not dependent on the agent's desires, and thus external to him. In epistemology, externalism refers to the view that the factors required for a belief to be epistemically justified may be cognitively inaccessible to the epistemic subject, and thus external to his mind.

This essay is concerned with externalism in the philosophy of mind and in the philosophy of language. In this context, externalism is the view that the contents of an individual's thoughts and the meanings of his words depend on systematic relations that the individual bears to aspects of his environment. Mental contents and word meanings are individuation-dependent on aspects of the physical and social environment of their subjects.

## Description of the Theory

The main road leading to externalism, proposed by Putnam [1] and Burge [2], draws on the semantic analysis of the truth conditions of that-clauses used to ascribe beliefs and other mental states.

### Twin-Earth Thought Experiments

Putnam asks us to consider the following ►twin earth thought experiment (cf. [3]): suppose S is an English speaker who uses the word "water" as much as anyone in his linguistic community. He doesn't have any considerable knowledge of the chemical properties of water. Suppose that there exists somewhere in a nearby galaxy a planet called "twin earth," which is a molecule-for-molecule duplicate of earth. The only difference between the two planets is that no water is present on twin earth. What is found there instead is a liquid which looks, tastes, and behaves like water but has the chemical composition XYZ and not $H_2O$. Like each one of us, S has a molecular duplicate on twin earth. Twin S has endured experiences that are just like S's, except that where S has encountered water, he has encountered XYZ; and neither of them is aware of the constitution of the liquids they refer to as "water."

At this point Putnam introduces two common assumptions about the meaning of mental states and their relation to language. Firstly, there is the assumption that the meaning of terms in a language is determined by the mental states of the speaker who uses them. Thus, the meaning of the term "water" is determined by the speaker's concept of water. Secondly, there is the assumption that reference is a component of the meaning of a term. So the meaning of "water" contains not only an intentional description of the character or stereotype of water, but also the referent, $H_2O$.

The reference of S's "water" expression is different from the reference of his twin's "water" expression. S's expression refers to $H_2O$ while twin S's refers to XYZ. Given that reference is part of the meaning, the meaning of S's "water" expressions is distinct from the meaning of twin S's "water" expressions. Also, if the meaning of an expression is determined by the concepts of the speaker, then the concept expressed by S's term "water" is different from the concept expressed by twin S's term "water." To translate the concept expressed by the twin earthian word "water" into English we have to coin a new word, perhaps "twater." Due to the difference in concepts, S and twin S express different thoughts when both of them utter, for example, "Gee, water is wet!". Putnam concludes that mental states involving natural kind terms don't supervene on physical states of our brains but on the physical states of our environment.

Putnam's twin earth example exploits the fact that in the case of a natural kind term such as "water," the nature of the referent plays an essential role in individuating the concept associated with the word. Burge [2], Dretske [4], Fodor [5] and others have developed versions of the twin-earth thought experiment that are not limited to natural kind terms.

### Varieties of Externalism

The numerous types of externalism can be classified according to two criteria. Firstly, different forms of externalism take different aspects of the environment to be constitutive for the individuation of mental content. Secondly, the dependency relation between brain states and environmental states, which is said to be constitutive of mental content, comes in various strengths. The first criterion concerns the supervenience base of contents, and the second criterion concerns the nature of the supervenience relation.

Different versions of externalism take different kinds environmental facts as responsible for the determination of thought content. According to Putnam's causal-essentialist externalism, it is the (chemical) structure of the designated objects that determines the meaning of natural kind terms. Burge's social externalism suggests that it is the linguistic norms of society which determine thought content. In Davidson's [6] view, the thought contents of a speaker are determined by the physical and social properties with which both the speaker and his interpreter are in contact. According to Dretske's [4] informational semantics, thought content is dependent on the informational states. What links the belief about water to water is that, under normal conditions, water causally contributes to one's having beliefs about water.

The supervenience relation between mental states and environmental states comes in different strengths. One sort of externalism (e.g. [2]) insists that you could not have, say, a belief that water is wet unless there was some relation between you and water. Had you never come across water, beliefs about water would not be available to you. But this doesn't mean that there was necessarily a time when you were in the presence of water. It might be that water was described to you by others who have been in contact with it or that you simply theorize about the chemical composition of an illusionary substance called "water." This version of externalism entails only the weakest kind of supervenience. Other externalists (e.g. [4]) hold that for you to have beliefs about water (assuming "water" is a simple concept), you must have had some causal contact with water during your lifetime. An even stronger version might hold that you need to be in direct contact with water to have beliefs about water.

## Objections to Externalism

One objection to externalism concerns action explanation. Since your twin on twin earth is a molecule-for-molecule duplicate of you, the two of you perform the same kind of behavior. When you are thirsty, you may say "I would like to drink some water"; when your twin on twin earth is thirsty he will say the same thing. Your verbal expressions are identical.

It seems reasonable to suppose that the parallelism of behavior indicates a parallelism of action and of intentional states. For if the behavioral output is the same why should the intentional input be different? The problem, however, is that given externalism, you and your twin entertain different intentions when both of you say "I would like to drink some water." Your twin wants to drink twater, you want to drink water. The difference between twater-thoughts and water-thoughts is therefore a difference that, behaviorally speaking, makes no difference. The externalist notion of content seems to drop out as part of the theoretical apparatus of behavior causation and action explanation.

Externalists have tried to respond to this challenge by arguing that you and your twin's behavior is in fact different. When your twin and you desire to drink "water" and believe the glass in front of you to be filled with "water," both of you perform the same bodily movements – you take the glass and empty it. But even though the bodily movements are the same, the behavior is different. Behavior has to do with why one does what one does. Whereas your twin intends to drink twater, you intend to drink water (cf. [7,8]).

Another objection to externalism comes from the intuition that we can know, just by reflection (or a priori), about our own mental contents. Suppose you hold a belief that you express by saying "water is wet." Given externalism, the content of your belief depends on the kind of entity designated by "water." But then it seems you can know the content of your belief only if you know what substance you are in contact with – $H_2O$, XYZ, or whatever else. Knowledge of your own thought contents seems to require investigation of external content-determining circumstances. Hence, if mental contents are determined by environmental states, then, since reflection can reveal only intrinsic properties of mental states, a priori knowledge of one's mental contents seems to be impossible.

In response to this objection, some philosophers have tried to render externalism compatible with the idea that we know about our thought contents just by reflection. Consider the first-order thought "water is wet" and the simultaneously entertained self-referential thought "I believe that water is wet." The content of the first-order thought is contained (or included) in the content of the second-order thought, and the contents of both thoughts are determined by the same causal relations of which one may be ignorant. No matter which environment one lives in, the content of the second-order thought cannot come apart from the first-order thought by which it is causally sustained. For this reason, some proponents of externalism claim that their theory does not have the consequence that knowledge of one's thought contents requires the investigation of one's environment (cf. [8,9,10]). For a comprehensive and up-to-date defense of externalism see Brown [11] and Goldberg [12].

## Exteroceptive

### Definition

Receptors and senses receive stimuli from the world external to the body and comprise vision, electric senses and magnetic senses, audition (hearing), gustation (taste) and olfaction (smell).

►Sensory Systems

## Extinction

### Definition

This learning occurs when a conditioned stimulus (CS) that used to signal the unconditioned stimulus (US) now signals omission of that US. The standard procedure for extinguishing a CS involves suspending all presentations of the US. Extinction is typically indexed by a decline in conditioned responding to the CS. Phenomena such as spontaneous recovery of the conditioned response (CR) and disinhibition of the CR have supported accounts that attribute the loss of conditioned responding during extinction to a masking process such as inhibition rather than to erasure of the original association between the CS and the US.

►Classical Conditioning (Pavlovian Conditioning)
►Theory on Classical Conditioning

## Extinction Learning

### Definition

A form of inhibitory learning, in which conditioned responses to conditioned stimuli decrease.

►Learning and Extinction

## Extinction Memory

### Definition

The associative or cellular processes responsible for the decrease in conditioned responding observed after extinction.

►Learning and Extinction

## Extinction Training

### Definition

The experimental procedure of extinction, characterized by the presentation of the conditioned stimulus in the absence of the unconditioned stimulus, that leads to a decrease in conditioned responses.

►Learning and Extinction

## Extracellular

### Definition

Literally means outside the cell. In all cells, a cell membrane exists which separates the intracellular and extracellular compartments. Partly due to the presence of transporters and ion channels within the cell membrane the extracellular concentrations of many ions is different compared to the intracellular environment.

►Membrane Biophysics
►Membrane Potential: Basics

## Extracellular Fluid (ECF)

### Definition

The extracellular or interstitial fluid surrounds the cells and is a component of the extracellular matrix.

## Extracellular Matrix

### Definition

A matrix composed of various proteins, sugar residues and lipids surrounding cells.

# Extracellular Protease

Yasuyuki Ishikawa, Sadao Shiosaka
Nara Institute of Science and Technology (NAIST), Structural Cell Biology, Nara, Japan

## Synonyms

Extracellular proteinase

## Definition

►Neuronal plasticity-related extracellular protease.

Secretory proteases or membrane-anchored proteases that catalyze hydrolysis of peptide bonds in extracellular proteins.

## Characteristics

### Quantitative Description

Almost all extracellular serine proteases are rather small proteins, ranging from 30 to 70 kDa, but some are large. Approximate molecular weights are 30 kDa (neuropsin), 70 kDa (tissue plasminogen activator: tPA), 85 kDa (plasmin), 97 kDa (neurotrypsin), and 400 kDa (reelin). Matrix metalloproteases (MMPs) are between 50 and 100 kDa; i.e. 65 kDa (MMP24), 72 kDa (MMP2), and 97 kDa (MMP9).

### Higher Level Structures

Protease or proteinase.

### Lower Level Components

Serine Proteases:

- Tissue plasminogen activator (tPA)
- Plasmin
- Neuropsin (KLK8, ovasin, TADG-14, kallikrein hK8, PRSS19)
- Protease M/neurosin/zyme (KLK6, hK6)
- Neurotrypsin (brain-specific serine protease BSSP-3, leydin, motopsin, PRSS12).
- Reelin

Matrix Metalloproteases:

Matrix metalloprotease 2 (MMP2, gelatinase A, gelatinase Type IV collagenase)
Matrix metalloprotease 3 (MMP3, stromelysin-1, proteoglycanase)
Matrix metalloprotease 9 (MMP9, gelatinase B)
Matrix metalloprotease 24 (MMP24, MT5-MMP)

#### *tPA and Plasmin*

tPA is a serine protease that catalyzes the conversion of plasminogen (zymogen) into plasmin, a serine protease with broad substrate specificity. The *tPA* gene is localized to chromosome 8p12 in humans and chromosome 8A2 in mice. tPA activity is regulated via inactivation by its inhibitor PAI-1. Modulation of the extracellular matrix may be related to hippocampal neural plasticity, such as learning and memory. Plasmin can degrade fibrin, factor X and a variety of extracellular matrix proteins (►extracellular matrix (ECM) proteins) such as ►laminin, vitronectin and DSD-1-PG/phosphocan. tPA and plasmin are well known proteases that are involved in the blood fibrinolytic system.

#### *Neuropsin (KLK8)*

Neuropsin is a secretory serine protease, and the human *neuropsin* gene is encoded in a gene cluster of the big kallikrein-like multigene family (19q13.3-4; *KLK* genes). The precursor form of neuropsin (proneuropsin) has a presumed signal peptide sequence and is released extracellularly via both regulated and constitutional pathways in the mouse. This non-active precursor is stored in the extracellular spaces, probably mostly in the ►synaptic cleft. ►Long-Term Potentiation (LTP)-associated synaptic excitation results in the activation of proneuropsin by an as yet unknown endoprotease.

#### *Protease M/neurosin/zyme (KLK6)*

Similar to neuropsin, protease M/neurosin/zyme is encoded in the same gene cluster as the kallikrein-like multigene (19q13.3-4; *KLK* genes). This enzyme has potential functions in the CNS, such as remodeling in brain injury. The enzymatic activity of KLK6 appears to be regulated by an autoactivation/autoinactivation mechanism. Mature KLK6 displays a trypsin-like activity and efficiently cleaves fibrinogen, collagen types I and IV, and alpha-synuclein in vitro.

#### *Neurotrypsin*

Neurotrypsin is a secreted protein of 875 amino acids, belonging to the subfamily of trypsin-like serine proteases. The neurotrypsin gene is localized to chromosome 4q25-q26 in humans. The enzymatic character is still unknown.

#### *Reelin*

Reelin was found as an extracellular matrix protein that relates to neuronal migration during development. Reelin is essential for proper cytoarchitectonic organization during CNS development. The *reeler* mutant mouse, with spontaneous Reelin null mutations, has defects in the cerebral cortex, hippocampus, cerebellum, and brainstem nuclei and gives rise to functional deficits, such as an ataxic gait and trembling. According to *in vitro* studies, Reelin has proteolytic activity that can degrade extracellular matrix molecules such as ►fibronectin and laminin. The effect of Reelin on neuronal migration may be mediated by its ability to modulate cell adhesion through its proteolytic activity.

### *MMP2, 3, 9 and 24*

Among a big family consisting of at least 25 MMPs, only 4 members, MMP2, 3, 9 and 24 are so far presumed to be involved in neural plasticity. Proteolysis of extracellular matrix molecules by MMPs may perform a permissive or inductive role in fiber remodeling and synaptogenesis initiated by deafferentation. MMP2 can degrade collagen type IV, the major structural component of basement membranes. MMP3 has a rather wide spectrum of substrate specificities and can degrade collagens (II, IV and IX), gelatin, aggrecan, perlecan, decorin, laminin, elastin, casein, osteonectin, ovostatin, entactin, plasminogen, myelin basic protein and IL-1beta, and can also activate precursors of MMP3 and 9. MMP9 can degrade gelatin, a denatured collagen. As for physiological substrates, MMP9 can degrade elastin, α1-proteinase inhibitor, tissue factor pathway inhibitor (TFPI), myelin basic protein, CTAP-III, PF-4, gro-α and activational processing of IL-8. MMP24 is a membrane-type MMP and can cleave fibronectin, but not collagen type I nor laminin.

## Higher Level Processes

Transcription, translation, and secretion.

## Process Regulation

Major regulation occurs in transcription, translation or secretion. Processing of tPA is regulated in a synaptic activity-dependent manner at the transcription level. Neuropsin is secreted as a precursor form with a constitutional and regulatory pathway. The proneuropsin is activated by synaptic depolarization. It is also known that the activity of extracellular matrix proteases is regulated by protease inhibitors such as serpins and TIMPs. A membrane type MMP (MMP24) is down-regulated by shedding by a furin-type convertase.

## Function

Some extracellular matrix proteases are involved in neuronal plasticity, neuronal degeneration and regeneration.

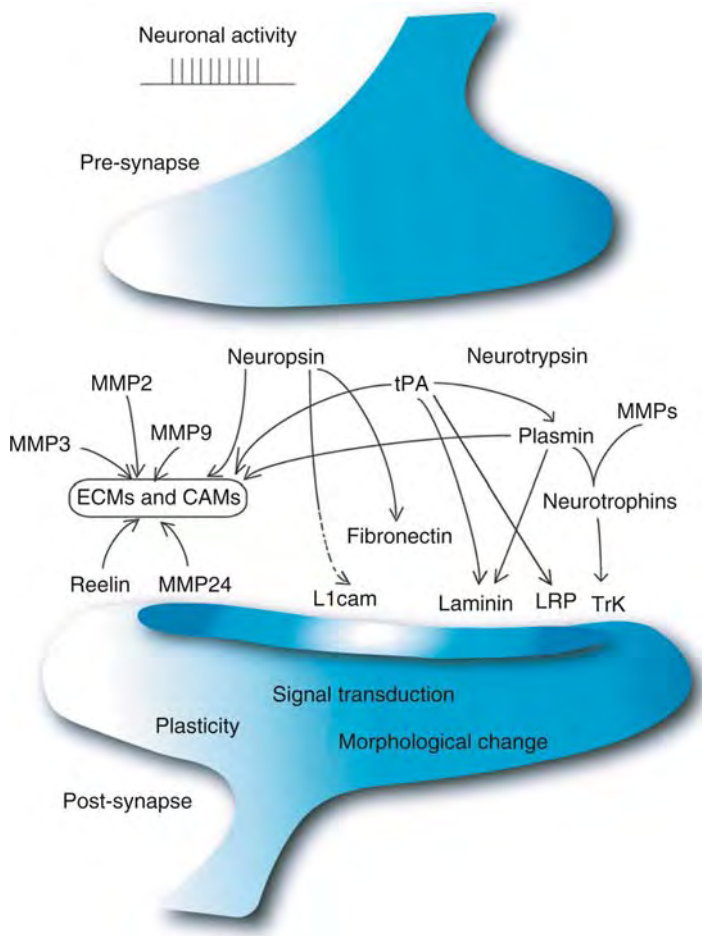
A number of extracellular proteases are known to be involved in neural plasticity in development. Adaptive synaptic change controlling complex neuronal circuits might be a basis for the neural plasticity. Recently, it has been reported that extracellular proteases and their inhibitors play a crucial role in the development and maintenance of dynamic synaptic connections. Indeed, some serine- and metalloproteases contribute to cell migration, axonal outgrowth and elongation, and elimination of overproduced synapses during ontogenesis.

A mechanical change in synaptic morphology is hypothesized for the acquisition, consolidation and retention of long-lasting memory [1]. Even in adults, they play roles in the processing of neuroactive proteins, and synaptic plasticity such as learning and memory processes. As meshwork matrix proteins and adhesion molecules that fill the synaptic cleft might form a solid connection of pre- and post-synaptic structures, the synapses may not be so freely altered in the non-stimulated or even in the excited state of the neurons. Therefore, some special mechanisms to regulate the synaptic morphology and/or synaptic movement in terms of plasticity might be necessary. As a plausible mechanism for the structural plasticity, a proteolysis system of extracellular matrix proteins was hypothesized [2]. Perhaps, an extracellular proteolysis system permits morphological changes in synapses, such as perforation, enlargement, angular change and synaptic movement in the contacting active sites, and, thereby, the synaptic machinery may control the acquisition and stabilization of learning (Fig. 1).

Some extracellular proteases are involved in the regulation of neuronal survival and death, probably through the degradation of extracellular matrix proteins (ex. tPA, neuropsin).

### *tPA and Plasmin*

tPA inhibitors can block the function of tPA in late phase-long term potentiation (►late-phase LTP (L-LTP)). Consistently, the *tPA* gene-knockout mouse shows selective interference of the L-LTP in the hippocampus [3]. tPA contributes to L-LTP with the activation of cAMP-dependent protein kinase and the cleavage of ►NMDA receptors. Zhuo et al. [4] have demonstrated that the binding of tPA to its cell surface receptor, the ►low-density lipoprotein receptor-related protein (LRP), activates PKA, which plays a key role in L-LTP. More interestingly, tPA, by activating the extracellular protease plasmin, converts the precursor proBDNF to the mature ►brain-derived neurotrophic factor (BDNF), and such a conversion is critical for L-LTP expression in the mouse hippocampus [5]. The tPA-dependent proteolysis of the extracellular matrix could intensify learning and memory behaviors, because increased proteolytic activity of tPA showed enhanced synaptic plasticity, as examined by magnified LTP and improved performance in spatial learning. Recently, Mataga et al. [6] reported that tPA has a permissive role for functional ocular dominance plasticity downstream of the excitatory-inhibitory balance that triggers it. In addition, tPA triggers experience-dependent ►spine loss. Thus, physiological plasticity in the visual cortex may gradually induce morphological refinements through the tPA-plasmin system. tPA is highly expressed not only in the hippocampus but also in the amygdala. Although the role of tPA in the hippocampus has been well studied, its role in the amygdala has not often been addressed. A group demonstrated that tPA promotes stress-induced neuronal remodeling in this region, and that tPA is critical for the development of anxiety-like behavior following stress.



**Extracellular Protease. Figure 1** Schematic representation of synaptic extracellular proteases.

### *Neuropsin*

Neuropsin is a secreted serine protease and is expressed in the hippocampus and amygdala. Neuropsin mRNA is expressed with high density in the pyramidal or magnocellular neurons of the hippocampal CA1-3 subfields, lateral amygdaloid and basolateral amygdaloid nucleus and at a very low density in the entorhinal cortex, medial septal and Meynert's nucleus. Therefore, it is conceivable that neuropsin is implicated in the modulation of neuronal function and plasticity. Indeed, the activation of neuropsin induced the cleavage of fibronectin and ►L1cam. Both fibronectin and L1cam are involved in the modulation of synaptic plasticity. The application of recombinant neuropsin significantly promoted ►early-phase LTP (E-LTP) induction and the anti-neuropsin antibody reduced potentiation. Therefore, neuropsin plays an important role in the modulation of LTP, especially in E-LTP. Further, activational processing of stored-zymogen occurs extracellularly by removing only four amino acids. This process indicates stringent regulation of plasticity in the synaptic machinery. These data suggest that neuropsin plays an important role in synaptic function through modifying extracellular environments [7]. Interestingly, it was reported that there are hominoid-specific isoforms derived from RNA splicing, neuropsin type II and its possible involvement in the brightness of the hominoid.

### *Neurotrypsin*

The most prominent expression of neurotrypsin is found in the cerebral cortex, the hippocampus and the amygdala. These structures are involved in the processing and storage of learned behaviors and memories. Using immuno-electronmicroscopy, neurotrypsin was localized in the presynaptic membrane and the presynaptic active zone of both excitatory and inhibitory synapses. Neurotrypsin is regarded as a candidate gene in synapse maturation and neural plasticity.

### *Reelin*

Reelin is essential for proper cytoarchitectonic organization during CNS development. Mutations of the *reelin*

gene in the mouse disrupt neuronal migration in several brain regions and give rise to functional deficits, such as ataxic gait and trembling. Thus, reelin is thought to regulate cell–cell interactions critical for cell positioning in the brain. Its function in the adult brain is far less well understood, but altered brain and blood reelin levels have been reported in some psychiatric disorders. An involvement of the reelin signaling pathway in neurodegeneration has been suggested.

### *MMP2, 3, 9 and 24*

MMPs constitute a large family of extracellular enzymes, which function to remodel the pericellular environment, primarily through the cleavage of extracellular matrix proteins. The balance between MMPs and their inhibitors [tissue inhibitors of metalloproteinases (TIMPs)] in the pericellular environment determines the significant proteolytic events in tissue remodeling. Particularly, experimental evidence has shown that MMP2 and 9 have potential functions of plasticity in the CNS. Remodeling the nerve and neuromuscular junctions accompanied by nerve crush or axotomy induces the activation of MMP2 and 9. MMP-9-blocking antibody affects granular cell axonal outgrowth and migration in the developing cerebellum. MMP9 is known to be related to process outgrowth of oligodendroglia. Nerve growth factor, laminin or retinoic acid, which are strong inducers of axonal outgrowth enhanced expression of MMP2, 3 and 9 in dorsal root ganglion cells. MMP24, a nongelatinase-type isoform, is predominantly expressed in differentiated neurons and regulates axonal growth.

## Pathology

tPA causes excitotoxic neuronal death, probably through the degradation of laminin. Laminins are extracellular matrix proteins that participate in neuronal development, survival and regeneration. tPA-deficient mice have been demonstrated to be resistant to excitotoxin-induced neuronal degeneration in the hippocampus and have an elevated threshold for seizure [8,9], indicating that the degradation of extracellular matrix, laminin, by the PA-plasmin system is a critical event in excitotoxic neuronal death. Laminins appear to be important components of the extracellular matrix in the CNS, and are critical for neuronal survival, as the loss of the laminin foundation can predispose neurons to excitotoxic death.

Neuropsin appears to be involved in nerve injury, because its mRNA in oligodendrocytes is increased after kainite injection in the central nervous system or knife cut injury of the optic nerve. Neuropsin is involved in the demyelination process accompanying injury. Of particular interest is the possible involvement of kallikreins in the pathogenesis of ►Alzheimer's disease (AD). Protease M/neurosin/zyme mRNA is down-regulated, while neuropsin mRNA is up-regulated in the hippocampus of Alzheimer's disease patients. MMPs are probably associated with Alzheimer's disease. Some data represented that MMPs are involved in the cleavage of ►amyloid precursor protein due to their α-secretase-like activity. MMP-9-deficient mice displayed delayed granular precursors and reduced programmed cell death. MMP9 is also related to the disruption of the blood brain barrier initiated by the intense neuronal and glial depolarization during stroke, head trauma and migraine.

Four-base pair deletion in the neurotrypsin gene was associated with autosomal recessive nonsyndromic mental retardation (MR). The 4bp deletion is most likely a null allele, as it is predicted to result in a shortened protein lacking the catalytic domain. These findings, therefore, indicate neurotrypsin as the first gene to be identified as the cause of a nonsyndromic autosomal recessive form of MR [10].

# Extracellular Proteinase

►Synaptogenesis

# Extracellular Recording

Uwe Windhorst
Göttingen, Germany

## Definition

Assessment of the electrical activity of nerve, glial and muscle cells by means of ►electrodes positioned in the extracellular vicinity of the cells.

## Purpose

Assessment of the electrical activity of nerve, glial and muscle cells in research and clinical settings, for analyzing the bioelectrical properties and function of such cells in various conditions and contexts.

## Principles

Changes in local transmembrane potentials ►membrance potential-basics reflect intra- and extracellular currents, which can be picked up by appropriately positioned electrodes, amplified and processed by means of electronic equipment in various ways. For example, when at an instant of time an ►action potential occurs in a nerve or muscle fiber, the membrane potential is reversed from negative interior to positive interior over a small area of membrane, whose extent depends linearly on ►conduction velocity. These local changes in intra- and extracellular potentials lead to potential differences with other non-excited membrane areas both on the inner and outer membrane sides. The differences, in turn, induce intra- and extracellular current flows along the fiber. Portions of the extracellular flow can be picked up by a pair of nearby electrodes (►bipolar recording) or a single nearby electrode with a reference electrode placed far away (►mono- or unipolar recording) [1].

With modifications, these principles apply to recordings made under the following circumstances:

- *Recordings from intact nerve trunks* (►neurograms) or *muscles* (►electromyograms). Such recordings almost always yield ►interference patterns of the superimposed activities of many cells (units), thus yielding ►multi-unit activity, and unless that is the objective, recording of ►single-unit activity requires specific recording and data processing techniques to isolate the activity of individual units. In many applications, compound (summed) multi-unit activity is recorded from these multi-stranded structures in response to electrical, magnetic or mechanical or other stimulation, which yields ►evoked potentials. Such investigations are frequent in neurology to determine whether neuronal pathways are interrupted or compound conduction velocities are normal or reduced. Such recordings can be acute or chronic, in the latter case by means of chronically implanted nerve electrodes (see below).
- *Recordings from filaments* in peripheral nerves, spinal roots or central tracts split down to thin filaments in acute animal preparations and humans. Again, such filaments often contain several active fibers, so that the recording consists of an *interference pattern* of superimposed action potential trains from several fibers (multi-unit activity).
- *Recordings from individual cells* or *groups of cells* in the peripheral or central nervous system, and muscles, by means of microelectrodes. Such recordings may yield single-unit activity from individual cells, or compound activity of pools of neurons (►field potentials) elicited by short electrical or magnetic or other stimulation of their axons or synaptic inputs.

## Electrodes

Depending on the purpose, extracellular electrode forms and recording methods show a large variability (e.g., [1]).

*Wire electrodes*. Nerves or filaments may be positioned on fairly rigid wire electrodes, or flexible wires may be inserted into nervous tissues, nerves, spinal roots or muscles.

*Suction electrodes*. It is often not technically feasible to mount long filaments on rigid wire electrodes, for instance when nerve or spinal root stumps are short. Using negative pressure, these stumps can then be sucked into a glass pipette or other fine tube filled with an electrolyte to make electrical contact [2]. With the suction electrode, extracellular recordings can easily be obtained from very small hearts (e.g., of insects), intestinal nerves and neurons, and muscles can be stimulated by an electrical pulse to the neurons innervating them. It is also possible to record from moving tissue using a plastic tube instead of glass.

*Chronically implanted nerve electrodes*. A number of electrode systems have been developed, which can be implanted chronically in animals or humans. They can be used to record from, electrically stimulate and/or pharmacologically modulate various nervous structures, ranging from peripheral nerves to spinal roots, central nervous tracts and nuclei. Among these systems are nerve cuffs, longitudinally implanted intrafascicular

electrodes (LIFEs) and wires implanted in spinal roots and/or tracts. Arrays of wires are now routinely being implanted into central structures to record simultaneously from several single neurons ([1,3]; also below).

*Microelectrodes*. ►Single-unit recordings have been routinely performed with fine-tip microelectrodes of sufficiently high resistance and low ►noise, which are made of several types of metal or carbon-fiber electrodes or glass micropipettes filled with electrolytes. Microelectrodes of different sorts can be adapted to various uses, and can be combined into *multi-electrode arrays*. They can be used for several purposes, e.g., to record from many different neurons simultaneously or from a neuron while drugs are simultaneously applied nearby. *Metal electrodes* are produced from stainless steel, platinum or iridium and coated, except for the tip, with various insulating materials. They have the advantages of stability and flexibility, low noise and sampling bias. They lend themselves particularly well to recordings in chronic preparations, for example from the monkey cortex, which must be reached by driving the electrode through the intact dura mater, or from individual fibers or small groups of fibers in human nerves (►microneurography), which must be reached by driving the electrode through the skin and deeper tissues. Metal electrodes may be combined with micropipettes used for iontophoretic application (►micro-iontophoresis) or ►pressure ejection of drugs. *Carbon-fiber electrodes* have the advantages of low impedance, integration into multi-barrel arrays with some of the barrels devoted to local iontophoresis and some (those containing a carbon fiber) to recording, marking of the extracellular recording site, and scanning the chemical environment of the cell via ►voltammetry [1].

## Multi-Electrode Recordings

Essential operations of the nervous system are executed by the interactions of many neurons, i.e., at the level of neuronal networks. To gain a deeper insight into these cooperative interactions requires the simultaneous recording from large, statistically representative samples of the constituent neurons. Many attempts at such multiple single-unit recordings have been made, using various configurations with fixed electrode arrays or with sets of independently movable wire or fiber electrodes [4,5]. Newer developments include implantable electrode arrays for ►multi-unit recordings in behaving animals, such as the tetrode technology and the micro-machined silicon-based electrode arrays.

*Tetrode technology*. Instead of using a single sharp-tip electrode of high impedance, the use of four spaced wires (tetrodes) increases the yield of units and enables low-impedance recording, which diminishes the risk of movement-induced artifacts in naturally moving animals [6]. Lightweight, implantable assemblies of independently movable tetrodes, whose *in situ* positions can be determined by ►magnetic resonance imaging (MRI), are available for recording of neuronal ensembles in behaving animals [7].

*Micro-machined silicon-based electrode arrays* with multiple recording sites are smaller than tetrodes and cause less tissue damage. The geometrically precise distribution of recording sites on multiple shanks allows for the recording of as many as a hundred well-separated neurons, and the determination of the spatial relationships of the isolated single neurons [8].

## Marking of Electrode Tracks

In many studies, it is important to be able to correlate neurophysiological recordings with neuroanatomy, i.e., to localize the neurons whose activities have been recorded. This problem is nontrivial, especially in chronic preparations where multiple electrode penetrations are made over many weeks or months. Various methods have been used to mark electrode tracks. *Electrolytic lesions* are the most common way of marking an electrode track, either at several places along the way or at the end. To make these lesions, small constant currents (5–10 mA) need to be applied for several seconds, say 20 s. These lesions can be seen in unstained histological sections, even after several months when the tissue is stained for markers of glial reactions such as cytochrome oxidase. On the other hand, lesions can cause extensive tissue damage and are often difficult to separate and identify in closely spaced multiple tracks. Stainless steel electrodes are particularly useful for marking the electrode tip position by depositing iron. The deposit is made visible as a Prussian blue spot by perfusing the animal with potassium ferrocyanide at the end of the experiment. Other methods involve stains such as thionin (Nissl stain), cytochrome oxidase and immunological staining using an antibody against glial fibrillary acidic protein [1].

## Attempts at Assessing Intracellular Events with Extracellular Electrodes

As ►intracellular recording with microelectrodes may be difficult or impossible, various methods have been used to assess transmembrane potentials with extracellular electrodes. One method of recording transmembrane potentials from elongated structures such as axons is the *sucrose gap technique* [1]. A second example is the *estimation of* ►*post-synaptic potentials* elicited by spike trains. Since intracellular recordings are difficult to achieve in freely moving animals and in humans (at least under normal circumstances), methods have been developed to indirectly assess ►excitatory postsynaptic potentials

E

(EPSPs) and ►inhibitory postsynaptic potentials (IPSPs) from extracellular recordings. The idea is that in a discharging neuron, the probability of postsynaptic discharge is in part due to membrane potential changes such as EPSPs and IPSPs. That is, an EPSP will transiently increase the firing probability and an IPSP will decrease it. However, the precise relationship between firing probabilities and potential changes is not straightforward because of the nonlinearity of the ►encoder transforming potential changes into discharge [1].

## Advantages and Disadvantages

### Advantages

In general, extracellular recording poses fewer problems than does intracellular recording. For single-unit recording, therefore, the selection of the microelectrode is not that critical. Moreover, the possibility of combining various types of electrodes into arrays allows for the simultaneous study of several questions. Thus, extracellular recording can be used for the following purposes.

*Neuron characterization and identification.* One goal of extracellular recording is to identify and characterize neurons. In this context, several parameters are of use [1]:

- *Location*. In invertebrate ganglia, individual neurons can be reproducibly identified from one animal to the next. In the *in situ* vertebrate CNS, this is not possible for individual cells, but certain classes of cells, such as the pyramidal cells of the cortex, can often be identified with the help of additional criteria such as their responsiveness to the electrical stimulation of particular fiber bundles (such as the cerebral peduncles in the case of pyramidal cells) or the depth of the electrode tip.
- *Response profiles.* The major impact of extracellular recording has been the description of the discharge patterns of neurons as they relate to sensory inputs and motor acts. This work has generated most of the presently available knowledge about the signal traffic through sensory-motor and other systems.
- *Pharmacological sensitivity.* Recording electrodes can be combined with micropipettes for microiontophoresis or pressure ejection of drugs, which enables the determination of the recorded neuron's pharmacological characteristics, or to simply make it discharge.

*Functional connections*. Extracellular recording can be used to infer functional connections between neurons. This pertains to both inputs and outputs of a neuron. The afferent connections of a neuron can be studied in several ways [1]:

- *Stimulation of afferent pathways*. One very common method is to electrically, magnetically or otherwise stimulate afferent pathways (e.g., peripheral nerves or central tracts or nuclei) and record from the postsynaptic neuron. The latencies of postsynaptic discharge may give some indication of the number of synapses interposed between the stimulated and the responding neurons.
- ►*Cross-correlation of the discharges of presynaptic and postsynaptic cells*. Another way is to use two (or more) extracellular electrodes to simultaneously record from presynaptic and postsynaptic neurons. Using cross-correlation techniques, connections between the neurons can be indirectly inferred. This method requires that all recorded neurons produce discharges at rather modest discharge rates. If they do not do so on their own, discharges can be evoked by iontophoretic application of excitatory substances, such as excitatory amino acids.

The *efferent projection* of a cell can be studied by electrically stimulating a cell's axon in some anatomical structure and recording the evoked (►antidromically conducted) action potential from the soma. The evoked action potentials should (i) have constant latencies, (ii) follow repetitive stimuli at high rate, and (iii) collide with ►orthodromic action potentials. Combined with distance measurements, this method may yield estimates of the cell's conduction velocity.

*Operation of neuronal networks*. Recordings by means of multi-electrode arrangements enable the study of cooperative interactions among large ensembles of neurons, even in behaving animals.

### Disadvantages

*Tissue damage* inflicted by electrodes inserted into nervous tissue is a serious limitation of any electrode or electrode arrangement and should be minimized as much as possible by appropriate design and configuration.

*Sampling bias*. Despite its relative ease and the importance of the results it provides, extracellular recordings pose certain problems. One is the *sampling problem.* Since large neurons produce more current than small ones, the larger the cells the easier it is for extracellular electrodes to pick up the currents produced by them. This leads to a sampling bias that favors bigger cells at the expense of smaller ones. In addition, unless there is a way of activating all cells, only spontaneously active neurons are sampled. Another factor may be the presence, type and dose of the anesthetic employed, which can be expected to influence the number and identity of spontaneously responsive neurons. These factors can result in an incorrect estimate of the proportions of different kinds of cells in a sample. This is particularly disturbing when their estimation is one of the motives for performing the study.

*Absence of sub-threshold intracellular events*. Extracellular recording yields much less information about signal processing within a cell than does intracellular

recording. For instance, slower membrane potential changes and postsynaptic potentials are not seen, and can only be estimated using very indirect statistical methods [1].

## Extraocular Motor Neurons

Stephen M. Highstein
Department of Otolaryngology, Anatomy and Neurobiology, Washington University Medical School, St. Louis, MO, USA

### Definition

Extraocular motor neurons (EOMs) innervate the muscles that move the eyes. There are six extraocular muscles inserted upon the eyeball bilaterally, and thus there are six subgroups of extraocular motor neurons bilaterally. Four subgroups reside in the midbrain oculomotor or third nucleus, namely the superior, medial, and inferior recti, and the inferior oblique. The superior oblique motor neurons reside in the midbrain trochlear or fourth nucleus, and the abducens or lateral rectus motor neurons are located within the abducens or sixth nucleus at the ponto-medullary junction. Extraocular motor neurons of the superior rectus and superior

oblique are contralateral to the muscles they innervate; the remaining four subgroups are ipsilateral.

►Internuclear neurons (INTs) are a group of neurons resident largely within the rostral half of the abducens nucleus. INTs send their axons across the midline at the level of their cell bodies to travel in the contralateral median longitudinal fasciculus (MLF). These axons terminate monosynaptically with excitatory synapses upon contralateral medial rectus motor neurons. Additionally, they emit axon collaterals that terminate within the midline intermediate, caudal and rostral nuclei of the MLF.

## Characteristics

### Quantitative Description

Motor neurons and internuclear neurons fire spontaneously when the eyes are at rest, and discharge with higher or lower frequency during eye movements. Their discharge frequency controls the length and tension of the extra ocular muscles, which translates into a rate-eye position sensitivity constant or "k" and a rate-velocity constant or "r." While k can be described as a linear function of eye position in the orbit versus firing frequency, r can only be described as a linear function for small eye movements. For eye movements larger than say 5°–7°, motor neuronal firing does not add an equal increment of firing increase for each increment of increase in the size of the eye movement. Thus, as far as eye velocity is concerned, extraocular motor neurons are usually firing in a non-linear range. Even though the neuronal firing rate that causes muscle fusion frequency is around 400 impulses/s, higher frequency bursts of up to 1,000 Hz serve to reach fusion more rapidly than slower bursts, translating into faster eye movements.

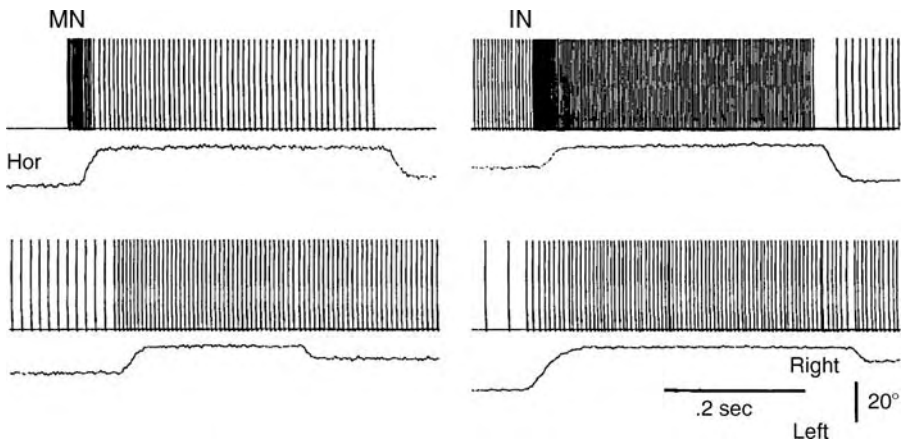
Figure 1 illustrates the firing properties of abducens motor neurons and internuclear neurons for horizontal eye movements. The tonic rate of both types of cell increases as the eye position deviates ipsilaterally. These neurons also have spontaneous firing activity when the eyes are at rest, and discharge with higher or lower frequency during eye movements.

Figure 2 a and b plots the relationships of tonic firing rate to eye position for motor and internuclear neurons, respectively, while C, D illustrates examples for populations of such neurons. Rate-position slopes of internuclear neurons are generally steeper than those of their motor neuronal counterparts, i.e. the sensitivity of internuclear neurons to static eye position is greater than that of motor neurons. Both cell types burst for rapid eye movements (saccades or quick phase of nystagmus) in their on-directions, and pause for such movements in their off directions. The greater sensitivity to both eye position and eye velocity of internuclear neurons might be due in part to the smaller size of the somata of these cells when compared to motor neurons. However, causality has yet to be strongly established [1].

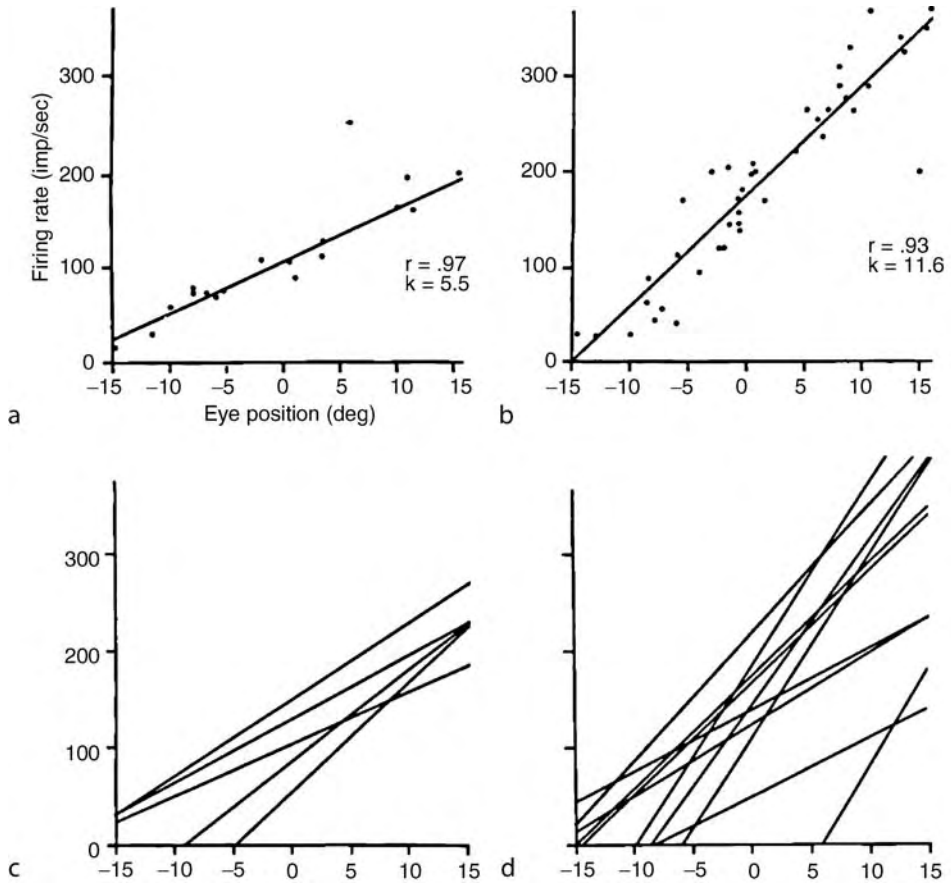
### Lower Level Components

Figures 3 and 4 illustrate the morphology of abducens motor neurons and internuclear neurons.

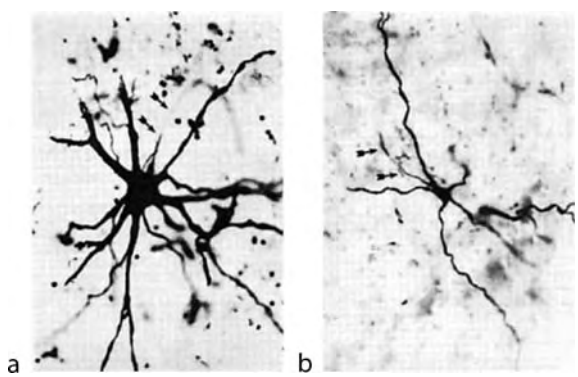
Figure 3 focuses on the somata and proximal dendrites of a typical motor (A) and internuclear (B) neuron. Generally, the internuclear cells are smaller with less complex dendritic trees. However, as illustrated in Figs. 3 and 4, internuclear neuronal dendrites of INTs are thicker than those of motor neurons of similar somatic size, and are generally straighter, and less highly branched than their motor neuronal counterparts [2].



**Extraocular Motor Neurons. Figure 1** Firing patterns of two motor neurons (MN left) and two internuclear neurons (IN right). The top two neurons had a high saccadic eye velocity sensitivity, while the lower cells had a low sensitivity (modified from [1]).



**Extraocular Motor Neurons. Figure 2** Eye position sensitivity of motor neurons (a, c) and internuclear neurons (b, d). The plots (a, b) illustrate the firing rate and eye position relationship for a motor and internuclear neuron, respectively. Eye positions ipsilateral to the neuronal somata are positive. The correlation coefficient ® of the linear regression line and the slope of that line (k) in spikes/degree are indicated. (c, d) are similar plots for several other motor and internuclear neurons, respectively (modified from [1]).

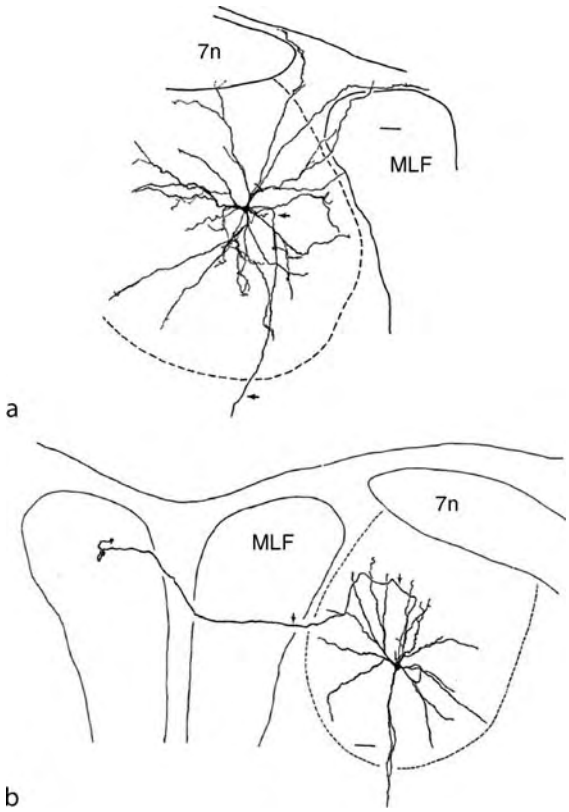


**Extraocular Motor Neurons. Figure 3** Photomicrographs of (a) an abducens motor neuron and (b) an internuclear neuron soma and proximal dendrites. The motor neuron somata measures roughly 34 × 47 μ while the internuclear neuron somata measures approximately 8 × 30 μ (modified from [2]).

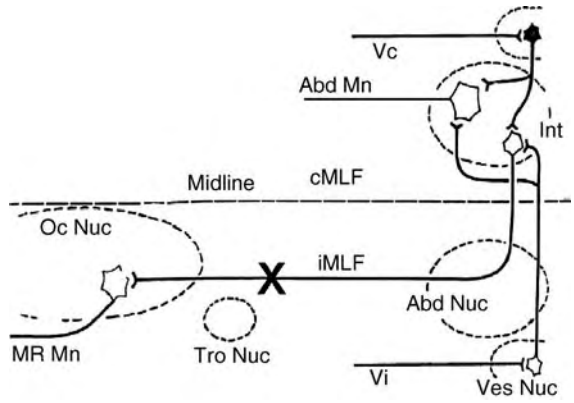
Jean Buttner-Ennever [3] pioneered studies on groups of small motor neurons that surround the main nuclei. The C-subgroup of the medial rectus is a case in point. These neurons have been shown to be more involved in fixation and slow eye movements than in rapid eye movements such as saccades. Research on the functional roles of these small EOMs is ongoing.

## Pathology

For many years it was thought that the motor nuclei within the brainstem contained only motor neurons whose axons terminated in muscle causing its contraction. Thus, it was surprising when Graybiel and Hartweig [4] demonstrated with anatomical techniques, that a sub-population of abducens or lateral rectus motor neurons had axons that crossed the midline to terminate within the contralateral oculomotor or third nucleus. Subsequently Highstein and Baker [5]



**Extraocular Motor Neurons. Figure 4** Coronal reconstruction of an abducens motor neuron (a) and an internuclear neuron (b). Arrows indicate axons. Neurons paired on the basis of soma shape. *7n*, facial nerve; *MLF*, medial longitudinal fasciculus. Scale; 100 μm (modified from [2]).



**Extraocular Motor Neurons. Figure 5** Schematic of the organization of abducens motor and internuclear neurons. Axons of Ints cross the midline to travel within the MLF and ultimately terminate monosynaptically upon contralateral medial rectus motor neurons (MR Mn). Filled neuronal somata have an inhibitory synaptic sign, and open somata terminate with excitation upon their targets. Vc and Vi, contralateral and ipsilateral VIIIth nerves, respectively. *Abd Mn*, abducens motor neuron; *c and iMLF*, contralateral and ipsilateral median longitudinal fasciculi, respectively; *Ves Nuc*, vestibular nuclei; *Abd nuc*, abducens nuclei; *Tro Nuc*, trochlear nuclei; *Oc Nuc*, oculomotor nuclei. X indicates the site of a putative MLF lesion.

demonstrated that these neurons carried the ascending commands for conjugate eye movements to the opposite medial rectus extraocular motor neurons (Fig. 5).

A conjugate eye movement requires the co-contraction or co-relaxation of the ipsilateral lateral rectus and the contralateral medial rectus extraocular muscles. These neurons that link the lateral and medial recti were therefore named internuclear neurons. Interruption of their axons causes a well-defined syndrome called ▶internuclear ophthalmoplegia. Patients affected by this syndrome have dysconjugate eye movements upon lateral gaze. Namely, with a left-sided syndrome, when attempting to look to the right the left eye does not cross the midline due to a failure of the medial rectus muscle to contract. The X in Fig. 5 indicates a lesion in the left MLF track. Rightward movement of the left eye is normally due to contraction of the left medial rectus muscle. However, the syndrome has removed the conjugate command innervation to this muscle carried by the axons of the internuclear neurons that ascend in the medial longitudinal fasciculus opposite to the side of their cell bodies of origin.

## Extraocular Muscle

### Definition

There are six extraocular muscles which act to rotate an eye about its vertical, horizontal, and antero-posterior axes: the medial rectus, the lateral rectus, the superior rectus, the inferior rectus, the superior oblique, and the inferior oblique. A given extraocular muscle moves an eye in a specific manner. For horizontal rapid eye movements, lateral rectus (LR) moves the eye away from the nose, while medial rectus (MR) moves the eye toward the nose.

►Extraocular Motor Neurons

## Extra-retinal Signals

### Definition

Non-visual signals used by the central nervous system to encode the position of the eyes in orbit. The brain must further combine these extra-retinal signals with visual (retinal) signals to allow the position of a visual target to be encoded with respect to any non-retinal coordinate system (head, trunk, body or gravio-inertial coordinate systems) useful for the programming of goal-directed movements. The relative contribution of efferent (oculomotor-related) and afferent (proprioceptive input) information to extra-retinal signals is still debated and varies with the behavioral task.

## Extrasomal Protein Synthesis in Neurons

Jan van Minnen
Department Cell Biology & Anatomy, University of Calgary, Calgary, AB, Canada

### Synonyms

Extrasomal protein synthesis – local protein synthesis, axonal protein synthesis, dendritic protein synthesis; Soma or cell body; mRNA, transcript

### Definition

Extrasomal protein synthesis describes the ability of ►neurons to synthesize proteins in micro-domains of neurons, located outside the cell body or ►soma.

### Characteristics

#### Introduction and Overview of Extrasomal Protein Synthesis

Neurons are the most polymorphous of all cell types in the animal kingdom. The cell body, or soma, extends many fine processes, which either receive (the ►dendrites) or transmit information onto other cells (the ►axons). Typically, a neuron contains many dendrites, but only one axon. Information gathering, processing and transmission are the most important task of neurons, and tiny structures called ►synapses are central to this process. A synapse is the point of functional contact between two neurons where information is generally carried by a chemical compound, the transmitter, from the presynaptic cell to the postsynaptic target. An electrical impulse invading a presynaptic terminal invokes calcium influx, which in turn facilitates transmitter release. The diffused transmitter (e.g., glutamate, dopamine, etc.) in turn binds to its respective receptors located on the postsynaptic membrane to alter its excitability. One neuron may contain many thousands of synapses which undergo dramatic structural and functional changes in response to either neuronal activity or various extrinsic factors (such as ►neurotransmitters, trophic factors, etc.). These changes could either be short or long-term and they form the basis for all forms of learning and memory. It is generally believed that only long-term changes in synaptic structure and function require new protein synthesis, however the precise source of this protein synthesis (soma or locally) remains controversial.

During the last decade, it has become clear that the synapses are extremely complicated structures. As mentioned above, they consist of a pre and postsynaptic element, where literally thousands of different molecules interact in a coordinated fashion to transmit the electrical signals from one cell to another. Changes in the molecular composition of the network of proteins in both pre- and postsynaptic neurons will result in either strengthening or weakening of the synaptic structure and hence the underlying transmission. Since a neuron may contain thousands of synapses, how does it modulate the synaptic strength of a particular subset of synapses? A number of years ago, Frey and Morris formulated the "synaptic tagging" hypothesis, using the well established model for synaptic strengthening and weakening, long term potentiation (LTP) and long term depression (LTD), respectively. They showed that long lasting (L)-LTP induction at a subset of synapses stimulates the synthesis of new plasticity related proteins (PRPs), that subsequently could be captured at

a second set of synapses, which had received a single stimulus that normally leads early (E)-LTP. The capture of these PRPS converted the E-LTP into L-LTP. They hypothesized that the single stimulus generates a "tag" at the synapse, which captures the PRPs, that are synthesized by the neuron [1]. These experiments raised questions concerning the origin and nature of the molecules that are responsible for the synaptic tagging. Going back to earlier findings by Steward and Levy in 1982, who detected the key component of protein synthesis, ►polyribosomes, near synaptic sites [2] opened the attractive possibility that proteins could be synthesized on site – in response to synaptic activity. Furthermore, this mechanism would also spatially restrict protein synthesis within a neuron to those synapses that were stimulated, thus allowing individual synapses to regulate their efficacy and morphology in a protein synthesis-dependent manner.

It is now well established that ►mRNAs localize to (activated) synapses and that translation of these mRNAs leads to synaptic plasticity. Most studies have been conducted on dendrites, but it is becoming more and more evident that in the presynaptic (axonal) compartment protein synthesis does also occur. Here, a number of topics relating to pre- and post-synaptic protein synthesis will be described briefly. For a comprehensive description of the many aspects relating to extrasomal protein synthesis, the reader is referred to a number of recent reviews [3–5].

## Dendritic Protein Synthesis

### *mRNAs in Dendrites*

One of the first mRNAs detected in dendrites was the microtubule-associated protein 2 (MAP2) mRNA. In the years to follow, many transcripts have been added to the list, and depending upon the methods used, it is estimated that there are somewhere between 40 (using in situ hybridization) and 400 (using array and PCR-based strategies) dendritically localized mRNAs. These mRNAs include cytoskeletal proteins, enzymes, integral membrane proteins and molecules involved in protein modification and degradation. Interestingly, a number of reports have identified transcripts coding for proteins involved in local protein synthesis, such as ribosomal proteins and translation initiation factors. These data suggest that dendrites can synthesize, at least in part, molecules that are required for their own dendritic protein synthesis, but the exact mechanism by which this is accomplished remains to be determined.

The dendritic mRNA population is dependent on synaptic activity and the developmental stage of the animal. Many mRNAs, present for instance in growth cones and branch points during development may be absent in mature dendrites. Furthermore, presence or absence of mRNAs is dependent on synaptic activity. A well known example is the upregulation and translocation to hippocampal dendrites of Arc mRNA in response to receptor activation. This dependency on activity and developmental phase raises questions concerning the mechanisms that are involved in the targeting of mRNAs. A number of these mechanisms will be described in the next paragraph.

### *Targeting of Dendritic mRNAs*

Both somal and extrasomal mRNAs are synthesized in the nucleus and subsequently transported to the cytoplasm. What factors determine whether an mRNA is to be exported to extracellular domains, or retained in the cell body? It is now clear that trans-acting RNA binding proteins that primarily bind to RNA stretches in the 3′-untranslated region (UTR) of mRNA are the key players. One of the best characterized mRNA binding proteins is the ►zip code binding protein 1 (ZBP1). Studies on fibroblasts showed that ZBP1 binds to a 51-nucleotide long stretch ("zip code") in the 3′ UTR of β-actin mRNA. In neurons, ZBP1 binds β-actin mRNA in the nucleus and moves into the cytoplasm, where it represses translation. ZBP1 belongs to the heterogeneous nuclear ribonucleoprotein (hnRNP) family of proteins. Other members are hnRNP A2 and the fragile X mental retardation protein (FMRP). In the cytoplasm, the mRNA binding proteins and bound mRNAs are packaged into RNA transport granules. These granules contain in addition to mRNA, ►ribosomes and other translational components, mRNA binding proteins, motor proteins and hnRNPs (e.g., ZBP1 and FMRP) [6]. Next, the mRNA granules are transported along the microtubule network to their destinations in the dendritic compartment. Other proteins with a role in mRNA transport in neurons are Staufen 1 and Staufen 2. Staufen was first characterized in the Drosophila oocyte as an mRNA binding protein, which emphasizes that mRNA translocation to direct localized protein synthesis is a well conserved mechanism in evolution.

### *Regulation of Translation of Dendritic mRNAs*

Once the complexes of mRNA and mRNA binding proteins have reached their destination in the dendritic compartment, the mRNAs have to be released from their translational repression in a coordinate fashion so that the resultant proteins meet the need of the activated synapse. This is likely accomplished by diverse patterns of synaptic activity that stimulate distinct signaling cascades. These cascades differentially target specific mRNA binding proteins to release their mRNAs. After this, the mRNAs are translated by the dendritic protein synthesis machinery. Probably the best described mechanism underlying the regulated translation of specific mRNAs involves the cytoplasmic polyadenylation element binding protein 1 (CPEB1). CPEB1 is involved in regulating LTP and is localized in dendrites and post-synaptic densities (PSD). CPEB1 recognizes a

cis-element in the 3′ UTR of a target mRNA and forms a complex with the 5′ cap mRNA which prevents the formation of the translation initiation complex. In response to extracellular stimuli, CPEB1 is phosphorylated and recruits polyA-binding protein and elongation factor (elF) 4G. This recruitment leads to polyadenylation and translation initiation. Presently, two proteins have been identified whose (dendritic) translation is regulated by CPEB1, CamKII and tissue plasminogen activator, but the translation of other mRNAs is likely to be controlled by CPEB1.

Another well-studied repressor of mRNA translation is the fragile X mental retardation protein (FMRP). Fragile X mental retardation is caused by a complete absence of the gene, or by a mutation in the mRNA binding domains which are localized in the 3′ UTR. Fragile X patients and mouse models of the syndrome have an altered spine number and morphology that may be the cause of the mental retardation. Functionally, FMRP is involved in the establishment of metabolic glutamate-receptor (mGluR) dependent LTD. The precise mechanism of how this is accomplished is still largely unresolved, but it has been shown that FMRP represses translation of its mRNA targets, whereas upon synaptic stimulation it may support translation of the mRNAs in the FMRP complex. Surprisingly, FMRP mRNA is also present in dendrites, and FMRP is locally synthesized upon mGluR stimulation, which, as mentioned above, leads to mGluR dependent LTD.

A second mechanism by which mRNA translation in dendrites can be regulated is through stabilization of specific mRNAs. For instance, HuD, an Elav (embryonic lethal abnormal vision)-like protein binds to an AU rich segment in the 3′ UTR of GAP-43 mRNA. This leads to stabilization of the mRNA, and it was demonstrated that this mechanism is involved in the formation of spatial memory in the hippocampus.

### *Role of Dendritic Protein Synthesis*

As mentioned above, dendritic protein synthesis plays a key role in synaptic plasticity. For the generation of L-LTP, transcriptional activity is required and therefore early studies focused on the role of translational control in the soma [1]. In 1996 the Schuman laboratory showed that protein synthesis in the dendritic field alone is sufficient to potentiate synaptic transmission. These authors used a hippocampal slice preparation in which the dendritic fields had been surgically isolated from their somata. After application of brain-derived ►neurotrophic factor (BDNF) they demonstrated that the synaptic transmission was potentiated between the CA3-CA1 synapses. This potentiation was sensitive to protein synthesis inhibitors, from which the authors concluded local dendritic protein synthesis was responsible for the strengthening of the synapses [7]). A similar study, using the same slice preparation, showed that mGluR1 stimulation resulted in LTD, which required dendritic, but not somatic protein synthesis. A challenge for the future will be to determine what proteins are synthesized and how they interact to mediate the long-term changes, given the fact that the synaptic proteome contains over 1,000 different proteins. Also, these studies assume that all synaptic protein synthesis takes place in the dendritic compartment, and ignore the possibility that protein synthesis may also occur in the presynaptic terminal. As will be described below, the axonal compartments, to which these presynaptic structures belong, have also the potential to synthesize proteins.

There are only a few examples in which the dendritic synthesis of a given protein has been directly related to changes in synaptic efficacy. In 2002, the Mayford laboratory created mice that lacked the dendritic targeting element of the CAMKIIα mRNA. This resulted in an almost complete absence of the CAMKIIα transcript in the dendritic compartment, whereas somal levels of mRNA and protein were only moderately affected. However, the postsynaptic density (PSD) of these animals contained only about 20% of the CAMKIIα protein. Behaviorally, these mice showed an impaired stabilization of synaptic plasticity and memory consolidation, in that they showed a reduced performance in the Morris water maze and contextual fear conditioning. Moreover, hippocampal slice preparations from these animals showed a diminished late-phase LTP.

In summary, it is now well established that mRNA translocation and subsequent regulated dendritic protein synthesis plays a crucial role in modulating synaptic efficacy and may thus form the basis for important brain functions such as learning and memory formation.

## Axonal Protein Synthesis

There are considerable differences in the morphology and molecular make-up of the axon compared to the dendritic compartment. As there are many dendrites, a neuron possesses only one axon, the length of which in large vertebrates may exceed several meters. Considering the enormous differences in volume between cell body versus axon (a conservative calculation shows that in a 1 m long axon it's volume exceeds that of the cell body at least 300 times) and the distance separating cellular components, it almost is a miracle that the distal axon not only survives but also performs autonomous functions.

The initial idea of how to provide axons with the necessary components to maintain the axonal integrity, such as e.g., cytoskeletal proteins, was that axonal proteins are transported anterogradely to the far reaches of axons. This possibility overlooked several constraints that are imposed by the extreme morphology of axons. If the soma is responsible for the supply, the

transport rate and capacity are the limiting factors. Axon transport has a fast and slow component, and the fastest rate reported is about 40 cm per day. Microtubule-based, fast axon transport carries vesicles and vesicle-associated proteins, such as receptor proteins. However, most cytosolic proteins, including cytoskeletal proteins, are transported at much slower rates, varying between 0.1 and 4 mm per day. (for review see [8]). Thus, cytoskeletal proteins would take at least 300 days to travel 1 m. Considering the half-life of proteins (e.g., tubulin $t_{1/2} \approx 1$ week), it is hard to imagine that these proteins could reach the distal axon in sufficient quantities to be of biological significance. Indeed, studies by Nixon in 1980, using radioactive precursors, demonstrated that some cell body synthesized proteins destined for the peripheral axon are degraded in the first few millimeters of the mouse optic nerve. This means that the neuron must either spend significant energy to generate extra proteins to account for degradation during transport or it has other means to replenish proteins that are lost during transport. Moreover, as mentioned above, the volume of the axon is about 300× that of the cell body, where all the synthetic machinery is located. To supply such an excess of volume intuitively seems an almost impossible task.

An alternative mechanism to provide the distal axon with proteins was suggested Lasek and colleagues. They demonstrated that ►glia cells supply axons with proteins. However, these studies did not provide an answer to how neuronal specific proteins, such as ►neurofilaments, are supplied to the axon. Theoretically, a simple and economical way for the axon would be to synthesize some of its own proteins. Such localized protein synthesis is now a generally accepted mechanism in dendrites (see above), however for axons this mechanism was dismissed for a long time by much of the neuroscience community. Nevertheless, a small group of researchers have supported the idea of axonal protein synthesis for over 40 years (for reviews see [3,8]), and have performed groundbreaking experiments. Many of these "axonal" studies were initially carried out in two model systems, the Mauthner axon of the goldfish and the giant axon of the squid, where the large caliber axons (40–80 μm and up to 1 mm diameter, respectively) provided pure ►axoplasm for biochemical and molecular analyses. To date, with the recent advancements in sensitivity of molecular biological and biochemical techniques, axons from higher vertebrates have now become more amenable for analysis.

### mRNAs in Axons

In 1987 Capano and colleagues reported a complex, heterogeneous population of mRNAs (over 200 different transcripts) to be present in the squid giant axon. Later studies showed axonal mRNAs included those encoding neurofilament, β-actin, β-tubulin, kinesin, enolase, nuclear-encoded mitochondrial proteins, heat-shock proteins and neuropeptides (for review, see [5]). Surprisingly, among the list of axonal mRNAs are species encoding ribosomal proteins and other components of the protein synthesizing machinery, such as translation initiation factors and chaperone proteins of the endoplasmic reticulum. These findings suggest that the axon, like dendrites (see above) can synthesize components of its own protein synthesizing and trafficking machinery.

### Targeting of Axonal mRNAs

β-actin mRNA has consistently been detected in many different axonal mRNA preparations (see above). The Singer laboratory showed differential localization of actin mRNAs in cortical neurons, with β-actin extending into axons and γ-actin being restricted to the cell body. The axonal targeting mechanism of the β-actin mRNA is comparable to the dendritic targeting described above, involving ZBP and a zip code in the transcript's 3′ UTR. This zip code is absent in γ-actin mRNA. It is not clear what mechanisms may drive other neuronal mRNAs into axons, but for a number of axonal transcripts it has been demonstrated that the targeting sequence resides in the 3′UTR. For instance for Tau mRNA, which localizes to developing axonal processes, a *cis*-element resides in the 3′ UTR that is recognized by RNA binding proteins including the Elav protein HuD. In other transcripts the zip code resides in the 5′ UTR, as was shown for the κ-opioid receptor mRNAs. There appears to be no consensus sequence in the 5′ or 3′ UTRs that dictates axonal mRNA localization, but rather secondary and tertiary structure of the mRNA determines its interaction with RNA binding proteins.

The translocation of mRNAs can be differentially stimulated by external factors. The Twiss and van Minnen laboratories showed that treatment of dorsal root ganglion (DRG) cultures with nerve growth factor (NGF) or BDNF increases the transport of β-actin, vimentin and peripherin mRNA into axons, whereas the transport of the majority of the other axonally localized mRNAs was not affected by these growth factors. Imaging studies indicate that mRNAs can be transported at rates approaching that of fast anterograde transport of cell body-derived vesicular proteins, about 10 cm/day for actin mRNA. The rapid delivery of mRNAs encoding cytoskeletal proteins to distal axons could easily exceed the rate of delivery of the proteins that are synthesized in the cell body, which are moved by slow ►axonal transport velocity. Thus, translocation of mRNAs offers an attractive alternative possibility for the delivery of cytoskeletal proteins to the distal reaches of axonal compartment.

### Identification and Functions of Axonally Synthesized Proteins

Work from Koenig's group demonstrated that mature vertebrate axons contain components of the translational machinery and as, noted earlier, localized protein synthesis in mature axons was hypothesized to replenish proteins that are degraded during transport [8]. However, the actual function of this localized protein synthesis remained speculative without any means to test this hypothesis, due to the inability to isolate "pure" axonal preparation from mature nerves. As a consequence, most of our knowledge on the role of axonal protein synthesis comes from *in vitro*, developmental and regeneration studies.

An emerging concept is that locally synthesized proteins play a key role in axonal growth and support the developing axons to reach their target tissues. Studies using *in vitro* preparations of isolated axons demonstrated that local synthesis is required for chemotrophic turning and growth cone collapse, and that guidance cues induce rapid synthesis of proteins such as β-actin, cofillin, β-thymosin and RhoA in the growth cone. Also, local synthesis is required for resensitization in responding to gradients of guidance cues [9]. Extracellular stimuli that regulate this axonal synthesis include Netrin-1, semaphorin 3A (Sema3A), and BDNF. The intracellular signaling cascades that lead to translational regulation in response to these axonal guidance cues have recently been identified. Erk 1/2 and $p38^{MAPK}$ are activated by axonal guidance cues and these signals can differentially regulate axonal protein synthesis. Sema3A locally activates Erk 1/2 leading to protein synthesis dependent turning of axons, while Netrin-1 activates both Erk 1/2 and $p38^{MAPK}$ leading to protein synthesis and proteolysis-dependent turning of axons. Furthermore, the involvement of CPEB to regulate localized translation of EphA2 mRNA in commissural axons should be mentioned. These data further strengthen the notion that axons and dendrites are likely to use similar mechanisms to regulate targeting and translation of mRNAs.

In addition to support axonal growth in developing axons, local synthesis plays a key role in regeneration. Using an *in vivo* peripheral nerve injury model, it was suggested that localized protein synthesis is required for axonal regeneration. The use of a culture preparation of dissociated injury-conditioned rat dorsal root ganglion neurons, made it possible to verify the potential of axons to synthesize proteins and to address their functionality. Axons isolated from these neurons synthesize proteins in culture and their growth cones rapidly retract upon inhibition of protein synthesis. A proteomics-based analyses of proteins translated by these isolated axons showed that a large number of different proteins are synthesized locally. Presently, the list of axonally synthesized proteins includes cytoskeletal proteins, neuropeptides, integral membrane proteins, heat-shock- and other chaperone proteins, anti-oxidant proteins, metabolic proteins, nuclear-encoded mitochondrial proteins as well as proteins that have been linked to neurodegenerative disorders [5].

A surprising new role of local axonal synthesis was recently described by the Fainzilber laboratory. They showed protein synthesis at the site of an axonal injury serves as a way to signal the cell body. Following a nerve crush, a signaling complex is assembled in axons immediately proximal to the site of the injury. The formation of this complex requires synthesis of importin β1 and vimentin, after which the newly synthesized proteins assemble into a retrograde signaling complex. Vimentin is subsequently proteolyzed and the cleaved vimentin serves as a scaffold to retrogradely transport activated Erk to the cell body where it initiates a regenerative response. A comparable mechanism of localized synthesis of importin with signaling to the nucleus was reported for dendrites of hippocampal neurons after NMDA receptor stimulation. This lends further support to the notion that plasticity and injury share common mechanisms and that axons and dendrites are likely to share common molecular mechanisms of localized mRNA translation.

The fact that axons and dendrites are capable of synthesizing a sizable portion of their own proteins raises questions about the basic biology of this process. It is a mystery how axons and dendrites can target locally synthesized proteins for membrane insertion, given that ►RER and ►Golgi apparatus are not ultrastructurally visualized in these domains [10]. In spite of this, membrane targeting of receptor proteins has been demonstrated. Spencer and colleagues injected an exogenous mRNA encoding a G-protein coupled receptor into axons separated from their cell body. The injected axons translated the mRNA, inserted the newly synthesized protein into the axonal membrane, and exhibited ligand-induced depolarization. Another example for localized translation and insertion of the integral membrane protein EphA2 was provided by the Flannagan laboratory. It will however be of great interest to delineate the mechanism(s) of protein synthesis and trafficking into axonal membrane. As further understanding of axonal protein synthesis is gained, the cellular mechanisms regulating this process may provide additional targets for modulating growth and repair of the injured nervous system.

From the above studies, it can be concluded that the axonal compartments of both vertebrate and invertebrate axons have the ability to synthesize proteins. The amount of axonal protein synthesis may vary from species to species, and may depend on the size or physiological state of the axon. To generalize, in large vertebrate (Mauthner) and invertebrate (molluscan) axons, protein synthesis appears to proceed at a higher rate than in mature mammalian axons. This assumption

is based on the facts that ribosomes, mRNAs and translational machinery are readily detectable in these axons, whereas they are very scanty in adult mammalian axons. Mammalian axons however are able to invoke the ability to synthesize proteins under particular conditions, such as injury and regeneration. Understanding the mechanisms by which axons acquire the ability to recruit the synthetic machinery and translocate specific mRNAs to the axonal domain holds great promise for the future to manipulate these processes.

### Unifying Principles of Dendritic and Axonal Protein Synthesis

Both the dendritic and axonal compartments of neurons have the ability to synthesize proteins. Most emphasis in dendrites has been on how localized protein synthesis impacts on synaptic strength and learning and memory formation, whereas in axons the focus was more on the significance in development and regeneration. Yet both dendrites and axons use similar principles to target and locally translate mRNAs, use similar RNA binding proteins, translate overlapping populations of mRNAs and translation can be regulated by similar intracellular and extracellular stimuli. It appears that axonal and dendritic translation are two sides of the same coin, and that the ability to locally synthesize proteins is an inherent property of the neuron which goes back to developmental mechanisms that initially shaped the nervous system.

### Synonyms

Visual association cortex; Visual psychic cortex

### Definition

Extrastriate visual cortex refers to a large number of well-defined cortical areas and less well defined cortical zones that are located anterior to ►primary visual cortex (►area V1 or ►striate cortex) which are implicated in visual function on the basis of their physiology, cortical connections, and/or behavioral contributions to visual perception.

## Characteristics

### Extrastriate Cortical Areas

Visual cortex of primates consists of a large number of discrete cortical areas and less well defined cortical zones. Traditionally, cortical areas are defined according to a number of criteria; cyto-, myelo-, and/or chemoarchitecture, topographic organization, cortical connections, electrophysiological properties of their constituent neurons, and behavioral deficits following lesions or deactivation [1,2]. Although individual areas are generally not identified by a single criterion, most well recognized areas are defined on the basis of three or more of these criteria. Accordingly, visual cortex of macaque monkeys has been subdivided into at least 35 discrete areas distributed across the occipital, parietal, temporal, and frontal lobes (see Fig. 1). In addition, several expanses of visual cortex retain the distinction of cortical zones since they have not been well characterized, and may eventually be recognized as new cortical areas or be recognized as being part of larger cortical areas characterized by anatomical or functional heterogeneity. In Fig. 1, areas visible on the slightly exploded view of the lateral view of the cerebral hemisphere are illustrated in panel A and the full, unfolded, cortical surface is illustrated in panel B. In addition, the division of cortical areas into well recognized cortical streams and functional modules are illustrated by their color (►Color) and pattern designations (see below).

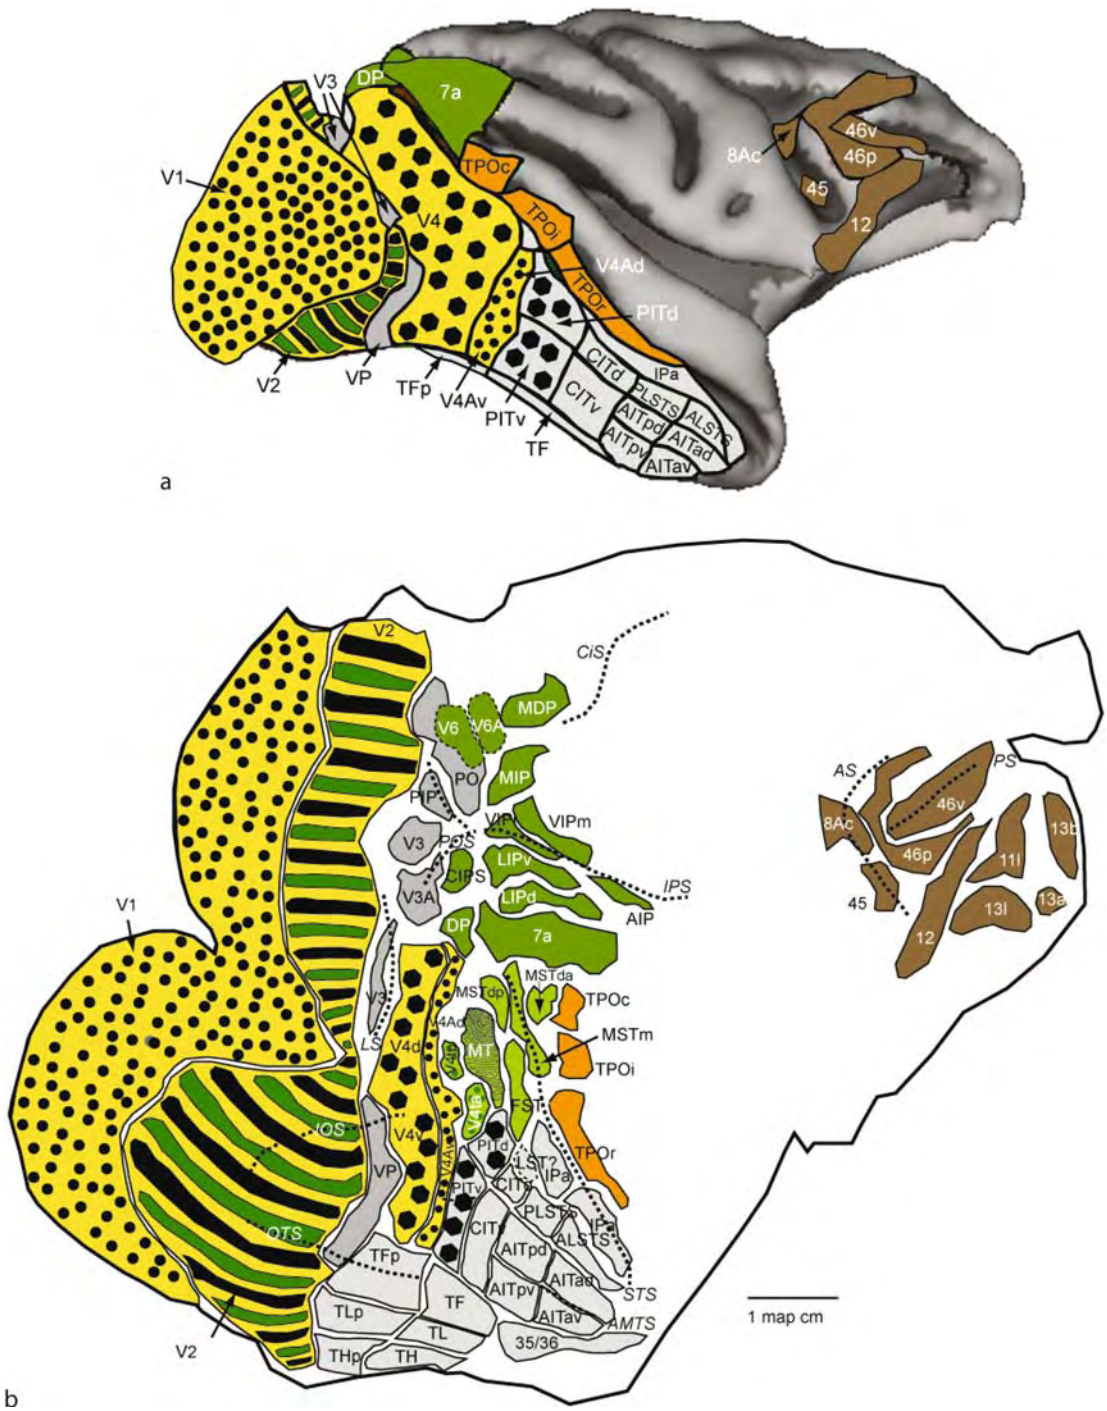
The occipital lobe contains a large number of extrastriate visual cortical areas that have been previously attributed to occipital architectonic areas 18 and 19 of Brodmann [3] or areas OA, OB, OC of von Bonin and Bailey [4]. The occipital lobe contains areas V2, V3 (V3d), VP (V3v), V3A, V4, V4Ad, V4Av, PIP, CIP, PO, V4t, and MT. A large number of extrastriate areas occupy temporal lobe cortex previously described as areas 20 and 21 of Brodmann [3] or TEO, TE, TEa/TEm of von Bonin and Bailey [4]. Currently recognized extrastriate temporal lobe areas include: PITd, PITv, CITv, CITd, AITpv, AITpd, AITav, AITad, FST, and one or more subdivisions of the anterior lateral bank of the STS (e.g. ALSTS and PLSTS). Parietal cortex contains a large number of extrastriate visual areas that participate in visual spatial analysis and visually guided eye and arm movements (►Visual space representation for action, ►Visual space representation for reaching). These parietal areas include areas LIPd, LIPv, VIPm, VIPl, AIP, MDP, MIP, V6, V6A, DP, and 7a. Frontal cortex contains several cortical areas that are implicated in various aspects of visual processing. Most posteriorly, area 8, the ►frontal eye fields, is involved in the generation of volitional ►saccadic eye movements. More anteriorly, area 46 is implicated in several aspects of visual memory, learning, and motor planning. In addition, areas 11, 12, and 13, on the orbital surface of the frontal lobe, are involved in the representation of the affective qualities of visual stimuli, which are conveyed to several visual subdivisions of the medial and lateral temporal lobe.

### Extrastriate Cortical Modules

Extrastriate cortical areas have often been described as containing discrete anatomical or functional modules. Area V2 contains the best-studied example of anatomical modules that reflect distinct physiological processes [5]. The anatomical basis for modularity in V2 was first revealed by the stripe-like pattern in tangentially sectioned tissue stained for the metabolic enzyme cytochrome oxidase. This anatomical stain reveals three parallel, stripe-like modules referred to as the cytochrome oxidase thick, pale, and interstripes (Fig. 2b). A multitude of anatomical pathway tracing studies revealed that these V2 stripes receive specific, largely parallel input from modular elements in V1; V1 cytochrome oxidase blobs project to V2 thin stripes, V1 inter-blobs project to V2 interstripes, and V1 layer 4B projects to V2 thick stripes. Similarly, these V2 modules project, in parallel, to several extrastriate areas and thus provide evidence for one type of functional streaming in visual cortex (see below). The anatomical organization and segregated inputs to these V2 functional modules are also reflected in the functional properties of their constituent neurons. Specifically, V2 thin stripes contain spatially organized maps of hue and luminance change [6] (see Fig. 2c), V2 interstripes contain spatially organized maps of contour orientation [7], and V2 thick stripes contain spatially organized maps of contour orientation and binocular disparity [7] (see Fig. 2d).

Additional evidence for the modular organization of extrastriate cortical areas comes from electrophysiological, anatomical, and functional imaging studies of area MT in owl and macaque monkeys. Area MT is a well-defined area whose neurons are almost exclusively selective for the direction of visual motion (►Visual motion processing). Early electrophysiological studies recognized the systematic order of preferred direction that changed with tangential movement of the recording microelectrode. Functional imaging in owl monkeys revealed the complete pattern of preferred direction and its relationship to orientation preference maps. Furthermore, neurons in MT are selective for binocular disparity (►Binocular vision) and it is believed that disparity, orientation, and direction are systematically mapped within MT functional modules. Finally, MT contains an additional form of modularity that appears to reflect the segregation of neurons on the basis of the degree of wide field surround suppression.

Evidence for a modular organization in area V4 has come chiefly from investigations of the clustered patterns of cortical connections linking it with well



**Extrastriate Visual Cortex. Figure 1** Visual cortical areas and zones in macaque monkey. (a) Lateral view of a partially opened macaque monkey brain illustrating the locations and sizes of 29 visual areas and zones. Cortical areas are color-coded by lobe: occipital (*yellow*), temporal (*light gray*), superior temporal (*orange*), parietal (*dark green*), frontal (*brown*) and by their associated cortical streams and modular organizations. Occipital areas without clear associations to single cortical streams are coded dark gray. Area V1 contains color-selective blobs (*black*) and interblobs (*yellow*). Area V2 contains color-selective thin stripes (*black*), motion/disparity-selective thick stripes (*green*), and orientation-selective interstripes (*yellow*). Area MT and associated areas are coded light green to reflect their association with the magnocellular-dominated cortical stream. (b) Unfolded map of macaque cortex illustrating the locations and arrangements of visual areas in occipital (*left*), parietal (*top*), temporal (*bottom*), and frontal (*right*) lobes.

(b) Cytochrome oxidase dense thin and thick stripes and pale interstripes in area V2. (c) Differential intrinsic optical image (*red/green – luminance*) indicating the color-preferring thin stripes (*dark regions*) in V2. Luminance-preferring domains in V2 thin stripes are bright. (d) Differential intrinsic optical image (*luminance* 45°: *dark regions – luminance* 135°: *bright regions*) indicating the orientation-preferring thick and interstripes in V2 that flank the thin stripes. (e) Differential intrinsic optical image (*red-green-luminance*) demonstrating color-preferring blobs in V1 and color spots in V2. (f) Differential optical image (luminance 45–135°) of orientation-preferring domains in V1 and V4.

defined modules in V2 and less well defined regions of posterior inferotemporal cortex. Following paired injections of distinguishable anterograde tracers restricted to individual V2 thin stripe and interstripe modules, labeled axon arbors were observed in largely segregated domains [8]. Unlike areas V1 and V2 that have distinctive cytochrome oxidase architecture, these large, segregated terminal fields provided clear evidence that the modular architecture observed in V2 was relayed and retained in area V4. In addition, paired distinguishable retrograde tracer injections in V4 that revealed segregated inputs from either thin or interstripes also demonstrated segregated modular domains in posterior inferotemporal cortex [9]. These anatomical experiments suggest that similar functional module types are present from V1 to intermediate levels of cortical processing in posterior inferotemporal cortex. Functional imaging studies have also demonstrated V4 cortical modules, but the precise correspondence of these modules to the thin and interstripe inputs from V2 remain to be determined. Nevertheless, V4 consists of a modular array of color-preferring (e.g. Fig. 2e) and orientation-preferring (e.g. Fig. 2f) modules somewhat similar to that observed in area V2.

A different type of modular architecture has been described for anterior inferotemporal cortex where neurons appear to be clustered by their selectivity for similar complex objects or shapes (►Visual object representation). Furthermore, adjacent "object modules" appear to represent similar, but functionally distinct complex shapes. These cortical modules, demonstrated by both standard electrophysiological recording and intrinsic optical recording techniques, may represent the highest form of functional module in the constellation of extrastriate cortical areas that subserve object recognition and perhaps visual memory.

## Extrastriate Functional Streams

It has long been recognized that extrastriate cortex of primates can be viewed as consisting of separate object recognition and spatial processing cortical streams [10] (►Visual processing streams in primates). This dichotomy was first based on behavioral observations following cortical lesions that suggested that temporal lobe areas were essential for object, "what" processing, while parietal lobe areas were essential for object, "where" processing. This basic dichotomy has received further support from electrophysiological studies of

receptive field properties (►Visual receptive fields) and anatomical studies of cortical pathways. More recently, the notion of separate "what" and "where" streams has been challenged by observations of rich interconnections between parietal and temporal lobe areas and by the demonstration of position selectivity in temporal lobe receptive fields and object form selectivity in parietal lobe neurons.

Initially, this high-level dichotomy was attributed to the parallel thalamo-cortical streams (►Geniculo-striate pathways) or their re-emergence from area V2. However, subsequent studies have recognized that these parallel inputs to V1 (parvocellular, konicellular, and magnocellular lateral geniculate nucleus, LGN) are recombined in V1 to form three new streams. First, a magnocellular-dominated stream emerges from layer 4B in area V1 to provide input to V2 thick stripes, V3, and area MT. Second, the konicellular stream is combined with elements of the magnocellular and parvocellular streams to form the color-preferring "blob" stream. Third, the parvocellular and magnocellular streams are combined to form the orientation-preferring "interblob" stream.

The blob and interblob streams of V1 project in a parallel and largely segregated manner to the cytochrome oxidase-defined thin and interstripes of V2. Although there is no doubt some crosstalk between streams via intrinsic connections within V2, these streams emerge to provide largely parallel, segregated inputs to discrete domains in V4 (Fig. 3; yellow and black domains). Furthermore, anatomical studies demonstrate that larger domains in posterior inferotemporal cortex (PITd and PITv) receive segregated inputs from these V4 compartments thus demonstrating the continuance of these parallel streams into temporal lobe "what" processing areas.

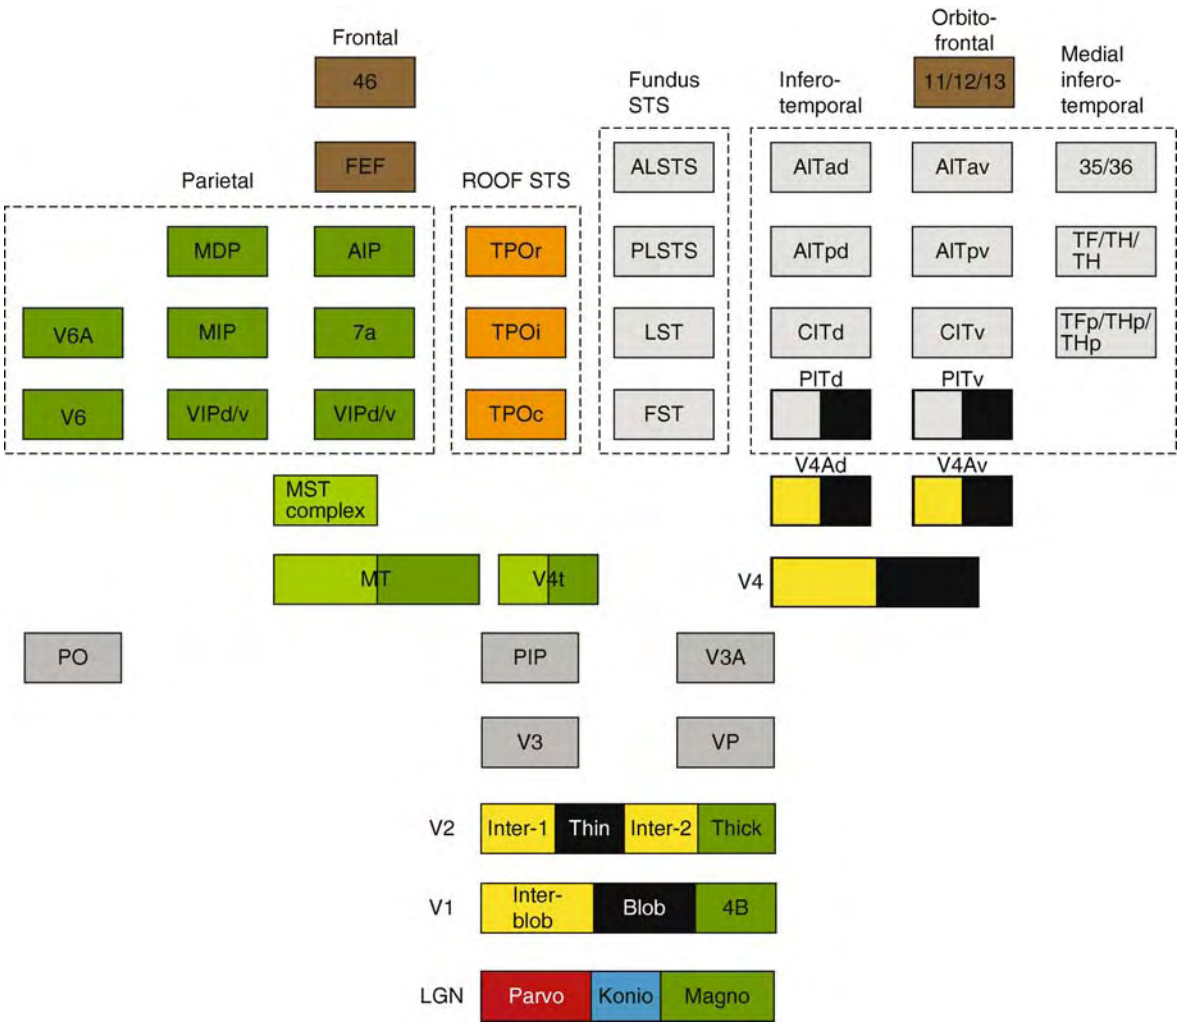
According to the earliest views of cortical streams, the motion/direction-selective stream arising from layer 4B of V1 and directed to V2 thick stripes, V3, and MT is utilized solely for the analysis of three-dimensional location necessary for the "where" stream. This narrow view of MT function has been revised by anatomical and physiological studies that demonstrated a modular organization within MT (see above) that serves to segregate neurons according to their degree of surround inhibition (local versus wide-field motion selectivity) and to segregate neurons according to their cortical projections. According to this view, neurons selective for local movement are segregated into bands in area MT that project to temporal lobe area FST, while wide-field bands project to the ►MST-complex that relays this information to several subdivisions of parietal cortex. The significance of the MT projection to FST and subsequent areas (e.g. LST) is exemplified by the observation of robust motion-defined object selectivity through many areas within the lateral bank of the STS in the temporal lobe.

A further distinction of cortical streams within parietal cortex has come from recent studies that demonstrate parallel sets of areas and cortical connections that subserve goal directed eye and arm/hand movements. According to this view, a subset of parietal areas, including areas LIPd/v are closely interconnected with frontal area 8Ac to provide spatial information necessary to guide saccadic eye movements. In contrast, a different subset of areas, culminating in area AIP are closely interconnected with hand and arm subdivisions of motor cortex and provide information necessary for object shape-guided hand and arm movements into extra-personal space (►Visual space representation for reaching).

## Hierarchical Organization

It has been a longstanding belief that the visual system is organized hierarchically such that, at its lowest level, thalamic inputs enter through primary visual cortex, V1, and that the highest levels of visual processing take place in the temporal and frontal lobes. This notion is supported by the study of receptive field properties that demonstrate local processing of a small number of visual properties in V1 and selectivity for complex objects at the highest processing levels of the temporal and frontal lobes. The search for "step-wise" increases in complexity of properties has been directed at intermediate levels of processing (e.g. V2, V4, MT, MST complex, etc.), but despite certain properties that support this simple hierarchy theory, it has remained somewhat obscure what properties change across these intermediate areas.

An alternative approach to the study of hierarchical processing in visual cortex comes from anatomical studies of the laminar origins and terminations of cortical pathways that interlink the 30 or more extrastriate visual areas [1]. Although there are some exceptions, it is largely agreed that three types of cortico-cortical pathways can be observed. Feedforward pathways arise from cells located in the supragranular cortical layers and their axons terminate in layer 4 and deep layer 3. Feedback pathways arise from infragranular layers and terminate outside of layer 4, usually in layers 1 and 6. Lateral pathways, thought to link cortical areas at the same hierarchical level, arise from both supragranular and infragranular layers and usually terminate in a column spanning all cortical layers. An overall cortical hierarchy is then constructed by making pairwise comparisons of the reciprocal pathways interlinking all cortical areas and placing each area one level above each area that provides it feedforward input. When this process is iteratively applied to all known visual cortical pathways it is possible to assign the more than thirty visual cortical areas to one of 7 (or more) distinct hierarchical levels. Figure 3 illustrates a subset of areas in macaque visual cortex and their hierarchical position according to



**Extrastriate Visual Cortex. Figure 3** Hierarchical organization of macaque visual cortex. Anatomical hierarchy of visual cortex based on the laminar patterns of cell bodies and axonal terminations of interconnected areas. Multiple-colored areas reflect modular subdivisions within areas V1, V2, V4, V4Ad, V4Av, PITv, PITd, MT, and V4t. The locations of extrastriate areas in parietal, frontal, and temporal lobes are indicated by solid colors as depicted in Fig. 1. This hierarchical array of a subset of visual cortical areas illustrates low level cortical modules and streams as well as the parcellations of higher cortical areas into larger domains. The areas enclosed by dashed boxes appear to reflect functional distinctions within the lateral and medial inferotemporal cortex, floor of the superior temporal sulcus, roof of the superior temporal sulcus, and parietal cortex.

this scheme. Recently, quantitative methods have been used to characterize the laminar patterns of origin for cortical pathways among the lower visual areas. This scheme introduces an anatomical distance metric between areas based on the proportion of supragranular cells in a given pathway. This analysis yields a hierarchy that in many ways is similar to the qualitative hierarchy described above, but differs in the assignment of a few areas.

It is important to reiterate that the above-described cortical hierarchy is based solely on anatomical principles and does not necessarily reflect notions of "stepwise" increases in functional complexity as one ascends the anatomical hierarchy. The lack of direct correspondence between the anatomical hierarchy and notions of stepwise increases in functional complexity can be due to many factors including cortical pathways that span many discrete hierarchical levels, convergent input from areas at multiple levels onto a given cortical area, as well as incomplete knowledge about which functional properties to assess stepwise hierarchical change. The hierarchical position of area MT provides a useful focus for consideration of many of these factors. First, MT is located at the fifth level, but receives feedforward inputs that span many hierarchical levels. For example, MT receives a direct feedforward input

from cells in layer 4B of V1 (level 1), from thick stripes in V2 (level 2), from areas V3 and VP (level 3), and from area V3A (level 4). Thus, in some anatomical and perhaps functional sense, MT could be considered only one level higher than each of these areas. The second point, that MT receives convergent input from multiple areas at different hierarchical levels might suggest that each of these areas provides MT neurons with different types of input that may not simply be described by obvious differences in "stepwise" complexity. Thus, the inputs from V1 may reflect local motion cues while the V2 thick stripe input might convey specific binocular disparity information. The third point about uncertainty in the right functional questions to ask may be related to the second point about convergent inputs. For example, comparison of receptive field properties of layer 4B and MT neurons with respect to simple motion and direction selectivity may not reveal differences that might be expected on the basis of their separation by four hierarchical levels. However, comparisons of receptive field properties on the basis of higher order motion processing (e.g. shape from motion) might reveal a fundamental difference that is constructed over multiple discrete hierarchical steps.

A related dimension underlying the interpretations of the visual cortical anatomical hierarchy concerns the timing of information flow through the hierarchy. At one level of analysis, the latency to initial activation in each cortical area might simply be related to the number of synapses between a given extrastriate cell and the input from V1. Using area MT as an example, an extrastriate latency hierarchy might place MT at the same level as V2 and V3, given each of these areas is only one synapse away from V1. Closer scrutiny of this issue suggests that extrastriate response latency is determined by a number of additional factors including the density of feedforward inputs, the axonal caliber of all associated "lower" cortical pathways, and the efficacy of any given visual stimulus to activate "lower" visual neurons. This analysis thus underscores the difficulties in interpreting neuronal latency data and indicates the necessity for evaluating and understanding the changes in neuronal functional properties at different levels of the visual cortical hierarchy.

►Evolution of Eyes

# Eye Movement System

►Evolution of Oculomotor System

# Eye Movements

## Definition

Any change of orientation of the eyes with respect to the head. They can be fast (e.g., "Saccades") or slow (e.g., "smooth pursuit"), "conjugate," or "disjunctive" and their goal can be either to shift the line of sight from one point of the visible world to another (e.g., "Saccades") or to stabilize the visual image on the retina (e.g., the "vestibulo-ocular reflex"). They are caused by the combined activation/relaxation of six extraocular muscles (see "Eye Muscles").

►Eye Movements Field

# Eye Muscle

## Synonyms

Extraocular Muscles

## Definition

Eye muscles are the six muscles (also known as extraocular muscles or EOMs) that rotate the eye. Horizontal eye rotations, usually referred to as horizontal eye movements, are produced mainly by the lateral and medial rectus muscles (also known as the horizontal recti). Vertical and torsional eye movements are produced mainly by the superior and inferior rectus muscles (vertical recti) in combination with the superior and inferior oblique muscles (obliques).

Department of Psychology, University of Sheffield, Sheffield, UK

## Synonyms

Oculomotor plant

## Definition

Mechanics of the ►eye muscles in combination with the connective and fatty tissues of the orbit (►orbital tissues) that surround the eyeball.

## Description of the Theory

### Introduction

Neural signals from the ocular motoneurons (OMNs) control eye position and velocity. They do so by producing forces via the eye muscles (extraocular muscles, EOMs), which act on the eyeball and surrounding orbital tissues to move the eye. The mechanics of the EOMs and orbital tissues determine the relation between the neural input and eye-movement output, and are therefore of interest to clinicians as a possible contributor to eye-movement disorders, to experimental neuroscientists as a prerequisite for understanding neuronal firing patterns in the oculomotor system, and to computational neuroscientists concerned with general principles of biological motor control.

We start with the mechanics of horizontal eye movements, which are simpler to understand as they are produced by rotation about a single (vertical) axis. We further simplify the problem by assuming that only the ►lateral and ►medial rectus muscles contribute to horizontal movements. Evidence supporting that assumption is considered later. We follow the convention of ignoring movements of the centre of mass of the eye relative to the orbit, so that the term *eye position* refers to the angle of rotation of the eyeball around its centre of mass.

### Orbital Mechanics in One Dimension

The equation of motion for rotation of a rigid body about a fixed axis is:

$$J\ddot{\theta} = G$$

where $G$ is the torque around the axis, θ is the angular position so $\ddot{\theta}$is the angular acceleration, and $J$ is the moment of inertia of the rigid body. In the case of the eyeball the torque has two constituents, one ($G_m$) exerted by the EOMs, and the other ($G_{OT}$) by connective and other tissues in the orbit, which act to restore the eyeball to its resting position.

$$J\ddot{\theta} = G_m + G_{OT} \quad (1)$$

Assuming the torques are produced by forces that act tangentially to the surface of the eyeball in the horizontal plane, at a fixed distance $r$ (= radius) from the vertical axis, then

$$J\ddot{\theta} = rF_m - rF_{OT} \quad (2)$$

where $F_m$ is net muscle force and $F_{OT}$ the orbital tissue restoring force.

It is helpful first to consider orbital mechanics in the static case, because this simplifies the problem in three ways: (i) the acceleration term is zero, (ii) the orbital-tissue force is dependent only on the elasticity of the orbital tissue, and (iii) the muscle force is unaffected by velocity terms.

## Orbital Statics in One Dimension

Figure 1a shows the left eye from above, rotated $\theta°$. around the vertical axis from its resting position.

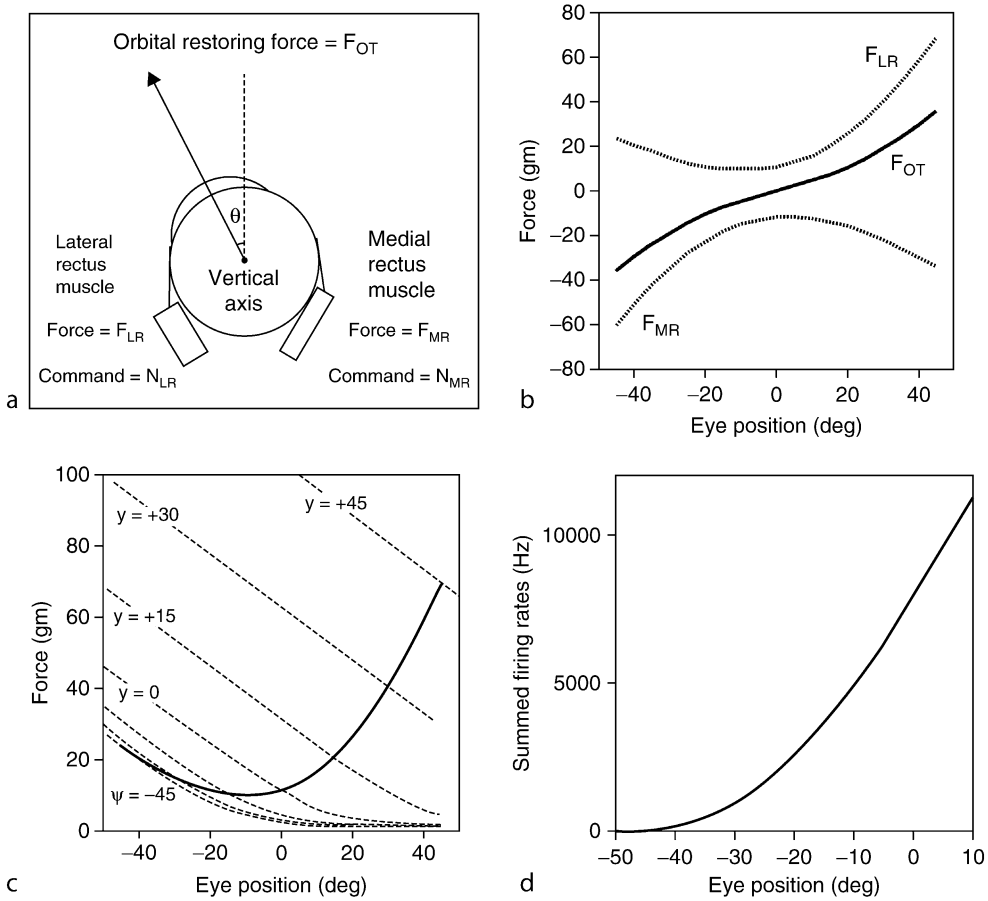
When the eye is static, the eq. of motion (1) becomes a force-balance equation $rF_m - rF_{OT} = 0$so that

$$F_{LR} - F_{MR} = F_{OT} \tag{3}$$

where $F_{LR}$ is the counterclockwise force produced by the agonist ►lateral rectus muscle, $F_{MR}$ the clockwise force of the antagonist medial rectus muscle, and $F_{OT}$ the elastic restoring force produced by the orbital tissue. These forces have been measured in human subjects as a function of eye position (Fig. 1b). The muscle forces change with eye rotation in a complex way, because muscle force $F_m$ is a function of both muscle length $l_m$ (which in turn depends on eye-position $\theta$), and the neural command $N_m$.

$$F_m = f(\theta, N_m) \tag{4}$$

The nature of this function is illustrated in Fig. 1c, which is derived from measurements of force in detached horizontal rectus muscles while the intact eye fixated on a series of targets at a range of horizontal eccentricities [3]. In these circumstances, neural command $N_m$ refers to the neural command corresponding to the intact eye's position. It can be seen that muscle force increases as the neural command increases, or as



**Eye Orbital Mechanics. Figure 1** (a) Diagram of eyeball stationary at $\theta°$. from its resting position, in the on-direction of the lateral rectus muscle. The agonist force $F_{LR}$ is balanced by the antagonist force $F_{MR}$ and the orbital restoring force $F_{OT}$. (b) The forces $F_{LR}$, $F_{MR}$ and $F_{OT}$ plotted against eye position. (c) Length-tension curves (…) for a horizontal rectus muscle (with muscle length specified by eye-position) for different levels of innervation $\psi$. The innervation is operationally defined as the OMN firing corresponding to eye position $\psi$ in normal conditions. The solid line joins those points for which muscle-length equals $\psi$, thus representing the tension in the muscle during normal behaviour. (d) Summed firing rates for a sample of horizontal rectus OMNs plotted against eye-position. Adapted from Fig. 2, 5 and 11 in Dean, Porrill and Warren [2].

muscle length increases. However, in the intact system, as the neural command increases and the eye rotates, the muscle shortens. The complex interaction between the two opposing factors of increasing neural command and shortening muscle is shown in Fig. 1c, and corresponds to the muscle force plots in Fig. 1b.

The final panel of the figure (Fig. 1d) indicates how innervation level varies with eye position. It is well known from recordings of single OMNs in alert monkeys that each OMN has an eye-position threshold below which it does not fire. The range of thresholds is large: some neurons fire throughout the oculomotor range (i.e. their thresholds are less than ~40° in the off-direction of the relevant muscle), whereas others have thresholds more than 10° in the on-direction. Thus, as the position of the eye changes in the appropriate direction, the number of OMNs that are firing increases, a process known as recruitment. Since the firing rate of an individual OMN varies linearly with eye position above threshold, the *sum* of OMN firing rates must be non-linearly related to eye position [2].

Overall, Fig. 1 illustrates the complexities of orbital mechanics for even the simplest case of eye-position control in one dimension. In particular, the mechanical properties of each eye muscle alter with eye position (Fig. 1c), both as the muscle changes length and as the number of recruited motor units varies. These complexities require explicit modelling. Two main types of model have been distinguished, labeled "biomechanically correct" and "idealized plant" models [4].

Biomechanically correct models start from the full version of eq. (3)

$$F_{LR}(\theta, N_{LR}) - F_{MR}(\theta, N_{MR}) = F_{OT}(\theta) \qquad (5)$$

and derive values for each of the terms by simulating the processes that underlie force-generation in muscles and orbital tissue. They are based on the pioneering work of Robinson [1]. One development has been to replace the lumped neural command shown in Fig. 1d with the firing rates of individual OMNs. By incorporating the behaviour of individual motor units, such distributed models can address general aspects of muscle control such as recruitment and the size principle, and also problems of motor control in general such as redundancy, when there are more commands available than variables to be controlled [2].

Idealized plant models simplify eq. (5) in order to clarify the basic tasks of eye-position control. A common strategy is to treat the two muscles as one (which requires only a single neural command) and then linearise the forces so that

$$F_{OT} = k_{OT}\theta$$

$$F_m = z_m N_m + k_m \theta \qquad (6)$$

where $k_{OT}$ is the elasticity of orbital tissue, $k_m$ the elasticity of the combined muscle, and $z_m$ the strength of the combined muscle (defined as change in isometric force produced by unit change in neural command). Overall eq. (5) becomes

$$z_m N_m = k_{tot}\theta \qquad (7)$$

where $k_{tot}$ is the total elasticity of muscles and orbital tissue. This idealised plant model has a control signal that is simply proportional to the desired eye position and is the basis for related models of ID dynamics and 3D statics discussed further below.

## Orbital Dynamics in One Dimension

When the eye is moving, the static eq. (3) needs to be replaced by the full eq. of motion (2) for rotations around the vertical axis. Each force term is now more complex than in eq. (2).

$$\frac{J}{r}\ddot{\theta} = F_{LR}(\theta, \dot{\theta}, N_{LR}) - F_{MR}(\theta, \dot{\theta}, N_{MR}) - F_{OT}(\theta, \dot{\theta})$$

The orbital force is viscoelastic, i.e. it is dependent upon both eye position and velocity, and the EOM forces are determined by neural command, muscle length, and rate of change of muscle length (which in turn are determined by eye position and velocity).

It would be natural to expect here an equivalent of Fig. 1, showing the force measurements relevant to the dynamic case. However, although the need for these measurements has been recognised for many years [5] there are still few data available, particularly for EOM forces as a function of muscle shortening or lengthening. It is therefore difficult at present to extend the available biomechanically correct models of orbital mechanics for the static case to the control of eye movement.

Progress has, however, been made with idealised plant models. In these, the globe's inertia is ignored and the mechanics of orbital tissue are approximated by ▶Voigt elements (Fig. 2a).

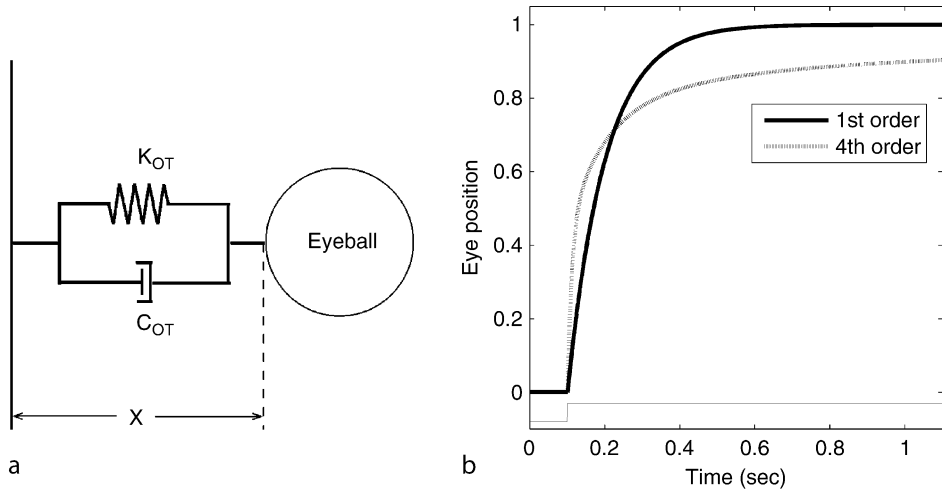
A Voigt element consists of a linear viscosity $(c_{OT})$ and linear elasticity $(k_{OT})$ in parallel, which gives the equation of motion

$$F_{OT} = k_{OT}\theta + c_{OT}\dot{\theta}$$

In the simplest case, where orbital tissue is treated as a single Voigt element, the restoring force $F_{OT}$ is split into independent elastic and viscous components. If each muscle is also treated as a single Voigt element, eq. (7) can be extended to become

$$z_m N_m = k_{tot}\theta + c_{tot}\dot{\theta} \qquad (8)$$

where $c_{tot}$ is the combined viscosity of the muscles and orbital tissue. This new equation illustrates two important points about the control of eye movements [5].



**Eye Orbital Mechanics. Figure 2** (a) Diagram of eyeball (*right*) attached to orbital wall (*left*) by a Voigt element, consisting of an elasticity *k* in parallel with a viscosity *c*. The length *x* of the element is defined relative to length = 0 at the primary position and is proportional to eye position *θ*. (b) Behaviour of Voigt element ("first order") in response to a unit step change in applied force (bottom trace). The length changes as an exponential function of time $1/k(1-e^{-t/T})$ with time constant $T = c/k$, which in the case illustrated is 0.1 s. Also shown is behaviour of four Voigt elements in series ("fourth order") with time constants of 0.01, 0.1, 1 and 10 s [5].

1. Gaze stabilizing reflexes such as the vestibular-ocular reflex (VOR) and optokinetic reflex (OKR) require the eye to be moved at a particular velocity. Eq. (8) shows that if the oculomotor plant had no elasticity, its velocity would simply be proportional to the neural command sent to it. The presence of the elastic term requires an additional force to offset it, which could be generated by the integration (and appropriate weighting) of a velocity command. Hence the idea of a neural integrator, which has proved extremely influential.
2. The viscous resistance of the plant means that a step change in neural command produces only a gradual change in eye position (Fig. 2b). To produce as rapid a change in eye-position as possible, an additional pulse of neural command is required to overcome this viscous resistance. The combination of the two signals is the classical "pulse-step" command that generates saccades.

In fact, orbital tissue is better approximated by four Voigt elements in series, which respond to a step input as shown in Fig. 2b. A simple velocity command now has to be adjusted in a more complex way than by integration, and the saccadic control signal will consist of pulse, step, and multiple slide terms that may last for several seconds. These changes mean that the actual firing patterns of OMNs are explained more accurately by a four element than one element model [1].

## Orbital Mechanics in Three Dimensions

A convenient way of representing rotations about a fixed axis in 3D is to specify (i) the axis as a vector **n** (bold symbols are used to denote vectors) in a head-fixed coordinate frame (Fig. 3), and (ii) the angle of rotation $\theta$ around that axis, as indicated in Fig. 1a.

In this angle-axis representation, the rotations considered so far would all have been about the vertical axis [0,1,0]. As in the case of 1D mechanics, we start with the control of eye position.

## Orbital Statics in Three Dimensions

For each position in 3D, the net torque exerted by the muscles ($\mathbf{G}_M$) must balance the restoring torque of orbital elasticity ($\mathbf{G}_{OT}$)

$$\mathbf{G}_M(\theta, \mathbf{n}) + \mathbf{G}_{OT}(\theta, \mathbf{n}) = 0$$

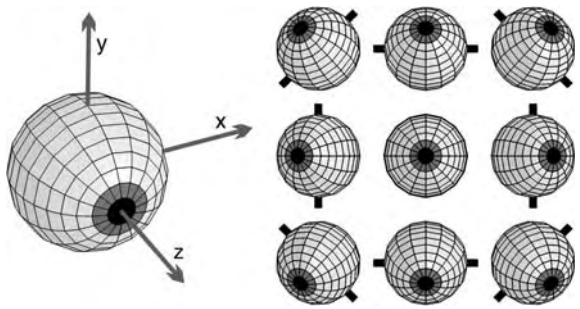
Both of these torques are functions of 3D eye position ($\theta$, **n**). The problem of producing the required muscle torque is simplified by the restriction that only a subset of possible eye positions (Fig. 3) are used for fixation. All these positions (termed Listing's positions) can be reached from the ▶primary position by rotation around some axis that lies in a plane (Listing's plane), which is close to the frontal (x-y) plane through the centre of the eyeball when the head is upright (Fig. 3).

The muscle torque $\mathbf{G}_M$ is produced by six EOMs, whose pulling directions are shown in Fig. 4.

As in the 1D case, the net torque exerted on the eyeball is a function of the force in each EOM, together with the direction in which it pulls.

$$\mathbf{G}_M(\theta, \mathbf{n}) = r \sum_{i=1}^{6} F_i(\theta, \mathbf{n}, N_i)\mathbf{m}_i(\theta, \mathbf{n}) \qquad (9)$$

The magnitude of the force for an individual muscle ($F_i$) depends on its neural command $N_i$, and on its length as



**Eye Orbital Mechanics. Figure 3** Left panel shows the coordinate system associated with the eye in primary position. This coordinate system does not move with the eye, but stays fixed relative to the head. Right panel illustrates Listing's law. The central globe represents the eye in primary position. In order to fixate horizontal or vertical ►secondary positions (here 30°.) from the primary position, the eye must rotate about the y-axis or the x-axis, respectively. In order to fixate tertiary positions from the primary position the eye rotates about oblique axes which still lie in the x-y plane. This plane is called Listing's plane. Changes in fixation which do not pass through the primary position (*e.g. top left to top right*) require an axis of rotation which lies out of Listing's plane. Redrawn from Fig. 1 of Tweed, Vilis (1990) Geometric relations of eye position and velocity vectors during saccades. Vision Res 30:111–127.

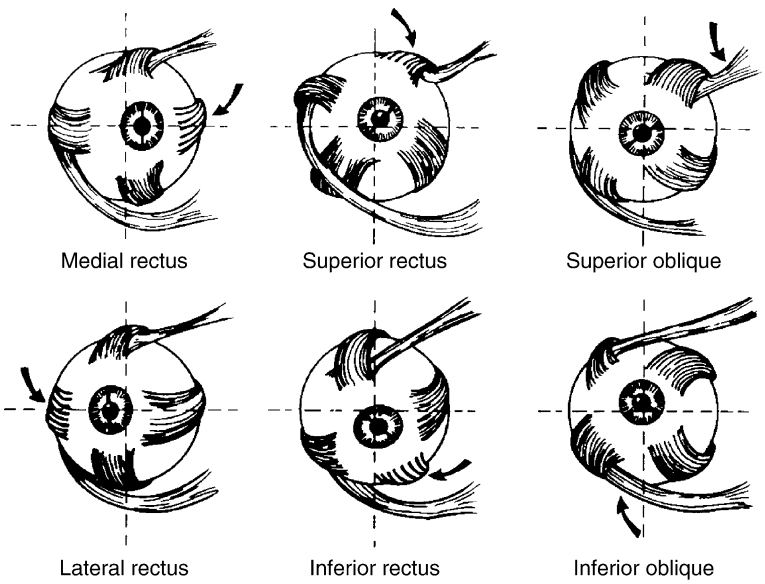
determined by eye position ($\theta$, $\mathbf{n}$), according to the geometrical arrangement of the muscles (cf Fig. 4). The torque generated by this force has magnitude $F_i r$, and acts about the axis $\mathbf{m}_i$ normal to the plane of action (this plane contains the centre of rotation of the eyeball, muscle insertion and direction of action of muscle at the insertion). This axis is also a function of eye position, as determined by muscle geometry.

The orbital-tissue torque $\mathbf{G}_{OT}$ is produced by the elasticity of the orbital tissue, which is mechanically more complex in 3D than 1D.

$$\begin{pmatrix} G_x \\ G_y \\ G_z \end{pmatrix} = \begin{bmatrix} k_{xx} & k_{xy} & k_{xz} \\ k_{yx} & k_{yy} & k_{yz} \\ k_{zx} & k_{zy} & k_{zz} \end{bmatrix} \begin{pmatrix} \theta_x \\ \theta_y \\ \theta_z \end{pmatrix}$$

This equation relates $\mathbf{G}_{OT}$ (with components $G_x$, $G_y$, $G_z$ around the axes of Fig. 3), to eye position $\boldsymbol{\theta}$ (with components $\theta_x$, $\theta_y$, $\theta_z$ around the axes of Fig. 3), using 3D elasticity $K_{OT}$. It can be seen that $K_{OT}$ is a 3×3 matrix (in fact the "elasticity tensor"), with terms representing the effects of rotation around one axis on torque around another ("off-diagonal" terms). Moreover, each term in the matrix could in principle itself vary as a function of eye rotation.

The first attempt at a biomechanically correct model of orbital statics in 3D was described by Robinson [1], and subsequently developed by Miller



**Eye Orbital Mechanics. Figure 4** Schematic representation of the action of the extraocular muscles. If muscles are innervated individually at the primary position, then the lateral and medial recti produce approximately horizontal movement, the superior and inferior recti produce vertical movement with a small component of ►torsion, and the superior and inferior oblique muscles produce torsional movement with a small component of elevation. (Reproduced from Carpenter RHS (1988). ►Movements of the eyes. Pion, London).To satisfy the torsional constraint of Listing's law, the neural commands to the vertical recti and the oblique muscles must be yoked.

[6]. However, there are two important differences between using these models for 3D eye-position, and for horizontal eye positions only. First, the measurements needed to characterise the 3D elasticity tensor are not available, so the models use a simplified version in which the off-diagonal terms are set to zero:

$$K_{OT} = \begin{bmatrix} k_x(\theta_x) & 0 & 0 \\ 0 & k_y(\theta_y) & 0 \\ 0 & 0 & k_z(\theta_z) \end{bmatrix}$$

In addition, the elasticity is assumed to be ►isotropic in Listing's plane (i.e. $k_x(\theta_x) = k_y(\theta_y)$). Secondly. the appropriate data for OMN firing rates in ►tertiary positions is surprisingly sparse [7], which means that crucial inputs to the model are undefined.

This second limitation requires that the model itself [6] be used to predict the patterns of neural commands that correspond to Listing's positions [8]. According to these predictions, the commands for horizontal fixations up to ~40° either side of the primary position are little affected by the eye's elevation, and similarly commands for vertical fixations are little affected by horizontal position. The horizontal and vertical commands are thus separable, making the system easy to control. The model's behavior indicates that vertical eye-positions are achieved by yoking together the neural commands to the ►inferior rectus and ►superior oblique muscles, and to the ►superior rectus and ►inferior oblique muscles; and that separability depends upon the presence of "►pulleys" (Fig. 5), that is restrictions on the paths of EOMs identified in scans of the orbit and attributed to rings of connective tissue around the EOMs [9].

These restrictions alter the direction of the net torque exerted by the six EOMs, so that it tends to move with the eyeball (Fig. 5b) rather than remaining fixed relative to the head (Fig. 5a).

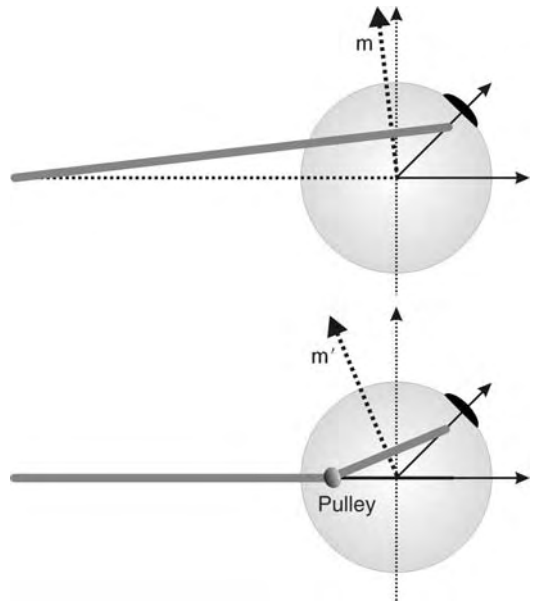
Unfortunately, idealised plant models in 3D have so far proved much less useful than their one dimensional (1D) counterparts. Since muscle length depends on 3D eye-position in a complex way, these models have ignored muscle elasticity altogether, so that equation (6) is reduced to

$$F_m = z_m N_m$$

However, the effects of muscle elasticity on EOM force are in fact substantial (Fig. 1c), and as a consequence the idealised plant models behave unrealistically, for example, producing Listing's positions with no neural commands to the oblique muscles [10].

## Orbital Dynamics in Three Dimensions

Extending orbital statics in 3D to orbital dynamics encounters two problems. First, some eye movements in 3D (e.g. those resulting from the VOR) generate eye positions that are not Listing's positions [4]. Secondly, whereas the static case dealt only with the muscle torques and neural commands required to maintain Listing's positions, the dynamic case has to consider the actual paths taken between Listing's positions.



**Eye Orbital Mechanics. Figure 5** The top panel shows a schematic side view of the plane of the action of a horizontal muscle when its motion is not constrained by a pulley. Since the origin of the muscle is well behind the globe both its plane of action and hence the moment vector **m** normal to the plane of action of the muscle change relatively little (relative to the head) as the eye elevates.The bottom panel shows the effect of constraining the muscle by a fixed pulley closer to the globe. The effect is to magnify the effect of eye elevation on the rotation of the plane of action and hence on the moment vector **m′** to the plane of action of the muscle. Both plane of action and moment vector tend to move with the eye.

Fortunately, it can be shown theoretically that any Listing's position can be reached from any other Listing's position by a rotation about a fixed axis, and that all the intermediate positions produced by such a rotation are also Listing's positions. Moreover, in practice saccadic and smooth pursuit movements follow these paths. However, the requisite axis of rotation only lies in Listing's plane for rotations that pass through the ►primary position. Other movements, for example, from the top left Listing's position in Fig. 4 to the top right position, have rotation axes that do not lie in Listing's plane. It can be shown that the rotation axis for this example is tilted $(\alpha/2)°$ from Listing's plane, where $\alpha$ is the elevation of the eye in the initial position, and that in general displacements through Listing's positions obey the "half-angle rule" [4].

This geometrical fact has serious implications for neural control. In the restricted case of rotations about a fixed axis the angular velocity $\boldsymbol{\omega}$ is given by

$$\boldsymbol{\omega} = \dot{\theta}\mathbf{n}$$

The resistive torque due to orbital tissue viscosity is proportional to $\boldsymbol{\omega}$, so if the axis of rotation $\mathbf{n}$ lies outside Listing's plane, so will the resistive viscous torque. The elastic restoring force, however, acts around an axis in Listing's plane. Thus, for fixation, the control signal always has to generate a torque in Listing's plane, whereas for some saccades and smooth pursuit movements the control signal must generate a torque that is not in Listing's plane. How can the controller achieve this?

Unfortunately, neither biomechanically correct nor idealised plant models in their current versions are of much help in answering this question. Extending the relevant equation of motion (1) for the 1D case to 3D gives

$$J\dot{\omega} = \mathbf{G}_m(\theta,\ \omega) + \mathbf{G}_{OT}(\theta,\ \omega)$$
$$\mathbf{G}_m(\theta,\omega) = r\sum\nolimits_{i=1}^{6} F_i(\theta,\omega,N_i)\mathbf{m}_i(\theta)$$

The torques exerted by the EOMs ($\mathbf{G}_m$) and orbital tissue ($\mathbf{G}_{OT}$) are now functions of both eye position (here denoted by $\boldsymbol{\theta}$ for convenience) and angular velocity $\boldsymbol{\omega}$. Measurements of neither muscle dynamics nor 3D orbital tissue viscosity are available. Nor indeed have the OMN firing patterns for saccades and smooth pursuit between ▶tertiary Listing's positions been well-characterised. Development of biomechanically correct models of 3D orbital dynamics is thus crucially hindered by absence of data.

On the other hand, idealised plant models of 3D dynamics have inherited the inadequacies of their static counterparts, and in addition ignored muscle viscosity. Thus, claims from these models that control of saccades and smooth pursuit could be simplified by appropriate movement of pulleys (cf Fig. 5) are difficult to evaluate. However, it should be noted that recent results from hybrid models suggest that pulley movement may act instead to keep the EOMs tangent to the eyeball [10]. Moreover, a scheme that requires six additional neural signals to move pulleys appropriately would not appear to qualify as simplified [7].

## Conclusions

This brief survey outlines the achievements and limitations of current models of orbital mechanics. Although some of the limitations arise because certain models ignore relevant data that are available, a more general problem is lack of appropriate measurements - despite their acknowledged clinical, experimental and theoretical importance. Three areas in particular merit further investigation:

1. The elasticity and viscosity of orbital tissue in 3D. Better understanding of these will underpin development of models of orbital tissue, using for example finite-element modelling techniques.
2. The dynamics of EOMs. These are poorly understood even for whole muscle, let alone at the level of the individual motor unit. Yet current genetic and histochemical studies emphasise the heterogeneity of EOM structure.
3. The firing patterns of EOMs for 3D fixations and movements. Until these are properly characterised, key issues such as neural versus mechanical contributions to eye-movement control, and premotor processing of neural commands, cannot be adequately addressed [7].

# Eye-Blink Conditioning

## Definition

Eye blink conditioning is one type of classical conditioning. Application of air puff to an eye makes

the eyelid close to prevent injury of the eyeball. This is a simple defensive reflex and air puff is called unconditioned stimulus. When sound is made before application of the air puff several times, the animal becomes to close eyes only hearing the sound. This phenomenon is the eye blink conditioning, and the sound is called conditioned stimulus.

# Eye-Hand Coordination – Planning and Neural Structures

Denis Pelisson, Claude Prablanc
Espace et Action Unité 864, INSERM/Université Claude Bernard – Lyon, IFR19 Institut Fédératif des Neurosciences de Lyon, Bron, France

## Synonyms

Eye-hand coupling; Visuo-manual coordination; Oculo-manual synergy

## Definition

Goal-directed movements of the upper limb are assumed by a number of neural mechanisms extending from the detection of the target to the execution and on-line guidance of the hand trajectory. Due to its organization, the visual system supplies the hand motor system with signals which depend upon the position fixated by the subject in 3-D space. Thus, the performance of the limb response depends strongly on eye movements, combining saccadic eye movements (2-D changes of the direction of the line of sight) and vergence eye movements (changes in depth of the distance of the fixation point). Eye-hand coordination refers to the various mechanisms which regulate the temporal coupling between eye and hand movements and thereby allow, through eye movements, the capture and the transfer of visual information to the limb motor system at appropriate time periods. Eye-hand coordination also refers to the outcome of these mechanisms on the performance of the two motor responses which is expressed by the spatial coupling between eye and hand.

## Characteristics

### Upstream Event/Conditions

During each behavioral phase (►Movement (or motor) planning and ►movement (or motor) programming phases, movement phase and error correction terminal phase), the limb motor system is provided with key visual information related to the subject's environment (ultimate goal, intermediate targets, distractors, obstacles, visual background…) and to the body and limb posture. The visual system is endowed with properties whereby visual detection and localization of a stationary target in 3-D space are best achieved in the central part of the visual field, whereas the detection of the speed and particularly of the direction of object motion are preferentially achieved in ►peripheral vision. Given these features, an optimal visual control of limb movements is expected to strongly rely on co-ordinated orienting movements of the line of sight toward the hand movement goal [1]. Such fast movements of the line of sight (►Gaze shifts) are achieved by saccadic eye movements, often accompanied by a head rotation and, when the target is located at a distance closer or further from the original point of gaze fixation, by disconjugate (vergence) eye movements. Thus, a strong impact of oculomotor control is expected for all types of visually-guided movements of the arm, such as discrete movements of the limb to a stationary object (pointing and reach-to-grasp responses) and continuous arm movements to track or catch a moving target. However, most studies directly investigating eye-hand coordination processes have been performed in relation to pointing responses.

When a subject moves his arm in order to point to an object, the line of sight also quickly moves in a saccadic fashion, most often without any conscious knowledge from the subject. When both the speed and the accuracy of the limb response are emphasized (speed accuracy trade-off), the eyes appear to lead the hand motion and to land on the target nearly at the time the hand starts moving, i.e. too late for the arm motor program to use post-saccadic (updated) visual information. It has been demonstrated that at least under such conditions, the motor commands driving the eyes and the limb muscles are initiated in parallel, the shorter reaction time and movement time of the eye being accounted for by a much lower inertia as compared to that of the limb [2]. Note that this parallel planning strategy of eye and hand movements is more advantageous than any sequential strategy in terms of overall response time, but is *a priori* disadvantageous with regard to hand movement accuracy because such a planning is based on low resolution target position signals detected under peripheral vision, when the eyes have not yet foveated (►Foveation) the target. Thus, to achieve good performance both in the temporal and spatial domains, the parallel planning strategy requires that correction mechanisms are able to efficiently control on-line the limb trajectory during the movement phase. Note that these correction mechanisms also require precise knowledge of initial conditions and more specifically of vision of the initial posture of the arm [2].

## Downstream Event/Conditions

### *Temporal Coupling*

Due to its functional advantage, the parallel planning of eye and limb response is likely to result from some dedicated coordinative mechanisms. A possible link between eye and limb motor systems is based on visual attention. Both eye saccade and hand pointing responses, when performed separately, are associated with an automatic – temporally and spatially specific – shift of visual attention to the target [3]. Moreover, in a combined eye-hand response task, gaze stays anchored on the target and cannot move towards another target until the hand pointing movement is nearly completed [1,4]. Altogether, these data suggest that the limited attentional resources focused on the visual target are shared by eye and hand motor systems and can hence contribute to eye-hand coordination.

Another aspect of temporal coupling has recently been described: in the monkey, saccades associated with a hand movement are faster than saccades generated separately from any hand motion. In this case, the information appears to flow from the hand to the eye motor systems. Whereas its functional advantage is uncertain, this effect on saccade speed – and the associated increased oculomotor drive – is a signature of dedicated neural coordinative mechanisms which come into play specifically when a combined eye-hand response is required.

### *Spatial Coupling*

In contrast to temporal coupling, there is no definitive evidence for a strong spatial coupling between eye and hand responses. The first approach has been to look for a correlation between the achieved (final) positions of eye and hand when subjects point in the dark towards either the remembered position of a visual target or towards a briefly flashed target. There have been some controversies between the results of the different studies, but the current bottom line agreement is that the correlation is quite weak [5]. Since in these conditions no visual control of the hand trajectory is possible, this suggests that, although triggered in parallel, the planning of eye and hand movements do not necessarily result from common spatial information. This also indicates that the direction of gaze in the dark *per se* does not provide useful information for hand movement guidance. Further studies have indeed indicated that a retinal stimulation should be combined with – and act as a gate for – ►extra-retinal signals of eye position [2]. The second approach is to search whether temporal or spatial dissociations between the eye and hand responses interfere with the spatial performance of the latter. This kind of dissociation is typically achieved by asking subjects to initiate and execute their hand movement to the target without moving gaze. The hand inaccuracy observed in this condition is a direct consequence of the poor spatial resolution of hand- and target-related visual signals encoded under peripheral vision (note that a decreased hand accuracy is also observed when only the head is prevented from moving as compared to a free eye-head-hand task, showing that a gaze position signal conveys more accurate information when based upon simultaneous orientation of eye and head than when based upon an eye movement alone). It can thus be expected that in the reverse situation, i.e. delaying hand response until the time the orienting saccade has been allowed to update target-related visual signals, the hand achieves maximal accuracy. Interestingly, however, this turns out to be true only when corrections of the on-going hand trajectory are prevented by turning the target off at movement onset [5]. This demonstrates that in this parallel strategy, which is used by default when the subject achieves a speed-accuracy trade-off (see above), the mechanisms allowing an on-line guidance of the hand trajectory are very efficient, owing to the saccade-contingent updated visual information. Concerning the effect of spatial dissociations, recent results indicate that hand movements are larger when the amplitude of the concomitant saccade increases by asking the subject to initiate it from a fixation point more eccentric than the initial hand position, and suggest that the parietal cortex integrates signals related to saccade amplitude with limb movement information. Other studies using two simultaneous targets, targets presented against an illusory background, or targets presented among distractors, have shown that eye and hand responses are usually affected by these stimulation conditions in a similar way but not necessarily by the same amount. In conclusion, current knowledge indicates that although the hand is not a slave to the eyes, gaze anchoring on the target during hand reaching contributes to a better hand accuracy under normal circumstances of parallel eye-hand planning.

## Involved Structures

Whereas definitive experimental evidence is still being searched at the behavioral level, eye-hand coupling is supported by numerous neurophysiological data. First, bi-modal (eye and hand) neural responses and effects of eye position on limb-related neuronal activity have been found repeatedly [6]. Second, studies of neurological patients and neurophysiological studies of normal subjects and animal models have further implicated some cerebral structures in eye-hand coordination. On the one hand, the cerebellum is involved in the temporal aspects of motor control in general and in the temporal coupling of eye and hand movements in particular. This cerebellar involvement has been demonstrated most clearly for visuo-manual tracking tasks [7].

On the other hand, the first electrophysiological recordings in the awake animal have suggested that, among the other structures participating in visuomotor transformations such as the basal ganglia and cerebellum, prefrontal and premotor cortices, the parietal cortex plays a central role in eye-hand coordination. Recent studies have confirmed and substantiated this hypothesis by delineating in this structure a number of neural processes which contribute to the temporal or spatial coordination between eye and hand. Indeed, as a multimodal integration node within the fast dorsal route from the occipital visual cortex to the motor cortex, the posterior parietal cortex is involved in sensory-motor transformation and in coordinates transformation for both eye and limb responses. The posterior parietal cortex is the neural centre where a linear modulation by gaze position (►Gain fields) of the target-related visual responses of neurons was first discovered [8]. Later, gain fields (►Gain modulation (gain field)) for arm movement-related activities have also been described in parietal areas as well as in the frontal lobe. The posterior parietal cortex is also involved in the control of shifts of visual attention and of the anticipatory displacement of visual receptive fields in relation to the generation of saccadic eye movements (►Saccade remapping: [9]). Recently, a specific role of the posterior parietal cortex in the automatic guidance of the limb movement trajectory toward a visual target has been suggested based on converging lines of evidence in human subjects [10]. Indeed, automatic corrections of the on-going hand trajectory performed by human subjects when pointing at a stepping target (non-consciously detected perturbation) are: (i) associated with activity in a parieto-cerebello-frontal network, and (ii) disrupted when the function of the posterior parietal cortex is transiently (application of transcranial magnetic stimulation) or permanently (►Optic ataxia patient) impaired. Other neural centers may additionally be involved. Among those is the superior colliculus, a subcortical structure whose role in the production of orienting eye and head movements is well-known, and which has recently been involved in the visual control of limb movements based on unit recording and electrical stimulation studies in animals.

## Methods to Measure This Event/Condition

Eye-hand coordination is a built-in property of the sensory-motor system. A privileged way to investigate eye-hand coordination is to experimentally dissociate eye and hand responses and to measure the effects of this dissociation relative to the baseline (no dissociation) condition. The dissociation can be made either or both in the temporal or spatial domain, and the effects measured at the behavioral and/or neural level. Behavioral measures involve the analysis of movement reaction time, movement duration and speed, terminal accuracy and, in rhythmic tasks, phase relationships between eye and hand. To evaluate the capability to guide the hand response trajectory on-line, i.e. a good measure of eye-hand coordination, experimental protocols based on the perturbation of the target or of the moving limb have been designed. These perturbations, which permit the opening of different feedback loops at critical times of the saccade or of the hand movement, are a powerful tool for the evaluation of the different control processes and sources of static and dynamic information (visual, kinesthetic, efferent copy) influencing the accuracy of an aimed movement. Neural measures are the recording of neuronal activity in trained behaving animals and the recording of functional cerebral activation in human subjects, complemented by the analysis of movement deficits after lesion/inactivation in animal models and human patients.

## Acknowledgments

We are very grateful to Drs. C. Tilikete and Y. Rossetti for their critical reading of the manuscript.

# Eye-Hand Coordination – Timing and Reference Frames

John F. Soechting
Department of Neuroscience, University of Minnesota, Minneapolis, MN, USA

## Definition

The static (stationary) target of a hand movement is typically defined by visual information, and most commonly, the target is foveated before or at the time the hand movement is initiated. This behavior raises two issues in motor control. First, is the timing of hand and eye movements in this situation coordinated, and if so, what is the pattern of coordination? Second, since the eyes can move in the head and the head can move relative to the trunk, in what frame of reference is the spatial locus of the target defined? In other instances, a target may be moving, such as in tracking or interception tasks. In these cases, the eyes and the hand are both in motion, the trajectories of eye and hand movements being similar in the case of pursuit tracking and conceivably quite distinct in the case of interception, such as catching a ball.

## Characteristics

### Eye-Hand Coordination for Static Targets

The temporal coordination of eye and hand movements to static targets has been shown to be task-dependent [1,2]. In the most simple case of a reaching movement to a single target, the target is initially foveated with a saccade, followed by a reaching movement to the target. In a reaction-time task, where the target is presented suddenly and the subject is instructed to move as soon as possible, hand and eye movements have nearly synchronous onsets. Since saccadic eye movements are much faster than hand movements, even then the eye arrives at the target before the hand and it has been claimed that gaze is locked onto the target until the hand arrives there. However, this strict temporal coupling between eye and hand movements is not obligatory, especially in more complex tasks involving sequential movements and requiring the manipulation of the object. For example, when subjects are required to transport a stack of blocks from one place to another while avoiding obstacles along the way, gaze is directed to salient landmarks: the blocks, the target location, and the obstacle [3]. In many instances, gaze is redirected to the subsequent target in the sequence, prior to the arrival of the hand at the landmark. Furthermore, the pattern of coordination between the eyes and the hand can change as subjects learn a novel motor task, such as using a manipulandum to control the motion of a cursor on a screen [2]. Initially, as the task was being learned and the motion of the cursor was essentially unpredictable, the cursor's motion was pursued visually. However, once the task was mastered, predictive saccadic eye movements to target locations were used here as well to define the goal of the movement.

In summary, findings on the temporal coupling between eye movements and hand movements emphasize the role of vision in defining the spatial goal of intended limb movements. Since it has been found that the eye often departs the target before the hand arrives there, this pattern of coordination also suggests that vision may a play a secondary role in mediating online corrections to limb movements, compared to the role of somatosensory information.

### Visually-defined Frames of Reference for Pointing

Ultimately, the goal of an arm movement must be defined in a frame of reference that is fixed to the trunk, since the mechanical actions of muscles, dependent on the posture of the arm, are defined in such a frame of reference [4]. Based on behavioral data, a shoulder-centered reference frame to define target location was proposed and it was suggested that there was a transformation of visual information about target location from a retinocentric frame of reference into a shoulder-centered one [5]. There, information about target location would be combined with information about limb posture, derived proprioceptively, to define a hand movement vector, i.e., the direction and amplitude of the movement that was required. In primary motor cortex, this movement vector is indeed defined in a frame of reference that is independent of gaze.

However, more recent results suggest that this hand movement vector is initially encoded in posterior parietal cortex in an eye-fixed frame of reference. Some of the evidence comes from behavioral data [1]. For example, subjects make errors in pointing to targets that are located eccentrically on the retina, overestimating the target's eccentricity. Importantly, this error is also made when subjects initially foveate the target, and saccade away from it before pointing to the remembered location of the target. Neural substrates for such an encoding of target location have been identified in an area of posterior parietal cortex related to arm movements [6]. Neural activity in that area is tuned for the retinal locus of a target, irrespective of where the target is relative to the body. Furthermore, the cells' responses remain best for a particular retinal locus of the target, irrespective of the initial posture of the hand. Changing the initial posture of the hand does alter the overall gain of the target-related activity, in a manner that suggests that hand location is also encoded in an eye-fixed frame of reference.

All of these observations have been made under static conditions, where the location of the target relative

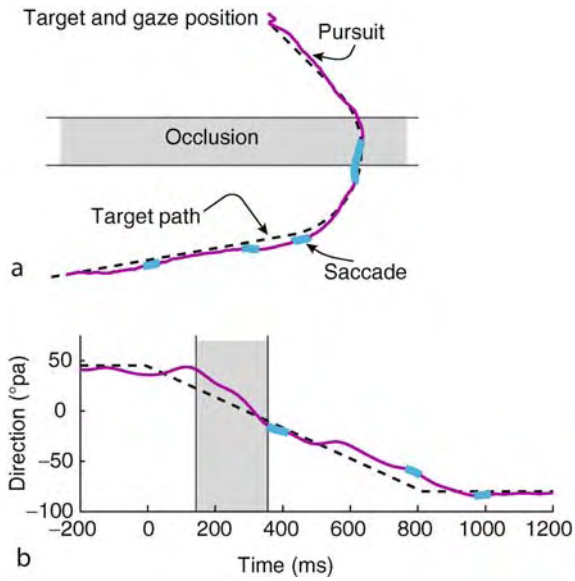
to the subject and its location relative to the direction of gaze do not change with time. It is not known whether these observations generalize to conditions where the target is in motion.

## Eye-Hand Coordination Under Dynamic Conditions

Situations where the target is in motion are not uncommon in everyday life. In some instances, the eyes and the hand move in concert, for example when tracking an object. In other cases, such as catching a ball, the two movements are disparate, the eyes tracking the target while the hand moves to intercept it. Finally, in some cases, the spatial goals of the two movements can be quite different. For example, when one drives along a winding road, the eyes tend to track the tangent point of the inside of a curve. It has been proposed that the heading of the car relative to this gaze angle defines the amount by which the steering wheel must be turned [7].

Conceivably, eye and hand movements could be controlled in parallel by independent channels. Certainly, the cortical areas associated with the control of hand movements are distinct from the areas driving eye movements. Nevertheless, there is considerable evidence that the kinematic profiles of eye and hand movements differ when the eyes and the hand move together, compared to when only one or the other modality is invoked [1,8]. For example, ocular tracking is more accurate when one tracks the motion of one's own arm compared to instances where the arm is moved by external means. Interventions that alter the gain of visual tracking affect the gain of manual tracking, and vice versa. Response latencies of eye and hand movements are also altered, depending on whether subjects use one or both modalities to track a moving target.

The interdependencies of eye and hand movements could arise from reciprocal connections between brain centers that control the two types of movements. However, they could also arise if part of the neural substrate responsible for controlling the two types of movements is shared by both. Interacting with moving objects, visually or manually, requires prediction and it is very likely that the mechanisms responsible for predicting target motion are shared by both modalities. The role of prediction has been studied most extensively for eye movements and it is known that the latency of smooth pursuit can decrease substantially from its normal value of 100 ms if the target motion is predictable; smooth pursuit may actually lead target motion in some instances [9]. Prediction can involve the timing of the onset of the motion, as well as the speed and direction of ongoing motion, for example when the target disappears transiently. In fact, as illustrated in Fig. 1, motion along a curve has been shown to be extrapolated [10].



**Eye-Hand Coordination – Timing and Reference Frames. Figure 1** Prediction during eye tracking. Subject tracked a target that initially followed a straight path and then followed the arc of a circle. The target was occluded shortly after it began to follow the curved path (a). Note that pursuit eye movements continued to curve throughout the occluded portion of the path, as can be seen in the plot of eye movement direction as a function of time (b). Adapted from [10].

Predictive mechanisms governing hand motion are not as well understood, but one might expect the quality of prediction to be the same for hand and eye movements.

## Definition

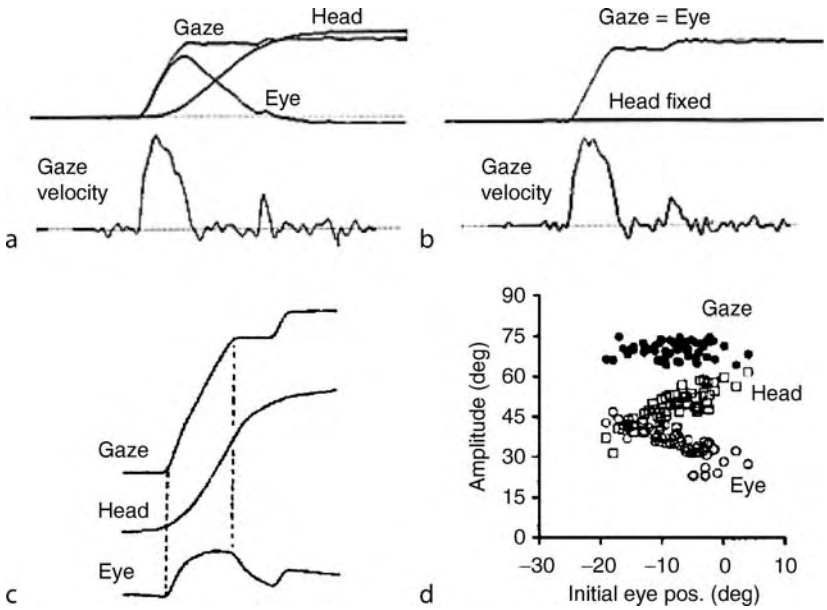
The control of the line of sight by the central nervous system is part of a larger visuomotor system allowing us to perceive, localize and recognize objects in the outside world. It is therefore an important research topic, and eye-head coordination further represents a good model for the study of the sensory-motor transformation mechanisms involved in the control of any multi-joint system. Eye-head coordination refers to the various mechanisms which contribute to orienting movements or to stabilization of the line of sight in space. This paper focuses on orienting movements and considers temporal and spatial coupling mechanisms, regulating respectively when and how much the ocular and cephalic body platforms move.

## Characteristics

### Upstream Event/Conditions

Orienting movements of the visual axis (gaze) are continuously required when animals visually explore their environment. A simple reason is that, in animals lacking panoramic vision, the visual field does not cover the whole surrounding space and furthermore, in higher mammals, the specialization of the central part of the retina (fovea) allows an optimal analysis of only a very small part of the central visual field. Thus, exploration of our visual environment requires frequent ►gaze shifts to foveate (►Foveation) objects of interest, separated by periods of active gaze stabilization during which visual analysis is performed. The eyes and the head are the two main body effectors, sometimes assisted by the trunk, that contribute synergistically to this gaze orientation and stabilization behavior. The low inertia eyeballs achieve fast and accurate orienting movements (saccades) to catch visual targets and to keep them in the foveal region of the visual field. As the desired amplitude of gaze movement increases, the amplitude of the eye saccade saturates and the contribution of the head becomes more prominent. The head is slower to move but has a larger operating range, allowing re-centering of the eyes in the orbit after each large ►gaze shift. This eye-head coordination pattern varies quantitatively between species as a function of the possible range of eye movements in the orbit (e.g. the oculomotor range of a cat is smaller than that of primates, leading to a larger contribution of the head to the gaze shift), but its qualitative features remain constant across species. Thus, the motor behavior yielding appropriate analysis of our visual environment involves precisely controlled and coordinated eye and head movements, involving for each platform all three degrees of freedom and additionally for the eyes, both conjugate and disconjugate movements. For simplification, we will focus on conjugate 2-D eye movements combined with 2-D head movements.

The neural control of combined eye-head gaze saccades is less well understood than the control of saccadic eye movements performed when the head is restrained [1]. A first issue of eye-head coordination concerns the relative timing between eye and head movement-initiation [2]. Behavioral investigations have revealed that this eye-head temporal coupling can vary according to experimental conditions. However, on average, for gaze shifts larger than 15°–20°, the head starts to move close to the eye saccade onset and therefore contributes significantly to the gaze shift (Figure 1). Note that the nearly concomitant initiation of eye and head displacements is the best strategy in terms of overall response time, but puts higher constraints on the neural processes controlling eye-head coordination. A second issue then concerns mechanisms by which the central nervous system regulates the size of each eye and head motor command in an appropriate way to bring gaze accurately onto the target [3]. This spatial coupling problem, involving a neural decomposition of a desired gaze displacement signal into eye and head motor commands, is complex because it must take into account both the very different mechanical properties of the eye and head platforms and the possible reflex interactions between them. Particularly, it supposes that the two antagonistic oculomotor responses – eye saccade and ►vestibuloocular reflex (VOR) – are precisely coordinated. Indeed, the gaze shift phase must be followed by perfect gaze stabilization as soon as the fovea is aligned with the target. This stabilization is due to the VOR which compensates for any residual head movement by



**Eye-Head Coordination. Figure 1** Kinematics of combined eye-head gaze shifts. (a–c) typical horizontal movement trajectories for 40° gaze shifts recorded in man (a) head free, (b) head fixed, and a 100° gaze shift in monkey (c). (d) effect of initial eye position on the coordination between eye and head for gaze shifts of nearly 70° in the monkey. The plot shows the amplitude of gaze shifts (filled circles), and of their eye (open circles) and head movement (open squares) components against initial eye position. producing a counter-rotation of the eyes (Figure 1). The accuracy of gaze shifts thus requires a very precisely timed switch between saccadic activity and VOR response.

## Downstream Event/Conditions

### *Temporal Coupling of Eye and Head Movement Initiation*

The general pattern of eye-head temporal coupling can be predicted from the different properties of the ocular and the cephalic mechanical systems. Indeed, the larger inertia of the head relative to the eye can account for the 10–20 ms average lag of the head in the initiation of natural orienting movements, since the same lag has been observed for movements evoked experimentally by electrical microstimulation of gaze-encoding structures like the ►superior colliculus (SC). However, on top of this average head lag, a number of factors have been shown to affect the precise temporal synchronization of eye and head movement initiation (sensory modality of the target, target predictability, size and direction of gaze shift, initial eye and head positions, verbal instructions, see [2]): the head lag tends to decrease or even reverses to a head lead for non visual or highly predictive targets, for vertical as compared to horizontal gaze shifts, when the head is initially deviated away from the intended gaze shift direction, and when subjects are specifically asked to align their head with the target. These changes in eye-head initiation pattern imply significant variations in the relative timing of eye and head neural commands (due in large part to variations of the latter), which in turn can be accounted for by the fact that the motor systems controlling each of the two platforms are not simply gated by a common mechanism. More specifically, head motor commands, including task-dependent intentional signals, can be sent to the spinal cord level while the pre-oculomotor neurons are still gated off by the omnipause neurons in the brainstem reticular formation, or conversely can be delayed – or suppressed – relative to the triggering of pre-oculomotor neurons.

### *Spatial Coupling*

A central question has been how the two antagonistic ocular responses – the orienting saccade and the compensatory VOR response – combine during the gaze shift. Stated differently, the problem is whether the VOR continuously operates, despite being counterproductive, during the orienting gaze shift. A first hypothesis postulated that the continuously operating VOR led to the central cancellation of the physical head contribution to the gaze shift. It is now quite firmly established that this ►linear summation hypothesis [4] does not hold, and that the VOR is inhibited during the gaze shift by the saccadic commands. Data to refute the summation hypothesis have been provided both by behavioral and neurophysiological experiments. The former demonstrated that head-unrestrained gaze shifts are faster than gaze shifts of the same size performed with the head fixed, which indicated that the head movement

contribution is not cancelled centrally by the VOR. In addition, specific head perturbation paradigms have been used to show that the modifications of the head trajectory during a gaze shift also affect gaze trajectory but not gaze final accuracy, owing to an ocular compensation unrelated to VOR. These observations indicate first that the VOR response does not adequately compensate for the head perturbations, signaling a momentary reduction of its gain during the gaze shift, and second that a central control of desired gaze displacement, independent of the status of the VOR, is involved in maintaining gaze terminal accuracy [5]. Thus, both the speed and the accuracy of gaze shifts can be optimized, leading to a performance compatible with the high functional value of orienting gaze shifts in everyday life. This conclusion is also supported by neurophysiological data. On the one hand, recordings from the so-called position-vestibular-pause (PVP) neurons, which constitute the intermediate link of the VOR 3-neurons arc, have shown a specific reduction of these neurons' head sensitivity during the saccadic part of gaze shifts in monkey [6]. Earlier data have indicated that a similar class of vestibular neurons in the cat are inhibited by saccadic burst neurons. On the other hand, several categories of neurons previously known to discharge in relation to saccadic eye movements in the head restrained condition have been shown to actually encode the total displacement of gaze (eye + head) in space: this has been shown for some saccadic burst neurons and omnipause neurons of the reticular formation, and for all burst neurons and fixation neurons of the superior colliculus. Although these findings are consistent with the ►gaze feedback hypothesis that was initially proposed to account for the maintenance of gaze accuracy despite VOR inhibition, the existence and neural implementation of such gaze feedback is still highly debated [7].

To summarize, gaze orientation towards a target of interest is based on a desired gaze displacement command, which has to be decomposed in separate commands for eye and head. The VOR response is inhibited during the saccadic part of the gaze shift and the gaze trajectory is controlled by internal feedback. The termination of the saccadic pulse generator activity, due to this feedback control, and the resumption of a unity VOR gain are both involved in the accurate termination of the gaze shift on the target, and in the subsequent gaze stabilization independently of any residual head movement.

## Involved Structures

To a large extent, the search for mechanisms responsible for eye-head coordination has so far focused on the brainstem, the superior colliculus and the cerebellum. As already stated above, a candidate neural substrate of the intra-saccadic VOR inhibition has been found at the brainstem level, involving an inhibition of PVPs neurons during saccades, likely arising directly from saccadic burst neurons. Note also that another pathway, this time excitatory and running in the opposite direction (from the vestibular complex to saccadic burst neurons), has been suggested in the cat to contribute to the triggering of an eye saccade and/or the acceleration of the eyes during head movement. Although these particular burster-driving neurons have not yet been found in monkey, this type of excitatory, anticompensatory, vestibulo-ocular pathway is probably required in all animals for the triggering of saccade during head movements when there is no explicit target (quick phases of vestibular nystagmus). The superior colliculus is another brainstem structure that has been intensively investigated in different animal species. Since nearly 40 years ago, we have known that saccadic eye movements produced by head-restrained animals are topographically encoded at the level of the deeper collicular layers. More recently, studies in the head-unrestrained cat or monkey have shown that this collicular motor map in fact encodes the saccadic shift of gaze in space rather than the displacement of the eyes in the orbit. Indeed, unit recording, electrical microstimulation and anatomical studies have demonstrated that the SC contains a gaze motor map, and proposed that the SC provides the brainstem pre-motor centers with a desired gaze displacement command [3,8,9]. A remaining question that has not yet found a consensual answer is how and where in the cerebello-reticular network this collicular gaze displacement drive is decomposed into separate commands for the eyes and head. Does this decomposition occur downstream from a gaze pulse generator controlled by a single gaze feedback loop, as postulated in the original gaze feedback hypothesis, or does it occur ahead of two separate (eye and head) generators each controlled by its own feedback loop? Does it occur before or after the level of the spatio-temporal transform (i.e. of the transformation between the neuronal population code used by the SC to represent the desired gaze displacement and the frequency code used by motoneurons)? Gaze-related SC output neurons have been shown to project to the reticular formation both to the eye-related bursters and to the ►reticulo-spinal neurons (RSNs). RSNs in turn send collateral projections to the eye-related premotor neurons and to the spinal pre-cephalomotor neurons. Thus, RSNs are ideally suited to carry this eye-head decomposition process, but additional research is necessary to understand what the specific role of the different subtypes of RSNs is [10]. In any case, the SC is viewed as a major sensory-motor interface between cortical centers, where the appropriate goal for gaze is selected and encoded topographically in gaze coordinates, and the brainstem reticular formation, where different neuronal populations use a frequency code to represent the individual eye and head components in their respective coordinate frames.

### Methods to Measure This Event/Condition

The neurophysiological description of eye-head coordination mechanisms has long been hampered by the difficult task of recording unit neuronal activities in the head-unrestrained animal; thus, although increasing recently, the amount of data collected in this condition is still modest relative to the vast amount of information on the oculomotor and the vestibular systems collected in the head restrained condition. The situation is even worse for human subjects, since the available neurophysiological methods (neuroimaging and transcranial magnetic stimulation) all require firm stabilization of the subject's head. At the behavioral level, however, several methods are now available to record eye and head movements simultaneously. Beyond describing natural eye-head coordination, behavioral approaches have allowed the development of mechanical head perturbation tests which constitute a privileged way to investigate eye-head coordination. These tests are now increasingly associated with neural recordings in animal studies, allowing us to resolve important issues like the saccade-related inhibition of vestibulo-ocular neurons, and the frame of reference used by oculomotor centers to encode saccadic commands.

## Eye-head Coupling

►Eye-Head Coordination

## Eye-Head Tracking

### Definition

The term "tracking" is used here in a general sense to describe the movement of gaze when the subject actively follows a moving target. When target motion is relatively slow, the term "gaze pursuit" is used more frequently than "tracking." During gaze pursuit eyes make a catch-up saccade shortly after the initiation of target motion and begin a smooth pursuit movement (cf. Smooth pursuit eye movements). The head starts its movement at a longer latency and accelerates to match the target velocity. During this time eye velocity falls to nearly zero and gaze pursuit is accomplished by the head while the eyes make only small corrective movements. The contribution of the head is however smaller if the target reverses periodically its direction. Tracking at high velocities consists of a head movement and a sequence of saccadic eye movements. Head movement is usually not smooth and shows accelerations synchronous with eye saccades. In spite of repetitive saccades orbital position of the eyes (relative to the head) remains close to the resting position because of the counter-rolling induced by the vestibuloocular reflex (VOR). Gaze movement in space and time resembles therefore a staircase of gaze saccades with steady gaze positions in between.

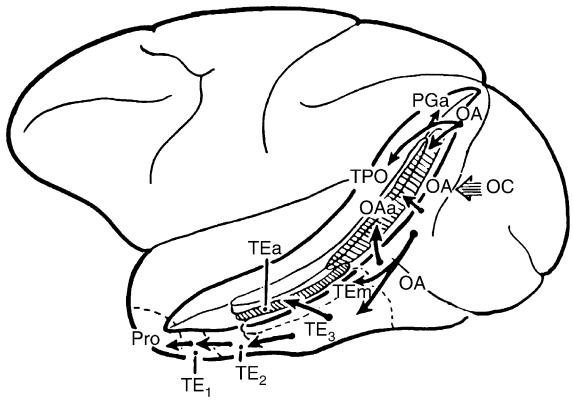
### Characteristics

#### Neuronal Responses to Faces in Different Temporal Lobe Cortex Visual Areas

Visual pathways project by a number of cortico-cortical stages from the primary visual cortex (Brodmann's area 17, striate cortex, area V1; ►Striate cortex functions) until they reach the ►temporal lobe visual cortical areas in which some neurons that respond selectively to faces are found [1–4]. The inferior temporal visual cortex, area TE (►cerebro-cortical area TE), is divided on the basis of cytoarchitecture, myeloarchitecture, and afferent input into areas TEa (►cerebro-cortical area TEa), TEm (►cerebro-cortical area TEm), TE3 (►cerebro-cortical area TE3), TE2 (►cerebro-cortical area TE2) and TE1 (►cerebro-cortical area TE1). In addition there is a set of different areas in the cortex in the superior temporal sulcus (►STS) [5] (see Fig. 1).

Of these latter areas, area TPO (►cerebro-cortical area TPO) receives inputs from temporal, parietal and occipital cortex; areas PGa (►cerebro-cortical area PGa) and IPa (►cerebro-cortical area IPa) from parietal and temporal cortex; and areas TS (►cerebro-cortical area TS) and ►TAa (►cerebro-cortical area TAa) primarily from auditory areas.

Considerable specialization of function was found in recordings made from more than 2,600 neurons in the architectonically defined areas [5]. Areas TPO, PGa and IPa are multimodal, with neurons that respond to visual, auditory and/or somatosensory inputs; the inferior temporal gyrus and adjacent areas (TE3, TE2, TE1, TEa and TEm) are primarily unimodal visual areas; areas in the cortex in the anterior and dorsal part of the superior temporal sulcus [e.g. TPO, IPa and IPg (►cerebro-cortical area IPg)] have neurons specialized for the analysis of moving visual stimuli; and neurons responsive primarily to faces are found more frequently in areas TPO, TEa and TEm, where they comprise approximately 20% of the visual neurons responsive to stationary stimuli, in contrast to the other temporal cortical areas in which they comprise 4–10%. Moreover, neurons with responses related to facial expression, movement, and gesture are more likely to be found in the cortex in the superior temporal sulcus, whereas neurons with activity related to facial identity are more likely to be found in the TE areas [3].



**Face Processing in Different Brain Areas.**
**Figure 1** Lateral view of the macaque brain (*left*) and coronal section (*right*) showing the different architectonic areas (e.g. TEm, TPO) in and bordering the anterior part of the superior temporal sulcus (STS) of the macaque (see text).

In human ►fMRI studies, evidence for specialization of function is also described [6,7] related to face processing (in the ►fusiform gyrus face area, which may correspond to parts of the macaque inferior temporal visual cortex in which face neurons are common); to face expression and gesture (i.e. moving faces) (in the cortex in the superior temporal sulcus, which corresponds to the macaque cortex in the superior temporal sulcus); to objects (in an area that may correspond to the macaque inferior temporal cortex in which object but not face representations are common, as described above) (►Visual object representation); and to spatial scenes (in a parahippocampal area which probably corresponds to the macaque ►parahippocampal gyrus areas in which neurons are tuned to spatial view and to combinations of objects and the places in which they are located [3,4]. However, there is much debate arising from these human fMRI studies about how specific each region is for a different type of function. The single neuron studies in macaques described above and below show that individual neurons can be highly tuned in that they convey information about face identity, or about face expression, or about objects, or about spatial view. The recording studies show that within these different classes, individual neurons by responding differently to different members of the class convey information about whose face it is, what the face expression is, etc., using a sparse distributed code with an approximately exponential firing rate probability distribution. The neuronal recording studies also show that each cytoarchitectonically defined area contains different proportions of face identity vs. object neurons, but that the proportion of face-selective neurons in any one area is not higher than 20% of the visually responsive neurons in a cytoarchitectonically defined area, so that considerable intermixing of specifically tuned neurons is the rule [5]. The neuronal recording studies also show that at the fine spatial scale, *clusters of neurons* extending for approximately 0.5–1 mm with tuning to one aspect of stimuli are common (e.g. face identity, or the visual texture of stimuli, or a particular class of head motion), and this can be understood as resulting from self-organizing mapping based on local cortical connectivity when a high-dimensional space of objects, faces etc must be represented on a two-dimensional cortical sheet (►Computational mechanisms for object and face recognition) [2,4]. Consistent with self-organizing map principles, there is a high concentration of face-selective neurons within a patch identified by fMRI [8], though face areas may be interspersed with non-face areas consistent with the neurophysiology.

## The Selectivity of One Population of Neurons for Faces

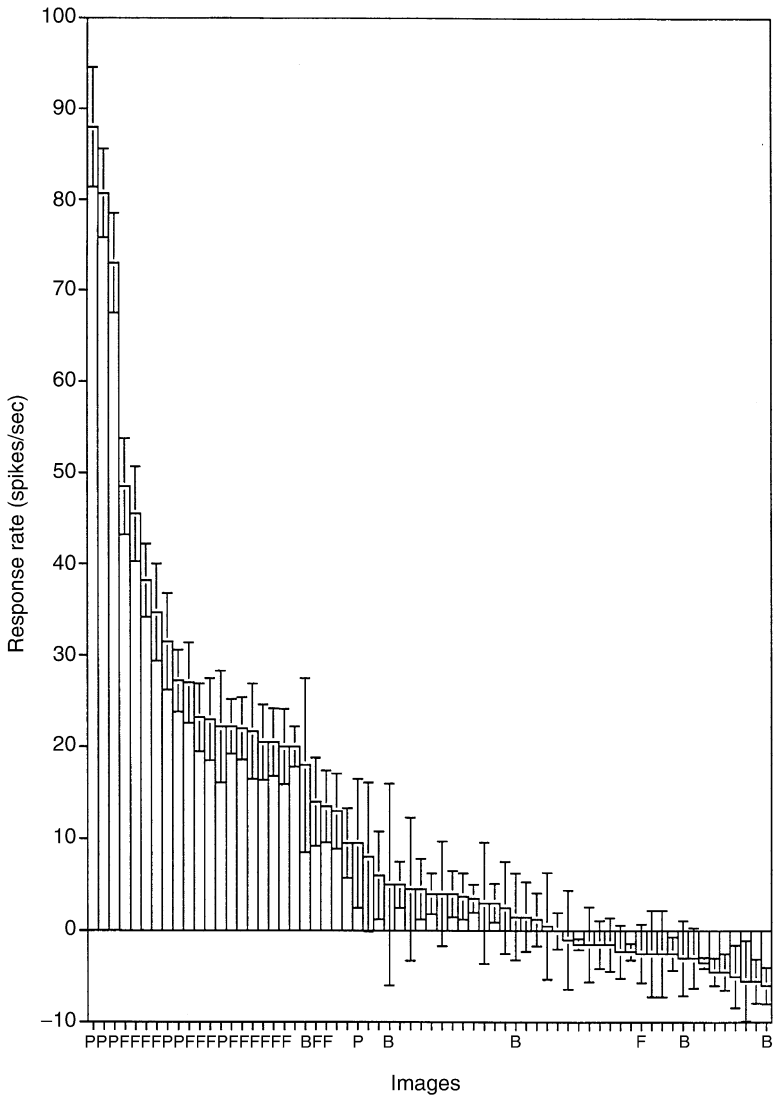
The neurons described in our studies as having responses selective for faces are selective in that they respond 2–20 times more (and statistically significantly more) to faces than to a wide range of gratings, simple geometrical stimuli, or complex 3-D objects [3]. These neurons are specialized to provide information about faces in that they provide much more information (on average 0.4 bits) about which (of 20) face stimuli is being seen than about which (of 20) non-face stimuli is being seen (on average 0.07 bits) [3,4]. These information-theoretic (►Information theory) procedures provide an objective and quantitative way to show what is "represented" by a particular population of neurons.

## Neurons Selective for Individual Face Features or for Combinations of Face Features

Masking out or presenting parts of the face (e.g. eyes, mouth, or hair) in isolation reveal that different cells respond to different features or subsets of features, and some require all the features to be present in the correct spatial configuration (i.e. not jumbled) [1,3,4].

## Distributed Encoding of Face Identity

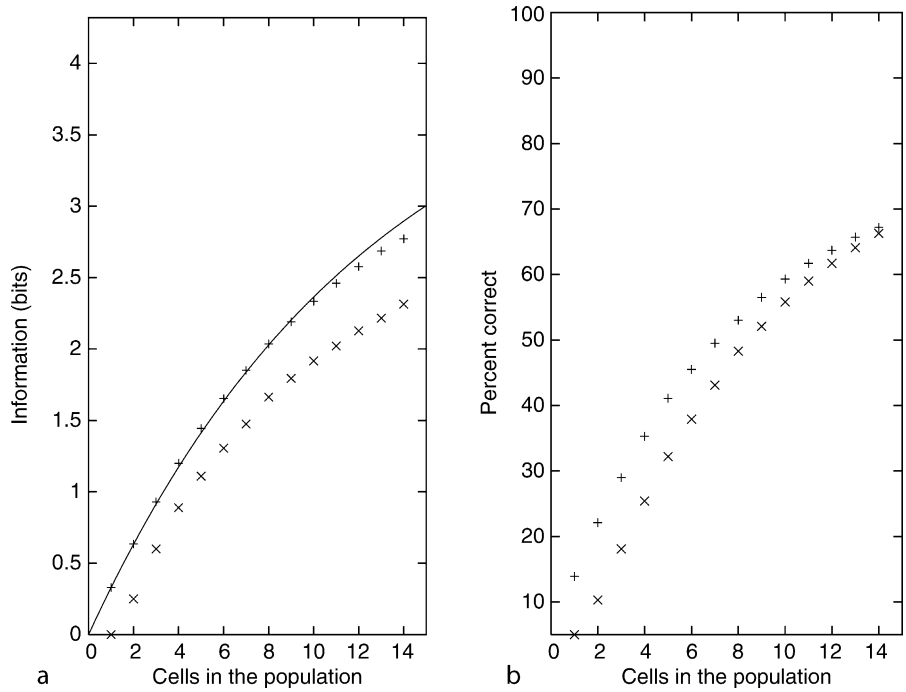
An important question for understanding brain function is whether a particular object (or face) is represented in the brain by the firing of one or a few ►gnostic (or "grandmother") cells, or whether instead the firing of a group or ensemble of cells each with different profiles of responsiveness to the stimuli provides the representation. It has been shown that the representation of which particular face is present is distributed. For example, in a study using 23 faces and 45 non-face natural images a distributed representation was found, with rather few stimuli producing high firing rates, and increasingly large numbers of stimuli producing lower and lower firing rates (see Fig. 2).



**Face Processing in Different Brain Areas. Figure 2** Firing rate distribution of a single neuron in the temporal visual cortex to a set of 23 face (F) and 45 non-face images of natural scenes. The firing rate to each of the 68 stimuli is shown. P indicates a face profile stimulus, a B a body part stimulus such as a hand. (See refs [3,4]).

Indeed, the firing rate probability distribution of many neurons is approximately exponential [3,4].

Complementary evidence comes from applying information theory to analyze how information is represented by a population of these neurons. The information required to identify which of $S$ equiprobable events occurred (or stimuli were shown) is $\log_2 S$ bits. (Thus 1 bit is required to specify which of two stimuli was shown, 2 bits to specify which of four stimuli was shown, 3 bits to specify which of eight stimuli was shown, etc.) The important point for the present purposes is that if the encoding was local (or grandmother cell-like), the number of stimuli encoded by a population of neurons would be expected to rise approximately linearly with the number of neurons in the population. In contrast, with distributed encoding, provided that the neuronal responses are sufficiently independent, and are sufficiently reliable (not too noisy), the number of stimuli encodable by the population of neurons might be expected to rise exponentially as the number of neurons in the sample of the population was increased. The information available about which of 20 equiprobable faces had been shown that was available from the responses of different numbers of these neurons increases approximately linearly with the number of neurons in the population (see Fig. 3), and thus the representational capacity increases exponentially with the number of neurons in the ensemble (Fig. 4) [3,4].



**Face Processing in Different Brain Areas. Figure 3** (a) The values for the average information available in the responses of different numbers of these neurons on each trial, about which of a set of 20 face stimuli has been shown. The decoding method was Dot Product (DP, x) or Probability Estimation (PE, +), and the effects obtained with cross validation procedures utilizing 50% of the trials as test trials are shown. The remainder of the trials in the cross-validation procedure were used as training trials. The full line indicates the amount of information expected from populations of increasing size, when assuming random correlations within the constraint given by the ceiling (the information in the stimulus set, I = 4.32 bits). (b) The percent correct for the corresponding data to those shown in Fig. 3a. (See refs [3,4]).

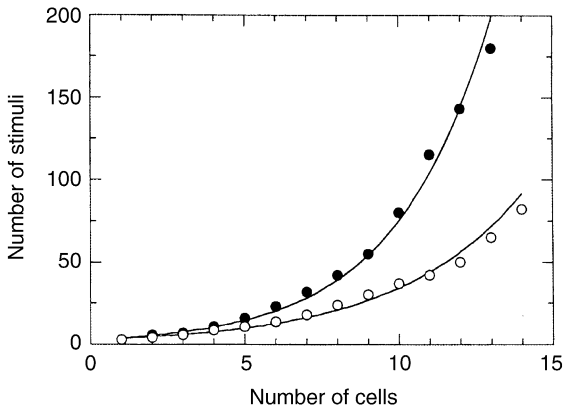
This is further evidence for distributed encoding, and for the power of the code used.

The code that is used in the inferior temporal visual cortex is primarily the number of spikes from each neuron (i.e. a rate code), for very little (not more than approximately 5% of the total information) was available from stimulus-dependent synchrony [3,4]. The same result was found in natural scenes in which two test images had to be segmented from a complex background, the features of each object had to be bound together, and the monkey had to use top-down attention (►Visual attention) to search for one of two images in a complex scene [3,4].

The advantages of the code that has been found include exponentially high coding capacity, readability by a neuronally plausible (synaptically) weighted sum of the firing rates of different neurons, resistance to noise, generalization, completion, graceful degradation or fault tolerance, and speed of readout of the information, as described elsewhere [3,4].

## Invariant Representations

One of the major problems that must be solved by a visual system is the building of a representation of visual information, which allows recognition to occur relatively independently of size, contrast, spatial frequency, position on the retina, angle of view, etc. This is required so that if the receiving associative networks (in e.g. the ►amygdala, ►orbitofrontal cortex and ►hippocampus) learn about one view, position, etc. of the object, the organism generalizes correctly to other positions, views etc. of the object. It has been shown that the majority of face-selective inferior temporal cortex neurons have responses that are relatively invariant with respect to the size of the stimulus [3,4], and the exact position of the face on the retina (translation invariance). Interestingly, the receptive fields become smaller (and still include the fovea) when faces or objects are seen against a complex natural background, and this helps with the ►binding problem [3,4]. It makes the interface to action simpler, in that what is at the fovea can be interpreted (e.g. by an ►associative memory in the orbitofrontal cortex or amygdala) partly independently of the surroundings, and choices and actions can be directed if appropriate to what is at the fovea [2–4]. Some neurons have view-invariant responses to faces (which would be useful for ►face recognition, and indeed these neurons tend to be tuned to face identity). Other neurons



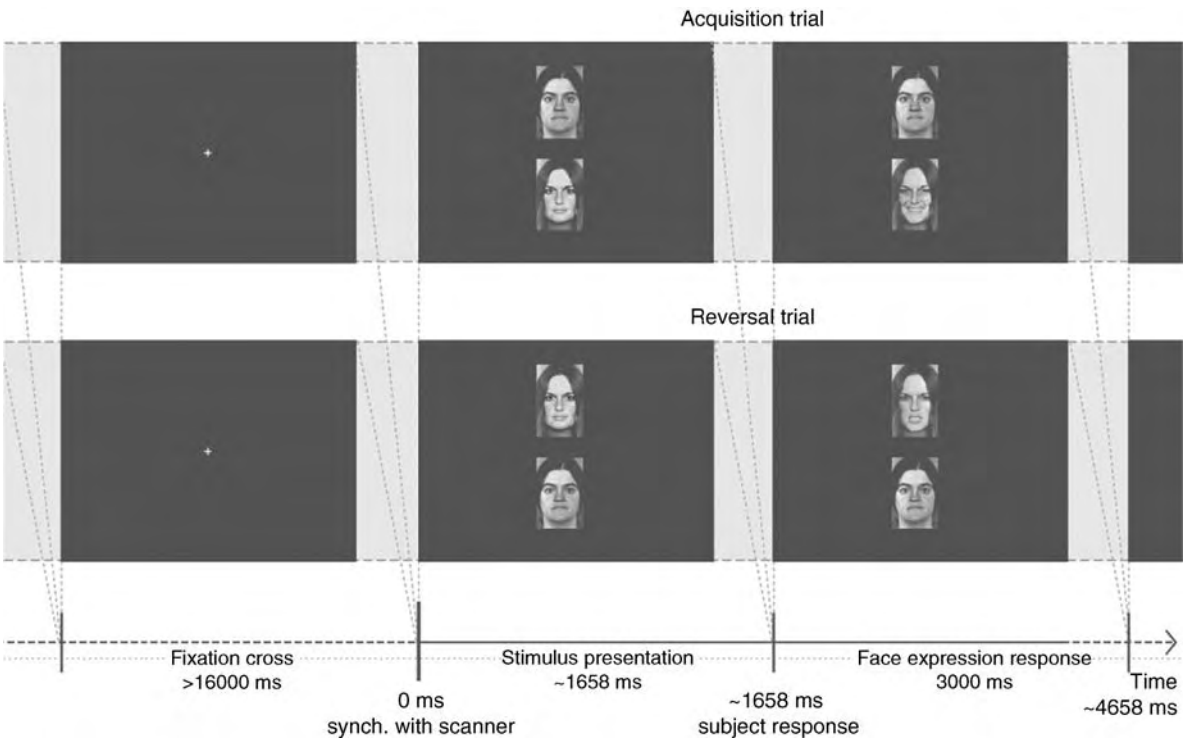
**Face Processing in Different Brain Areas. Figure 4** The number of stimuli (in this case from a set of 20 faces) that are encoded in the responses of different numbers of neurons in the temporal lobe visual cortex, based on the results shown in Fig. 3. The decoding method was Dot Product (DP, open circle) or Probability Estimation (PE, filled circle.) (See refs [3,4]).

have view-specific responses (which would be useful in social interactions), and indeed are found in the cortex in the superior temporal sulcus where some neurons are tuned to face expression, also useful in social interactions [3,4].

Possible computational mechanisms in the visual cortex for face recognition are described in the article by Deco and Rolls in this Encyclopedia (Computational mechanisms for object and face recognition), and elsewhere [2,4,9].

## A Representation of Faces in the Amygdala

Outputs from the temporal cortical visual areas reach the amygdala, and evidence is accumulating that these brain areas are involved in social and emotional responses to faces [10]. For example, we have identified a population of neurons with face-selective responses in the primate amygdala, some of which may respond to facial and body gesture. In humans, amygdala damage can impair the recognition of fear face expressions, and



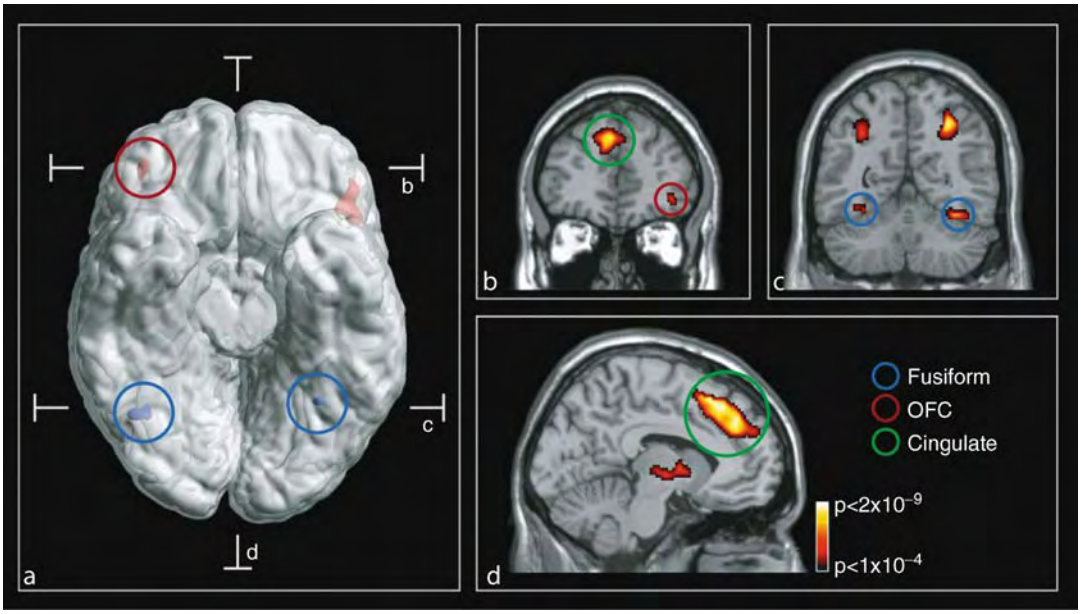
**Face Processing in Different Brain Areas. Figure 5** Social reversal task: The trial starts synchronized with the scanner and two people with neutral face expressions are presented to the subject. The subject has to select one of the people by pressing the corresponding button, and the person will then either smile or show an angry face expression for 3,000 ms depending on the current mood of the person. The task for the subject is to keep track of the mood of each person and choose the "happy" person as much as possible (*upper row*). Over time (after between 4 and 8 correct trials) this will change so that the "happy" person becomes "angry" and vice versa, and the subject has to learn to adapt her choices accordingly (*bottom row*). Randomly intermixed trials with either two men, or two women, were used to control for possible gender and identification effects, and a fixation cross was presented between trials for at least 16,000 ms. (After Kringelbach, Rolls (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. Neuroimage 20:1371–1383).

extraversion influences whether activations will be found to happy faces [10].

### A Representation of Faces in the Orbitofrontal Cortex

Rolls, Critchley, Browning and Inoue have found a number of face-responsive neurons in the orbitofrontal cortex, and they are also present in adjacent ►prefrontal cortical areas [3,4]. The orbitofrontal cortex face-responsive neurons, first observed by Thorpe, Rolls, and Maddison in 1982, tend to respond with longer latencies than temporal lobe neurons (140–200 ms typically, compared with 80–100 ms); and can convey information about which face is being seen, by having different responses to different faces. Some of the orbitofrontal cortex face-selective neurons are responsive to face gesture or movement, and others to face expression [3,4]. The findings are consistent with the likelihood that these neurons are activated via the inputs from the temporal cortical visual areas in which face-selective neurons are found. The significance of the neurons is likely to be related to the fact that faces convey information that is important in social reinforcement, both by conveying face expression, which can indicate reinforcement, and by encoding information about which individual is present, also important in evaluating and utilizing reinforcing inputs in social situations [10].

We have also been able to obtain evidence that non-reward used as a signal to reverse behavioral choice is represented in the human orbitofrontal cortex (see [10]).



**Face Processing in Different Brain Areas. Figure 6** Social reversal: Composite figure showing that changing behavior based on face expression is correlated with increased brain activity in the human orbitofrontal cortex. (a) The figure is based on two different group statistical contrasts from the neuroimaging data which are superimposed on a ventral view of the human brain with the ►cerebellum removed, and with indication of the location of the two coronal slices (b, c) and the transverse slice (d). The red activations in the orbitofrontal cortex (denoted OFC, maximal activation: Z = 4.94: 42,42,−8; and Z = 5.51; x,y,z = −46, 30, −8) shown on the rendered brain arise from a comparison of reversal events with stable acquisition events, while the blue activations in the fusiform gyrus (denoted Fusiform, maximal activation: Z > 8; 36,−60,−20 and Z = 7.80; −30,−56,−16) arise from the main effects of face expression. (b) The coronal slice through the frontal part of the brain shows the cluster in the right orbitofrontal cortex across all nine subjects when comparing reversal events with stable acquisition events. Significant activity was also seen in an extended area of the anterior ►cingulate/paracingulate cortex (denoted Cingulate, maximal activation: Z = 6.88; −8,22,52; green circle). (c) The coronal slice through the posterior part of the brain shows the brain response to the main effects of face expression with significant activation in the fusiform gyrus and the cortex in the ►intraparietal sulcus (maximal activation: Z > 8; 32, −60, 46; and Z > 8: −32, −60,44). (d) The transverse slice shows the extent of the activation in the anterior cingulate/paracingulate cortex when comparing reversal events with stable acquisition events. Group statistical results are superimposed on a ventral view of the human brain with the cerebellum removed, and on coronal and transverse slices of the same template brain (activations are thresholded at P = 0.0001 for purposes of illustration to show their extent). (After Kringelbach, Rolls (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. Neuroimage 20:1371–1383).

Kringelbach and Rolls used the faces of two different people, and if one face was selected then that face smiled, and if the other was selected, the face showed an angry expression. After good performance was acquired, there were repeated reversals of the visual discrimination task. Kringelbach and Rolls found that activation of a lateral part of the orbitofrontal cortex in the fMRI study was produced on the error trials, that is when the human chose a face, and did not obtain the expected reward (see Figs. 5 and 6).

An interesting aspect of this study that makes it relevant to human social behavior is that the conditioned stimuli were faces of particular individuals, and the unconditioned stimuli were face expressions. Moreover, the study reveals that the human orbitofrontal cortex is very sensitive to social feedback when it must be used to change behavior (see [3,4,10]).

To investigate the possible significance of the neurons in the orbitofrontal cortex with face-related inputs, we also tested the responses to faces of patients with orbitofrontal cortex damage. We included tests of face (and also voice) expression decoding, because these are ways in which the reinforcing quality of individuals is often indicated. Impairments in the identification of facial and vocal emotional expression were demonstrated in a group of patients with ventral frontal lobe damage who had socially inappropriate behavior (see [3,4,10]). The expression identification impairments could occur independently of perceptual impairments in facial recognition, voice discrimination, or environmental sound recognition. The face and voice expression problems did not necessarily occur together in the same patients, providing an indication of separate processing.

To obtain clear evidence that the changes in face and voice expression identification, emotional behavior, and subjective emotional state were related to orbitofrontal cortex damage itself, and not to damage to surrounding areas which is present in many closed head injury patients, we performed further assessments in patients with circumscribed lesions made surgically in the course of treatment [3,4]. We found that some patients with bilateral lesions of the orbitofrontal cortex had deficits in voice and face expression identification [3,4]. (The same group of patients had deficits on a probabilistic monetary reward reversal task, indicating that they have difficulty not only in representing reinforcers such as face expression, but also in using reinforcers (such as monetary reward) to influence behavior.) Some patients with unilateral damage restricted to the orbitofrontal cortex also had deficits in voice expression identification. Patients with unilateral lesions of the antero-ventral part of the anterior cingulate cortex and/or medial prefrontal cortex area BA9 were in some cases impaired on voice and face expression identification.

F

# Facial Nerve (VII)

## Synonyms

N. facialis (N.VII)

## Definition

The facial nerve conducts three qualities:

- Motor efferents for innervating the mimetic muscles: Nucleus: nucleus of the facial nerve
- Visceromotor control: parasympathetic innervation of salivary and lacrimal glands. Nucleus: salivatory nuclei
- Somatosensory control: sensory innervation of the tongue (anterior 2/3) and of the external ear

Qualities (2) and (3) are mediated by the intermediate maxillary nerve (V2) which is a permanent part of the facial nerve. Skull: internal acoustic meatus. Peripheral damage to the facial nerve leads to facial paresis. Depending on the localization of the lesion, symptoms with different degrees of expression are manifest even including complete paralysis of the ipsilateral facial musculature.

►Nerves

## Facilitation of Synaptic Transmission

### Definition

The increase in postsynaptic response to presynaptic release of neurotransmitter that occurs during trains of stimuli. At the neuromuscular junction as well as other synapses, facilitation is thought to be due to increased release of neurotransmitter from the presynaptic terminal.

►Neuromuscular Junction

## Facioscapulohumeral Dystrophy

### Definition

Inherited, autosomal dominant, relatively mild muscular dystrophy that affects both sexes, usually starts in adolescence and affects face and shoulder girdle.

## Faintness

### Definition

Lack of strength with a feeling of giddiness, swaying of ground or surrounding objects, and impending loss of consciousness (pre-syncope; see ►syncope).

## False-Belief Tasks

### Definition

Tasks which require a child to attribute a belief to another that differs from his own, e.g. a false belief.

Young three-year-olds and autistic children with a verbal age under 5 years regularly fail these standard tests, while normally developing four-year-olds pass, because they understand that people have false beliefs and act on them.

►Theory Theory (Simulation Theory, Theory of Mind)

## False Memories

### Definition

Memories for details or entire events that never occurred.

►Memory Distortion

## False Memory

►Memory Distortion

## Falsification

### Definition

Falsification is an operation to be performed on theories. A theory is said to be falsified or refuted if it (i) contradicts an observation sentence and (ii) the truth of this observation sentence has been established.

►Information

## Falx Cerebelli

### Definition

The tuber vermi and pyramid vermis are located quite deep between the two cerebellar hemispheres. Into this cleft, resting on the occipital bone, protrudes an evagination of dura mater, which, shaped like a sickle, follows the course of this groove. This sickle-shaped evagination of the dura mater is called the falx cerebelli. Its bigger counterpart is called the falx cerebri. This divides the two cerebral hemispheres.

►Cerebellum

## Falx Cerebri

### Definition

The dura mater forms a tough, sickle-shaped (falx – sickle) layer of tissue that stretches over the entire

length and depth of the longitudinal fissure of cerebrum.

At the cranium it forms a cavity, the superior sagittal sinus, and likewise at its free end: inferior sagittal sinus.

►Meninges & Cisterns

## Familial Hemiplegic Migraine (FHM)

### Definition

Rare subtype of ►migraine with aura (MA) and is caused by three genes: CACNA1A (FHM1), ATP1A2 (FHM2), and SCN1A (FHM3). It is unclear at present how these mutations may trigger migraine attacks as well as, in particular, the accompanying ►hemiplegic features and, in some families, paroxysmal or progressive ►ataxia and ►epileptic seizures. Possibly, mutations in CACNA1A alter $Ca^{2+}$ influx and currents in neurons, possible factors of cortical ►spreading depression, which could underlie the migraine aura. Also, abnormal intracellular $Ca^{2+}$ concentrations could alter ►neurotransmitter release. ATP1A2 mutations might entail faulty ►$Na^+/K^+$ exchange leading to abnormal $K^+$ concentrations and subsequent depolarization and increased tendency for spreading depression, and/or abnormal $Ca^{2+}$ concentrations because of the concomitant activation of the $Na^+/Ca^{2+}$ exchanger.

►Headache

## Familial Periodic Paralyses

### Definition

Familial periodic paralyses comprise a group of hereditary diseases resulting from ►channelopathies (dysfunctions of ion channel proteins) and characterized by repetitive attacks of flaccid muscle weakness (potentially cardiac arrhythmias), a third of the patients developing permanent muscle weakness and degeneration at older age. In ►hyperkalemic periodic paralysis (loss of muscle strength) and ►hypokalemic periodic paralysis, mutations affect the ►voltage-gated $Na^+$ and $Ca^{2+}$ channels (essential for ►action potential generation and muscle ►excitation-contraction coupling). Slow, long-lasting depolarization of the sarcolemma during the attacks appears to inactivate $Na^+$ channels, prevent the initiation of action potentials and leading to ►electromyographic silence. In the Andersen syndrome, the gene defect also affects the heart muscle, raising the danger of ventricular arrhythmias.

►Action Potential
►Electromyography
►Excitation-contraction Coupling
►Hyperkalemic Periodic Paralysis
►Hypokalemic Periodic Paralysis

## Familial Spastic Paraplegia

### Definition

Familial spastic paraplegia refers to a group of genetic disorders of the central nervous system affecting primarily the upper motor neuron pathways. They are characterized by slowly progressive disability associated with hyperactive tendon reflexes and increased muscle tone in the legs with Babinski responses. There are more than 30 different genetic subtypes inherited as autosomal dominant, autosomal recessive, or x-linked disorders. They may be uncomplicated or complicated (associated with other phenomena such as mental retardation, ataxia, or seizures).

►Neurogenetic Diseases

## Familiarity

### Definition

Familiarity is psychological experience of sensing that a stimulus or event as has previously been experienced.

The feeling of familiarity is generally distinguished from the concomitant recollection of the contextual details in which the stimulus was originally encountered.

►Recognition Memory

## Familiarization

### Definition

Process through which the novelty of a sensory stimulus (and more generally of a context, device, or cognitive

F

task), and related reflex-like actions of the organism, are decreased. Familiarization influences the encoding of a stimulus at several levels of the sensory pathway, and therefore modifies the neurophysiological and behavioral responses to the stimulus already experienced. It may also interfere with subsequent learning events involving that stimulus (such as Pavlovian conditioning). In reducing the reactivity to familiar cues, this process indirectly contributes to orient the attention towards other information from the surroundings. Familiarization differs from habituation, which only occurs after a sustained repeated exposure to a stimulus.

►Attention
►Classical Conditioning (Pavlovian Conditioning)

## Farad (F)

### Definition

Farad (F) is the unit of capacitance: capacity of a condensor to carry a charge of one coulomb with a potential difference of 1 V between two plates.

## Fascia

### Definition

A collagen fiber reinforced sheet of connective tissue. It contains collagen fibers running in many directions.

►Intramuscular Myofascial Force Transmission

## Fascicle

### Definition

A bundle of axons surrounded by a multicellular laminated perineurial sheath. Axons are loosely packed inside fascicles within the endoneurial connective tissue. Also, a group of muscle fibers surrounded by perimysium.

►Skeletal Muscle Architecture

## Fasciculations

### Definition

Visible, fine, rapid flickerings of skeletal muscle occurring in neurogenic ►muscle dystrophies, reflecting synchronous contractions of all muscle fibers in a ►motor unit whose ►motoneurons are progressively degenerating.

## Fast and Slow Twitch Muscle Fibers

### Definition

Whole muscle is comprised of individual cells known as muscle fibers. Differences in twitch properties and fatigability delineate muscle fiber types. Fibers classed as "slow twitch" exhibit low speeds of shortening and tend to be fatigue resistant. Fibers classed as "fast twitch" exhibit high speeds of shortening and tend to be fatigue sensitive. In addition, fast twitch fibers tend to display PTP.

►Force Potentiation in Skeletal Muscle
►Motor Units

## Fast Fourier Transform

### Definition

An efficient algorithm for computing the Discrete Fourier Transform.

►Signals and Systems

## Fast Spiking

### Definition

Some neurons are capable of high-rate repetitive discharge with little decrease in rate upon prolonged stimulation.

►Action Potential

## Fastigial Nucleus

### Synonyms
►Nucl fastigii

### Definition
The fastigial nucleus receives its afferents (i) from the Purkinje fibers of the vermis cerebelli, (ii) directly from the vestibular apparatus and (iii) via collaterals from the vestibular nucleus. Its efferents course as the uncinate fasciculus via the inferior cerebellar peduncle to the vestibular nuclei and the reticular formation on the contralateral side.

►Cerebellum

## Fastigial Oculomotor Region (FOR)

### Definition
A part of the caudal fastigial nucleus (the most medial of the deep cerebellar nuclei) that participates in the control of saccadic and smooth-pursuit eye movements.

The FOR receives input from the oculomotor vermis (vermal portions of lobules VIc and VII) and various brainstem nuclei.

►Cerebellum – Fastigial Oculomotor Region (FOR)
►Cerebellum – Role in Eye Movements

## Fastigium

### Definition
The cerebellum rests on the roof the fourth ventricle. Endowed with a sharp gable, this roof penetrates deeply into the trunk of the arbor vitae.

This gable-shaped extension is called the fastigium. It is also an eponymous designation for the fastigial nuclei situated in the cerebellum.

►Cerebellum

## Fatal Familial Insomnia (FFI)

### Definition
A rare, hereditary brain disease characterized by disrupted sleep (insomnia), motor abnormalities, and hyperactivation of the autonomic nervous system caused by a dual mutation in the gene encoding prion protein (PrP). The mutant protein aggregates to cause plaque development in the thalamus. The disease progresses into complete sleeplessness, is untreatable, and ultimately fatal between 7 and 36 months from onset. It was first detected by the Italian doctor Ignazio Roiter in 1979.

►Sleep Homeostasis

## Fatigue

### Definition
The reversible decline in the muscle performance due to prolonged or intense muscle activity. Fatigue due to metabolic and/or ionic changes in the working muscle itself is known as “peripheral” fatigue.

►Force Potentiation in Skeletal Muscle

## Fatty Acid Amide Hydrolase or FAAH

### Definition
Fatty acid amide hydrolase or FAAH is an enzyme that hydrolyzes bioactive amides including the endogenous cannabinoid anandamide to free arachidonic acid and ethanolamine. It is therefore viewed as an attractive drug target. FAAH was cloned in 1996 by Ben Cravatt at The Scripps Research Institute.

►Cannabinoids

## FDG

### Definition
The fluorinated analogue of glucose, labeled with fluorine-18 (18F); 2-[18F]-fluoro-2-deoxy-D-glucose;

the most common radiotracer for Positron Emission Tomography (PET).

►Positron Emission Tomography

## Fear Conditioning

### Definition

A learning task in which an initially neutral stimulus (the conditioned stimulus) acquires the capacity to elicit defensive responses after it has been associated or paired with a noxious stimulus (the unconditioned stimulus).

►Emotional Learning/Memory

## Fear Extinction

### Definition

A decrease in conditioned fear responses to a conditioned stimulus previously associated with an aversive unconditioned stimulus. Studies of fear extinction have been prominent in determining the neural circuitry of extinction.

►Learning and Extinction

## Fear Memory

### Definition

Memory of an event that evoked fear-based responses.

►Emotional Learning/Memory

## Feature-based Attention in Vision

### Definition

Feature-based attention refers to mechanisms by which a particular feature (e.g. a color, or shape of an object) is selected for further processing and its evoked response is enhanced in the visual system. Feature-based attention can select either an entire feature dimension such as color versus motion or an aspect within a feature dimension such as red versus green. At the neural level, feature-based attention is a global mechanism that enhances processing of the selected feature regardless of where attention is directed spatially.

►Visual Attention

## Feature Extraction

### Definition

The process by which nervous systems detect the occurrence of specific stimulus features.

## Feedback

### Definition

Feedback reflects the use of system measurements (sensors outputs) to determine system actions (actuator inputs).

►Control

## Feedback Control of Movement

Arthur Prochazka
Centre for Neuroscience, University of Alberta, Edmonton, AB, Canada

### Synonyms

Reflex; Reaction; Report; Error detection; Control system

### Definition

Information about the output of a process derived from sensors and delivered as an input to a controller of that process.

## Characteristics

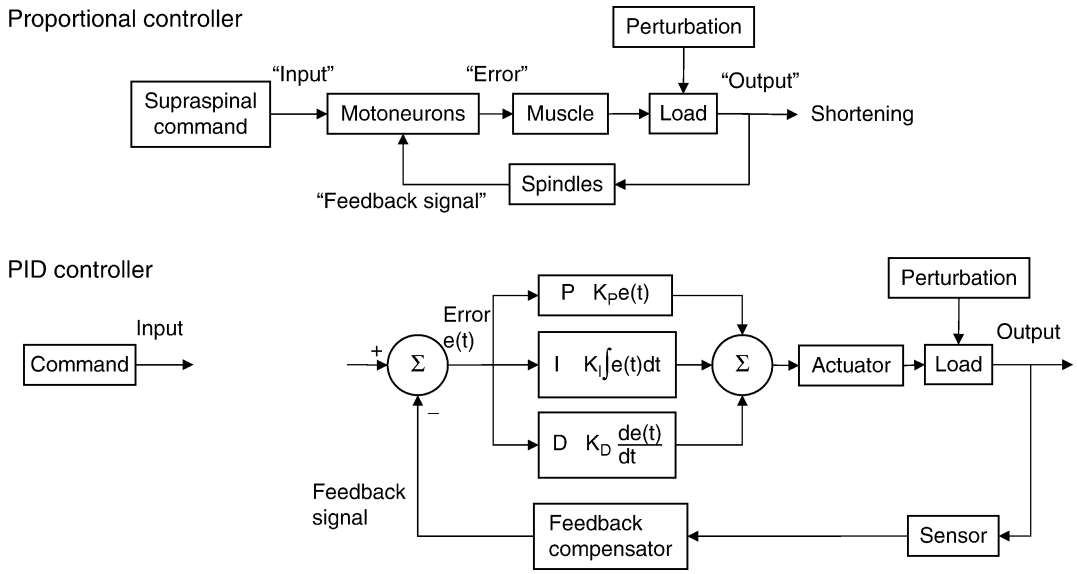
The word *feedback* was coined in 1948 by Norbet Wiener for the emerging field of *Cybernetics*. It is used extensively in engineering, generally in relation to *control systems*. In neurophysiology it is used to describe the signals entering the central nervous system (CNS) from sensory afferents. The CNS uses these signals to control a large number of bodily functions. For example, feedback from arterial baroreceptors is used by neural networks in the brainstem to control blood pressure via the heart and vasoconstrictor muscles. Many of these bodily functions maintain constancy of the internal environment, a process termed ►homeostasis.

With regard to the control of bodily movement, signals from a variety of receptors are involved, including mechanoreceptors in muscles, joints and skin, as well as higher-order receptor organs such as the eyes, ears and vestibular apparatus. All levels of the CNS from the spinal cord to the cerebellum and cerebral cortex receive feedback from mechanoreceptors and all these levels are involved to some extent in controlling even the simplest limb movements.

Historically, the study of movement control began with observations in the eighteenth and nineteenth centuries on simple responses to limb perturbations in animals in which the spinal cord had been severed, thereby eliminating supraspinal mechanisms. The underlying premise, first explicitly stated in 1864 by Ivan Sechenov in his book *Reflexes of the brain*, was that all movements, no matter how complex, could be broken down into elemental sensori-motor reactions called reflexes. By studying many types of reflex, one would eventually understand complex motor control. It is interesting to note that the Roman poet Ovid used the word *reflex* in the sense of *bring back*. Substitute *feed* for *bring* and we have *feedback*. Various types of feedback system exist in technology and whenever a new variant is developed, it is not long before a parallel is drawn with a CNS control function. The main types of feedback control are:

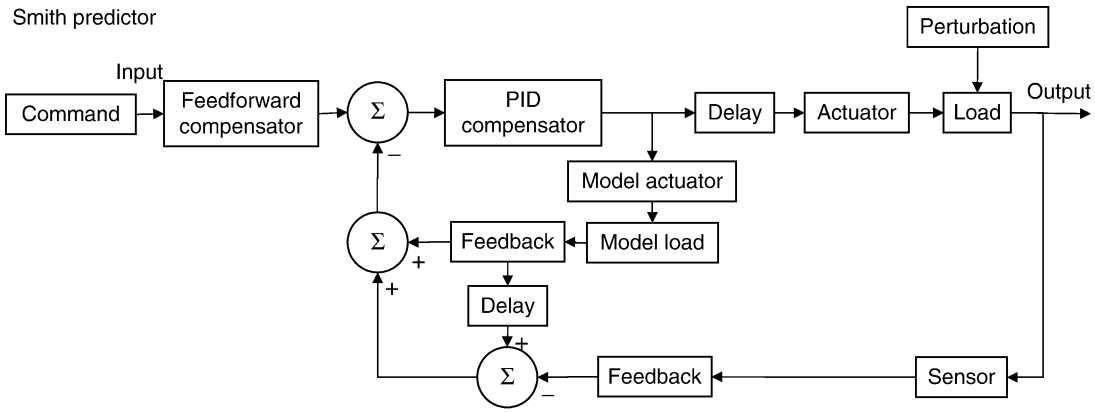
1. Finite state control (arguably the simplest form of feedback control). A sensor monitors a variable (e.g. the angular position of gearwheel in a clock). When the variable reaches a pre-set value, a new state in the process is initiated (e.g. a bell rings). In 1874, A. Freusberg found that when the hind-limb of a spinally-transected dog was dropped from a flexed position, at some point in the descent, the flexor muscles were suddenly activated and the limb flexed upward again. If the downward movement was stopped before this point, no reflex flexion occurred, indicating that a pre-set amount of extension was required to trigger the flexion phase. Later it was shown that during locomotion, it is not only the amount of extension or flexion, but also the amount of force being generated that determines when the spinal cord switches between the stance and swing phases of locomotion [1]. In finite-state control, sensory thresholds, actuator states and state-transition rules are rigidly defined. Movement control in animals is no doubt more flexible than this.
2. Proportional control (►Servo control). This is a continuous form of feedback in which a comparator continuously computes the difference (*mismatch or error*) between a sensed variable (*output*) and the desired value of that variable (*input*) and causes an actuator (e.g. muscle) to minimize this error. The output is thereby made to follow variations in the input or command signal. Furthermore, external perturbations that cause an error are automatically resisted. The error computation is equivalent to subtracting the feedback signal from the input signal, hence "negative feedback." The spinal feedback loop comprising ►muscle spindles, motoneurons and the muscles they innervate (Fig. 1) is often likened to a proportional negative feedback loop. The advantage of proportional feedback control is that variations in muscle function, e.g. fatigue, are automatically compensated for, because the feedback loop minimizes the error between output and input by appropriately modulating the drive to the muscle. The higher the loop gain (the product of the gains of all the elements in the loop) the better the error correction, but if there are significant delays around the loop and if the loop gain is high, uncontrolled oscillation can develop at a cycle period of two times the delay. The feedback signal effectively adds an error rather than subtracting from it, hence the term "positive feedback."
3. Compensated control. When nonlinear properties of the actuator and load are known, it is advantageous to include components in the forward and feedback pathways of the control loop that compensate for these nonlinearities. This can improve response time and accuracy by allowing a larger loop gain before instability occurs. Numerous types of compensators have been developed in technology. The type commonly used as an analogy of biological control is the proportional integral differential (PID) controller, which is a proportional controller with additional differentiating and integrating elements in either the forward or feedback pathway (Fig. 1b). In *self-organizing* or *adaptive* compensators, the compensation parameters, e.g. the coefficients $K_P$, $K_I$ and $K_D$ in Fig. 1b, are continuously updated on the basis of performance assessments. Because there are many ways to assess performance and to change parameters, adaptive controller design is an art form. The neurophysiological term for the adjustment or updating of transmission parameters is *plasticity*.

F



**Feedback Control of Movement. Figure 1** (a) A simple proportional feedback loop used as an analogy for the stretch reflex. Note that spindle input caused by muscle lengthening excites motoneurons which causes muscles to shorten, so this is an example of a negative feedback loop. (b) The general schema of a proportional-integral-differential controller. The three parallel elements (P, I, D) have separate gains that are adjusted to best compensate for inadequacies of the load-moving actuator.

4. Predictive control. If imminent loading and obstacles can be predicted it is often advantageous to alter the command with an element that provides feedforward compensation (Fig. 2). Another form of prediction that compensates for a known delay in the forward path is implemented with an internal feedback loop that models the actuator and load, but without a delay (Fig. 2). This internal loop can therefore have a high loop gain without becoming unstable. The actual delayed response (output) is compared to the internally delayed modeled response. The residual error is passed back into the internal loop for follow-up correction. This type of controller is called a Smith predictor [2], and it has been suggested as a model for the cerebellar control of movement.
5. Probabilistic control (e.g. Fuzzy logic, Kalman filters, Bayesian controllers etc). In these, sensory inputs are weighted according to past experience. The weighted sensory inputs then essentially "vote" for a particular direction and size of change in the actuators. Fuzzy logic controllers allow multiple inputs to control multiple outputs (MIMO control) in a manner that is understandable in linguistic terms. The weights (membership functions) are "hand-crafted" by the designer according to knowledge of the task and actuator properties. Bayesian controllers use an algorithm to predict sensory inputs according to the statistics of previous trials. Probabilistic control has also been proposed for the cerebellum.
6. Artificial neural nets. Commands and sensory signals are delivered to an input layer of computing elements, each of which assigns weighting factors to them and delivers its output through multiple connections to computing elements in the next layer, which assigns further weights. The final output layer, whose elements may be likened to motoneurons, controls multiple actuators. Layers between the input and output layers are called hidden layers and their elements may be likened to interneurons. The weighting factors are "learned" or progressively adjusted to reduce performance errors in successive iterations. Various methods of adjustment have been tried, including the best known one, back-propagation, whereby weights are adjusted according to "cost" (i.e. performance error). The adjustments proceed from the output layer backward through the successive hidden layers to the input layer. Artificial neural nets show some of the structural organization of biological neural systems and like neural systems they are capable of adaptation. A key biological insight they have provided is that hidden layer elements (interneurons) can show activity patterns that are not related to inputs or outputs in obvious ways, yet contribute to overall performance. This provides a plausible explanation for the finding that the activity of many neurons in the motor cortex of monkeys performing motor tasks is not obviously task-related even though these neurons probably contribute to the control of the task.



**Feedback Control of Movement. Figure 2** General schema of a feedforward predictor combined with a Smith predictor.

Over the last two decades the following developments have changed the way neurophysiologists think of feedback in the control of movement

1. The formalization of the concept of "internal models" whereby multimodal sensory input is processed to produce muscle commands based on internal predictions of the biomechanical consequence of these commands [3]. The *Smith predictor* (Fig. 2) is a good example of a controller having an explicit internal model.
2. Input from muscle receptors causes the abrupt phase-switching between stance and swing in the step cycle. Finite-state rules have been proposed, that describe these phase transitions in a variety of animal species. Fuzzy logic, which uses combinations of weighted sensory inputs rather than sets of fixed thresholds, may provide a more realistic analogy [4].
3. The discovery of positive force feedback during locomotion. During static posture, feedback from ►tendon organs, the force-sensing receptors in a muscle, reflexly inhibits the motoneurons of the muscle. During locomotion, tendon organ inhibition switches to excitation. This is positive force feedback. Unlike in a linear PID system, positive force feedback of muscles remains stable because when muscles shorten they produce less force for a given change in input, thus automatically limiting loop gain [5].
4. During locomotion, the portion of muscle activation attributable to spinal reflexes mediated by muscle receptors is smaller and more delayed than previously assumed. The stretch reflex contribution is only really significant when the centrally generated activation is weak [6].
5. In the presence of vision, locomotor movements are adjusted to terrain two or three steps in advance [7]. Firing of motor cortical neurons is correlated with these predictive changes. This suggests that predictive control is extremely important, at least for human gait.
6. The notion has emerged of the cerebellum being a state analyzer, performing probabilistic operations on sensory input analogous to Bayesian statistics or Kalman filtering [8].

## Concluding Remarks

Systems that combine central pattern generation (internal models), finite-state rules and PID control of limbs are now commonly used to control walking robots [9]. Presently the most advanced walking robot, the Honda Asimo humanoid robot, has three levels of control: (i) local PID control about individual joints, (ii) finite-state phase switching and hazard rules and (iii) a global command comprising a moving target of ground reaction force against which the actual ground reaction vector is compared. Models incorporating these feedback control systems have been used successfully to analyze human locomotion [10].

## Feedback Error Learning

### Definition

Learning or training of internal inverse models by approximating a teacher signal with feedback control signals. Supervised learning becomes problematic when a teacher signal is provided in a coordinate system different from that of inverse-model outputs, the problem known as a distal teacher problem. Specifically, for motor learning, an error in a movement consequence is usually evaluated in the visual or proprioceptive coordinate, whereas a teacher signal for inverse models should be in the motor-command coordinate. The idea behind feedback error learning is that feedback control signal, though delayed due to sluggish sensory transmission, can approximate a teacher signal in the motor-command coordinate and can hence be used for training inverse models. Recent physiological and human brain imaging studies showed that the cerebellar circuit indeed realizes a certain type of feedback error learning.

## Feedback Loops in Chronobiology

Gianluca Tosini
Circadian Rhythms and Sleep Disorders Program, Neuroscience Institute, Morehouse School of Medicine, Atlanta, GA, USA

### Definition

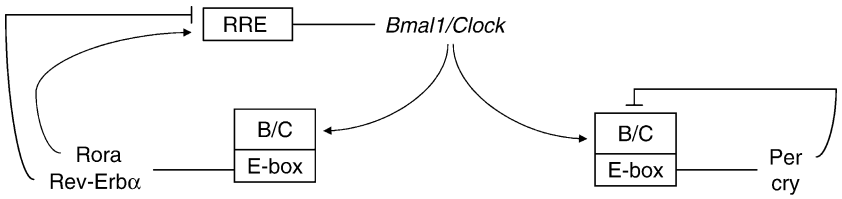
Feedback is a process in which part of an output signal is passed to the input and, thus, contributes to the regulation of a system. *A* negative feedback loop tends to slow down a process, whereas a positive one produces an acceleration of a process. In this essay we will describe examples of feedback loops in the field of chronobiology at three different organizational levels: molecular, cellular and organismal.

### Characteristics

#### Molecular Feedback Loops: The Autoregulatory Transcription-Translation Feedback Loops

The molecular mechanism that generates the circadian ►rhythmicity involves two interlocking transcription-translation feedback loops, which consist of positive and negative components (Fig. 1).

The autoregulatory feedback loops begin when two basic helix-loop-helix-PAS domain transcription factors, ►CLOCK and ►BMAL1, form heterodimers, bind to specific DNA regions (►E-boxes), and activate the transcription of ►*Periods* and ►*Cryptochromes* genes. Once the CRYPTOCHROME and PERIOD proteins in the cytoplasm have reached predetermined levels, they begin to form heterodimers. Then they translocate into the nucleus to inhibit the transcription of the *Cryptochromes* and *Periods* genes by blocking CLOCK/BMAL1-mediated trans-activation (negative feedback loop). This inhibition leads to the decrease of PERIODS and CRYPTOCHROMES levels in the cytoplasm and, thus, to a decrease in the formation of the heterodimers until the levels of these heterodimers are insufficient to inhibit the transcription of the *Periods* and *Cryptochromes* genes [1]. Another positive feedback loop involves the products of two orphan nuclear receptors (*Rev-Erba* and *Rora*). These two proteins



**Feedback Loops in Chronobiology. Figure 1** In mammals the autoregulatory feedback loop is composed of two independent feedback loops. The positive feedback loop involves the transcription factors *Bmal1* and *Clock,* which form heterodimers and activate the transcription of *Period* (*Per*) and *Cryptochrome* (*Cry*) genes. In the cytoplasm, PERIOD and CRYPTOCHROME proteins form heterodimers that enter the nucleus and interact with BMAL1/CLOCK (B/C), thus inhibiting the transcription (negative feedback). BMAL1 and CLOCK also stimulate the transcription of *Rev-Erbα* and *Rora.* REV-ERBα protein inhibits *Bmal1* transcription whereas RORa protein enhances *Bmal1* transcription.

regulate the rhythmic transcription of *Bmal1* by competing for the binding of the *Rev-erb*/►*Ror* (RRE) elements present on the promoter region of the *Bmal1* gene. REV-ERBα represses *Bmal1* transcription, whereas RORa activates *Bmal1* transcription [2].

## Cellular Feedback Loops: The Retinal Circadian Clock System

A series of studies over the last two decades has shown that the vertebrate ►retina (mammals included) contains an intrinsic circadian clock that controls many functions within the tissue. Several investigations have also shown that circadian rhythmicity in many of these functions is maintained *in vivo* after lesion of the ►suprachiasmatic nuclei (SCN), the master circadian clock located in the brain of the hypothalamus and, in a few cases, *in vitro*. ►Melatonin, visual processing and disk-shedding are among the retinal circadian rhythms that may persist *in vitro* or after the lesion of the master ►circadian pacemaker located in the hypothalamus [3].

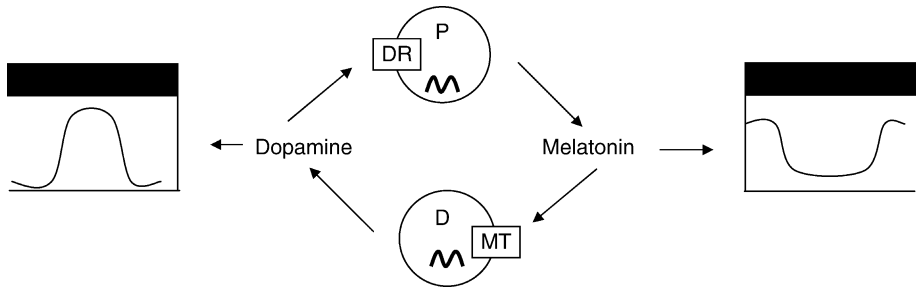
Melatonin and dopamine play opposing roles in the regulation of retinal adaptive physiology. Dopamine functions as a signal for light and, thus, is involved in the phenomenon of light-adaptation, whereas melatonin mediates dark adaptations. The synthesis and release of both melatonin and dopamine are under circadian control, with melatonin released at night and dopamine during the daytime. Melatonin inhibits the release of dopamine via its action on melatonin receptors, while dopamine inhibits the synthesis and release of melatonin by acting on dopamine receptors present on the melatonin-synthesizing cells. Therefore, the melatonin synthesizing photoreceptor cells and the dopaminergic amacrine cells form a cellular "feedback loop" that regulates circadian retinal physiology (Fig. 2).

Until recently, the working of this "feedback loop" was unclear, but in the last few years many details about the working of this cellular feedback loop have been revealed. Recent experimental evidence has demonstrated that dopamine rhythmicity in the retina is not required for the generation of circadian rhythmicity in the melatonergic system since a circadian rhythm in melatonin levels persists following destruction of the inner retina or in isolated photoreceptor layers [4]. Such a result demonstrates that the generation of the circadian rhythms in melatonin levels is independent, although it can be modulated by dopamine. Conversely, it seems that dopamine rhythmicity is dependent upon the presence of melatonin since retinal dopamine content and metabolism are in circadian melatonin-proficient mice, but not in melatonin-deficient mice [5]. Moreover, daily administration of melatonin restores the circadian rhythms in the dopaminergic system in melatonin-deficient mice [5]. Similarly, administration of Luzindole (a melatonin antagonist) to cultured retina abolishes the circadian rhythm of dopamine [6].

Therefore, it can be concluded that, in the mammalian retina, the pacemaker is likely to be located in the photoreceptors, and it appears to be necessary to generate the circadian rhythm in the dopaminergic system. In contrast, the circadian rhythmicity of the dopaminergic system is not necessary for the generation of the melatonin circadian rhythm in photoreceptors. However, the removal of the dopaminergic inputs may affect the phase of the circadian oscillation, thus demonstrating that the feedback from the dopaminergic cells is important to stabilize and determine that phase of the retinal circadian system.

## System Feedback Loop (The Birds' Neuroendocrine Loop)

The circadian organization of birds is rather complex since these organisms possess multiple photoreceptive structures and circadian pacemakers. In some species, the ►pineal gland plays a dominant role as circadian pacemaker, whereas in other species, the eyes may be more important. In some instances, the generation of circadian rhythm requires inputs from the hypothalamic pacemaker. (See [7] for a recent review.) Early studies on house sparrow reported that overt circadian rhythms could not be sustained in animals in which the pineal gland had been removed. However, these studies also revealed that the avian SCN possesses oscillatory



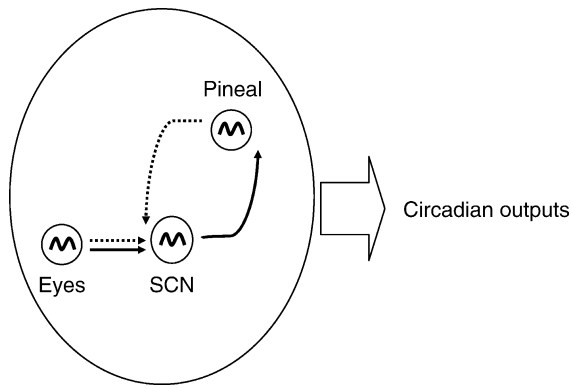
**Feedback Loops in Chronobiology. Figure 2** Melatonin is synthesized from the photoreceptors (P) during the night and acts on melatonin receptors (MT) located on dopaminergic neurons (D) in the inner retinal to inhibit dopamine release. Conversely, dopamine inhibits melatonin synthesis via dopamine receptors (DR) located on the photoreceptors. Therefore, in the retina, melatonin forms an autoregulatory feedback loop.

properties. For example, circadian rhythms can be observed for a few days – and in some case for weeks – after the pineal gland or the eyes have been removed; in some cases, a single light pulse could restore rhythmicity for a few circadian cycles (six or seven) in pinealectomized sparrow held in constant darkness. Similarly, cyclic light conditions or administration of melatonin restored rhythmicity in behaviorally arrhythmic pinealectomized birds [8].

These experimental data led to the hypothesis that none of the components of the bird circadian system are capable of generating long-term self-sustained rhythmicity, but self-sustained circadian rhythmicity is generated by the mutual interaction between and among the different components of the birds' circadian system (Fig. 3).

This hypothesis, known as the "neuroendocrine feedback loop," was proposed by Menaker and Cassone [9] to explain the sparrow's circadian organization. According to this model, during the day, the SCN, via a neural connection, inhibits pineal melatonin synthesis while, at night, the pineal *via* melatonin inhibits SCN neuronal activity. In this model removal of one of the oscillators and its feedback will lead to the damp-out of the remaining oscillator and, thus, to the abolishment of circadian rhythms at the organismal level. Therefore, this neuroendocrine loop synchronizes the different structures that contribute to the stability and precision of the system.

Experimental data suggest that this model can also be applied, with some modifications, to other species of birds in which the ocular pacemaker may play a key role for the maintenance of rhythmicity. For example, in pigeons, removal of the eyes alone, or pinealectomy alone, does not abolish circadian rhythms, whereas pinealectomy combined with blinding abolishes the circadian rhythms of locotomor activity and body temperature [7]. Daily infusion of melatonin may restore circadian rhythmicity. In the Japanese quail, enucleation renders the bird arrhythmic, while pinealectomy does not significantly affect the circadian



**Feedback Loops in Chronobiology. Figure 3** In birds, circadian oscillators are present in the pineal gland, eyes, and the SCN. The pineal gland plays its role on the SCN via melatonin (dashed line), while the SCN acts on the pineal gland via a neural connection (solid line). The eyes can act *via* melatonin and *via* neural connection on the SCN. Removal of one of these organs may induce a dampening of circadian rhythmicity in the organisms.

rhythm of body temperature and/or locomotor activity. Bilateral resection of the optic nerves affect circadian rhythmicity only in a small number of birds, suggesting that humoral (melatonin) and neural outputs from the eyes play an important role in the circadian system of this species [7].

Although this model has been proposed for the bird, other investigations have reported that a similar feedback system organization may also be present in reptiles [10].

## Fenton Reaction

### Definition

The reaction in which $Fe^{2+}$ ions react with hydrogen peroxide ($H_2O_2$) to produce hydroxyl radicals and hydroxide ion: $Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO\cdot + OH^-$. $Fe^{3+}$ can be regenerated to $Fe^{2+}$ by hydrogen peroxide, producing additional peroxyl radicals: $Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HOO\cdot + H^+$. The Fenton reaction utilizes small amounts of $Fe^{2+}$, acting as a catalyst, to convert hydrogen peroxide to more reactive oxygen radicals.

### Definition

Fibromyalgic Syndrome is characterized by musculo-skeletal pain, fatigue, neuro-vegetative symptoms and sleep disturbances.

►Neuroendocrinology of Psychiatric Disorders

## Fibronectin

### Definition

Contributes to the composition of the extracellular matrix and is known to play an important role in cell adhesion as well as neural migration. Fibronectin is a glycoprotein dimer made of two structurally similar peptides held together by disulfide bonds. It is able to interact with numerous molecules including type IV collagens, fibrin, heparin as well as some membrane receptors such as integrins.

## Fibrosis

### Definition

Deposits of collagen, a connective tissue, in a wound or at sites of chronic inflammation.

## Fick's First Law

### Definition

In 1855 the German physiologist Adolf Eugen Fick introduced Fick's law of diffusion, which describes the diffusion of a gas across a fluid membrane:

$$J_{diff} = -D\partial[\mathrm{C}]\partial x$$

$J$ is the diffusion flux (molecules $s^{-1}cm^{-2}$); $D$ is the diffusion coefficient ($cm^2\ s^{-1}$) and $[C]$ is the concentration of ion (molecules $cm^{-3}$).

►Ion Transport

## Fictive Locomotion

### Definition

Stepping-like rhythmic activity recorded in ventral roots or peripheral nerves in paralyzed and deafferented animals, i.e. in the absence of sensory information.

## Fictive Motor Pattern

### Definition

The activation pattern of motor neurons (usually recorded with ENGs) observed in a preparation without movement. Movement may be prevented either by

removal of all muscles or by neuromuscular chemical blockade.

►ENGs (Electroneurographic Recordings)
►Scratching

## Fictive Movements

### Definition

The pattern of motor commands produced by activated central pattern generators (CPGs) while output to muscles is prevented.

►Central Pattern Generator (CPG)
►Mastication

## Field Potential

### Definition

Summed electric response of many cells recorded by invasive microelectrodes in the CNS and evoked by short electric or magnetic stimulation of their axons or synaptic inputs.

►Extracellular Recording

## Fight-or-Flight Response

### Definition

Fight-or-flight response is the response of animals to acute stress. As first described by Walter Cannon in 1939, is the reaction to a threat or strong emotion. Is a motor behavior accompanied and sustained by a generalized activation of the sympathetic nervous system This response was later considered the first stage of a general adaptation syndrome that regulates stress responses in vertebrates and other organisms.

## Filiform Papillae

### Definition

(Papilla: small protuberance, Filum: thread) Filiform papillae are keratinous structures emerging from the surface of the tongue epithelium. They are densely packed on the central axis and more sparse on the lateral edges filiform papillae cover the dorsal tongue from the sulcus terminalis to the tip. There are two types of morphologically distinguishable filiform papillae: those composed of a base shaped like a dome (primary papilla) surmounted by 5–30 elongated conical spikes (secondary papillae) and those composed of a single conical spike (solitary papilla) These structures which do not contain taste buds are made of layers of epithelial cells expressing keratins. Defective desquamation of some cells composing the cony spikes is associated with a condition called “black hairy tongue” characterized by the transformation of filiform papillae into “hairlike” elongated cornified spines.

►Taste

## Filopodium

### Definition

The extension of a long, slender cytoplasmic expansion supported by a microfilament core, found on a

migrating cell or neuronal growth cone. Filopodia may contain many receptors on their surface allowing them to sense the local environment. Their elongation and retraction movements can occur rapidly owing to the fast polymerization and depolymerization of the supporting actin filaments.

►Axonal Pathfinding and Network Assembly

## Filter

### Definition

An algorithm or a component that reshapes a signal to achieve a given performance goal in some domain, usually the frequency or the time domain.

►Signals and Systems

## Final Common Pathway

### Definition

The integration of all information reaching a skeletal muscle.

## Finite Difference Method

### Definition

A numerical method for solving the physical equations used in cardiovascular mechanics, particularly those governing fluid flow. In this case a Taylor series approximation of the governing Navier-Stokes partial differential equations produces a system of discrete equations for computation.

►Cardiovascular Mechanics

## Finite Element Method

### Definition

A numerical method for solving continuum equations such as those governing the large deformations that occur in blood vessel walls and the heart walls. The material domain (such as the heart wall) is divided into small blocks or "elements." Discrete variables defined at points called "nodes," located at the corners of these elements, are used to interpolate fields that vary continuously within the elements and across the element boundaries.

►Cardiovascular Mechanics

## Firing Field

### Definition

A discrete region of an environment where a place cell exhibits a high firing rate. A place cell can have zero, one or several firing fields in an environment. Place field is a synonym.

►Spatial Learning/Memory

## Firing Patterns

►Temporal Coding

## Firing Rate

### Definition

The number of action potentials or spikes generated per unit of time in neurons.

## First- and Second-Order Cues

### Definition

First-order stimuli are defined by luminance or color and can be detected by Fourier analysis. Second-order

stimuli are defined by cues such as texture, disparity or contrast and cannot be detected by Fourier analyses.

There is disagreement as to whether these two types of stimuli are processed by common mechanisms, entirely different mechanisms, or whether the mechanisms are initially separate but combine after some nonlinear process (e.g., half-wave or full-wave rectification).

►Visual Illusions

## First Cranial Nerve

►Olfactory Nerve

## First-Person Authority

### Definition

The idea of first-person authority is that there is something special about knowing our own minds. For example, the way Mary knows what she herself thinks and feels is notably different from the way she knows what her sister Alice feels and thinks. Traditionally, this was tried to spell out in terms of the infallibility and incorrigibility of judgments about one's own mind.

►Behaviorism
►Logical

## First-Person Perspective

### Definition

First-person perspective is constitutive for consciousness, processed in an egocentric reference frame and centered upon one's own body as opposed to the thirdperson perspective, from which an organism has access to the behavior of others.

►Emergence

## First Piola-Kirchhoff Stress

### Definition

The flux tensor corresponding to the flux of linear momentum (i.e. the surface traction) in the Lagrangian formulation. Also called Piola stress.

►Mechanics

## First Somatosensory Cortex, SI

►Somatosensory Cortex I

## Fishes

►Evolution of the Visual System: in Fishes

## Fission

### Definition

The regulated separate of two bilayer membranes resulting in a "pinching-off" that produces two separate membrane-bound compartments. The opposite of membrane fusion, and thus the defining step of endocytosis or vesicle retrieval from the plasma membrane; facilitated by the protein dynamin.

►Synaptic Proteins and Regulated Exocytosis

## Fitness

### Definition

The ability of an animal to produce offspring, i.e. to pass on its genes to the next generation.

A discrimination is made between direct (own offspring) and indirect or inclusive fitness (offspring produced by relatives).

## Fitts' Law

### Definition

A relationship that defines a tradeoff between movement time and accuracy, originally proposed by Fitts in 1954. It is based on the premise that the rate at which information is transmitted by the central nervous system is limited.

►Eye-Hand Coordination
►Movement Sequences

## Fixation

### Definition

The act of holding the visual axis relatively immobile on a location in space, usually for the purpose of exploring a visual scene. To see during fixation, ocular micro-movements are necessary to assure that the visual image is never perfectly stable on the fovea. Overt (covert) attention occurs when attention is (is not) directed at the fixated location.

►Fixation System

## Fixation Neurons

### Definition

They discharge during fixation of targets and pause for saccades, both ipsiversive and contraversive. Also called tectal pause neurons (TPNs).

►Saccade, Saccadic Eye Movement
►SC – Tectal Long-Lead Burst Neurons

## Fixation Point

### Definition

Usually a fixated spot of light, a terminology used most often in laboratory experiments (Fig. 1a of essay Fixation System).

►Fixation System

## Fixation-related Neurons

### Definition

Neurons whose discharge is specifically related to the act of fixating a location in space, irrespective of whether fixation occurs in the light or dark.

►Fixation System

## Fixation System

Daniel Guitton
Montreal Neurological Institute, McGill University, Montreal, QC, Canada

### Definition

To inspect our surroundings we use a sequence of rapid displacements of the eyes, called saccades, interspersed by ►fixation periods in which the fovea is aimed at specific locations on the visual scene (►visual fixation). During fixation periods, the eye is not completely immobile but is subjected to very small drifts and resetting micro-saccades – essential for accurate perception – each responsible for eye position changes with an overall standard deviation of ~0.1° in each of the horizontal and vertical planes [1]. This essay is concerned with the putative ►fixation system – not with ocular micro-movements – that maintains, though not perfectly, the line of sight on a particular location in visual space.

When we search for a specific feature in a visual scene, we clearly need to attend to what we fixate. However, fixation and attention are not obligatorily linked; we can fixate on a point in space while attending to another. For example, during a search task for a

specific item within a spatially-distributed set of items, we can simplify the search by attending to a subgroup of items, based on a specific feature of this subgroup such as color. We can then select an object, within that color group, for further fixation and analysis, even if it is not currently being fixated. At the other extreme, we can fixate idly without attending to anything at all in the external world.

Brain imaging reveals regions implicated in attentive fixation, compared to idle fixation [2]. Further evidence for an active fixation system is that: (i) In patients suffering from the "spasm of fixation" syndrome, saccade generation is impaired in the presence of a foveal ►fixation point, but it is normal when no fixation point is present [3]. (ii) Saccade reaction times are longer when a subject must first break active fixation rather than start from an idle state [4]. (iii) Frontal lobe lesions can result in the inability to maintain fixation and suppress reflex saccades in the anti-saccade task [5]. (iv) Attentive fixation elevates the threshold for evoking saccades by electrically stimulating several oculomotor areas of the brain (e.g. [6]). (v) Neurons exist with fixation-related activity, which I shall review below.

## Description of the Theory

### *Brainstem Motor Mechanisms for Holding the Eye Immobile*

#### *Circuits in the Pons*

During fixation periods between saccades, any unwanted discharges, or "noise," in burst neurons could cause unwanted variations in eye position and this would hinder precise fixation control. Such unwanted discharges in burst neurons are inhibited by "omnipause" neurons (OPNs), which fire steadily during fixation periods and "permit" saccades by ceasing to discharge for the duration of eye saccades made head-fixed, and gaze saccades made head-unrestrained. Hence OPNs are part of a motor fixation system; their tonic discharge that suppresses saccades is independent of whether the eyes are involved in either idle or active fixation.

#### *The Midbrain's Superior Colliculus and Fixation Control*

Burst and omnipause neurons are "go-no-go" elements in saccade control, and their supervision by higher level structures is thought to require a major contribution by the midbrain's superior colliculus (SC). The SC is a layered structure whose superficial layers contain visually-responsive neurons organized as a retinotopically coded visual map, with the foveal representation in the rostral pole and with increasingly eccentric positions in the visual field represented progressively more caudally. By comparison, the deeper layers are organized into a motor map – coextensive with the visual map above – that encodes the vector of saccadic eye-head gaze shifts. Large gaze shifts are driven by neurons in the caudal parts of the motor map, whereas smaller gaze shifts are encoded more rostrally.

In the rostral pole of the motor map, is the so-called ►fixation zone containing cells with fixation-related discharges [7,8]. Some of these cells (Fig. 1b, Tonic foveal visual neurons) have foveal receptive fields and discharge tonically when the monkey fixates a light spot (FS), and cease discharging when FS is momentarily turned off (the "gap" in Fig. 1a), even though a monkey is attentively fixating the same location in the dark. Other cells (Fig. 1c, Pure fixation neurons, also called ►superior colliculus fixation neurons, SCFNs) fire tonically, beginning when the animal attentively foveates a discrete light spot and keep discharging during the gap.

The gap discharge can be higher, the same, or lower than the tonic fixation firing frequency (Fig. 1c, shaded outline). By comparison these cells do not discharge during idle fixation. The activity of eye fixation neurons pauses, like OPNs, during both eye and gaze saccades in head-fixed and head-unrestrained animals, respectively.

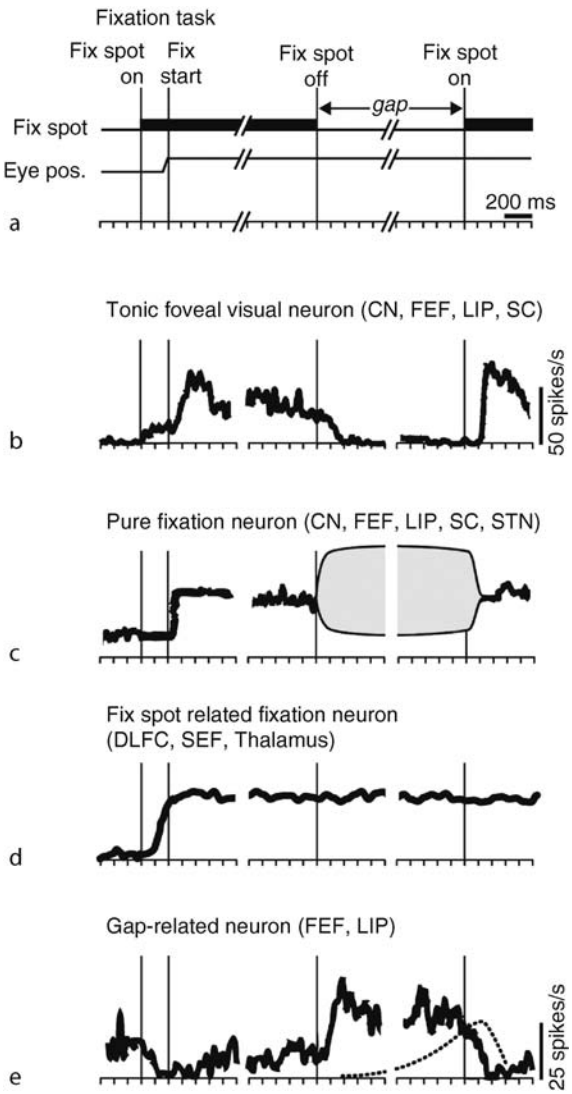
SCFNs project to, and excite, OPNs that themselves inhibit the eye saccade generator (e.g. [9]). Furthermore, SCFNs may inhibit the SC motor map as shown by electrical stimulation and by the response of neurons on the motor map (having off-foveal receptive fields), whose discharge is decreased when a monkey attentively fixates a foveal light spot [7]. This and other evidence suggests that SCFNs are part of an active motor fixation system that prevents the occurrence of unwanted saccades by gating eye or gaze saccades. However, the timing of SCFN reactivation at saccade end is too late to stop saccades and other, yet unknown, mechanisms are required.

### *Fixation-Related Signals in Frontal Brain Structures*

#### *Frontal Eye Field (Fef)*

There is an FEF fixation zone situated in about the rostral bank of the inferior arcuate sulcus, near the zone encoding small saccade vectors [10]. This FEF zone is similar to the SC fixation zone in that it contains pure fixation neurons and stimulation there suppresses saccades directed both contralaterally and ipsilaterally. However, FEF fixation-related cells (►fixation-related neurons) are also scattered throughout the FEF territory [11,12]. These authors have shown that the FEF sends saccade-related and fixation activity to the SC, a projection important in the control of voluntary saccades. According to ref. 12, there are four types of FEF neurons that project fixation-related activity to the SC. Three are illustrated in Fig. 1, using a slightly different nomenclature than they proposed: (i) Tonic foveal visual neurons (Fig. 1b) and (ii) Pure fixation neurons (Fig. 1c, similar to SCFNs in the rostral SC) each project about equally to the rostral and caudal SC, suggesting that they do not drive SCFNs. (iii) Neurons

F



**Fixation System. Figure 1** Schematic representation of different types of fixation-related firing frequency profiles found in different monkey brain regions (adapted from Fig. 4 in Ref [12]). The traces and firing frequency scales in panels b and e are examples of FEF neuron discharges taken from Fig. 4 in Ref [12]. The nomenclature is novel and attempts to capture essential features of the different fixation discharge patterns found throughout the brain. (a) Fixation task: a monkey makes a saccade (Eye position trace) to foveate the fixation spot (FS), shortly after its presentation. FS remains on for a random time and then is briefly extinguished (the "gap") for a random time, typically of about 500 ms and then turned on again. Monkey is required to maintain fixation of the FS or its remembered location in the dark, during the gap. (b) Tonic foveal visual neuron fires only when monkey foveates the visible FS. This example is from a FEF neuron [12]. (c) Pure fixation neuron (in superior colliculus, called superior colliculus fixation neuron, SCFN). These cells discharge just after the saccade that brings the fovea into the FS and firing frequency continues steadily during fixation. Some neurons maintain this discharge rate steadily during the gap; others either increase or decrease their gap firing frequency in the range indicated by the shaded area. (d) Fix spot related fixation neuron begins firing soon after FS on, and continues throughout saccade to FS and when FS is either on or in gap. Gap-related firing frequency profile may vary (not illustrated), as for SC. In SEF, DLFC and thalamus these neurons also encode eye position. (e) Gap-related neuron has little foveal visual response, but is strongly activated when monkey fixates attentively in the dark. This example is from a FEF neuron [12]. Dotted line shows response of LIP gap-buildup cell [19]. Abbreviations *CN*, *DLFC*, *FEF*, *LIP*, *SC*, *SEF*, *STN* refer to brain areas (see text) where fixation-related activity, of the type illustrated, is found.

with a gap-related signal (Fig. 1e) are the main type of FEF-SC projection neuron and are nearly silent while the monkey attentively fixates a visible FS, and fire specifically during the gap (Fig. 1a) when the monkey is required to maintain fixation, in the dark, on the location occupied previously by FS. (iv) Other neurons have a foveal visual receptive field, a presaccadic pause in activity and elevated firing at saccade termination.

### *Supplementary Eye Field (SEF)*

Fixation spot – related fixation neurons (Fig. 1d) are the main type of fixation-related neuron found in the SEF, a frontal region implicated in controlling eye and gaze saccades. Unlike pure fixation neurons, the fixation related discharge of these neurons is triggered by the onset of FS and begins before and lasts throughout the saccade to FS. Some increase, others decrease their activity with attentive fixation [13]. The fixation-related tonic firing frequency is modulated by eye position during attentive fixation. This discharge property is also present in the posterior parietal cortex (see section below). However, while it is the visual activity of parietal neurons that is mostly affected by eye-position changes, the SEF fixation neurons are more implicated in encoding motor space [14]. The information carried by these neurons could permit the internal representation of the position of attended targets, relative to the head (or body), for the purpose of controlling target-directed motor behavior in 3D space. Interestingly, focal stimulation of the SEF evokes saccades that are directed to a location in the orbit corresponding to the eye position preferred by cells recorded at the stimulated site [14].

### *Other Regions of Frontal Cortex*

Other studies have reported neurons with fixation-related activity that resembles "fixation spot related fixation neurons" (Fig. 1d) in regions extending beyond the classical boundaries of the FEF and SEF [15,16].

Activity in some of these cells was induced when the monkey fixated a stimulus linked to reinforcement, also an important component of fixation-related discharges in the basal ganglia (see below).

### Fixation-Related Signals in the Parietal Lobe

Neurons in area 7a, with large visual receptive fields that include the fovea, can have enhanced visually-evoked discharges to para and extra-foveal targets during attentive fixation of either a light spot or in the dark (as in Fig. 1b) [17]. Their firing rate can also encode gaze position in 3D space even in the dark [18]. As noted above for SEF, these neurons as a population could encode the spatial position of targets of interest.

Fixation-related activity in area LIP has been studied in a task similar to that in Fig. 1a [19]. Cells were found with firing frequency profiles similar to those shown in Figs. 1b, c and e. The gap-related firing frequency profile (Fig. 1e) either rises abruptly after gap onset (followed by a slow decay) or increases slowly. The "abrupt" type has been found in the FEF, but not in SC. In LIP, as in SC and FEF, the tonic activity of pure fixation neurons pauses during saccades, but the timing of the pause is more loosely related to saccade onset and end, suggesting that LIP is not implicated in driving fixation-related cells in FEF and SC.

### The Basal Ganglia and Subthalamic Nucleus

#### Caudate Nucleus (Cn)

Regions of the primate CN are implicated in linking cognitive and motivational sets to the generation of appropriate saccade commands. The CN receives cortical inputs, notably from FEF, SEF and LIP, as well as limbic structures and substantia nigra (reviewed in [20]). CN discharge properties are complex, being related to either/or combinations of, expectation of target, expectation of reward, spatial location of target, fixation, breaking of fixation, and type of motor response (e.g. eye or limb).

Some CN neurons resemble pure fixation neurons (Fig. 1c) except that their discharge requires the fixation behavior to lead to reward [20]; they do not discharge when a non-rewarded spot is attentively fixated. During the gap (Fig. 1a), their activity decreases substantially but does not entirely subside. Other CN neurons display visually-evoked discharges when the monkey is fixating a light spot (Fig. 1b) – even if this behavior is not directly rewarded – and pause during saccades from one visible spot to another. The discharge of some of these visual cells is spatially selective to fixations of a light spot located in a specific zone on the screen facing the monkey. Such cells are silent in the dark even if fixation is rewarded.

#### Substantia Nigra Pars Reticulata (Snr)

The SNr is a major output structure of the basal ganglia, and is implicated in controlling saccadic eye movements via an inhibitory projection to the SC. A decrease in SNr tonic discharge has been reported in response to a visual stimulus or saccade [21]. Some SNr cells have large bilateral visual receptive fields that are most sensitive to a foveal stimulus. The fixation-related responses of these cells are complex, context-dependent and have not been tested in the paradigm of Fig. 1a. Their task-selective activity decrease was proposed to specifically facilitate saccades to remembered targets or to newly appearing targets by disinhibiting selective regions of the motor map of the SC. There are sustained increases in SNr firing during fixation [22], a property compatible with increased inhibition of the SC motor map. None of these discharge patterns seem compatible with SNr projections to SCFNs.

#### The Subthalamic Nucleus (Stn)

Neurons in the ventral STN participate in visuo-oculomotor behavior and receive projections from FEF, SEF and CN. The same STN region projects to the SNr and back to CN [reviewed in 22]. Some visually driven STN neurons have fixation-related activity similar to that in Fig. 1b [22]. There is no eye position sensitivity. Other reward-related pure fixation neurons, with activity that declines in the gap period, discharge specifically when the animal fixates a target, or its location in the dark (Fig. 1c), and the discharge does not depend on whether eye or limb is used to obtain the reward. STN fixation-related discharges are similar to those in the CN and could be due to CN or frontal inputs.

### The Thalamus

Fixation spot related fixation neurons (Fig. 1d) have been found in the central thalamus [23] and subdivided about equally into two types whose firing patterns, when a FS is turned on, are mirror images of each other; one with increased tonic firing (fix+), the other with decreased firing (fix–). When the monkey looks away from the FS, the tonic firing frequency of fix + cells decreases before the saccade that breaks fixation. Thalamic fixation cells do not encode eye position in space.

## Overview

The maintenance of stable fixation is a prerequisite for performing saccade tasks. I have overviewed evidence supporting the existence of an active neural fixation system, whose function is polyvalent (see also [24]) and still needs much research to be fully elucidated. So far, the motor correlates of fixation-related discharges seem most clear in the SEF, FEF and SC and most certainly in OPNs. As discussed in previous sections, a reasonable hypothesis is that fixation-related discharges in FEF, SC and OPNs function to suppress the saccadic eye movement system, to assure that off-foveal distractor stimuli do not divert gaze away from a foveal target of interest. By comparison, fixation related activity in

parietal cortex and SEF could be important in salient target selection and localization at the visual and motor ends of the sensory-motor transformation spectrum, respectively. Activity in the basal ganglia, subthalamic nucleus and parts of frontal cortex seem implicated in linking fixation behavior to the receipt of reward, but how these regions contribute to fixation is unclear.

# Fixation Zone

## Definition

A sub-region of a brain area/structure containing neurons with fixation-related discharges; e.g. there are fixation cells (Fig. 1b of essay Fixation System) in the fixation zone of the rostral superior colliculus.

►Fixation System

# Fixational Eye Movements

## Definition

Small involuntary movements of the eye that incessantly occur during visual fixation. Usually classified into three types: microsaccades, miniature saccadic jumps produced a few times per second; drift, slow random

gaze fluctuations between successive micros; tremor, high-frequency oscillations of very small amplitude superimposed on drift.

►Microsaccades
►Ocular Drift

## Fixed Support Strategy

### Definition

A reaction to postural perturbation in which the feet (and/or upper limbs) remain in contact with the supporting surface (or surfaces). Also commonly referred to as "in place" or "feet in place" reactions.

►Postural Strategies

## Fixing a Position by Sighting

### Definition

Observing size and relations among distant landmarks from a stationary location, to determine one's location on a map. The concept is taken from ship navigation and applied to animal navigation.

►Spatial Learning/Memory

## FK506 Binding Protein (FKBP12, Calstabin1)

### Definition

An isomerase enzyme that binds specifically to RyRI (4 molecules per tetrameric channel or 1 molecule per RyR monomer), the sarcoplasmic reticulum $Ca^{2+}$ release channel in skeletal muscle, that stabilizes the closed state of the channel and facilitates coupled gating between neighboring channels that enhances the $Ca^{2+}$ transient during excitation-contraction coupling.

►Excitation-Contraction Coupling

## Flaccidity

### Definition

Softening and extreme yielding of skeletal muscle to stretch.

## Flash-Bulb Memory

### Definition

A strong and long-lasting memory of an emotionally arousing experience.

►Emotional Learning/Memory

## Flashing Ratchet

### Definition

The phenomenon that a Brownian particle that switches between two, directionally biased, potentials can undergo directed motion.

►Brownian Ratchet

## Flat Contact

### Definition

Synaptic contact between cone photoreceptors and mainly OFF bipolar cells, located at the base of the cone pedicle.

►Photoreceptors
►Retinal Bipolar Cells

# Flavor

Thierry Thomas-Danguin
Flavour Perception Group: Peri-receptor Events and Sensory Interactions, UMR1129 FLAVIC, ENESAD, INRA, Université de Bourgogne, Dijon Cedex, France

## Synonyms

Flavour

## Definition

The flavor is a sensory percept induced by food or beverage tasting. It relies mainly on the functional integration of information transmitted by the chemical senses: olfaction, gustation and oral and nasal ►somatosensory inputs. For a food item, there is a qualitative fusion of the different sensory inputs to form a single perceptual unit which is the food item's flavor. Flavor may be influenced by other sensory inputs such as texture or color.

## Characteristics

### Quantitative Description

During food consumption and when food is not yet in the mouth, the olfactory system and nasal trigeminal system can detect volatile compounds released by the food matrix. Once in the mouth and during food matrix breakdown, tastants, odorants and ►chemesthetic substances are mixed with saliva while volatile compounds are released into the oral headspace. Tastants and chemesthetic substances reach mucosal papillae and can be detected by gustatory and trigeminal systems. In the meantime, odorants and volatile chemesthetic substances reach the nasopharynx and olfactory mucosa retronasally. They can then be detected by the olfactory and nasal trigeminal systems.

All physico-chemical aspects of oral stimuli interact with oral and olfactory surfaces, which transduce theses properties. It is thus expected that many interactions among sensations from the oral cavity occur at a peripheral level [1]. However, the two sensory modalities of olfaction and gustation are clearly distinct in the periphery. Thus, integration may not occur until the level of the cortex [2]. Central or peripheral multisensory integration is obvious through perceptual interactions observed between the chemical senses.

Odorants and volatile chemesthetic substances reaching the nasal cavity and the olfactory mucosa, orthonasally or retronasally, can stimulate both olfactory receptor cells and other chemoreceptors of the trigeminal nerve. Therefore, the trigeminal nerve often contributes to an irritating attribute to odors. Odors were also shown to inhibit irritation and conversely, chemesthetic irritant substances could decrease the perception of odors. This occurred without attenuation even when an irritant entered one nostril and an odorant the other [3]. These results revealed that odor–irritation interactions may take place centrally in the nervous system.

Similarly, in the mouth, tastants and chemesthetic substances can stimulate both gustatory receptor cells and oral endings of the trigeminal nerve. Several tastants become irritants when their concentration increases and trigeminal inputs may contribute to taste quality. Taste–irritant interactions can rely on multiple routes. Trigeminal activation can affect the physiology of the lingual epithelium through the release of substance P from peripheral terminals of ►nociceptors. It could also affect the activity in the ►NTS (►nucleus of the solitary tract, also innervated by the ►chorda tympani) via direct afferent inputs and/or via modulatory effects possibly mediated via ►substance P release in the NTS.

►Psychophysical studies in Human showing interactions between odors and tastes, when they are experienced in mixtures, clearly evidence integration between these two distinct modalities. Central cross-modal integration was reported for subthreshold taste and smell [4]. Human subjects, exposed to a ►subthreshold concentration of a tasteless cherry-almond odorant (benzaldehyde) associated with a subthreshold concentration of an odorless sweet tastant (sodium saccharin), were able to detect the combination. This cross-modal summation of subthreshold concentration demonstrates that neural integration of taste and smell inputs is occurring. However, this summation has been reported only for ►congruent taste and smell pairs. Indeed integration between benzaldehyde and monosodium glutamate (umami taste) does not occur, suggesting that experience with the paired taste and odor stimuli is necessary for integration to occur [5]. At a ►suprathreshold level perceptual interactions between taste and smell were also observed. In general, taste–odor interactions are strongest when they are congruent. Taste can thus enhance odor intensity or the reverse. When a sucrose solution contains a tasteless sweet-congruent odor, the rating of sweetness is higher than that of the sucrose solution by itself [6].

For the taste–odor enhancement effect to occur, the odor and taste components need to be perceptually congruent. This perceptual congruency is especially revealed when people attributed differences in the olfactory component of foods as a gustatory difference. Odor-induced taste interaction phenomena appeared to share several characteristics with ►synesthesia, in which a stimulus in one sensory modality reliably elicits a consistent corresponding stimulus in another modality [7]. The basis for this synesthesia may be odor–taste learning, which occurs via simultaneous repeated exposure to both odor and taste. This learning appears to be implicit and highly resistant to extinction

and interference. It is interesting to notice that to be so efficient, only a single taste–odor association is necessary for the learned synesthesia to be established. In such a view, the unitary flavor percept is built over time by repeated experience of sensory phenomenon appearing to originate from the oral cavity [8]. This phenomenon may rely on autoassociation neural networks (autocorrelation memory), implicated in episodic and short-term memory. Indeed, such networks can retrieve the full learned activation pattern upon presentation of only a part (e.g., an odor) of a previously learned input signal (odor–taste pair). The ►hippocampus is a classical biological example of this type of network and can be involved in taste–odor pairings. However, it has also been argued that the putative autoassociative network is part of the olfactory system itself. Taste–odor synesthesia, which can be learned implicitly, may involve recurrent attractor autoassociation networks in which the ►pyriform cortex, ►insula and ►orbitofrontal cortex (OFC), and possibly ►entorhinal cortex and hippocampal formation. These structures are thus suspected to play a critical integrative role as hubs [1].

Neuroimaging studies were performed in order to find neurophysiological correlates of flavor perception. The main aim of these studies was to isolate a network of regions that are likely to be responsible for taste/odor integration. Independent presentation of a tastant or an odorant produces overlapping activation in regions of the insula and ►operculum, the orbitofrontal cortex (OFC), and the anterior cingulated cortex. It is noteworthy that the insula, operculum, OFC and anterior ►cingulate cortex are also sensitive to somatosensory stimulation of the oral cavity.

Single-cell recording studies in monkeys indicated that integration across sensory modalities is reflected in the presence of multimodal neurons that receive converging sensory information [2]. It was especially suggested that the orbitofrontal cortex may act as a region for convergence of multiple sensory modalities including chemosensation. Neurons of the orbitofrontal cortex of the macaque were thus found to respond to stimulation of the taste, olfactory, or visual system. Many of theses neurons were unimodal, but were found in close proximity to each other. Some single neurons showed convergence, responding for example to taste and visual inputs, taste and olfactory inputs and olfactory and visual inputs. Some of these multimodal single neurons had corresponding sensitivities in the two modalities, in that they responded to sweet taste, and in an olfactory discrimination task to fruit odor. The different types of neurons (unimodal in different modalities, and multimodal) were frequently found close to one another [9]. Taste and smell-responsive cells were also found in the insula/operculum. The presence of unimodal representation of taste, odor, and oral touch in the insula, frontal operculum, and OFC of the human and nonhuman primate suggests that these regions play a key role in integrating the disparate sensory inputs that give rise to the flavor perception. This integration relies not only upon multimodal neurons but also upon the information coded across networks of unimodal neurons [8].

Several of the neuroimaging studies have been performed in Humans in order to compare unimodal stimulation with a taste or an odor to bimodal (simultaneous) presentation of the same tastes and odors. The results indicated activation in the frontal operculum, ventral insula/caudal OFC, and anterior cingulate cortex to a taste/odor mixture. In some studies the response was even found to be supra-additive, in that greater activity was observed when the subjects received a taste/odor mixture compared to the summed neural activation evoked by independent stimulation with the taste and the odor components. Importantly, the ventral insula/caudal OFC region is likely analogous to the area where multimodal neurons were reported in monkeys.

These neurophysiological studies clearly indicate that odor–taste integration does occur at the neural level. Taste–odor integration occurs at earlier stages of processing and is likely to be influenced by experience and affective factors such as the physiological significance of a given stimulus, since learning and affective processing are the primary functions of this cortical zone. The possibility of a very early cortical integration of the sensory components of flavor is consistent with the fact that taste perception is almost always accompanied by oral somatosensation and ►retronasal olfaction [8].

Many studies have highlighted the importance of spatial or temporal contiguity in facilitating cross-modal sensory integration. Indeed, temporal and spatial contiguity may be crucial determinants of odor/taste integration because they promote perception of disparate taste, odor, and oral somatosensations as a common object. It has been especially argued that the perception of smell through the retronasal route, as compared to the ►orthonasal one, could be a key factor for odor/taste integration to occur. Indeed during food or beverage consumption, taste perception is almost always accompanied by oral somatosensation and retronasal olfaction. It would thus not be surprising that the mode of olfactory stimulation (i.e., orthonasal vs. retronasal olfaction) may be important in the formation and perception of food flavor. Similarly, an artificial delay imposed between odor and taste perception is not favorable for an odor/taste mixture to be perceived as a single entity [8].

The flavor may be influenced by sound in relation to texture perception, but also several somatosensory perceptions (temperature, texture) and vision (color and shape). For example a study tested both naïve and experienced subjects on red and white wines. Both groups classified the wines according to the contrasting

tastes of red and white wines. However, the reds included whites that had been colored red, showing that the color had an overriding effect on the perceived flavor and especially the terms chosen for the descriptions of the flavor of the wines [10]. Moreover, it is likely that visceral and other satiety-related signals reach the orbitofrontal cortex and modulate the representation of food flavor.

All these observations highlight the unitary nature of the flavor perception. Moreover, it has also been reported that when odors and tastes are sufficiently integrated as flavors, they are resistant to attentional manipulations. That is the reason why several scientists proposed that flavor perception relies on a functional sensory system with inputs from somatosensation, gustation, and olfaction, where the key is the meaning of the sensation rather than its precise organ or site of origin [8].

## Flavor

The sense of "taste," combining smell, taste, touch, hearing and vision.

►The Proust Effect

## Flexible Behavior

►Cognitive Elements in Animal Behavior

## Flexion Reflex

### Definition

A flexion reflex (or "flexion (or flexor) withdrawal reflex") is a contraction of limb flexor muscles that is evoked by a nociceptive stimulus and that withdraws the limb from the stimulus. A flexion reflex is entirely spinally mediated. Excitation of cutaneous nociceptive afferents activates oligosynaptic spinal interneuronal pathways that excite flexor muscles and concurrently inhibit antagonist extensor muscles. Flexion reflexes are often exaggerated when disorders of spinal cord or brain disturb supraspinal control of spinal cord pathways.

►Conditioned Reflexes

## Flexor Reflex Afferents

### Definition

Flexor reflex afferents refer to the group of nociceptive afferent neurones that transmit information via Aδ and C afferent fibers and produce the flexor withdrawal reflex.

These afferents make polysynaptic connects that are excitatory to flexors and inhibitory to extensors. They also make widespread connections throughout the spinal cord that have the opposite effect, i.e., excitation of extensors and inhibition of flexors. The later connections are typically made to heterogenous muscles that control other joints primarily for the control posture.

## Floccular Lobe

### Definition

The flocculus and ventral paraflocculus.

## Flocculonodular Lobe

### Synonyms

►Lobus flocculonodularis

### Definition

The vermis segment nodulus and the hemisphere segment flocculus together form the flocculonodular lobe.

Phylogenetically it is very old and is thus called the archicerebellum. Since its afferents come mainly from the vestibular nuclei (vestibulocerebellar tract), the "vestibulocerebellum" is another synonym.

►Cerebellum

## Flocculus

### Definition

A part of the vestibulocerebellum adjacent to the cerebellar hemispheres and overlying the eighth cranial nerve. This is the phylogenetically oldest part of the cerebellum, and its structure is archetypical of the cerebellar cortex. Its major neuron is the Purkinje cell whose axon is the sole cortical output and employs the transmitter gamma-amino butyric acid or GABA. It receives two inputs: (i) from mossy fibers and (ii) from climbing fibers. Mossy fibers are the axon terminals of cerebellar-projecting brain stem neurons and excite the dendrites of granule cells that, in turn, give rise to parallel fibers that excite Purkinje cell dendrites. Each Purkinje cell dendritic tree receives hundreds of thousands of parallel fiber synapses. In the flocculus, mossy fiber discharges signal head velocity and eye velocity and position. Climbing fibers originate from the inferior olivary complex in the medulla and provide a powerful excitatory input to the Purkinje cell.

Each Purkinje cell receives only one climbing fiber. Climbing fiber spikes contain complex signals, some of which are related to retinal slip. Floccular Purkinje cell axons terminate upon vestibular nucleus neurons that, in turn project to extra ocular motor neurons innervating the extra ocular muscles. The flocculus participates in the generation of smooth pursuit eye movements and control of the vestibuloocular reflex (VOR).

## Flocculus Hypothesis

### Definition

Proposed by Ito, and according to it, the flocculus is a recalibration device for the vestibuloocular reflex (VOR). The VOR exemplifies a feed forward control system, because there is no immediate feedback to correct any faulty outcome of its resultant eye movements. Inadequate performance of the VOR would therefore result in slippage of the visual image on the retina, degrading vision.Without some internal mechanism to correct this error, performance might remain inadequate or worsen.

The credence of this hypothesis was strengthened when Maekawa and Simpson demonstrated that the flocculus was the recipient of visual signals via the climbing fiber pathway that monitored the constancy of visual images. Ito proposed that the climbing fiber spikes provided an error signal that gradually corrected the VOR performance, until it was near perfect. This progressive change in the internal floccular parameters was termed "motor learning" and it was supposed that the VOR would be improved by an adaptive modification of its performance by the visual information contained in climbing fiber discharges. This hypothesis was in good agreement with Marr's proposal that the cerebellum was intimately involved in motor learning.

Marr theorized that the climbing fiber discharge contained an error signal that acted as a teacher to the mossy fiber-granule cell-Purkinje cell pathway. This error signal might change the character or gain of the parallel fiber to Purkinje cell synaptic transmission that, in turn might modify the motor output. Thus the VOR side path through the cerebellar flocculus serves to modify the gain of the VOR. When Ito discovered cerebellar long-term depression (LTD) he added a further corollary to the hypothesis that speculated that

F

LTD was the mechanism that controlled synaptic transmission and the VOR gain.

# Floor Plate

Atsushi Tamada
Laboratory for Neuronal Growth Mechanisms, RIKEN Brain Science Institute, Wako, Saitama, Japan

## Synonyms

Ventral plate; Septum medullae

## Definition

Transient thin neuroepithelial structure located along the ventral midline of the central nervous system of vertebrates.

## Characteristics

### Description of the Structure/Process/Conditions

The central nervous system of the vertebrates derives from an embryonic hollow columnar structure called the neural tube. The neural tube can be dorsoventrally divided into four fundamental regions, the roof, alar, basal and floor plates on the basis of morphological appearance (Fig. 1a).

The floor plate is a thin and narrow structure situated along the ventral midline [1]. It is connected with laterally located basal plates, separating the left and right halves of the neural tube. The floor plate consists of neuroepithelial cells with radial fibers extending from the ventricle to the ventral pial surface. The expression pattern of molecular markers indicates that the floor plate is composed of two distinct cell populations, the medial and lateral floor plate cells [2]. Anteroposteriorly, the floor plate exists at all levels of the neural tube from the forebrain to the spinal cord (Fig. 1b). It is closely associated with the underlying ►notochord, a rod-like mesodermal structure. Since the typical morphological appearance is lost in the anterior brain regions, the anterior limit of the floor plate is not so clear. Molecular expression patterns suggest that the floor plate extends at least to the caudal diencephalon, where the notochord terminates. Although many marker molecules are uniformly expressed in the floor plate, some of them are differentially expressed along the anteroposterior axis, implying the anteroposterior heterogeneity of the floor plate [3].

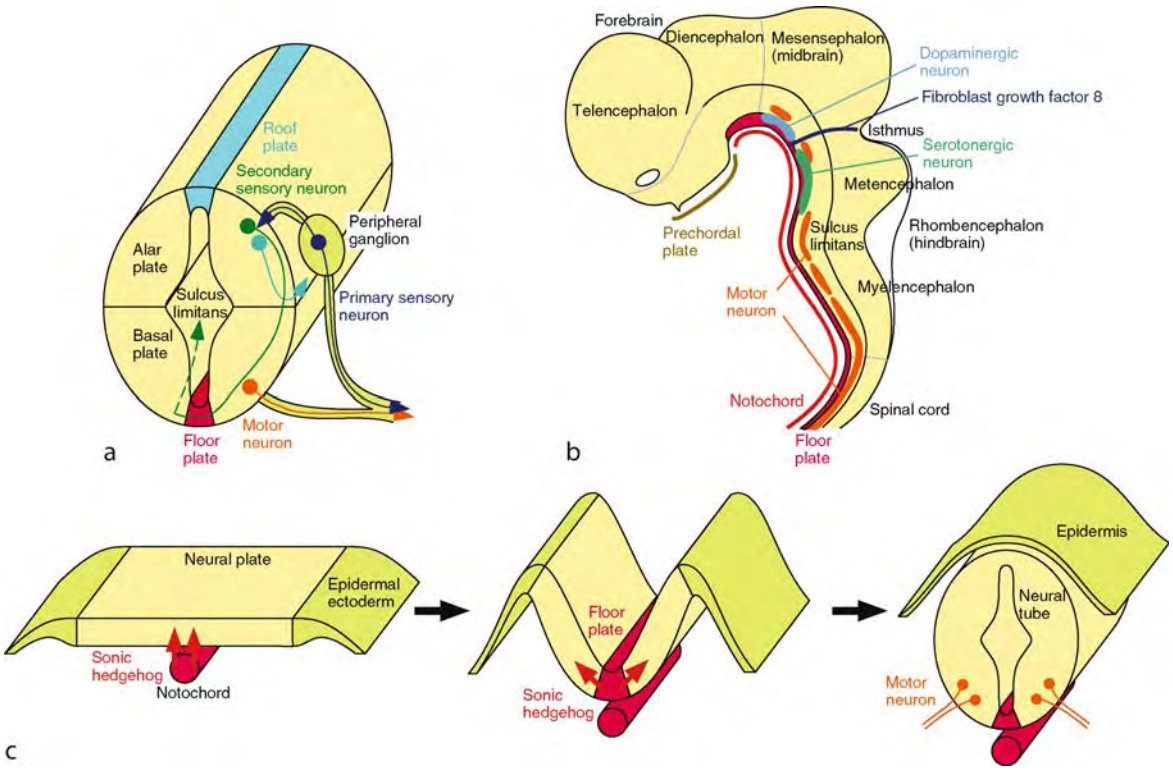
The floor plate itself is a non-neurogenic structure, whereas the adjacent basal plate and the alar plate are highly neurogenic. These regions generate a variety of neurons during development. Some of them project their axons across the ventral midline floor plate to targets on the contralateral side of the neural tube. Thus the floor plate is the site of the decussation of the contralaterally projecting axons. The floor plate is a thin and distinct structure at early embryonic stages, but it gets thick and indistinct by overwhelming cell growth in the basal plate and formation of axon decussation. It gradually disappears during development, remaining as a rudimentary structure called the septum medullae.

### Regulation of the Structure/Process/Conditions

Although the origin of the floor plate and the mechanism of its formation have been extensively studied, they are still controversial [2–4]. In the prevailing view, the floor plate is considered to originate from the neural ectoderm, which is ectoderm determined to become a neural tissue. However, fate-mapping studies indicate that the floor plate originates from both the ectoderm and the ►node, the axial mesoderm generating the notochord [2–4]. Recent studies further demonstrated that ectoderm-derived cells contribute to the anterior floor plate whereas node-derived cells contribute the posterior floor plate. Thus the floor plate seems to have a dual origin from both the ectoderm and the mesoderm. The floor plate and the notochord could share the same precursor cells located in the node.

The floor plate appears at the stage of neurulation, when the flat neural plate is converted into a hollow neural tube (Fig. 1c). Neurulation accompanies a series of dynamic morphogenetic events. At first, the neural ectoderm thickens to form the neural plate. The neural plate folds inward at its median hinge point, which later becomes the floor plate. During this morphological change, the presumptive floor plate stays closely associated with the notochord. Then the lateral margins of the neural plate fuse at the dorsal midline, which becomes the roof plate. Finally, the closed neural tube is pinched off from the epidermal ectoderm that surrounds the neural plate.

The mechanisms of floor plate specification have been extensively studied. In the classical induction model [5], notochord cells are the source of an instructive inducing signal that mediates floor plate differentiation in the overlying central neural plate cells (Fig. 1c). In vitro and grafting experiments demonstrated that an additional floor plate was induced in the lateral neural plate when a supernumerary notochord was placed adjacently. Conversely, removal of the notochord resulted in the absence of the floor plate. This induction model was further supported by identification of a secreted molecule, Sonic



**Floor Plate. Figure 1** Schematic view of developing vertebrate central nervous system. (a) Columnar organization of the neural tube. (b) Longitudinal organization of the neural tube. Positions of neurons induced by the floor plate are indicated. (c) Morphogenetic events and Shh signaling during neural tube formation.

hedgehog (Shh), as a mediator of the inductive signal. Shh was originally identified as a vertebrate homologue of the Drosophila segment polarity gene hedgehog. Gain-of-function and loss-of-function experiments in chickens and mice suggested that Shh plays a crucial role in floor plate induction. However, induction by notochord and Shh cannot explain the findings in zebra fish [2,3]. Floor plate cells are present in several mutants lacking the notochord, whereas floor plate cells are greatly deficient in mutants that lack the ►prechordal plate but possess a differentiated notochord. In fish, Nodal, a member of the transforming growth factor ß (TGFß) family, which is expressed in the prechordal plate, appears to play a major role in floor plate differentiation. A dual model in which notochord-derived Shh signaling induces posterior floor plate whereas prechordal plate-derived Nodal signaling induces anterior floor plate has recently been postulated to explain these conflicting findings.

## Function

The mechanism of floor plate specification is still controversial as described above, but the function of the floor plate seems to be well conserved among vertebrate species. Although the floor plate is a small and transient structure, it has multiple functions as an organizing center for the development of the brain and the spinal cord. It plays crucial roles in dorsoventral patterning of cell differentiation, positive and negative guidance of axon growth and regulation of cell migration at and near the ventral midline.

### *Patterning of Cell Differentiation*

The neural tube generates a variety of cells depending on the position along the dorsoventral axis. In the spinal cord, motor neurons that project their axons to peripheral targets differentiate in the basal plate, whereas secondary sensory interneurons that receive peripheral inputs from axons of the peripheral ganglia differentiate in the alar plate (Fig. 1a). Grafting and in vitro experiments have demonstrated that the notochord can induce motor neurons as well as the floor plate as described in the previous section [5]. While floor plate cells were induced in the region adjacent to the ectopic notochord, motor neurons were induced in a region a short distance away. At a slightly later stage, the floor plate itself acquires the same inductive activity as the notochord (Fig. 1c). The floor plate can induce motor neurons and homogenetically induce itself. Molecular studies have indicated that a single molecule, Shh, can account for both floor plate induction and

motor neuron induction [5]. Shh can elicit ectopic floor plate and motor neuron development. Conversely, disruption of Shh results in the absence of the floor plate and motor neurons. Moreover, the choice of responding cell fate appears to be dependent on the concentration of Shh. Differentiation into the floor plate requires higher concentration of Shh than differentiation into motor neurons.

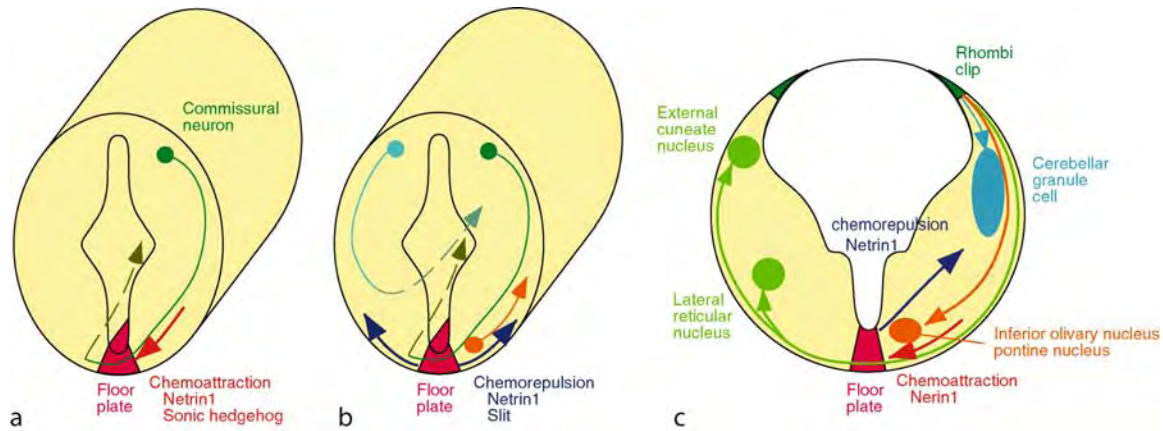
The ability of floor plate-derived Shh signal to control the differentiation of the ventral cell types is not restricted to the spinal cord. It can also induce motor neurons in the midbrain and the hindbrain, which have a similar dorsoventral organization to that of the spinal cord (Fig. 1b). Furthermore, Shh is involved in the development of region-specific neuronal populations that develop near the floor plate. Floor plate-derived Shh signals play crucial roles in the differentiation of two types of monoaminergic neurons, dopaminergic neurons of the substantia nigra in the midbrain and serotonergic neurons of the dorsal raphe nucleus in the hindbrain (Fig. 1b) [6]. In this case, Fgf8, a member of the fibroblast growth factors expressed by the isthmus another organizing center between the midbrain and the hindbrain, collaborates with Shh in determination of the cell fate. The floor plate-derived Shh signal can also induce oligodendrocytes, which later migrate to be distributed throughout the central nervous system.

### Axon Guidance

Another important function of the floor plate is to regulate the growth of axons [7]. Based on the bilaterally symmetrical organization of the neural tube, axonal projections can be divided into ipsilateral projections to the targets on the same side and contralateral projections to those on the opposite side. The ventral midline floor plate is an intermediate target of contralateral projections. Many neurons formed in the alar plate project their axons to the contralateral targets in a stereotyped pattern (Fig. 2a).

These axons initially grow ventrally along the circumferential axis, grow toward and across the ventral midline floor plate, turn at a right angle on the contralateral side and finally grow anteroposteriorly along the longitudinal axis toward the targets. These neurons include spinal cord commissural neurons, secondary sensory neurons in the caudal hindbrain and the deep cerebellar neurons in the rostral hindbrain. It has been demonstrated that the floor plate releases diffusible molecules that guide these commissural axons toward their source. Such mechanism is called chemoattraction. A molecule that mediates the chemoattraction by the floor plate was identified as a laminin-related secreted molecule, Nerin-1. Later, it was found that Shh also functions as another chemoattractant to the commissural axons.

Unlike contralateral projections, specific mechanisms do not seem to be required in the floor plate for formation of ipsilateral projections. However, in some cases, the floor plate actively regulates the axon guidance of the ipsilateral projections. The floor plate has an activity to repel these axons at a distance. Such a mechanism is called chemorepulsion, an opposite mechanism to chemoattraction. Floor plate chemorepulsion appears to function against two types of ipsilaterally projecting axons. One is an axon that originates near the floor plate and grows dorsally away from the floor plate. The other is an axon that



**Floor Plate. Figure 2** Role of the floor plate in axon guidance and cell migration. (a) Floor plate ►chemoattraction is involved in the guidance of commissural axons. (b) Floor plate ►chemorepulsion plays roles in guidance of ipsilaterally projecting axons by pushing axons dorsally away from the midline (*orange*) and preventing ventrally growing axons from crossing the midline (*light blue*). Chemorepulsion also appears to prevent re-crossing of commissural axons (*green*). (c) The floor plate is involved in tangential migration of cerebellar and precerebellar neurons.

initially grows ventrally toward the floor plate but later changes growth direction before reaching the floor plate (Fig. 2b). Chemorepellents, molecules mediating chemorepulsion, have been identified in the floor plate. Netrin-1, which acts as a bifunctional molecule, repels subsets of motor axons. Later, Slits, another family of secreted proteins containing leucine-rich repeats and EGF-like motifs, were found to function as a chemorepellent at the floor plate.

Commissural axons, once guided to the floor plate by chemoattractants, should grow beyond the floor plate without being captured by the same cues. Commissural axons lose responsiveness to the chemoattractant Netrin-1 after reaching the floor plate. Instead, they appear to acquire responsiveness to the chemorepellent Slits, which may prevent re-crossing into the floor plate (Fig. 2b) [8].

In addition to chemoattractants and chemorepellents, the floor plate also expresses a variety of contact-mediated axon guidance molecules. They include F-spondin and cell adhesion molecules of the immunoglobulin superfamily. It has been demonstrated that floor plate guides commissural axons across the midline in a contact-dependent manner via an interaction between two immunoglobulin superfamily cell adhesion molecules, TAG-1 and NrCAM [9].

### *Cell Migration*

It has recently been suggested that cell migration shares common mechanisms with axon guidance. The rhombic lip, the structure located at the dorsal margin of the alar plate of the hindbrain, generates a variety of cells that migrate tangentially along the circumferential axis (Fig. 2c). The rhombic lip in the rostral hindbrain generates cerebellar granule cell precursors. These cells are repulsed by Netrin-1, which appears to prevent their ventral migration out of the cerebellum. The rhombic lip in the middle and caudal hindbrain generates neurons of precerebellar nuclei that project axons to the cerebellum. These include pontine, inferior olivary, lateral reticular and external cuneate nuclei. All of these neurons migrate tangentially migrate toward the floor plate. Some of them stop before reaching the floor plate, whereas the others migrate across the floor plate and settle on the contralateral side. It has been demonstrated that floor plate chemoattraction plays crucial roles in migration of these neurons toward the ventral midline [10].

# Fluid Homeostasis

## Definition

Total body water (TBW) is approximately 60% of the total body weight in a young adult human male and approximately 50% of the total body weight in a young adult human female. The prototypical 70-kg male has approximately 42 l of TBW (60% of 70 kg). Of these 42 l, approximately 60% (~25 l) is intracellular, and 40% (~17 l) is extracellular. Extracellular fluid is composed of blood plasma, interstitial fluid, and transcellular fluid. Total body fluid volume is determined by the rate of fluid intake and loss from the organism. The equilibrium between intake and loss is essential for long-term survival. The volumes of all the compartments of the body are determined by

many factors involved in the control of the cellular and extracellular electrolyte concentrations. Ion concentration gradients and fluxes, hydrostatic and osmotic pressures, neuralendocrine- paracrine factors, and physical factors determine the total volumes within the various compartments.

►Blood Volume Regulation

## Fluorescence

### Definition

Fluorescent molecules capture the energy of photons (light), and release part of it as photons with less energy (i.e. light with a longer wavelength). For example, green fluorescent molecules absorb blue light, and emit green light.

►Functional Imaging

## Fluorescence-activated Cell Sorting (FACS)

### Definition

A method to separate a heterogeneous mixture of biological cells into two or more containers, one cell at a time, based upon the specific light scattering and fluorescent characteristics of each cell. For example, by labeling a specific neuronal subtype with fluorescent proteins (e.g. GFP or YFP) under a specific promoter, labeled neurons can be sorted by FACS.

### Definition

A microscopic technique to measure mobility of fluorescence-labeled molecules and organelles from the recovery of fluorescence after photobleaching.

## Fluorescence Resonance Energy Transfer (FRET)

### Definition

Fluorescence resonance energy transfer is a distance-dependent interaction between the electronic excited states of two dye molecules in which excitation is transferred from a donor molecule to an acceptor molecule without emission of a photon.

## Fluorescent Tracers

### Definition

Neuroanatomical tracers (see below) visualized in tissue because they emit light at a particular wavelength when illuminated with light of another wavelength, i.e., they fluoresce.

## Flux

### Definition

In a balance equation, the flux term accounts for the distributed input or output per unit area of the boundary

and per unit time. If the conditions of Cauchy's theorem are satisfied, the flux term can be expressed in terms of a linear operator on the normal to the boundary, called the flux tensor.

►Mechanics

## Fly

### Definition

Insect of the order Diptera. Flies have a highly developed visual system and flight apparatus. Flies are used as model systems for analyzing visual capabilities of insects and for investigating mechanisms of flight (see essay on "Neuroethology of fly vision").

## FM1-43

Masami Takahashi
Department of Biochemistry, Kitasato University School of Medicine, Japan

### Synonyms

N-(3-Triethylammoniumpropyl)-4-(4-(dibutylamino) styryl) pyridinium dibromide

### Definition

Synthetic ►fluorescence dye.

### Purpose

The size of ►synaptic vesicles and secretory vesicles are so small, it is difficult to follow the vesicle recycling in real time. FM dyes including FM1-43 are used for the real-time measurement of ►exocytosis and ►endocytosis in living neurons as well as in many kinds of cells.

### Principles

FM1-43 is an amphiphilic molecule consisting of a lipophilic tail linked to a positively charged head through a double-bond bridge. Various analogues having different structures and properties have been constructed (Fig. 1).

The length of the lipophilic tail determines the affinity of the dye to lipid membranes, and FM1-43 having a four-carbon tail needs a longer washout time than that of FM2-10 with two-carbon tail. Dyes with shorter tails stain membranes less brightly than those with longer tails. The fluorescent properties of the dye are governed by the double-bond bridge and the excitation and emission of FM4-64 having three double bonds that are both red-shifted.

The following characteristic features of FM dyes are useful for the study of exocytosis, endocytosis, and vesicle trafficking: (i) FM dyes are incorporated into membranes reversibly. When dye is applied in the extracellular solution, all surface membranes become stained and the cell can be destained by washing with dye-free medium. (ii) FM dyes selectively stain only the external leaflet of the lipid bilayer since they do not "flip-flop" across membranes. Permanent plus charge in their hydrophilic head prevent these dyes becoming diffused through membranes, and thus they will not stain membranes in cytoplasm. (iii) FM dyes are almost nonfluorescent in water, and their quantum yield increases dramatically when they are incorporated into membranes 1–3).

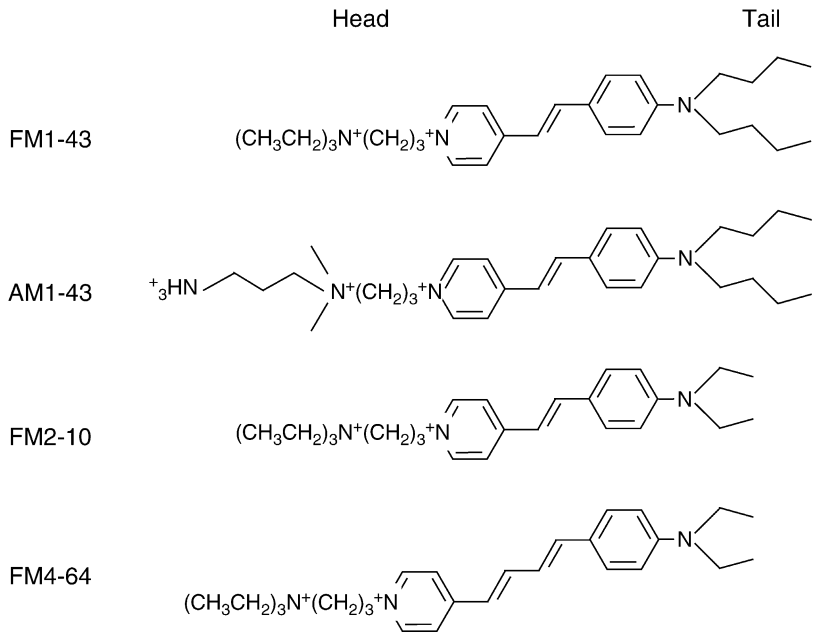
Extracellular membrane is stained with FM dye by incubating the cells with FM dyes (Fig. 2, step 1). On stimulation, vesicular membrane is fused with cellular membrane and is further stained with FM dye (step 2).

In preparations including nonneuronal cells where recycling of secretory membrane is less apparent, the process of exocytosis can be monitored from an overall increase in surface fluorescence. In neuronal preparations where recycling of secretory membrane is apparent, exocytosis can be monitored as dye is released from prestained vesicles through destaining. After the membranes are endocytosed, the cells are washed out with dye-free solution, the extracellular membranes are then destained, however, the endocytosed membrane is still stained since the dye concentration in vesicles is still high. Thus, only endocytosed vesicles are stained with FM dye in this step (step 3). Second stimulation induced exocytosis of FM dyes in the vesicles, which induces a release of FM dye in the vesicle membrane (step 4).

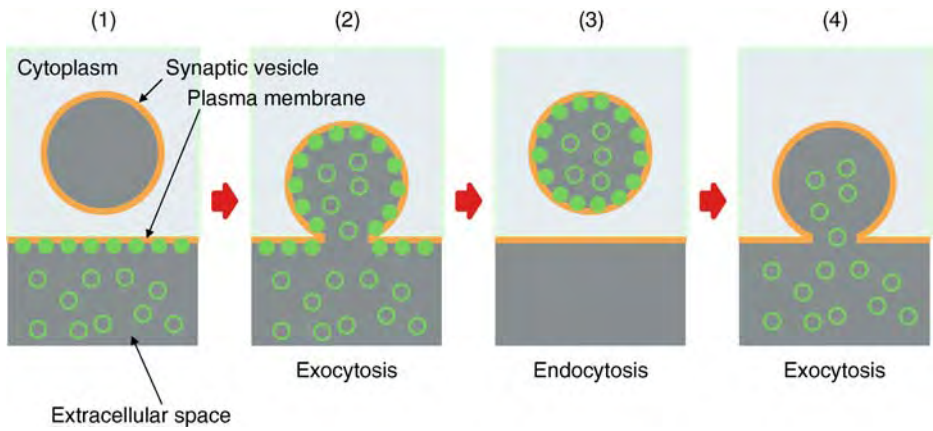
### Advantages

1. FM dyes are excellent specific markers of presynaptic function.

   Although immunocytochemical analysis reveals the existence of exocytotic proteins, it is not possible to see whether the site is functionally active or not. FM dye is quite useful as a marker of presynaptic release sites in cultured neurons as well as brain slice preparations in living state. The background fluorescence may raise a problem in thick preparations, however, various useful methods have been developed to reduce the background. Cylodextrins are toroidal molecules with a hydrophilic exterior and hydrophilic interior, and efficiently binds free



**FM1-43. Figure 1** Molecular structures of FM1-43 and its derivatives.



**FM1-43. Figure 2** Measurement of exocytosis with FM dyes. *Open green circles* represent free FM dyes in water which are almost nonfluorescent. *Filled green circles* represent FM dyes incorporated into external leaflet of the lipid bilayer. They are highly fluorescent in the hydrophobic environment.

FM dye. Since it is water soluble, FM dyes remaining in the extracellular solution can be readily washed out. Sulforhodamine 101 (S-Rhd) is also used to quench FM1-43 fluorescence via ►fluorescence resonance energy transfer (FRET).

AM1-43, in which an aldehyde-reactive amine has been added to the hydrophilic tail, is useful for the co-application of immunohistochemistry on fixed and permeabilized cells. Since AM1-43 is more amenable than FM1-43 to standard aldehyde fixation and detergent permeabilization protocols, it is well preserved in sections for immunocytochemistry. The localization of FM dye is also analyzed on an electron microscopic level by a photoconversion of FM dye in the presence of diaminobenzidine (DAB).

2. FM dyes are useful to reveal properties and distribution of various vesicle pools.

Physiological studies show the existence of different functional "pools" of vesicles in presynaptic terminals as well as in ►endocrine cells. Different vesicle pools are visualized either by electron microscopy using FA1-43 photoconversion in central ►synapse

or by fluorescence images in ►neuromuscular junctions. ►Fluorescence recovery after photobleaching (FRAP) is also used to monitor movement of vesicles within clusters.

3. FM dyes are useful to measure exocytosis and endocytosis separately.

   Exocytosis and endocytosis are accompanied with a change in cell membrane surface area, which can be monitored by a change in cell capacitance (►Capacitance measurement). However, it is not possible to measure these phenomena separately. The combination of whole cell capacitance recording with FM1-43 imaging allows simultaneous, independent measurements of exocytosis and endocytosis. Green Fluorescent Protein (GFP)-tagged proteins have been used extensively to monitor secretory vesicle biogenesis, trafficking, and secretion. If cells are transfected with a releasable GFP-tagged secretory granule protein and also stained with FM4-64, it is possible to monitor individual secretory granules before, during, and after membrane fusion.
4. FM dyes are useful to study exocytosis of nonneuronal cells.

   Recently, it has been shown that various cells which had not been identified as secretory cells release various hormones, growth factors and cytokines by regulated exocytosis. FM dyes have been successfully used to study the exocytosis of various nonneuronal cells such as glial cells, brown fat adipocytes and eggs.
5. FM dyes could be used to detect some difference in membrane properties.

   FM1-43 fluoresces with different colors depending on its microscopic environment. For example, when a frog nerve-muscle preparation is stained with FM1-43, Schwann cell vacuoles fluoresce orange-red, myelin appears green, and synaptic vesicles are yellow-orange. Quantum yield of FM dyes change depending on the microscopic environment. The plasma membrane lipid composition is asymmetric and most of the phosphatidylserine resides on the inner leaflet. FM dye is incorporated on the outer leaflet. Membrane asymmetry is disrupted in apotosis, which causes a large increase in FM1-43 quantum yield. Thus, FM dye can be used to monitor membrane disruption accompanied with apotosis.

### Disadvantages

In some cases, the fluorescence change of FM dyes may not reflect membrane recycling.

As described above, the fluorescence intensity and spectrum of FM dye may not change by exocytosis and endocytosis, but by other changes in membrane properties. Thus, special caution might be necessary in some cases.

## Focal Contacts

### Definition

Focal contacts are transmembrane anchorage sites that link the actin cytoskeleton of the cell to other cells or

extracellular matrix. Cell adhesion molecules (CAMs), the transmembrane proteins of focal contacts, are divided into three structural families: (i) integrins, (ii) cadherins, and (iii) IgCams. These proteins allow the growth cone to form adhesive contacts with the surrounding substratum. Signaling proteins, such as FAK, Rho and Src, are also localized at focal contacts in growth cones.

# Folk Psychology

Holm Tetens
Institut für Philosophie, Freie Universität Berlin, Berlin, Germany

## Definition

In everyday life, we constantly ascribe mental states, such as perceptions, sensations, feelings, ideas, beliefs, desires and dreams, to ourselves and other people and describe, explain, criticize, justify and judge, with reference to the mental states ascribed to a person, their observable behavior and actions on the one hand and their internal states and character on the other hand. For example, we often explain the fact that a person P acts in manner a by referring to the practical syllogism: (i) P wants to bring about state Z. (ii) P believes himself to be in situation S and furthermore believes that action a is the best means in situation S to bring about Z. (iii) So P acts in manner a. Or we predict, for example, that person P will be afraid in a certain situation S by referring to the fact that P has already shown fear in similar situations and, on other occasions, has expressed the belief of being afraid of situations of type S. *Folk psychology* can in the first instance be understood as the aforementioned mutual ascription of mental states and the resulting description, explanation, prediction and justification of behavior, action and the internal states of persons.

In a certain respect, the philosophical and academic mind-body problem would not exist without folk psychology. For the human sciences, especially brain science, attempt to describe and explain human behavior and action solely as processes controlled by neurons. Mental states as understood by folk psychology do not figure in the explanans of these neuroscientific explanations and, in accordance with theoretical standards, should not appear there. Hence the fundamental problem of how the folk psychological and neuroscientifical descriptions and explanations of a person relate to each other arises. Is folk psychology compatible with the findings of neuroscience, or are they mutually exclusive? Or is it possible that they complement each other and only provide a comprehensive and satisfactory description and explanation of persons when they are combined? All three positions are held in the controversial debate about the relation between folk psychology and scientific theories.

Against the background of the question of how folk psychological and scientific descriptions and explanations of persons relate to each other, it becomes understandable that the *status of folk psychology* is at the centre of the debate in the philosophy of mind. One of the main points of discussion is *whether folk psychology should be regarded as a theory or whether it constitutes something completely different*. Two other controversial questions ensue, namely whether folk psychology is *completely or mainly true or completely or mainly false* and *whether folk psychology can be replaced by a scientific, in particular a neuroscientific theory, or not*.

## Descriptions of the Theory

How folk psychology and scientific theories about human beings relate to each other hinges fundamentally on the question of whether folk psychology is a theory at all. Many philosophers of mind answer in the affirmative [1,2]. According to this view, folk psychology consists of concepts, rules of their correct use, (possibly) folk psychological laws, standards of correct description and explanation and rules of confirmation and falsification. When describing, explaining or predicting another person's or one's own behavior in everyday life, one uses this set of concepts, laws and methodological standards in exactly the same way scientists use their theories. This, as it is called, "theory-theory" is opposed by the "simulation theory" [3]. According to the simulation theory, folk psychology is based on practical abilities and decision procedures. In order to predict what a person will do, we put ourselves in their position and then decide what we would do in such a situation ourselves.

It is, however, not clear whether there is a real opposition between the theory-theory and the simulation theory [4]. Presumably both views merely emphasize or overemphasize different aspects of folk psychology. From a functional point of view folk psychology with its descriptions, explanations and predictions exhibits all the characteristics of a theory. In that respect, the theory-theory gets it right. However, in contrast to our scientific theories, which are learned and further developed explicitly as theories only by a minority of experts, folk psychology is mastered by everybody and is, in any case, not acquired explicitly as a theory. Instead, we are introduced to folk psychology in the course of our socialization and thereby acquire the practical abilities to interact appropriately and communicate with others on the basis of our folk psychological language. That speaks in favor of the simulation theory. Furthermore, the debate about whether folk psychology is a theory possibly constitutes a rather fruitless controversy insofar as folk psychology not only serves the theoretical purposes of description, explanation and prediction, but also comes into play when we judge, criticize and justify our behavior, or even our character, coordinate our social lives through communication and organize it in general.

Can folk psychology be replaced by scientific theories and, indeed, should it be replaced by them? The most radical answer has been given by proponents of eliminative materialism [5,6]. According to the eliminative materialists, folk psychology is a theory, as it attempts to describe, explain and predict a person's behavior.

F

However, they regard folk psychology as a theory that is largely false and entirely inadequate and which can offer at best a partial explanation of many phenomena, but most often no explanation at all. Eliminative materialists like to compare folk psychology to magical beliefs or medieval belief in witchcraft. Just as magical beliefs and belief in witchcraft were completely replaced by scientific theories, folk psychology will turn out to be an explanatorily and prognostically false and hopelessly inferior theory as the human sciences, especially neuroscience, advance, and will therefore have to give way to these far superior theories.

Most philosophers of mind believe that eliminative materialism goes too far in its criticism of folk psychology. There are various reasons for this, the most important of which is probably that it can hardly be denied that we successfully explain certain phenomena observed in others or ourselves using the means of folk psychology, and, to a certain extent, even predict them successfully [1,7–9]. If folk psychology really failed prognostically to the extent claimed by the eliminative materialists, it would be completely incomprehensible how human interaction, that relies fundamentally on successful prediction of human behavior, can to this day still be based on folk psychology. For it is a fact that cannot be overemphasized that all our social practices, even those within the domain of science and research itself, are organized in accordance with folk psychology. This is not to say that one should, as some philosophers of mind tend to do as a reaction to eliminative materialism, regard folk psychology as a theory that is almost completely true [1], but it can surely, to a certain extent, be regarded as a correct and explanatorily and prognostically successful theory. This view is not contradicted by the fact that many phenomena, such as perception and motion or psychiatric conditions cannot be described, explained or even predicted correctly in terms of folk psychology. With regard to these phenomena folk psychology has always had to give way to undeniably more adequate scientific theories, and will probably have to do so even more in the future.

To this day there has been no final and uncontroversial answer to the question of how folk psychological descriptions and explanations relate to the scientific descriptions and explanations of persons. However, this controversial open-endedness of the debate should not come as a surprise; quite the contrary – the opposite would be surprising. For if we were able to give a final and unanimous answer, that would amount to nothing less than the final solution of the philosophical mind-body problem. Let us take a look at an example. Suppose the identity theory, according to which mental states are identical to brain states, were correct. Then one would have to be able to make plausible that, whenever we talk about mental states in terms of folk psychology, we are really referring to brain states. Folk psychological explanations would have to be transformable into neuroscientific explanations. If such a transformation were successful, it would have been proved that folk psychological and neuroscientific descriptions and explanations of a person are compatible with each other. However, to date the identity theory has neither been proved nor refuted in the philosophy of mind. And the situation regarding the other proposed solutions to the mind-body problem is much the same.

But regardless of how the relation between folk psychology and scientific theory has been described or how it will be described in the future, the following should be clear from the outset: If the human sciences claim to be able to describe and explain human behavior in its entirety, they will also have to, at least in principle, be able to describe and explain how folk psychology itself evolved and why human societies with all their cultural variants are successfully based on it. For the latter is a fact that is confirmed for each of us every day in numerous encounters with others.

In the philosophy of mind and the public debate about the mind-body problem and its consequences, it is often overlooked or not sufficiently emphasized that, because of the points made above, the question of whether scientific theories are able to replace folk psychology is not an entirely theoretical question, but also has a far-reaching normative dimension. Our everyday life, even our entire human culture, is still based on folk psychology. To pick out just one aspect: fiction, theatre, music and painting, cultural and social sciences and the arts, even wide areas of academic psychology and medicine are unthinkable without folk psychology and its language. Nobody can seriously imagine what our everyday lives or, indeed, a humane and acceptable civilization would look like without folk psychology, and how scientific theories, such as theories about the brain, could fulfill these functions adequately. Even if, one day, it should emerge that scientific theories are able to describe, explain and predict all aspects of a person better than folk psychology, the question would nevertheless remain of whether we really want to completely replace folk psychology with scientific theories and whether we can accept the moral consequences.

### Synonyms

Food anticipation; Circadian food anticipatory activity (FAA); Food-entrainable rhythms; Food-entrainable pacemaker (FEP); Food-entrainable oscillators (FEO)

### Definition

►Phase and period control of endogenous circadian (24-h) oscillators and overt rhythms by daily schedules of food availability.

### Characteristics

#### Circadian Rhythms, Oscillators and Entrainment

Daily rhythms of biochemistry, physiology or behavior expressed by most living organisms are generated by endogenous, cell-autonomous (intracellular) ►oscillators cycling with a periodicity that closely approximates the solar day (hence "circadian", L. about a day). To ensure optimal coordination of circadian rhythms both internally and with local environmental time, ►circadian oscillators can be synchronized (entrained) by periodic environmental or physiological stimuli ("►zeitgebers", G. time-givers). The dominant environmental zeitgeber for most organisms is the daily ►light-dark (LD) cycle.

Light acutely delays circadian rhythms at dusk and early night, and advances circadian rhythms at late night through dawn. These phase adjustments serve to offset small differences in the duration ("►period") of the circadian and LD cycles, and ensure a characteristic phase relationship between circadian rhythms and local time, manifest as ►nocturnal (night-active) and ►diurnal (day-active) "chronotypes". In mammals, circadian rhythms are coordinated by a master ►circadian pacemaker, comprised of a population of neuronal circadian oscillators ("►clock cells") located in the ►suprachiasmatic nuclei (►SCN), a region of the mediobasal hypothalamus directly innervated by the ►retina.

In many organisms, circadian rhythms can also be entrained by ►non-photic stimuli, which may include

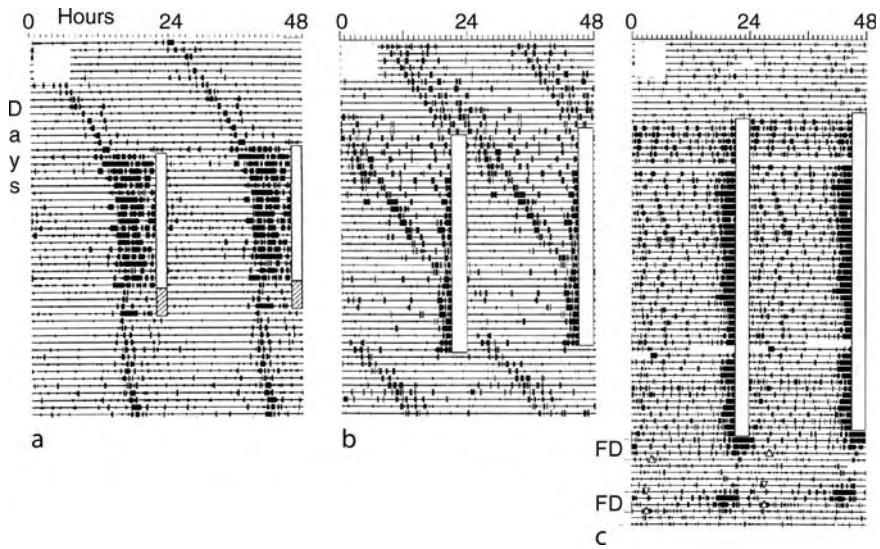
daily cycles of temperature, social or nonspecific arousal, or food availability. While ►entrainment by food has been demonstrated in a variety of vertebrate species, its properties and mechanisms have been well-characterized in only a few species of mammals, primarily rats, mice and hamsters.

## Formal Properties of Food-Entrainment in Mammals

Circadian rhythms persist ("►free-run") in constant light or dark, a property that is fundamental to the concept of endogenous, self-sustaining circadian oscillators. If food availability is restricted to a fixed time of day (e.g. a 4-h meal alternating with a 20-h fast) for a week or more, ►free-running rhythms may entrain to mealtime, typically with the daily active phase (denoted by the Greek letter "α") of the circadian rest-activity cycle beginning prior to (anticipating) mealtime [1,2]. If food is then unrestricted, circadian rhythms resume free-running from the apparent phase of entrainment. In these cases, common in Syrian hamsters (e.g. Fig. 1a) and some marsupials and mouse strains, the SCN master circadian pacemaker appears to be entrained, and with it all behavioral and physiological rhythms. Food availability, or some correlate, thus can act analogously to light by entraining (setting the phase and period) of the entire circadian system. The phase of entrainment is adaptive, by ensuring that animals are awake and active prior to mealtime, and metabolically prepared for food ingestion, digestion and absorption.

In other species or in the presence of a LD cycle, the response to daily schedules of food-availability is typically more complex, and reveals an underlying multi-oscillator circadian system in which one pacemaker (the SCN) is entrained primarily or exclusively by light, while most circadian oscillators elsewhere in the brain and body are entrained by food [3,4,1,5]. This uncoupling of circadian oscillators and rhythms by restricted feeding may also occur in constant light or dark, such that the light-entrainable, SCN pacemaker free-runs, while ►food-entrainable oscillators remain synchronized with mealtime. An additional layer of complexity is that some variables (e.g. locomotor activity) appear to be jointly controlled by both light-entrainable and food-entrainable oscillators, while others (e.g. ►pineal melatonin secretion) may be directly regulated by only one.

These complex responses were first discovered and remain best illustrated in common strains of the laboratory rat, *Rattus norvegicus* (hereafter "the rat"). Rats of this species are nocturnal, preferring to forage and feed at night. They are also opportunistic; wild rats will exploit a source of food that is available in the day, and laboratory rats will adapt to an exclusively daytime feeding schedule. Adaptation is facilitated by apparently loose coupling between light-entrainable and

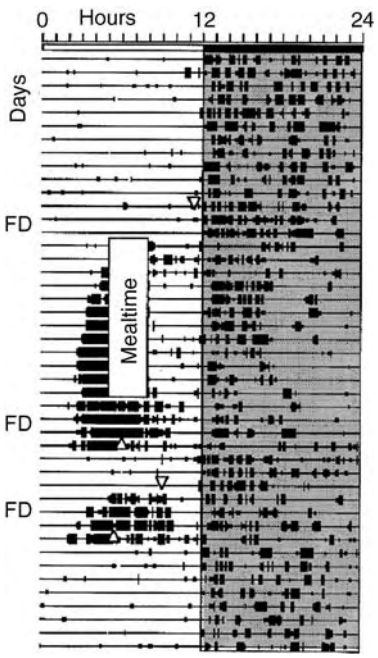


**Food Entrainment. Figure 1** Wheel running activity rhythms of rodents subjected to restricted daily feeding schedules, in standard "raster" or "actogram" format. Each panel represents activity of a single animal. Time within a day is plotted in 10 min bins from left to right. Consecutive days are aligned both horizontally and vertically (i.e. the record is double-plotted). Vertical deflections on the lines indicate time bins when activity counts were registered. During restricted feeding, mealtime is indicated by the opaque vertical bar. The beginning and end of bouts of total food deprivation are indicated by inverted and upright triangles, respectively. (a) Syrian hamster in constant dim light, with food and water access restricted to 3-h/day. (b) Rat in constant dim light with food restricted to 3-h/day. (c) Rat with complete SCN-ablation in constant dim light, with food restricted to 3-h/day, or food deprived for 72-h (FD). Note that SCN-ablation eliminates circadian rhythms when food is available ad-libitum.

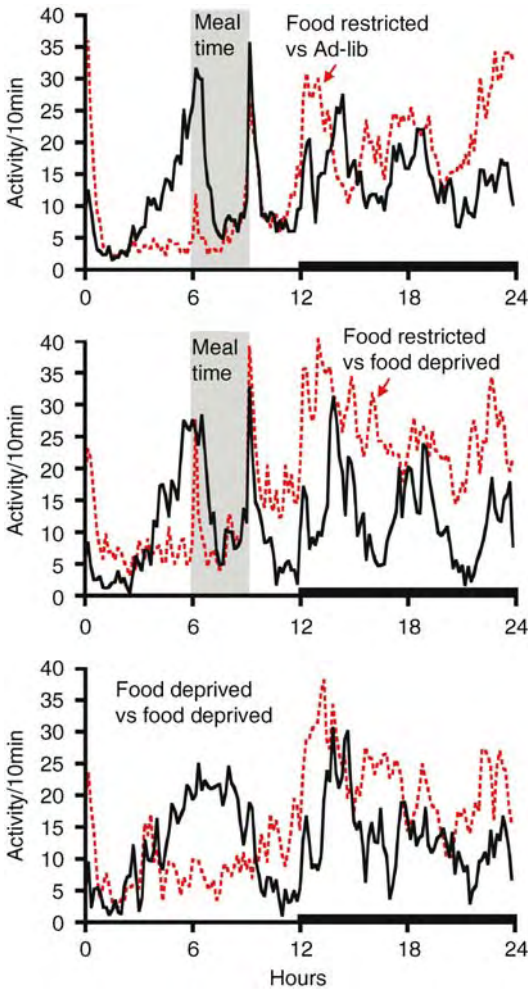
food-entrainable oscillators in this species, as can be inferred from rhythm dissociations in rats exposed to both LD and feeding schedules. Lab rats entrained to a LD cycle and restricted to a single 2–4 h meal in the middle of the light period (the rest phase of the circadian cycle in nocturnal species, designated "ρ") within a few days exhibit increased locomotor activity beginning 1–3 h before mealtime (Fig. 2). The waveform of this bout of "►food-anticipatory activity" (FAA) shows a steep positive slope until mealtime, and stabilizes within 1–3 weeks (Fig. 3a). In rats, nocturnal activity persists, but typically at a lower level.

The magnitude of FAA and the direction of change of nocturnal activity are dependent on both the species and the specific behavior measured. In the absence of a LD cycle, the previously nocturnal bout of activity free-runs with a species-specific circadian periodicity, while FAA emerges or persists with a periodicity of exactly 24 h (Fig. 1b). Again, the likelihood of such dissociation is greater in rats than hamsters and mice, but examples exist for all of these species. Expression of two circadian rhythms with different periods indicates joint control of activity by separate light- and food-entrainable oscillators. Body temperature also exhibits food- and light-entrainable components, while circadian rhythms of pancreatic and hepatic enzymes, insulin and glucocorticoids appear to be predominantly regulated by food, with levels rising prior to mealtime. Pineal melatonin secretion is the only strong example of a circadian rhythm that appears to be exclusively light-entrainable.

A simple explanation for FAA is that it reflects an hourglass process, whereby premeal activity is triggered each day when energy depletion (hunger) reaches some threshold. However, food-deprived rats



**Food Entrainment. Figure 2** Wheel running activity rhythm of a rat in a light-dark cycle subjected to total food deprivation (FD) for 2–4 days and to restricted daytime feeding (3-h/day). The daily dark period is denoted by shading. The beginning and end of bouts of total food deprivation are indicated by inverted and upright triangles, respectively.



**Food Entrainment. Figure 3** Group mean average waveforms of general cage activity (recorded by infra-red motion sensors) in rats under different feeding conditions. (a) Rats anticipating a 3-h midday meal (*solid line*) or with free-access to food throughout the day (*dashed red line*). (b). Rats anticipating a 3-h midday meal (*solid line*) or subjected to 72-h with no food (*dashed red line*, no prior experience with midday feeding). (c) Rats subjected to 72-h food deprivation, either immediately after 3 weeks of midday feeding (*solid line*), or with no experience of restricted midday feeding (*dashed red line*). Lights-off is denoted by the heavy bar along the x-axis.

that have not experienced a regular mid-day feeding time do not exhibit an activity waveform similar to food-entrained rats (Fig. 3b). General activity levels may increase with prolonged deprivation, but the timing of this activity is non-specific, and the intensity of activity does not accelerate to a mid-day peak. Moreover, once a food anticipatory rhythm is established, it persists during prolonged (3–5 day) bouts of total food deprivation, and reappears at the same time of day during subsequent bouts of total food deprivation after a few days or more of ad-libitum food access (Figs. 1c, 2).

Another explanation for FAA is that it is the outcome of an associative learning process, whereby rats learn that certain phases of their light-entrainable circadian pacemaker are predictive of food availability. However, food-anticipatory rhythms emerge and persist normally in rats with complete SCN-ablation and also in constant light or dark (Fig. 1c).

Careful experimentation with different feeding schedules has revealed that FAA exhibits all of the canonical properties of an entrained, circadian clock-controlled rhythm [3,4,1,5]. If meal intervals are outside of the circadian range (~22–31 h), anticipatory rhythms do not emerge (so-called "►limits to entrainment"); however, in rare but instructive instances, if already established, anticipatory rhythms may uncouple and free-run. Within this range, the duration of FAA (conceptualized as the ►phase-angle of entrainment) varies systematically with the period of the feeding cycle. If mealtime is acutely shifted by 6–12 h, FAA shifts gradually, not immediately. These properties are evident in both intact and SCN-ablated rats, and indicate that FAA is driven by a physically separate circadian oscillator that is self-sustaining and entrainable by feeding-related stimuli.

## Molecular and Neural Mechanisms of Food-Entrainment

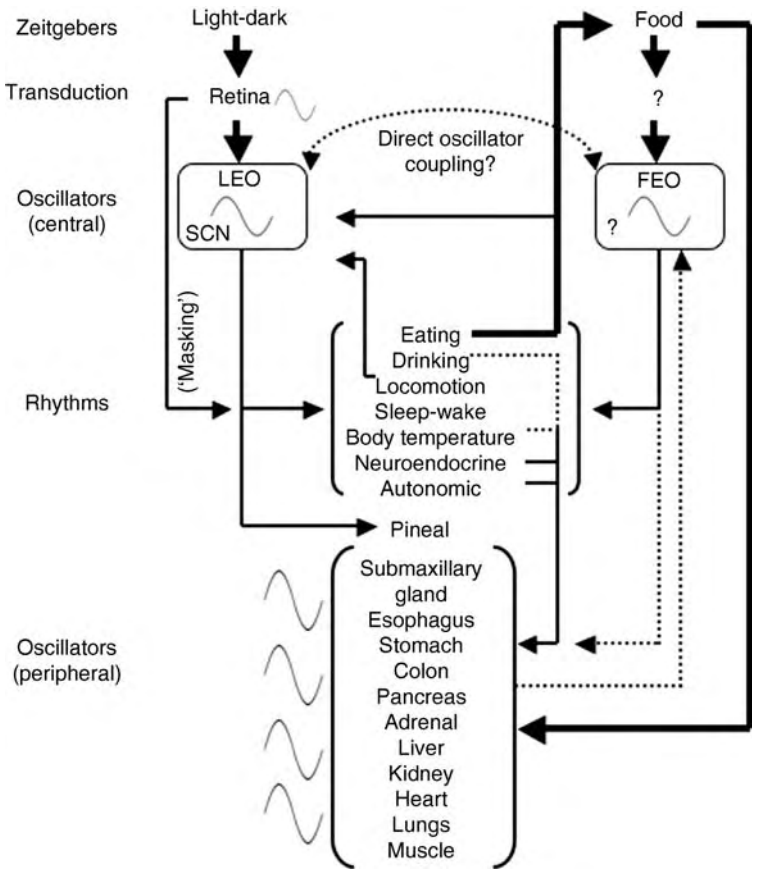
Circadian oscillations in SCN clock neurons are currently thought to be generated by interlocking negative and positive transcriptional-posttranslational feedback loops of so-called circadian clock genes and their protein products, including the *period* genes (*per1* and *per2*), the *cryptochromes* (*cry1* and *cry2*)), ►*clock*, ►*Bmal1*, and ►*rev-erbα* [6]. The discovery of clock genes in the SCN was quickly followed by recognition that these genes are also expressed rhythmically in many brain regions outside of the SCN, and in most if not all peripheral organs and tissues [6,7]. Clock gene rhythms in the SCN are reset (and thereby entrained) by light (transduced by photosensitive ►retinal ganglion cells that release ►glutamate and ►PACAP in the SCN) and in the presence of a LD cycle are not shifted by restricted daily feeding schedules that generate FAA. By contrast, clock gene rhythms in most peripheral organs are readily uncoupled from LD cycles and fully reset by daily feeding schedules. Numerous brain regions also exhibit clock gene rhythms reset by feeding time. A working conceptual model is that circadian rhythms in mammals are regulated by a hierarchically organized, distributed population of neural and peripheral oscillators driving local brain and organ functions (Fig. 4).

The SCN master pacemaker sits at the top of this hierarchy, and under normal circumstances regulates the phase and period of oscillators elsewhere, thereby synchronizing rhythms within and between physiological systems, and coordinating the ensemble of oscillating tissues with local time by its sensitivity to LD cues. When food intake is controlled by the environment instead of by the SCN, ►peripheral oscillators and many neural oscillators shift to maintain synchrony of behavior and physiology with mealtime. Feeding-related signals that mediate entrainment of neural and peripheral oscillators remain to be identified.

The locations of oscillators and neural circuits that generate food-anticipatory behavioral rhythms are not yet conclusively identified. Peripheral oscillators entrained to feeding schedules could conceivably drive circadian rhythms of FAA via autonomic afferents or hormones acting on the brain. Evidence to date suggests that peripheral oscillators do not serve this function, because the phase of these oscillators can be dissociated from behavioral food anticipatory rhythms by several days of ad-lib food access interposed between 3–4 day bouts of total food deprivation in rats previously entrained to a daytime meal [8]. During food deprivation, the behavioral rhythm reappears with its former daytime peak (Figs. 1c, 2), while the peripheral rhythms revert to a nocturnal phase, presumably reset by SCN-dependent nocturnal food intake when food is freely available. Also, in mice bearing a mutation of the *Clock* gene, the food anticipatory behavioral rhythm persists robustly during a 2-day food deprivation, while food-entrained rhythms of gene expression in at least two peripheral tissues, liver and heart, damp out [9].

Conversely, $Per2^{brdm1}$ mutant mice exhibit normal entrainment of peripheral oscillators to restricted daytime feeding, but lose food-anticipatory behavioral and temperature rhythms [10].

Loss of food-anticipatory rhythms in $Per2^{brdm1}$ mutant mice confirms a critical role for circadian clock genes, and provides a target for brain mapping studies to locate potential sites of FAA-generating clock neurons. Clock gene rhythms induced or reset by daily feeding schedules have been identified in numerous brain regions, including neocortex, limbic and extrapyramidal systems, thalamus and hypothalamus [10,7]. Lesions of many of these areas have no effects on food anticipatory rhythms [1,8,10]. Ablation of the dorsomedial hypothalamus (DMH), nucleus accumbens or nucleus of the solitary tract has been reported to attenuate or prevent food-anticipation in one study each, but not in other studies. Paraventricular



**Food Entrainment. Figure 4** Elements of the mammalian circadian timekeeping system, illustrating known sites of circadian oscillators (denoted by sine-waves), and known (*solid lines*) or potential (*dashed*) routes of coupling between zeitgebers (timing signals) and oscillators, and among oscillators. Heavier arrows indicate stronger entraining signal, relative to other entraining signals. Zeitgebers can be environmental (light) or behavioral (food ingestion, locomotor activity). *LEO* light-entrainable oscillator (or pacemaker); *SCN* suprachiasmatic nucleus; *FEO* food-entrainable oscillator (or pacemaker), which may be a collection of oscillators distributed across different brain regions, with different groups controlling different output rhythms.

hypothalamic lesions can attenuate food anticipation in one measure of behavior but not another, while ablation of the DMH, infralimbic cortex or hypophysis can eliminate the premeal rise of body temperature, without blocking behavioral anticipation. Entrainment of behavioral and autonomic rhythms by feeding may involve a distributed population of neuronal circadian clock cells, with different sites contributing to different rhythms, and multiple sites contributing to behavioral rhythms.

Elaboration of the neural and molecular mechanisms of food-entrainment may provide targets for the development of novel ►chronobiotics. More generally, the profound effect of temporally restricted feeding schedules on circadian organization of physiology raises the possibility that disruption of normal eating patterns, secondary to eating disorders, other disease processes, aging, and ►shiftwork, may account for some of the health consequences of these conditions.

# Force Depression/Enhancement in Skeletal Muscles

Walter Herzog
Professor, Faculty of Kinesiology, Calgary, Canada

## Synonyms

History dependence of force production; Residual force depression/enhancement; Steady-state force depression/enhancement

## Definition

Force depression (FD) is defined as the loss of steady-state ►isometric force, which occurs after shortening of an activated ►muscle or muscle fiber, when compared to the steady-state force obtained in a purely isometric contraction at the same muscle/fiber length (Fig. 1). The term "steady-state" here refers to the idea that any transient forces associated with the dynamic shortening of the muscle/fiber have subsided.

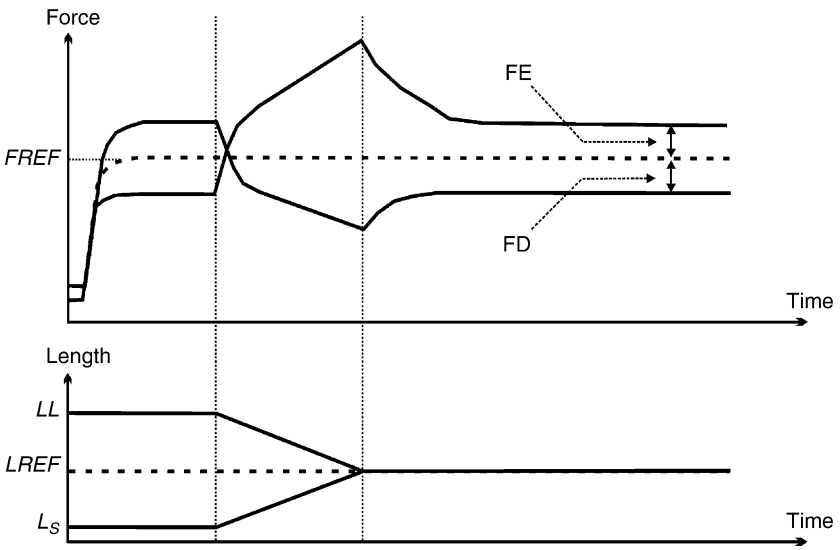
►Force enhancement (FE) is defined as the gain in steady-state isometric force that occurs following stretch of an activated muscle or muscle fiber, when compared to the steady-state force obtained in a purely isometric contraction at the same muscle/fiber length (Fig. 1).

## Characteristics

Quantitative Description: Force depression of skeletal muscle following shortening was described systematically for the first time more than half a century ago [1]. Since that time, FD has become a well-recognized and acknowledged property of skeletal muscle contraction, although there is great controversy as to the mechanisms producing FD. Interestingly, FD is not explained within the classical framework of the ►sliding filament theory [2] or the ►cross-bridge theory [3] of muscle contraction. However, the following relationships have been consistently observed: Force depression increases with increasing magnitudes of shortening (Fig. 2a), with increasing force during shortening (Fig. 2b), with increasing mechanical work during shortening, and with decreasing speed of shortening (Fig. 2c).

Furthermore, the amount of force depression for given shortening conditions depends on the length of the muscle, with peak FD observed near the plateau region of the ►force-length relationship. Force depression is long lasting (i.e. in excess of 30 s in cat soleus at physiological temperature), but can be abolished instantaneously by deactivation of the muscle for a period of time that is long enough for force to fall to zero (Fig. 2d). Furthermore, FD is associated with a parallel decrease in ►fiber stiffness [4] in the force depressed compared to the isometric reference state. Force depression occurs during electrically stimulated and voluntary contractions, and loss of force associated with FD can reach peak values of more than 50% [5].

Force Enhancement: Force enhancement (FE) of skeletal muscle following stretch was also first described in a systematic manner by Abbott and Aubert [1]. Like force depression, FE is a well recognized property of skeletal muscle contraction, is not explained within the framework of the classical sliding filament and cross-bridge theories, and the following relationships have been recognized and accepted in the scientific community: Force enhancement increases with increasing magnitudes of stretch (Fig. 3a) and increasing



**Force Depression/Enhancement in Skeletal Muscles. Figure 1** Schematic force-time and length-time histories of an activated muscle. When an activated muscle is shortened and then held isometrically, the force produced at the short length is smaller than the corresponding steady-state force obtained for a purely isometric contraction at that short length ($F_{REF}$). This loss of force associated with active shortening is called force depression (FD). Similarly, when an activated muscle is stretched and then held isometrically, its force at the long length is greater than the corresponding steady-state force obtained for a purely isometric contraction at the long length ($F_{REF}$). This gain in force associated with active muscle stretch is called force enhancement (FE).

muscle/fiber length, and is independent (or nearly so) of the speed of stretch. Since FE occurs at all muscle lengths, it is also seen on the plateau of the force-length relationship, where it may exceed the maximum isometric force (Fig. 3b) of the muscle/fiber by as much as 20%. Force enhancement at long muscle/fiber length is associated with a passive component that contributes part, but not all, of the force increase following muscle stretch (Fig. 3c). Force enhancement, like FD, is long lasting (>30 s in cat soleus at physiological temperature), but can be abolished instantaneously by deactivation of the muscle such that force drops to zero, except if part of the FE is contributed by the passive component [6]. The passive component of FE persists even after deactivation and complete loss of force. There is some controversy about whether FE is associated with an increase in ►muscle/fiber stiffness. Force enhancement, like FD, can reach magnitudes for specific stretch conditions of up to 50% above the isometric steady-state force obtained in purely isometric reference contractions.

## Higher Level Structures

Force depression and force enhancement are observed on the whole muscle level.

## Lower Level Components

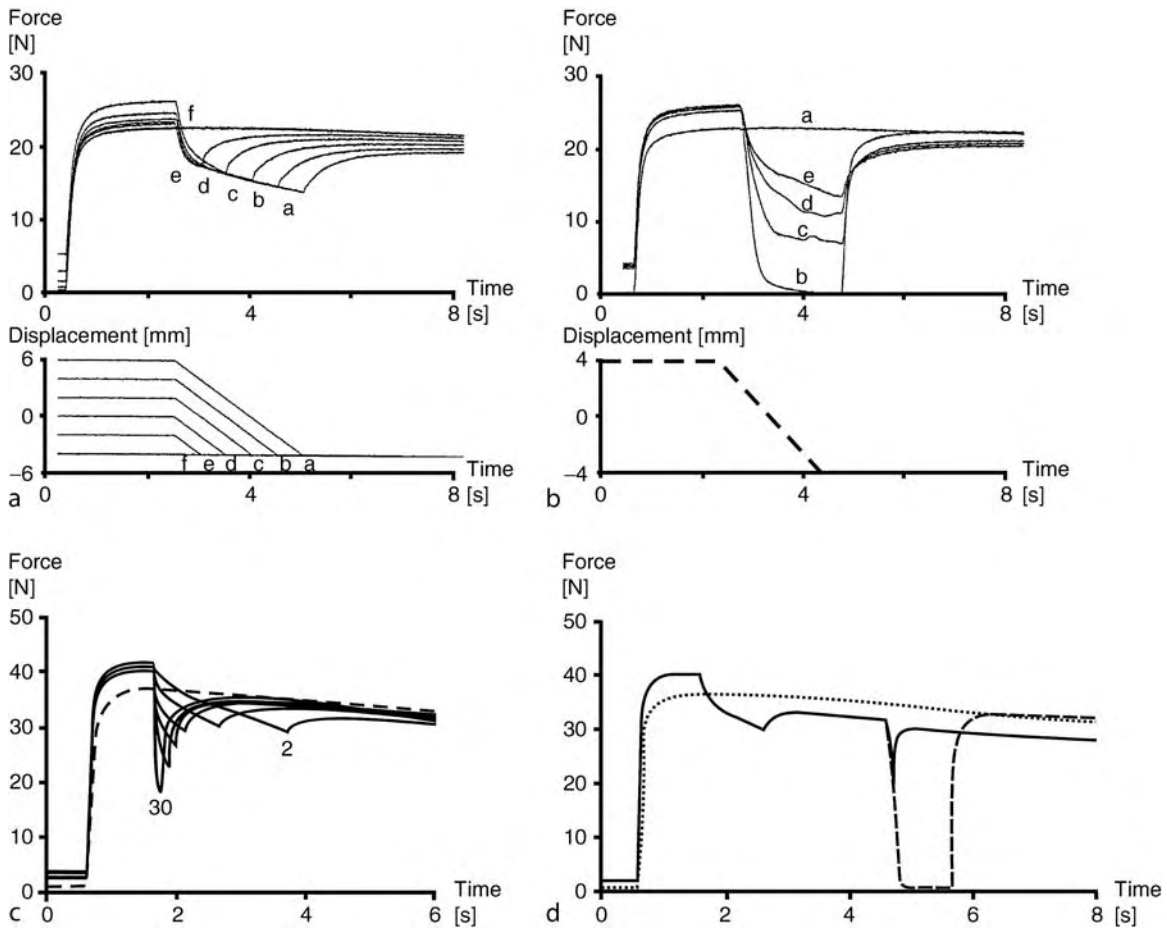
Force depression and force enhancement are also observed in single fibers [4], and FE has also been verified in single ►myofibrils [7]. However, neither force depression nor force enhancement have ever been observed in single ►actin-►myosin interactions, therefore, it is not clear at present whether FD/FE are properties associated with the basic molecular mechanisms of muscle contraction, or if they occur at some higher structural level, such as the ►sarcomeres, only.

## Structural Regulation

It is not known how force depression and force enhancement are regulated. The following explanations are the most likely processes, based on the author's experience. They may turn out to be entirely wrong, and should be viewed as working hypotheses.

Force depression may be associated with a stress-induced inhibition of cross-bridges in the actin-myosin ►overlap zone that is newly formed during shortening. This hypothesis was first proposed by Maréchal and Plaghki [8]. It would account for the relationship of FD with the magnitude and speed of shortening, the force during shortening, and the loss of muscle stiffness in the depressed compared to the reference state. It would also fit with the observed relationship between FD and the mechanical work of the muscle during shortening, and would be consistent with the long lasting nature of FD and the fact that FD can be abolished by releasing the force on the muscle. However, direct testing of this hypothesis has proven difficult, and further work is required to gain direct insight into the mechanisms associated with force depression.

The most likely explanation for the mechanisms underlying force enhancement must include an active

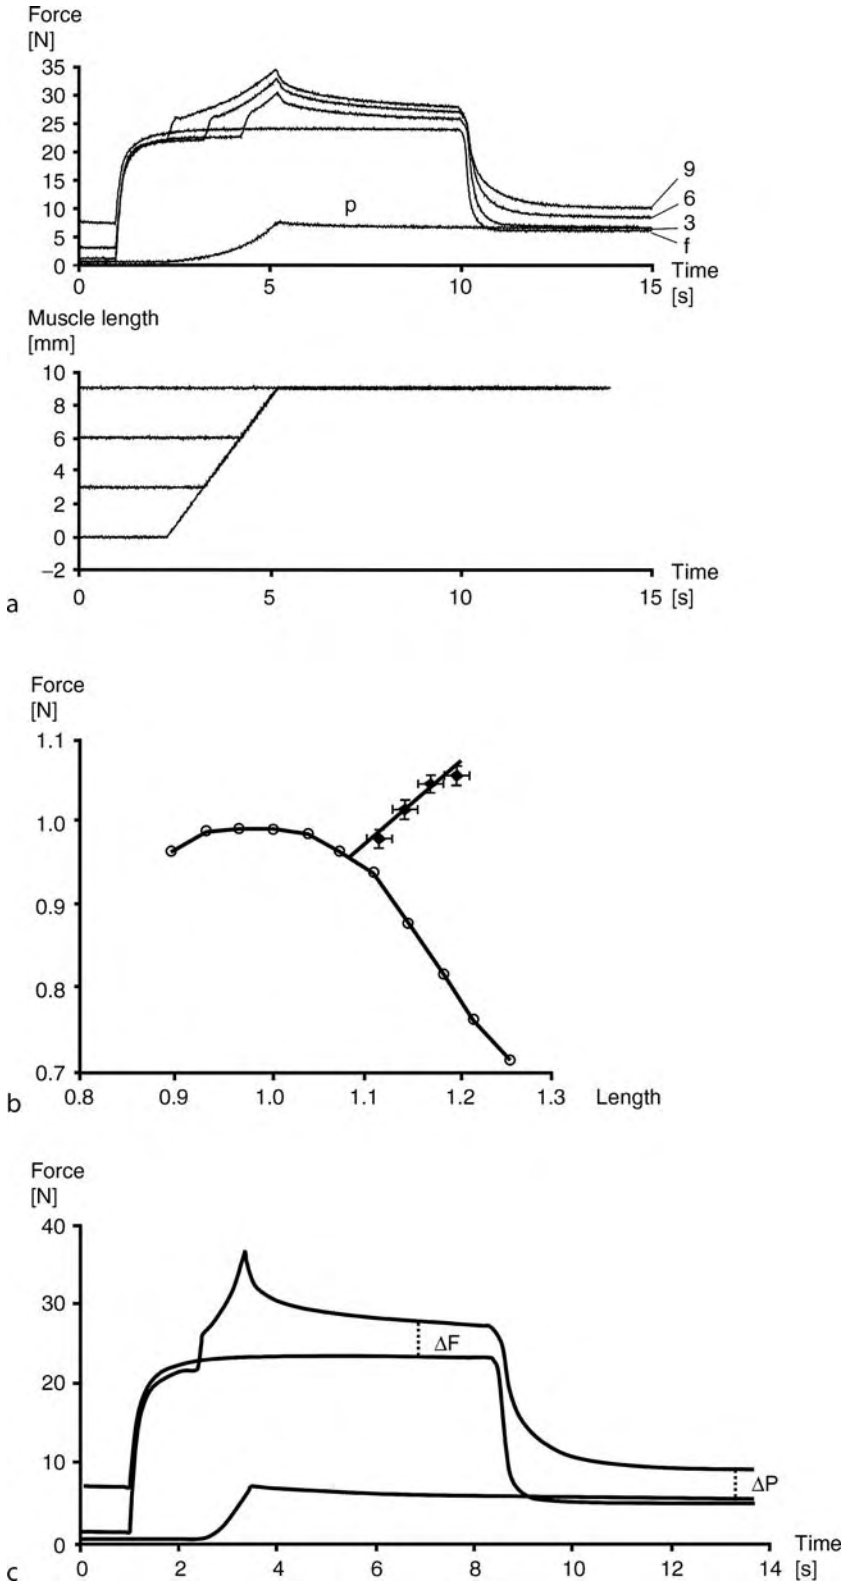


**Force Depression/Enhancement in Skeletal Muscles. Figure 2** Force-time and length time histories of isometric reference contractions and isometric-shortening-isometric test contractions that produce force depression. Force depression is known to increase with increasing magnitudes of muscle shortening (a), with increasing force during shortening (b), with decreasing speeds of shortening (note, the amount of shortening is constant; 30 represents the force-time trace for shortening at 30 mm/s, 2 the one for shortening at 2 mm/s (c), and force depression can be abolished by deactivating the force-depressed muscle just long enough for force to drop to zero (*dashed line*) (d).

and a passive component. At present, an explanation based on a stretch-induced decrease in the ►rate of cross-bridge detachment would account for many of the experimental observations associated with the active component of FE. This mechanism would account for the increase in stiffness observed in the force-enhanced compared to the isometric reference state [6], and might easily be fitted to the observation that FE increases with increasing magnitudes of stretch. It has also been observed quantitatively that the transient force decrease immediately following active muscle stretch and the force decay following deactivation are slower from the force-enhanced compared to the isometric reference state. However, the above proposal for FE is based on indirect and tentative arguments and must be thoroughly tested in the future.

The most popular mechanism for FE has been the sarcomere length non-uniformity theory [e.g. 9]. In this theory, FE is associated with a stretch-induced instability of sarcomere lengths on the descending limb of the force-length relationship. However, this theory cannot be the sole explanation for FE, because it inherently does not allow for FE on the ascending limb of the force-length relationship (but this has been observed on numerous occasions [e.g. 1]. Furthermore, steady-state FE, according to this theory, cannot exceed the maximum isometric force observed at muscle/fiber ►optimal length (but again, this has been observed in whole muscle and single fiber preparations (e.g. Fig. 3b).

The passive component of force enhancement appears to be associated with a structural element that is in parallel with the cross-bridges, and that is elongated upon sarcomere or fiber stretch. The molecular spring ►titin, which provides some of the physiological passive force in muscle, has been implicated to cause the observed passive FE [6]. Recently, it has been demonstrated that titin



**Force Depression/Enhancement in Skeletal Muscles. Figure 3** Force-time and length-time histories of stretch contractions with increasing magnitudes of stretch (a). Force enhancement and passive force enhancement increase with increasing stretch magnitudes (f, isometric reference contraction; 3, 6, and 9, stretch contractions of 3, 6, and 9 mm magnitude; p, passive, 9 mm stretch).

changes its stiffness properties as a function of calcium concentration [10]; a property that would fit perfectly with the observed passive force enhancement, but direct proof of titin's involvement with the passive component of FE has not been found.

## Function

Force depression and force enhancement have been observed primarily in muscle/fiber preparations that were activated artificially through electrical stimulation. The fact that these properties also exist during voluntary contraction has only been verified recently [e.g. 5] for maximal voluntary contractions. Since muscles are not electrically stimulated or maximally activated during most normal everyday movements, it is not clear if FD and FE play a functional role in the control and regulation of normal movements. Unpublished pilot data from our group suggest that FD and FE occur to a similar relative degree during submaximal voluntary contractions in the human adductor pollicis muscle. If these results are confirmed, the functional relevance of FD and FE may be studied. At present, it appears that FD does not serve any functional purpose, as any loss of force associated with specific contractile conditions implies that a given force must be attained with an increase in activation, and thus presumably an increased effort and increased metabolic cost. Therefore, force depression might be a property that is based on a structural or functional insufficiency of the actin-myosin motor.

In contrast to force depression, force enhancement is associated with a gain in force. Therefore, a given force can be achieved and more easily maintained following stretch of an activated muscle than that achieved in a purely isometric contraction. Presumably, this reduces the required activation and decreases the metabolic cost associated with producing a given level of force following stretch.

The passive component of force enhancement appears to occur only at muscle/fiber lengths that are toward the end range of normal physiological use and beyond. Therefore, it appears that the passive FE is most effective when a muscle is stretched actively beyond its normal range of motion. Such contractile conditions have been associated with muscle injury, thus the passive component of FE may be viewed as an "emergency break" for accidental over stretching of muscles.

# Force Potentiation in Skeletal Muscle

Rene Vandenboom
Faculty of Applied Health Sciences, Brock University, St. Catharines, ON, Canada

## Synonyms

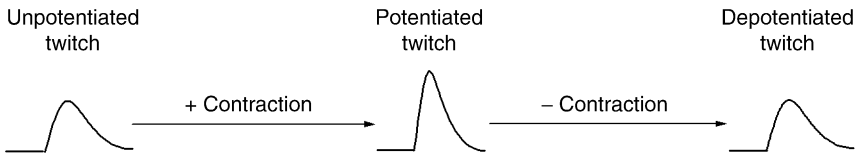
Postactivation potentiation (PAP); Posttetanic potentiation (PTP)

## Definition

Vertebrate skeletal muscle functions as a biological motor, converting chemical energy to mechanical energy to generate force and do work that powers movement [1]. An important property of muscle mechanical function is that it is history-dependent and as such is sensitive to previous muscle activity. An important example of this history-dependence is "force potentiation," defined as the transient increase in ►isometric twitch force evoked by prior contractile activity (Fig. 1).

Experimentally, force potentiation is readily observed in ►fast-twitch skeletal muscles isolated from rodents [2–7] as well as in human skeletal muscle [8]. Although the physiological function of force potentiation is uncertain, it is hypothesized to be an important modulator of skeletal muscle locomotor function [9].

General model showing change in isometric twitch force evoked by electrical stimulation (+stimulation) of rodent fast-twitch skeletal muscle. Compared to



**Force Potentiation in Skeletal Muscle. Figure 1** General model for force potentiation. Example of how isometric twitch force is increased electrical stimulation (+stimulation) of rodent fast-twitch skeletal muscle. Compared to the unpotentiated twitch (left) the amplitude of the potentiated twitch (middle) is increased by N50% and may exhibit a faster time course. In the absence of further activity (-stimulation) twitch force amplitude resumes pre-stimulation levels ("depotentiated" twitch) over the course of several minutes.

the unpotentiated twitch (left) the amplitude of the potentiated twitch (middle) is increased by ~75%. In the absence of further activity (−stimulation) twitch force amplitude resumes pre-stimulation levels ("depotentiated" twitch) over the course of several minutes.

## Characteristics

Several different model- and stimulation-dependent classes of force potentiation have been described. Although the experimental setting under which these responses are evoked may differ, the basic response is essentially the same, i.e., an increase in isometric twitch force observed during or following muscle activity. As an example, posttetanic potentiation (PTP) refers to the increased twitch force evoked by high-frequency electrical stimulation of rodent fast-twitch skeletal muscle (in vitro or in situ). In contrast, *staircase* refers to the progressive increase in twitch force observed during low frequency stimulation of rodent fast-twitch or human skeletal muscle [7]. On the other hand, the increase in performance observed following voluntary contraction of human skeletal muscle in vivo is termed *postactivation potentiation* (PAP).

An important aspect of force potentiation is that it may occur coincident with reductions in high-frequency tetanic force [6]. Thus, because force potentiation process selectively enhances low-frequency forces, it does not represent a simple "scaling-up" of overall muscle force generating capability. The molecular mechanism for PTP in animal muscle appears to be an increased sensitivity of the contractile proteins to suboptimal levels of calcium-activation mediated by phosphorylation of the myosin regulatory light chains (R-LC) [7,10]. As recently pointed out by Zhi et al. (2005), the molecular mechanism for staircase potentiation of mouse fast-muscle may be more complex and may, in addition to phosphorylation of the myosin R-LC, involve contraction-induced changes in the level of calcium ion delivered to the contractile proteins [7]. Clearly, more work is needed to clarify the contribution of these respective mechanisms to staircase in animal skeletal muscle. Finally, although evidence supports a casual link between phosphorylation of myosin and both PTP and PAP of human skeletal muscle [8,9], the influence exerted by altered calcium activation to these responses, as well as to staircase potentiation, is unclear.

Although force potentiation is an important feature of human skeletal muscle, this review will focus on data from animal studies that provide compelling evidence linking myosin R-LC phosphorylation to PTP of fast-twitch skeletal muscles from the mouse and rat hindlimb.

## Quantitative Description

### General

The presence of force potentiation is usually assessed by comparing twitch responses obtained before (pre-) and after (post) muscle contractile activity. The magnitude of potentiation is calculated as the percent increase in isometric twitch force (i.e., post/pre) that is produced. Under optimal conditions, twitch force may be increased twofold; the precise characteristics of the potentiated twitch are however specific to the prevailing experimental conditions. For example, PTP is very temperature sensitive; the magnitude of potentiation of mouse extensor digitorum longus (EDL) muscle is inversely related to temperature in the range 15–35°C [3,4]. Moreover, biological factors such as fiber type also influences force potentiation; in animals, contraction-induced increases in twitch force are inversely proportional to muscle oxidative potential [4].

Posttetanic potentiation or PTP has been most extensively studied using fast twitch muscle from the mouse (in vitro) and rat (in situ). In general, studies using rat fast muscle (EDL or white gastrocnemius) show that isometric twitch force may be increased by 50–100% above pre-tetanic values [3,5]. Although saturatable, the extent of force potentiation tends to increase with increasing frequency and/or durations of stimulation. For example, Manning and Stull (1982) used rat EDL to show that the extent of twitch potentiation induced by 1-s of stimulation was increased as frequency was increased from 10 Hz to 80 Hz [3]. Similarly, when stimulation frequency was held constant (200 Hz), twitch force potentiation increased as duration was increased from 50 ms to 2,000 ms [3]. Interestingly, the stimulation parameters required to saturate the force potentiation response may lie beyond

the time and frequency domains for muscle activation in vivo.

The extent of force potentiation observed in mouse muscle is generally less than that observed in rat muscle. For example, in the temperature range 25–35°C, the peak potentiation observed in mouse EDL muscle is only 30–35% above pre-stimulation values [4,6]. The greater twitch potentiation noted for rat vs. mouse muscle generally noted may be primarily due to differences in experimental conditions; studies using rat muscle are generally performed at warmer temperatures than are studies using mouse muscle. Interestingly, when studied at similar temperatures (20–25°C) the extent of twitch force potentiation reported for rat and mouse EDL muscle is similar [3,4]. For example, when measured 20 s after a brief ►tetanus, isometric twitch force of mouse EDL muscle maintained at 30°C was potentiated by 75% [7].

### *Time Course of PTP in Rodent Muscle*

Under non-fatiguing conditions, the time-course of potentiation is such that twitch force peaks shortly after stimulation before decaying with an initial fast and a subsequent slow time course [3–5]. This characteristic time-course is influenced by temperature. For example, at 35°C, PTP is highest immediately following stimulation before declining steeply to pre-stimulation levels. At 25°C however, PTP tends to peak only after many seconds have elapsed following stimulation; thereafter, PTP slowly declines to pre-stimulation levels over a period of several minutes. Regardless of temperature, excessive contractile activity may also cause ►fatigue, a process that may complicate the time-course of PTP by delaying its appearance and/or diminishing its magnitude.

### *Correlation of PTP with Myosin R-LC Phosphate Content in Rodent Hindlimb Muscle*

Several studies performed on mouse and rat skeletal muscle demonstrate that electrical stimulation of quiescent muscle induces large and rapid elevations in myosin R-LC phosphate content. For example, brief high-frequency or prolonged low-frequency stimulation of mouse EDL muscle in vitro elevates R-LC phosphate content from basal to near maximal levels (i.e., from ~0.15 to ~0.75 moles phosphate per mole R-LC [4,6–8]. Similar findings have been reported for rat muscle studied in situ [3,5]. The strong associations between stimulation-induced increases in myosin R-LC phosphorylation and the magnitude of twitch force potentiation observed coincident with this increase provided by these studies supports the notion that phosphorylation of the myosin R-LC is the molecular basis for PTP [3–5,7].

## Higher Level Structures

Myosin is the major structural and contractile protein of muscle. Myosin is a large (~520 kD) molecule formed by the dimerization of two heavy chain monomers, an assembly that produces an assymetrical molecule with two "heads" linked to a single rod or "tail" [1]. As a molecular motor, myosin enzymatic (myosin ATPase) activity is coupled to structural changes within the head producing a molecular force that powers muscle contraction [1].

## Lower Level Components

Covalently bound to each myosin head are two structures known as the myosin light chains (~20 kD). These subunits, known as the "essential" and "regulatory" light chains, appear to be important components for myosin motor function. Of these species, the regulatory light chain (R-LC) is phosphorylatable.

## Structural Regulation

The addition of a negative charge to the myosin head via phosphorylation of the R-LC has been observed to alter myosin head configuration, an effect that may increase myosin head mobility relative to the thick filament [reviewed in 9].

## Lower Level Processes

Sweeney et al. (1993) provide a comprehensive analysis of the processes regulating R-LC phosphorylation in vertebrate skeletal muscle [9]. Skeletal muscle contains a calcium – calmodulin dependent kinase enzyme termed skeletal muscle myosin light chain kinase (skMLCK). Although vertebrate skeletal muscle may also contain a smooth muscle MLCK isoform, it is the activity of the skMLCK isoform that appears to dominate myosin R-LC phosphorylation in skeletal muscle [7]. In this regard, the phosphate content of the R-LC is regulated via a signaling cascade wherein the intracellular calcium levels that govern muscle contraction also activates skMLCK to catalyze the transfer of a phosphate moiety from ATP to the R-LC. Dephosphorylation of the R-LC is accomplished via a phosphatase enzyme whose activity appears to be unregulated. At rest, phosphatase activity exceeds MLCK activity and R-LC phosphorylation is maintained at a low level. During muscle activity skMLCK activity increases to a point that favors phosphorylation of the R-LC. The magnitude of this increase is both stimulation frequency- and stimulation duration-dependent. Another order of regulation is achieved through a several-fold higher skMLCK content in fast-than ►slow-twitch muscle fibers, a difference that accounts for why R-LC phosphorylation is greater in fast- than in slow-muscle fibers [5].

## Process Regulation

In a simple, two-compartment model for muscle force regulation, twitch force potentiation can be due

to either an increase in the calcium signal for contraction or to an increase in the sensitivity of the contractile proteins to the calcium signal for contraction. To date, most evidence supports the idea that force potentiation is due to R-LC phosphorylation-mediated increases in the sensitivity of the contractile proteins to calcium. For example, Persechini et al. (1985) used ►permeabilized rabbit psoas muscle fibers to show that phosphorylation of the R-LC increases isometric force in response to suboptimal, but not saturating, levels of calcium activation [10]. The mechanism by which phosphorylation of the myosin R-LC increases the sensitivity of the contractile proteins to subsaturating $Ca^{2+}$ may involve alterations to myosin head configuration caused by the addition of a negatively charged phosphate moiety to the R-LC. For example, there is structural evidence to suggest that phosphorylation of the R-LC shifts the myosin head from the thick filament backbone [9]. This phosphorylation-induced offset of the myosin head from the thick filament is hypothesized to increase the mobility of the myosin head relative to the thin filament, an effect that may facilitate the rate constant describing the formation of force-generating states (i.e., *fapp*) particularly when the thin filament is suboptimally activated by calcium ion [9]; in contrast, myosin phosphorylation does not appear to alter the reverse rate constant, i.e., the transition of force-generating to non-force generating states (*gapp*). In intact muscle, this mechanism would be expected to enhance force during twitch and/or low frequency stimulation [8], conditions not expected to achieve full calcium-activation of the contractile proteins [9].

Although several studies have documented strong associations between R-LC phosphate content and PTP, the most compelling evidence that myosin phosphorylation mediates twitch force potentiation comes from experiments performed on mice in which the gene coding for skMLCK has been ablated [10]. Compared to muscles from wild-type mice, EDL and soleus muscles isolated from knockout mice ($skMLCK^{-/-}$) expressed minimal skMLCK [7]. Thus, although tetanic stimulation (175 Hz for 2 s) of wild-type EDL elevated myosin R-LC phosphate content from basal levels to ~0.50 moles phosphate per mole R-LC, tetanic-stimulation of $skMLCK^{-/-}$ muscles did not elevate myosin R-LC phosphorylation above the very low, constituent level of myosin phosphorylation at rest. Moreover, although tetanic stimulation of wild-type EDL potentiated twitch force by ~75%, identical stimulation of $skMLCK^{-/-}$ EDL did not produce any PTP [7]. Although it is unclear as to why $skMLCK^{-/-}$ muscles from knockout mice displayed small basal levels of myosin phosphorylation (i.e. ~0.10 moles phosphate per mole of R-LC), the fact that stimulation of these musces did not elevate myosin R-LC phosphorylation nor potentiate twitch force provides evidence that these phenomena are functionally related in mouse EDL muscle (at 30°C). An interesting point in the data of Zhi et al. (2005) is that the ablation of skMLCK did not completely inhibit the staircase potentiation of EDL muscle [10]. For example, repetitive stimulation (10 Hz for 15 s) of wild-type EDL muscles potentiated twitch force by ~50% compared to the first twitch; this outcome was coincident with elevations in myosin R-LC phosphate content to ~0.50 moles phosphate per mole of R-LC [7]. On the other hand, although stimulation of $skMLCK^{-/-}$ EDL did not elevate myosin R-LC phosphorylation above baseline levels (see above), twitch force was potentiated by ~30% during the low-frequency train [7]. Thus, although these data strongly implicate a causal link between myosin phosphorylation and PTP, they also indicate that additional factors may contribute to staircase potentiation in mouse EDL muscle [7].

## Function

From a teleological perspective it is appealing to think that vertebrate striated muscle normally operates in a "potentiated state" in vivo. That is, repetitive or prolonged muscle activity may lead to sustained elevations in myosin R-LC phosphate content, a condition that may enhance muscle mechanical and metabolic properties compared to the fatigued but unphosphorylated state [6,8]. Moreover, although the isometric twitch is a poor surrogate for assaying physiological function of muscle, there is evidence to suggest that myosin phosphorylation may also enhance the dynamic properties of fast-twitch skeletal muscle. Although phosphorylation of the myosin R-LC does not enhance unloaded shortening velocity [4,10], it may augment loaded shortening velocity [2]. Thus, in addition to enhancing isometric force development, the potentiation process may augment ►isotonic muscle function. It is hypothesized that, by increasing the ability of cycling crossbridges to attain force-generating states on the thin filament, myosin phosphorylation may shift a given isotonic load toward the "faster" end of the ►force–velocity relation [2,9]. Although complicated by many different aspects of neural activation in vivo (e.g., high frequency activation of concentric and eccentric muscle forces) it seems reasonable to expect that activity-induced elevations in myosin R-LC phosphorylation may operate to enhance the dynamic properties of working fast-skeletal muscle in vivo. Finally, it should be mentioned that it is still unclear as to whether myosin phophorylation mediated force potentiation operates to increase, decrease or does not change the economy of muscle contradiction. This information is vital if we are to fully understand the teleological role of myosin phosphorylation and the ability of this molecular mechanism to modulate dynamic function of fast-twitch skeletal muscle in fatigued and un-fatigued states.

## Synonyms

FFR

## Definition

The ►force-frequency relation (FFR) is the sigmoid relationship between a muscle's activation frequency and isometric force output. The FFR is classically derived by plotting the peak force responses to trains of electrical pulses across a wide range of frequencies (see Fig. 1). At low stimulation frequencies (e.g., ≤5 pps) the FFR is flat, as no summation of force occurs in response to successive stimuli, resulting in a series of isolated twitches (Fig. 1b, region I). With increasing stimulation frequency, summation of force can be observed, resulting in a steep rise in the FFR (Fig. 1b, region II). At sufficiently high frequencies of stimulation, the responses to individual stimuli cannot be delineated and a smooth tetanic contraction is observed; and there is little further increase in peak force with increasing frequency (Fig. 1b, region III). Studies often quantify differences in the FFR by reporting the frequency needed to produce a set percentage of maximum force (e.g., the frequency required to produce 50% of maximum force).

## Characteristics

### Quantitative Description

#### *Force Production*

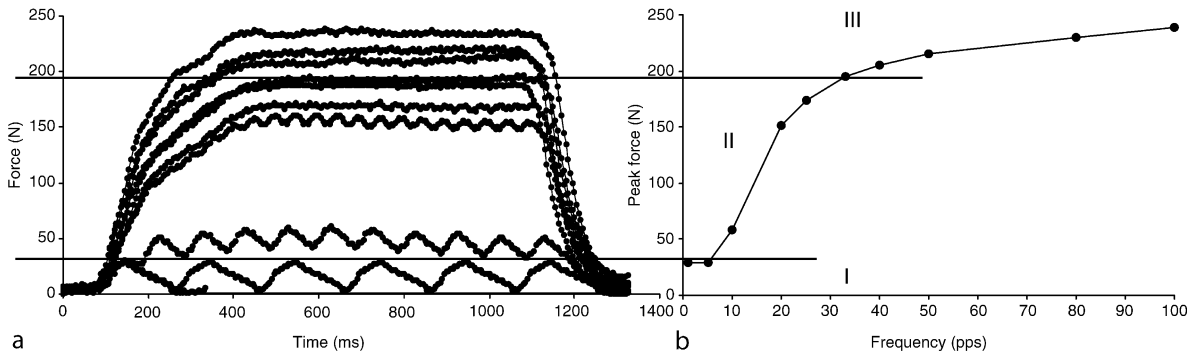
During voluntary contractions, there are two basic mechanisms used by the CNS for modulating the force produced by a muscle: ►*recruitment* and ►*rate coding (frequency modulation)*. During electrical stimulation of skeletal muscle, force can be modulated by varying the intensity and frequency of the stimulation pulses, analogous to the processes of recruitment and rate coding. The FFR essentially describes the effect of rate coding.

#### *Recruitment*

The size principle describes a process for the orderly recruitment of motor units during voluntary contractions, with the smallest ►motor units recruited first and the larger motor units recruited with successively stronger contractions [1]. During direct electrical stimulation to the motor nerve, the recruitment order is reversed; the largest motor units are recruited first, and progressively smaller units are recruited with increasing stimulus amplitude. During neuromuscular electrical stimulation (NMES) with surface electrodes, however, recruitment appears to be more variable and less orderly than that observed during voluntary contractions or during direct nerve stimulation.

#### *Rate Coding (Frequency Modulation)*

The other mechanism used by the CNS for modulating muscle force is varying the discharge rate of those motor units that have been recruited. During voluntary contractions both recruitment and rate coding grade force, making it difficult to separate their effects on



**Force-Frequency Relation of Skeletal Muscle. Figure 1** Raw force traces (a) and the corresponding force-frequency relationship (b) of the quadriceps femoris muscle in a young healthy individual. At low stimulation frequencies (e.g., ≤5 pps) the FFR is flat, as no summation of force occurs in response to successive stimuli, resulting in a series of isolated twitches (b, region I). With increasing stimulation frequency, summation of force can be observed, resulting in a steep rise in the FFR (b, region II). At sufficiently high frequencies of stimulation, the responses to individual stimuli cannot be delineated and a smooth tetanic contraction is observed; and there is little further increase in peak force with increasing frequency (b, region III).

force production. Most studies have therefore relied on NMES to investigate the FFR. The classic, electrically elicited FFR, however, tends to overestimate the discharge rates observed during voluntary contractions. The asynchronous discharge of motor units during volitional contractions serves to smooth the contraction (at low forces and discharge rates) and produces greater forces at each mean motor unit activation frequency than are possible with synchronous activation of NMES. The FFR plotted during synchronous electrical stimulation has provided many important insights into the factors that affect this relation.

### *Factors Influencing the FFR*

The contractile characteristics of a muscle affect its FFR. The rates of force development and relaxation, which are a function of the myosin heavy chain and sarcoplasmic endoplasmic reticulum calcium ATPase protein profiles of the fibers in the muscle, affect the frequency at which summation of force begins to occur (leftward boundary of region II in Fig. 1b) and the frequency needed to produce maximum tetanic force. The faster the contractile rates, the further to the right the FFR should lie.

Each muscle does not display a consistent FFR. The FFR observed in any given muscle is a function of the muscle's length and recent contractile activity. Thus, a single sigmoid curve cannot accurately portray the true FFR of any muscle.

### *Muscle Length*

Changes in muscle length may affect the FFR by altering force transmission and force-generating capacity (also see muscle ►force-length relation). For example, increasing muscle length increases passive tension, which in turn, reduces the amount of slack that the muscle must take up prior to transmitting force. This preferentially enhances the force measured at lower stimulation frequencies, thus shifting the FFR to the left. Conversely, the FFR would be shifted to the right in shortened muscles.

The sliding filament theory also predicts that variations in muscle length will affect muscular force generation by altering the degree of ►myofilament overlap. The maximum isometric tension that skeletal muscle can generate at different lengths has been well-studied. At any muscle length other than optimum, sub-maximal forces are generated by the muscle. Virtually all investigators have found maximum force at lengths that allowed maximum overlap of the thin and thick filaments, and nearly linear declines in force at longer and shorter lengths.

In addition to these mechanical effects of muscle length, it has been suggested that the $Ca^{2+}$ -sensitivity of the myofilaments is influenced by muscle length [2], with sensitivity reduced at short muscle lengths. Such a reduction in $Ca^{2+}$ -sensitivity would shift the FFR to the right. Thus, alterations in the FFR with changing muscle length may reflect both changes in force transmission and force generation.

### *Contractile History*

Muscular contraction is associated with a number of phenomena that have been observed to influence the FFR. For example, contractile activity increases muscle temperature, which is associated with an increase in the contractile rate of the muscle. Such increases in contractile rate might be expected to shift the FFR to the right.

Both tetanic and sub-tetanic [3] stimulation, as well as voluntary contractile activity, produce muscle potentiation [4] resulting from a $Ca^{2+}$ -activated myosin light chain phosphorylation, which increases the probability of actin–myosin interaction. Potentiation results as an increase in twitch and subtetanic force production, no effect on maximum tetanic tension, and a shift of the FFR to the left.

Another method of increasing the probability of actin–myosin interaction, and thus a leftward shift in the FFR, is to activate muscle using stimulation trains that elicit the ►catchlike property. The catchlike property of skeletal muscle is a tension enhancement produced when an initial brief high frequency burst of pulses (2–4 pulses) is used at the onset of subsequent subtetanic stimulation train [3]. Such tension enhancements at subtetanic stimulation frequencies by the catch-like property are attributed to increased calcium release by the ►sarcoplasmic reticulum caused by the initial high frequency burst at the onset of the stimulation train. Another mechanism attributed to force enhancements is that the catchlike property causes increased muscle stiffness and thus better transmission of the force generated by the existing crossbridges. As the catchlike property enhances force production of stimulation trains with lower mean frequencies, a leftward shift in the FFR is observed [3].

If contractile activity is maintained for a sufficient period of time, muscle fatigue will occur, and this can also influence the FFR. Bigland-Ritchie and associates [5] have shown, for the human adductor pollicis muscle, that following fatigue, the twitch contraction time decreased slightly and the half relaxation time markedly increased. Based on these findings and the fact that motor unit firing frequencies were shown to decrease markedly during sustained, fatiguing, maximum voluntary contractions, Bigland-Ritchie and associates suggested that the FFR should shift to the left as a muscle begins to fatigue. This assertion assumed, however, that fatigue would affect force equally across all frequencies.

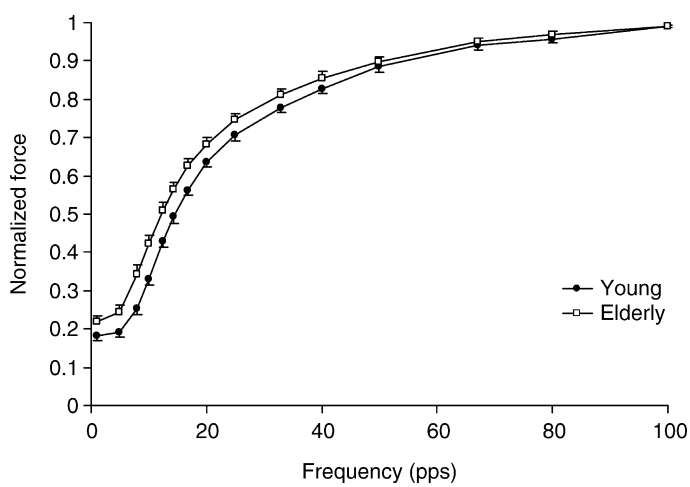
More recent work appears to disprove this assumption and has shown a shift in the FFR to the right during fatigue [6]. In several different human muscles, the FFR is shifted to the right when the muscle is fatigued by electrically or volitionally induced contractions. The shift in the FFR is the result of a greater attenuation of the twitch force than the tetanic force (i.e., a decrease in the twitch to tetanus ratio) [6]. This phenomenon is termed low-frequency fatigue, and occurs due to a reduction in $Ca^{2+}$ released per stimulus. As a result of this impairment, force production is markedly impaired at low stimulation frequencies, whereas high-frequency stimulation (50 pps) produces sufficient $Ca^{2+}$ release to permit full cross-bridge interaction to occur [7].

## Function

Rate coding is one of two primary ways that the CNS controls muscle force output. Similarly, during exogenous electrical activation of skeletal muscles, the timing of the presentation of successive pulses markedly affects the rate of force development, the amount of peak force produced, and the rate and amount of fatigue produced.

## Pathology

The effect of pathology on the FFR probably varies with the nature of the changes that accompany the specific condition. Increased age, for example, is believed to induce excitation–contraction "uncoupling" in skeletal



**Force-Frequency Relation of Skeletal Muscle. Figure 2** Normalized quadriceps femoris force-frequency curves from young (N = 20) and elderly (N = 20) individuals showing a leftward shift for elderly individuals. Error bars represent standard deviations.

muscle [8], a phenomenon that would be expected to shift the FFR to the right. However, aging is also associated with a reduction of Type II fiber area, which should induce a leftward shift. A number of investigators have, in fact, observed a leftward shift in the FFR in aged versus young muscle, suggesting that the shifts in myosin isoform composition have greater effect than diminished twitch forces observed in aged muscle. Other, more severe, pathologic conditions such as cerebral palsy and spinal cord injury have recently been shown to affect the FFR. In both conditions, a leftward shift in the FFR has been observed [9,10] (see Fig. 2). Although it is attractive to explain such shifts in the FFR by suspected changes in myosin heavy chain expression, the two conditions are associated with opposite shifts in fiber type, fast toward slow in cerebral palsy and slow toward fast in spinal cord injury, indicating that other factors must be at work. Interestingly, both conditions are associated with greater twitch and subtetanic force responses than uninvolved muscles, which are factors expected to shift the FFR to the left [9,10].

# Force–Velocity Relationship of Skeletal Muscle

David C. Lin
Programs in Bioengineering and Neuroscience, Washington State University, Pullman, WA, USA

F

## Definition

The force-velocity relationship describes how muscle force depends upon the velocity of movement or *vice versa*.

## Characteristics

### Quantitative Description

The seminal experiments of A.V. Hill showed that the velocity of shortening in actively contracting skeletal muscle depended upon the force with which the muscle was loaded. Hill believed that the functional significance of these experiments was that an internal viscous resistance within the muscle had to be overcome in order for shortening to take place [1]. Although this theory proved to be incorrect, the fact that force and velocity are interrelated is important because quantifying force–velocity (F–V) characteristics is a crucial assessment of muscle contractile properties for modeling purposes, and for revealing the optimal mechanical conditions under which a specific muscle performs motor functions.

#### *Measurement of the F–V Relationship*

Ideally, measurement of the F–V relationship is the simultaneous measurement of steady-state force and steady-state velocity during steady-state activation. The term "steady-state" implies that a quantity does not change over time. However, due to the interaction of F–V property with other dynamic properties, it is virtually impossible to obtain steady-state conditions for both force and velocity. Hence, the experimental protocol used to measure the F–V properties can influence quantitative measurement of the F–V curve.

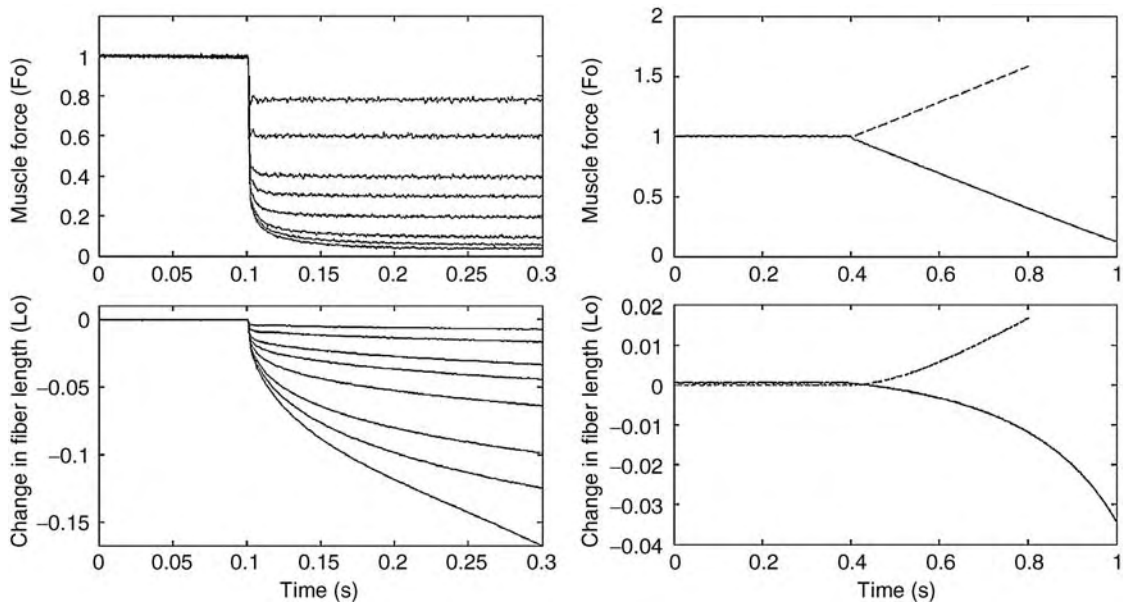
The most widely used method to measure F–V properties is the application of "isotonic" loads. In the isotonic experimental paradigm, the muscle is activated while being held at a constant length (i.e. isometric). Once the isometric force ($F_o$) is constant, the force in the muscle is changed and set to a new constant level, the isotonic force. The change in force produces a change in length in the muscle. If the isotonic force is less than the isometric force, the muscle will shorten, and if the isotonic force is greater than the isometric force, the muscle will lengthen. The change in length usually contains a fast transient response immediately after the imposition of the isotonic load,

followed by a near constant slower velocity in the muscle (Fig. 1). However, the magnitude of velocity tends to decrease with time and usually does not reach a steady-state. Thus, most investigators choose an arbitrary time period, where initial transients have diminished and velocity is relatively constant, to measure the muscle velocity. It should be noted that the choice of the time period does influence the quantitative measurement of the F–V relationship. The experiment is repeated several times to obtain a series of discrete F–V data points.

The second method is the isovelocity experimental paradigm. This experimental protocol is similar to the isotonic experiments except that muscle velocity is controlled and muscle force measured. Usually, the resulting force response is also not a true steady-state response, and force is measured in a specific time window or at a specific muscle length. The characterization of the F–V properties also requires a series of experimental trials to obtain a series of F–V data points. The third method is a "slack test." In this method, the muscle is fully activated and then rapidly shortened by a specific distance, causing the muscle to become slack and muscle force to become zero. The muscle shortens in this unloaded condition until the slack is removed and force is redeveloped. Usually, the experiment is repeated several times with different distances of imposed slack, and the slope of the slack distance versus time to force redevelopment is equal to the "unloaded shortening velocity" ($V_o$). A shortcoming of the slack test method is that it only provides one data point for the F–V relationship.

A fourth method which has not been widely used to characterize the F–V relationship is to apply a "force ramp," which is a linear change in force over time [2]. In this method, the force-controlled perturbation is applied and velocity measured from the resulting length change (Fig. 1). In this method, neither force nor velocity reaches a steady-state, thus the F–V measurement is under more dynamic conditions and can be more sensitive to other experimental parameters (e.g. the rate of force change). A major difference between this method and other methods is that only one experimental trial is needed to record the F–V property for shortening (another trial would be needed for lengthening), instead of a series of experimental trials. This is advantageous because exposing muscle to a series of activations with shortening or lengthening could change the state of the muscle due to fatigue and/or structural damage and lead to inconsistencies in the data collection.

In summary, several methods can be employed to measure the F–V relationship in constantly activated skeletal muscle. However, none of the methods truly measure a steady-state property, and all methods have a certain degree of arbitrariness which influences the quantitative measurement of the F–V relationship.



**Force–Velocity Relationship of Skeletal Muscle. Figure 1** Isotonic experimental trials (*right column*) for a chemically skinned rat *medial gastrocnemius* single fiber at 12°C are shown for eight different isotonic levels. Force ramp experimental trials (*left column*) for chemically skinned human *soleus* (type I) single fiber at 22°C are shown for shortening (*solid*) and lengthening (*dashed*) movements. Muscle force and length are normalized to their isometric values.

### Shortening F–V Relationship

The F–V relationship has been measured for shortening movements (i.e. force less than $F_o$) in experimental preparations at all muscle structural levels (myofibril, single fiber, motor unit, and whole muscle) and in muscles from a broad spectrum of species. Most of the studies are performed with chemically skinned single fibers or whole muscles and in amphibian or mammalian muscle. Remarkably, plots of force versus velocity (or velocity versus force) for shortening movements obtained from almost all muscles by using any of the methods discussed previously have the same mathematical description, that of a hyperbolic equation [3]. The hyperbolic equation, often termed Hill's equation, is expressed as:

$$(F + a)(v + b) = (F_o + a)b \qquad (1)$$

where $F$ is the muscle force, $v$ is the muscle velocity (shortening is defined as positive velocity), and $a$ and $b$ are parameters that vary from muscle to muscle (see Lower Level Components and Process Regulation). Examples of the shortening F–V relationship for slow and fast human muscle fibers are shown in Fig. 2.

One of the key values of the shortening F–V relationship is the velocity at zero force. From isotonic experiments, the values of $a$ and $b$ from Hill's equation are usually fitted to the data, and the velocity at zero force can be estimated from the equation (1). This estimate of velocity at zero force is called "maximal shortening velocity" ($V_{max}$). Interestingly, measurements of $V_{max}$ and $V_o$ are significantly different (10–20%) [4], although theoretically they should be similar. Moreover, $V_{max}$ estimates from the force ramp methods also show differences from isotonic measurements [2]. These discrepancies in the estimate of velocity at zero force also show that the quantitative measurement of the F–V relationship varies with the experimental method.

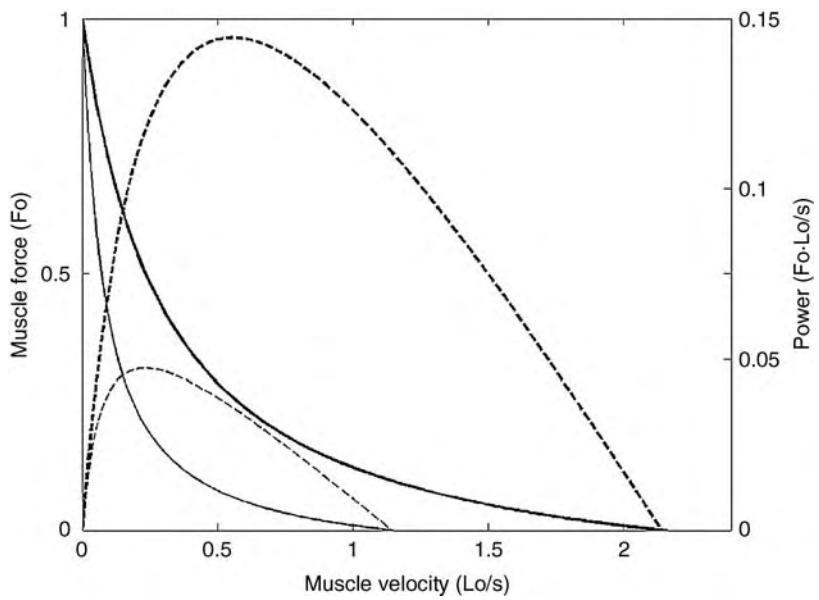
### Lengthening F–V Relationship

The F–V relationship in lengthening has not been recorded nearly as frequently as for shortening movements. A reason for this is that lengthening F–V data tend to be more variable than shortening data. This is partly due to the damage incurred during lengthening movements, which can result in structural irregularities, such as sarcomere non-uniformity [5]. In the few experimental studies, the F–V relationship has been characterized by a hyperbolic equation of the form:

$$(2F_o - F - a')v = (F_o - F)b' \qquad (2)$$

where $a'$ and $b'$ are constants and $v$ is negative to represent a lengthening velocity.

Due to the uncertainty and variability of the lengthening F–V data, other approximations have been used to characterize the F–V relationship. Namely, that as lengthening velocity increases, the force saturates between 1.4 and 1.8 times $F_o$ with an exponential



**Force–Velocity Relationship of Skeletal Muscle. Figure 2** The force–velocity (*solid lines*) and power–velocity (*dashed lines*) relationships for chemically skinned human single fibers at 20°C. Shown are the hyperbolic curves (equation (1) in text) based on data obtained in slow (type I) fibers (*thin line*) and fast (type IIa) fibers (*thick line*) by He et al. (2000 #305). Muscle force is normalized by isometric force ($F_o$) and muscle length by optimal muscle length ($L_o$).

type expression describing the relationship of velocity to force [6]. The ambiguity of how best to mathematically describe the lengthening F–V relationship reflects that lengthening movements are much more complex in nature than shortening movements.

### *Factors that Influence the F–V Relationship*

Generally, F–V data are normalized by $F_o$ and the length of the muscle at which muscle generates the most isometric force (called "optimal muscle length," $L_o$), as shown in Fig. 2. However, there are several factors that can influence the shape of the F–V curve. First, the muscle length at which force and velocity are measured affects the F–V curve, especially in lengthening movements [6]. Second, the activation level affects the shape of the F–V both quantitatively and qualitatively. In shortening movements, $V_{max}$ decreases as the activation level decreases [7]. In lengthening movements, force during lengthening velocities can be less than $F_o$ for low levels of activation [8].

Besides these two external influences on the F–V relationship, there are important intrinsic factors. Portions of the myosin contractile protein (see Lower Level Components), namely the heavy chain and light chain portions of the myosin molecule, have different isoforms expressed, which can be grouped roughly into slow (type I) and fast (type II) isoforms. Due to differences in reaction rates between the myosin isoforms that bind with actin (see Lower Level Processes), the type of isoform is strongly correlated with the shape of F–V relationship. For instance, $V_{max}$ of a single muscle fiber is almost wholly determined by the type of myosin heavy chain (MHC) and myosin light chain (MLC) found within a single fiber, and the difference in $V_{max}$ between slow and fast fibers can be several fold (Fig. 2).

Moreover, certain factors, such as the pattern of neural activation and mechanical load, influence whether slow or fast isoforms are expressed. Thus, the F–V relationship is highly plastic to meet the needs of a motor function (see Process Regulation and Function).

## Lower Level Components

Several components within a muscle are responsible for force and movement generation. For a muscle with steady-state activation, implying that intracellular calcium level is constant, the main components responsible for the dynamic features of muscle contractions are the myosin and actin contractile proteins. The myosin molecule has two globular heads, each of which can be subdivided into two portions: the myosin heavy chain (MHC) portion is the top of the head and interacts with actin to form a ►crossbridge (actomyosin); and a pair of myosin light chains (MLC), which are called the essential and regulatory light chains.

## Lower Level Processes

Muscle force and movement are generated by the cycle of ►crossbridge attachment, myosin head rotation, and detachment via ATP hydrolysis. This cyclic process of ►crossbridge attachment and detachment is responsible for the conversion of chemical energy (in ATP) to mechanical energy (work). An important aspect of the cycling behavior of ►crossbridges is the rate of cycling: fast myosin isoforms cycle faster than slow isoforms. The faster cycling rate allows the muscle with fast isoforms to generate faster movements, which is reflected in the F–V relationship (e.g. a greater $V_{max}$). In other words, the kinetics of the ►crossbridge cycle, or the rate at which attachment and detachment of ►crossbridges occurs, varies according to the contractile protein isoforms, especially those of the MHC and MLC.

## Process Regulation

One of the most important aspects of skeletal muscle is its ability to have widely divergent properties. Specifically, as discussed earlier, the F–V curves of different muscles can vary dramatically. This flexibility arises from the process of the contractile proteins constantly undergoing remodeling, and the expression of the isoform provides a direct link to meeting the functional demands placed on the muscle. A common example of this plasticity occurs in exercise. According to the mechanical demands of an exercise paradigm, such as endurance versus short-term high power training, the contractile protein isoforms expressed will be of a slow or fast type, and thus a muscle can switch from having predominately slow fibers to predominately fast fibers (or *vice versa*) [4]. Thus, the contractile process is regulated by the expression of contractile protein isoforms. By changing the percentage of slow and fast fibers within a muscle, the F–V curve can be adapted to meet the needed motor function (see Function).

## Function

The importance of the F–V relationship to motor function is that the F–V curve of a specific muscle is often "tuned" to match its predominant mechanical function. Roughly speaking, a muscle can serve two mechanical functions: maintaining posture, where the velocity of movements is relatively small; and generating movements, where the velocity of movements is relatively large. Power, which is the product of force multiplied by velocity, gives an indication of how much mechanical work can be produced in a given amount of time. Thus, for postural tasks, power output by the muscle should be optimized for slower velocities and for movements, power should be optimized for faster velocities.

The F–V curve can be easily transformed into the ►power–velocity (P–V) curve by multiplying force

times velocity to yield ►power (Fig. 2). In shortening movements, the P–V curve has a velocity ($V_{opt}$) where power output is at a maximum. $V_{opt}$ is generally one-quarter to one-third of the value of $V_{max}$. $V_{opt}$ for postural muscles is much smaller than that for muscles predominantly activated during fast movements. Muscles that serve both postural and fast movement functions tend to have intermediate values for $V_{opt}$. In terms of regulation of function, the plasticity of contractile protein isoforms, which in turn influences the F–V curve, gives a muscle the ability to adapt and match any changes in the mechanical demands of the muscle.

An excellent example of $V_{opt}$ matching the mechanical demands of a specific muscle has been shown in frog muscles involved in jumping. Lutz and Rome [9] found that the primary muscle activated during the first 50 ms of the takeoff phase was the *semitendinosus* (a muscle between the hip and knee joints) and that it shortened at a nearly constant velocity of 3.43 $L_o$/s ($L_o$ is optimal fiber length). From the measured F–V curve, $V_{max}$ of the frog *semitendinosus* was estimated to be 10.35 $L_o$/s and $V_{opt}$ to be 3.44 $L_o$/s. Thus, the muscle shortened with a velocity equal to $V_{opt}$ so as to optimize the ►power output to maximize the jump. Tuning $V_{opt}$ is also of particular importance in cyclic movements, such as those which occur in locomotion. The main muscles used for sustained swimming in fish have been found to shorten at velocities near $V_{opt}$ for those muscles [9].

# Forced Desynchrony

## Definition

An experimental protocol designed to allow for the accurate assessment of human circadian rhythms. This protocol separates circadian (time dependent) and homeostatic (behavioral state dependent) contributions to sleep propensity and cognitive performance. Subjects are placed on a light-dark/rest-activity schedule that is much longer or shorter than 24 h, to which the endogenous circadian clock is unable to entrain, allowing it to free-run according to its own period. In this way, the effect of exogenous factors, such as sleep and activity, on variables of interest can be assessed at all circadian phases.

►Circadian Rhythm
►Internal Desynchrony

# Force-Length Relationship

## Definition

The force-length relationship describes the dependence of the steady-state isometric force of a muscle (or fiber, or sarcomere) as a function of muscle (fiber, sarcomere) length. It is characterized by a positive slope (i.e. force is getting greater as length increases) at short lengths (the so-called ascending limb of the force-length relationship), a zero slope (the so-called plateau region) at intermediate lengths, and a negative slope (i.e. force decreases with increasing lengths; descending limb of the force-length relationship) at long muscle lengths.

This property of muscle has been known since the mid nineteenth century, and has been described on the sarcomere level in a classic paper by A. Gordon, A. Huxley, and F. Julian in 1966. The force-length relationship is considered one of the basic properties of muscle.

# Forebrain

## Definition

Rostral part of the brain composed by the telencephalon and the diencephalon. It lies rostral to the mesencephalon and contains the superior centers involved in the control of sensorimotor, autonomic and endocrine functions, in emotional behavior, as well as in cognitive functions such as learning and memory.

# Forensic Neuropsychiatry

Joachim Witzel
Central State Forensic Psychiatric Hospital of Saxony-Anhalt, Schnöggersburger Weg 1, Uchtspringe, Stendal, Germany

## Synonyms

Neuropsychiatry; Neuroimaging; Biological psychiatry

## Definition

Neuroimaging in Forensic Psychiatry is concerned with the supply of additional information about the relationship between psychiatric abnormalities and legal violations and crimes. As we still face a considerable lack of available biological criteria, evaluation and therapy in forensic psychiatry are restricted to psychosocial and mental criteria of offenders' personalities. However, recent advances in neurosciences will allow a much closer approach to the neural correlates of personality, moral judgments, and decision-making. Thus, forensic neuropsychiatry increases our available techniques in judging mentally ill criminals by biopsychosocial and objective criteria. Determination of free and voluntary decision-making as well as brain-behavior relationships will be accomplished by neuroimaging techniques.

## Characteristics

### History/Background

In the past years we have faced a tremendous development of neurobiological techniques in neuroimaging to assess neuronal correlates of psychological disorders which lead to dramatic changes in personality. These changes result in an alterated attitude of probands towards their own way of living and to society in general as well. Now that we have just started to understand some aspects of these alterations of the brain and will be able to find out to some extent the reasons that contribute to the development of psychopathologic symptoms, for example, sexually deviant behavior. While in the past this subject was approached merely by psychological means, investigations in the field of forensic neuropsychiatry now shed some light onto this important field of investigation.

In general forensic psychiatry is concerned with psychiatric abnormalities which result in legal violations and serious crimes. Due to the inavailability of specific biological criteria, evaluation and therapy in forensic psychiatry were so far limited to the psychosocial and mental criteria of offenders' personalities. However, the tremendous recent advances in neurosciences now allow a closer approach to the neural correlates of personality, moral judgments, and decision-making as well. It has therefore been proposed to discuss the introduction of biological criteria in the field of forensic psychiatry, and to establish rules to which extent such biological criteria will be a better and more reliable choice in judging mentally ill criminals, by also using available information based on specific biologically based assessment procedures which up until now could only be obtained by complicated technical means [1].

We are now entering a decade in which we will also use biopsychosocial and objective criteria, and we will finally be able to accomplish psychosocial and subjective criteria in forensic evaluation using neuroimaging techniques. Altogether these different methods might be helpful for each other to give a better result judging probands, when they are assessed and used correspondingly. The responsibility of having conducted a criminal act will no longer be defined by judging free and voluntary decision-making alone, but rather by brain-behavior relationships based on neuroimaging techniques.

Psychosocially-determined mental processes thus can be judged in a more appropriate way by estimating the degree of biopsychosocially-determined neural processes which had been involved in the complicated procedure which finally led to committing a serious crime. It might be concluded that the development of more detailed and differentiated biologically-based assessment methods in neuroimaging in the near future will contribute to a paradigm shift in forensic psychiatry, which will have profoundly essential implications for offenders, forensic psychologists and psychiatrists, the law and for society in general [1].

### Forensic Neuropsychiatry in Prisoners

According to biological investigations, we found a huge number of scientific articles dealing with the prevalence of mental illness to be found in prisoners. Indeed, these findings reported a considerably higher incidence of psychiatric illness in prisoners than was estimated in the past. The data indicated that it was increased tremendously compared to the findings

in the general population [2]. Our own results confirmed these findings: even in German prisons the prevalence of mental illness was obviously much higher than in the general population.

So we have to face the problem that there might be a relationship of delinquency on one hand and mental illness on the other. All prisoners who exhibited symptoms of serious mental illness at the time they committed crimes should have been psychiatrically investigated in the course of legal judgement.

Up until now we strongly referred to social aspects when judging probands who had committed a crime. In many cases they were sentenced to prison without a serious mental illness being documented at all. Of course, there is no doubt that suboptimal conditions in social life will contribute to the exhibition of a criminal way of living, but alas we are lacking the decisive link to find the reason for it. Investigations about e.g. the interference of social aspects in developing an antisocial career neglected to find out to what extent and in which way biological changes of the central nervous system might contribute to this development. So we will have to perform numerous investigations to understand better to what extent the behavior of probands could be influenced by neurobiological alterations.

## Neuroimaging in Forensic Psychiatry

Reflecting the highly complex structure of the human central nervous system, we should be aware that the finding to be expected will not be able to clarify all questions. In general, contradictory results will be found which have to be taken together like parts of a puzzle to give more detailed information about the impact of biological alterations of the brain in committing a crime. There will be no easy solution, and it will take hard work in the future to get more insight into this very important problem and to what extent mentally ill offenders should be exculpated due to the fact of biological changes.

Indeed, there are numerous scientists in the world who still deny a relationship between biological alterations of the brain and the changed behavior originating from this. They still propose that even striking psychical changes in a personality could be explained by neglecting biological aspects.

At present we are more and more able to give strong evidence that there is proof of a close relationship between biological changes and alteration of the personality itself. We faced during the past few years numerous investigations about differentiated psychiatric symptoms resulting in crimes and biological changes [3,4]. This may be judged as a first step towards a better understanding of highly complex aspects of deliquency and biological changes of the central nervous system. In accordance with the development of very sensible techniques, we will be able to increase our knowledge in this field and to give answers which will be based more and more on scientific investigations – instead of proposals and opinions.

In the past years we have seen that sexual delinquency is able to cause considerable increased public concern as it is very often connected with sexual perversion. In general, the victims of such persons, mostly sexually perverted men, are children as well as women. In a modern world in which information is in easy reach of anybody now, we realize a considerably increased interest in the general population regarding sexual crimes, which is even bigger, when mentally ill probands are accused of having committed a serious crime. Alas, up until now it was not possible to find appropriate correlates for criminal behavior of such perpetrators. So we could not answer the question, why sexual deviances occur in a certain percentage of men and not in others and why treatment is so very difficult to perform successfully in some of them [3]. We just concluded, referring to specific environmental influences, that they might support conditions which made men act in a sexually deviant and criminal way.

Even lacking a sufficient number of investigations, we may dare to say, taking into account recent results in investigations on neuroscience, that there is a striking impact of neurobiological aspects on criminal behavior [1] – in contrast to the opinions we faced before without using the technical assistance of neuroimaging. For example, in a MRT-study on pedophilic men who had been sentenced to forensic psychiatry because of having committed serious paedophilic crimes, we got some more information about its biological sources. In detail it was shown that alterations which were described as a hypotrophy of the brain of the pedophilic perpetrators examined was significantly increased compared to a healthy control group. Namely the right amygdala and bilateral closely related structures were considerably affected [3].

It seems remarkable that these findings were paralleled by the results of a former investigation which demonstrated neurodevelopmental disturbances in a group of paedophilic perpetrators performed by Blanchard et al. in 2003. Obviously there are a lot of questions yet to be answered, but we have just started to learn that neuropsychiatric research will not only be helpful to explain biological changes of mentally alterated probands. The recent findings documented by the help of modern neuroimaging are unavoidable as further investigations in this field will give additional answers which were not to be obtained up until now. So we found in paedophilic criminal probands that hypothesized regions relevant for the processing of erotic stimuli in healthy individuals showed reduced activation levels during visual erotic stimulation. These results are

now discussed to be the source of impaired recruitment of key structures that may contribute to an altered sexual interest of these patients towards adults [4].

In forensic psychiatry as well as in prisons we find numerous persons suffering from personal disorders or "psychopathy," which was described by Hare in 1991. Those persons are not able to learn to deal with others in an empathic way, starting from a very young age [5]. They often exhibit very an extraordinarily aggressive behavior, which they use to achieve mostly illegal aims. They also usually react aggressively towards others, when they feel attacked.

These specific patterns of aggressive behavior are well known to be connected with structural changes of the central nervous system which have been detected in frontal and temporal areas of the brain. Obviously the brains of such persons are impaired to deal appropriately with emotional information as the function of frontal and temporal areas is decreased [5,6].

As we know that the risk of such persons to be involved in committing serious crimes is dramatically increased compared to the general population, the structural brain damages of persons diagnosed with "psychopathy" seem to be a very important source of such aberrant and illegal behavior. There can be no doubt that there is a close relationship between defects of the central nervous system and the increased ability to commit crimes in such probands [5,6].

Comparing probands sentenced to prison and those who were sent to forensic psychiatry we feel that there is obviously no striking difference between those groups regarding the mental illnesses found in them. With the help of technical methods of forensic neuropsychiatry which will allow us to delineate one group from another, we can conclude that in both groups there are similar structural changes to be seen. In fact, these results could be achieved under the presumption of installing subtle neuroimaging techniques which are well elaborated to give detailed information. Seemingly, there is a high percentage of structural brain alterations to be found in persons who committed serious crimes, as well in prisoners as in patients of forensic psychiatry. Further investigations on this most important subject are underway.

The more we will be able to increase the quality of information supplied by modern techniques of forensic neuropsychiatry, the more we will be able to detect biological alterations in mentally ill probands, no matter where they have been sentenced to, either prison or forensic psychiatry. So the widespread opinion about neuroimaging techniques applied and their inability to contribute to the assessment of mentally ill perpetrators cannot be agreed so far. In contrast, their impact on diagnostic and prognostic questions will increase, if modern and subtle techniques are used.

It is remarkable that in prisoners as well as in forensic psychiatric patients we find similar alterations of the central nervous system, although they had been judged in a different way at court regarding their responsibility in committing a crime. The detection and the assessment of the changes of brain, however, is a first step towards the support of the opinion that criminal conduct could be motivated in a very high percentage by neurobiological changes of the central nervous system. No matter where the treatment or detachment will take place later on, it will be necessary to be aware of the fact that e.g. a high percentage of sexually perverted persons having committed serious crimes, will be found to bear such biologically detectable alterations of the central nervous system [3,4]. It will be a question of time, when these finding will find a way into general assessment procedures as a golden standard which will be demanded by the courts prior to an accused person being sentenced to jail or a detention hospital [1].

As the way the legal systems deal with mentally ill criminals seems not to be closely related to recent neurobiological findings, we will face a paradigm shift in the treatment of a considerably large percentage of prisoners, which in many cases will not be delineated from forensic psychiatric probands anymore. This, however, will result in a dramatic change in the view of such probands. In the future, applying neuroimaging methods will make the process of being sentenced to a prison or detention hospital more understandable as it will refer to scientifically achieved standards of forensic neuropsychiatry.

So, we should take into consideration that neuropsychiatry will open a door to understanding the striking differences in probands referring e.g. to their ability and risk of criminal conduct.

In the past we were not able to explain these striking differences in an adequate way and even more, we were not able to treat such probands in an appropriate way. Now, at least, we can start to understand the mechanisms of alterated behavior of mentally ill criminals. This will be the first step to developing cures for those who could not be healed by traditional methods in psychiatry up until now. In this way neuroimaging will broaden our knowledge about mental illness and the consequences arising from it. Accordingly, it represents the lacking link in psychiatry to make us understand why probands act in a way which is so very different compared to general standards of behavior. It will replace a merely moral judgement and will give us the tools to find explanations for it.

## Ethical Issues in Forensic Neuropsychiatry

Recent results in the neurosciences clearly point out that decision-making is not limited to a psychosocially-determined mental process; much more, it can be

referred to as a bio-psychosocially-determined neuropsychological process. Thus, decision-making might not be as free and previously assumed voluntary as presupposed in forensic psychiatry at present. Numerous scientists have found decision-making not only to be modulated by cognitive functions, as emotional functions may not be neglected judging this complex process [7–10]. For example, the absence of emotions results in highly aberrant decision-making. This could be shown regarding cold-hearted murderers and extremely violent criminals.

At present, there is no doubt how important the crucial role of emotions in committing a serious crime is. Differential involvement of cognitive and emotional functions might imply different characterizations of decision-making. In this aspect cognitive functions like e.g. categorization, judgment, and distinction will allow the probands to make a choice and preferable alternatives. They will represent a subsequently free and voluntary selection of the most appropriate ones from which it is estimated by the individual that he will profit the best.

Another ethical problem concerns the informed consent. In general, informed consent is well known from psychiatric clinical investigation. However, in forensic psychiatry or any other detention hospital the situation is different for both the patients and the doctors. Even when the patients are prepared to take part in an investigation and give their informed consent, considerable doubt may remain whether this agreement is as voluntarily as it might seem. In fact, forensic patients in detention hospitals might assume that they will have to suffer from considerable disadvantages resulting e. g. in a much longer period of their stay in hospital or prison if they do not agree to participate and give informed consent. On the other hand, patients might expect their personal support of scientific investigations might have some positive impact upon their therapeutic evaluation and risk assessment. From this, their expectancy to be discharged sooner might arise.

So we will have to find ethical standards, which will allow us to perform neuroimaging studies in prisoners and patients of forensic psychiatry in an appropriate way as they are urgently needed to clarify the questions mentioned above. Whatever the decision of a prisoner or patient concerning the proposed investigations will be, it should never interfere with the therapy and the risk assessment of any proband. So prior to any scientific investigation in this field, we should pay attention to conditions and rules which will allow the protection of probands from any disadvantages.

These constraints can only be excluded, if we can assure an absolute separation between the staff performing investigations and those who will do daily forensic psychiatric treatment and risk assessment as well. If not, the informed consent could be considered invalid.

This means that we face an urgent need to establish golden ethical standards in forensic neuropsychiatry in order to obtain valid informed consent in forensic patients and prisoners in performing neuroimaging investigations. Using them we will be assured that the voluntary and free decision of forensic patients as well as prisoners is really as free and voluntary as it should be to be the basis of scientific investigation in this very difficult field.

## Synonyms

Object perception; Perceptual grouping; Surface perception; Figure-ground perception

## Definition

Form perception refers to our ability to visually perceive objects in the world in response to the patterns of light that they caste on our ►retinas.

## Characteristics

When an observer gazes steadily at a stationary object, form perception is facilitated by miniature ►eye movements, such as tremors, drifts, and microsaccades, that cause visually responsive cells to respond more vigorously to the object whenever the eyes move [1]. Motion of an observer relative to the object also refreshes cell responses. Even when cells respond vigorously, form perception represents a major challenge for the brain because our retinas have a large blind spot and retinal veins that impede light from reaching photodetectors (►Photoreceptors) (Fig. 1). How does the brain compensate for these holes in the visual world?

Boundary and surface processes facilitate this goal. Boundary processing includes ►perceptual grouping, ►boundary completion, and ►figure-ground separation. ►Surface processing includes compensation for variable illumination, also called "discounting the illuminant," and surface filling-in (►Perceptual filling-in) using the surviving illuminant-discounted signals. These processes are carried out in different visual processing streams (►Visual processing streams in primates; ►Extrastriate visual cortex) within the visual cortex (Fig. 2). Both streams go through the ►Lateral Geniculate Nucleus (LGN), which transmits signals from the retina to the primary visual cortex (Brodmann's area 17, striate cortex, area V1) (►Striate cortex functions). Two streams (in blue) compute boundaries and surfaces. The third stream is sensitive to visual motion. The boundary stream goes from retina through the LGN "parvo" stage (named for its "parvocellular" cell type; ►Geniculo-striate pathway) to the cortical stages V1 interblob, V2 interstripe, area V4, and on to inferotemporal cortex. The surface stream goes from retina through LGN parvo to V1 blob, V2 thin stripe, V4, and inferotemporal cortex (Striate cortex functions; Extrastriate visual cortex).

Why are there several cortical processing streams? Theoretical and experimental evidence suggests that they compute *complementary* properties [2], or properties akin to a lock fitting its key, or puzzle pieces fitting together. Each stream exhibits complementary strengths and weaknesses. Inter-stream interactions overcome these complementary deficiencies and generate percepts of conscious form.

What are these complementary interactions? Figures 3a and b illustrate three pairs of complementary properties using visual illusions (►Visual illusions). By viewing Fig. 3b, our brains complete a ►Kanizsa square boundary even though the image contains only four black pac-man figures on a white background. In this way, form boundaries are completed over the blind spot (Fig. 1). Thus many form percepts that appear to be "real" are "visual illusions." What we call a visual illusion is often just an *unfamiliar* combination of boundaries and surfaces.

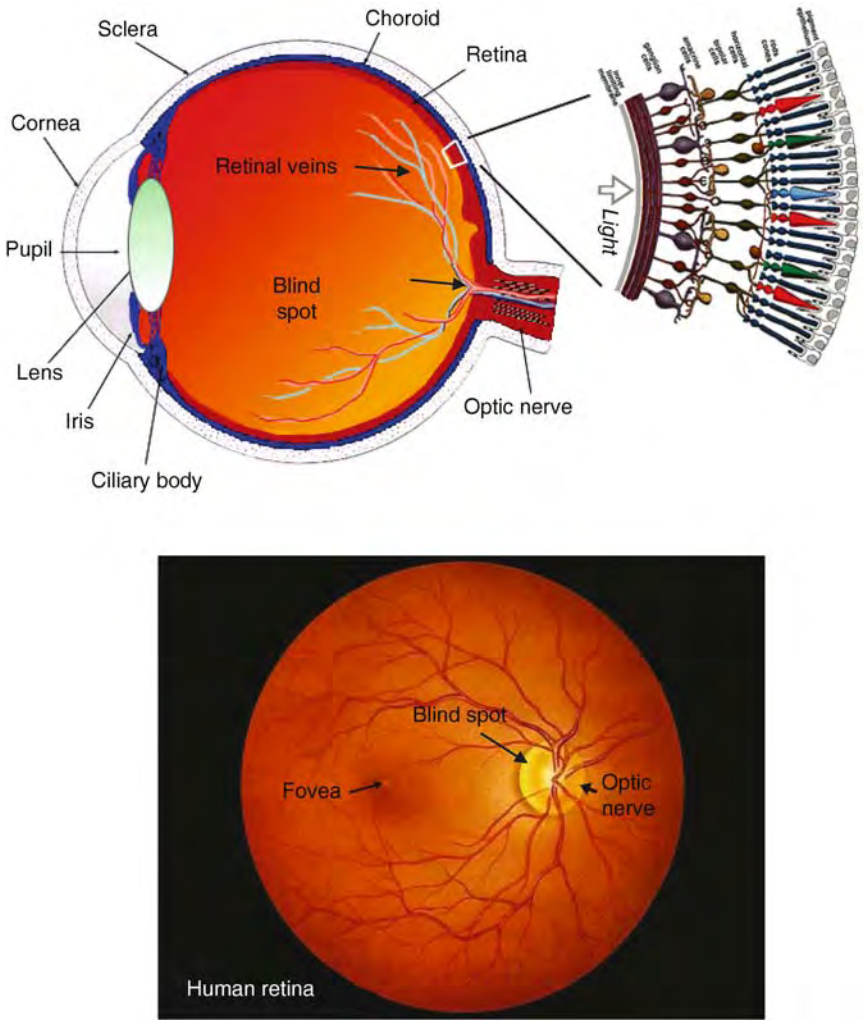
Visual boundaries and surfaces obey complementary computational rules in the following sense. In response to the images in Figs. 3a and b, boundaries form *inwardly* in an *oriented* manner between cooperating pairs of (almost) like-oriented and (almost) collinear inducers, such as the edges of the four pac man, or pie shaped, inducers.

### All Boundaries are Invisible

The square boundary in Fig. 3a can be recognized even though there is no visible brightness or color difference on either side of the boundary. It is perceptually invisible, or "amodal." Figure 4a illustrates another invisible boundary that can be consciously recognized. FACADE theory [3] predicts that *all boundaries are invisible* within the interblob cortical stream (Fig. 2).

Why are all boundaries invisible? The vertical boundaries in Fig. 3a form between black and white inducers that possess opposite contrast polarity (black-to-gray or white-to-gray) with respect to the gray background. The same is true of the boundary around the gray square in Fig. 3c. To build a boundary around the entire square form, despite these contrast reversals, the boundary system pools, or adds, signals from pairs of ►*simple cells* that are sensitive to the same orientation and position, but to opposite contrast polarities. Pooling occurs at the ►complex cells in the V1 interblob area (►*Visual subcortical and cortical receptive fields*).

By pooling light/dark and dark/light contrasts at each position, boundaries become *insensitive* to contrast polarity, so that "all boundaries are invisible." These pooled signals activate the *inward* and *oriented* boundary completion process that forms the illusory square in the V2 interstripe area [4]. Figure 3 summarizes these three properties of boundary completion.



**Form Perception. Figure 1** A side view of an eye shows the blind spot and retinal veins. A top view of the photo-sensitive retina shows how big the blind spot and veins are relative to the fovea, which has the highest resolution for form vision.

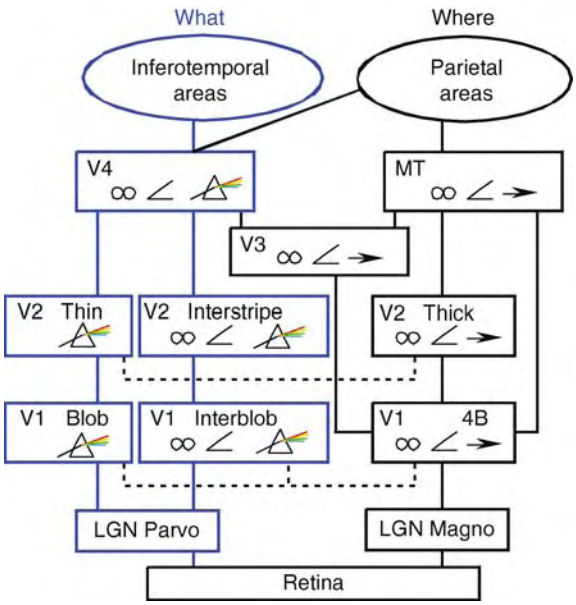
Boundary completion helps to perceive continuous geometrical forms, discontinuous texture-defined forms, and to separate figures from their backgrounds (Fig. 5). Boundaries arise as coherent patterns of excitatory and inhibitory signals across cortical feedback circuits. Classical geometrical ideas such as points and lines are replaced by nonlinear neural networks that do on-line decision-making to select and complete the statistically most favored boundary groupings of a scene, while suppressing noise and incorrect groupings.

## Only Some Surfaces Can Be Seen

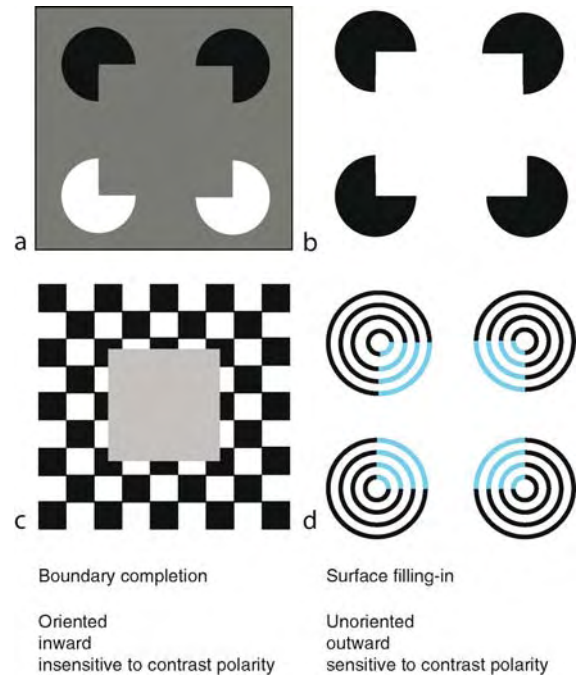
If boundaries are invisible, then how do we see anything? An early stage of surface processing compensates for variable illumination, or *discounts the illuminant*. Otherwise, illuminant variations could seriously distort all percepts. Discounting the illuminant attenuates color and brightness signals except near regions of sufficiently rapid surface change, such as edges or texture gradients. "Feature ▶*contours*" are selected at such positions and thus are relatively uncontaminated by illumination gradients.

Neural models have proposed how these feature contour signals trigger, at later processing stages, a filling-in process that completes surface representations [5]. Filling-in can allocate brightness and color to particular depths on a 3D surface via a process called *3D surface capture* (Fig. 6).

*Neon color spreading* [6] illustrates filling-in. In Fig. 3d, boundaries of the black circular segments cause small breaks, or *end gaps*, in the boundaries of the blue



**Form Perception. Figure 2** Three processing streams in visual cortex. Boundaries are computed through the interblobs, and surfaces through the blobs, at multiple stages until area V4. Cortical cells have different selectivities to image properties. For example, rainbow = tuned and/or opponent wavelength selectivity (incidence at least 40%), angle symbol = orientation selectivity (incidence at least 20%), spectacles = binocular disparity selectivity and/or strong binocular interactions (area V2; incidence at least 20%), and right-pointing arrow = direction of motion selectivity (incidence at least 20%). (Adapted with permission from "Concurrent processing streams in monkey visual cortex," by E.A. DeYoe and D.C. van Essen (1988) Trends Neurosci II:223. Copyright 1988 by Elsevier.)



**Form Perception. Figure 3** (a) Opposite-contrast Kanizsa square shows that both opposite-contrast polarity and same-contrast polarity collinear edges can group together, and that both sorts of groupings are part of the same boundary completion process. Because two pac men are darker than the background gray, and the other two are lighter than the background gray, they induce lightening and darkening effects that cancel out within the Kanizsa square, thereby creating an invisible, or amodal, square percept that is recognized but not seen. (b) Same-contrast Kanizsa square is visible because all four black pac men induce brightness signals within the square that create a brighter square after surface filling-in. (c) Pooling of opposite contrast at every position along the square borders illustrates how the brain can build an object boundary around a textured background and thus why "all boundaries are invisible." (d) Neon color spreading vividly illustrates the computationally complementary properties of boundary completion and surface filling-in that are summarized at the bottom of the figure.

circular segments. Blue color spreads through these gaps *outwardly* in an *unoriented* way until it hits a boundary or attenuates due to its spread. Filling-in can lead to visible percepts because it is *sensitive* to contrast polarity. These three properties of surface filling-in (outward, unoriented, sensitive to contrast polarity) are complementary to those of boundary completion (Fig. 3).

Another striking example of filling-in is the watercolor effect. In Fig. 7, the interior of the light blue regions is really white! Neon color spreading and the watercolor effect have both been explained using boundary completion and surface filling-in [7].

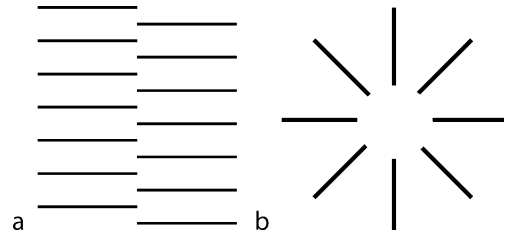
The mechanisms that fill in surface representations across the blind spot can also do so after discounting the illuminant. They also clarify how we see continuous blue surfaces, such as the sky, despite the fact that the spatial distribution of blue cones on the retina is very sparse [8].

## 3D Form Vision and Figure-Ground Separation

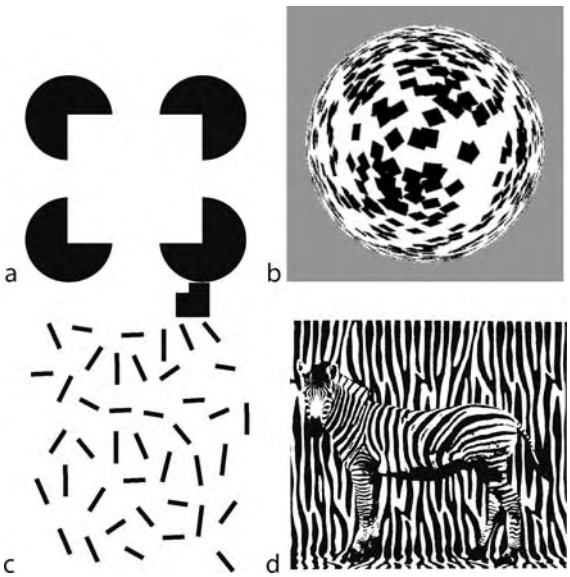
How do two eyes work together to generate percepts of 3D form, including percepts of occluding and occluded forms in depth (Fig. 5). Multiple problems need to be solved [3], including:

*3D Surface Capture and Filling-in*. How do multiple depth-selective boundary representations interact with multiple depth-selective surface filling-in domains to selectively *capture* brightness and color signals at prescribed depths (Fig. 6)?

*Binocular Fusion, Grouping, and daVinci Stereopsis.* How are the depth-selective boundaries formed that

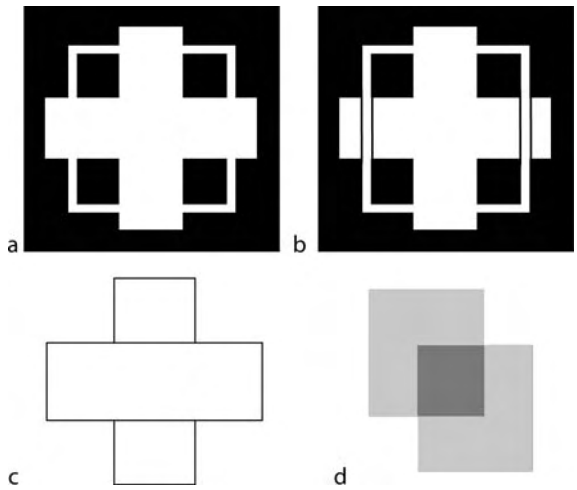


**Form Perception. Figure 4** (a) The vertical boundary that is induced by the offset horizontal grating is invisible, or amodal. It is an invisible percept, and thus cannot be seen, but nonetheless can be consciously recognized. (b) The circular disk in the ►Ehrenstein illusion can be both seen and recognized because the circular boundary traps different levels of filled-in brightness inside and outside its contour.

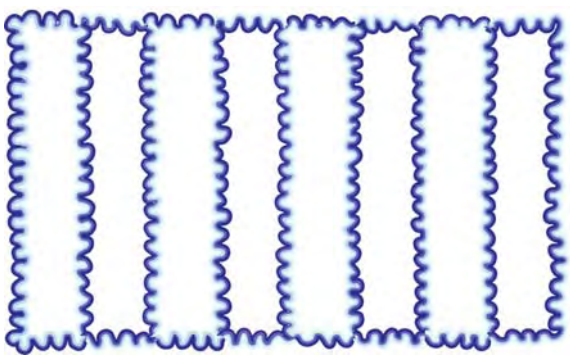


**Form Perception. Figure 5** Examples of perceptual grouping and boundary completion: (a) An illusory square emerges from the four pac men to be seen as the well-known Kanizsa square. (b) A discrete texture in a 2D picture can generate a percept of a continuous 3D surface by differentially activating a multiple-scale plexus of form-sensitive boundaries that is called a *boundary web*. (c) Collinear lines can pop-out from a field of randomly oriented lines by being linked by an emergent boundary. (d) An emergent boundary can separate the figure of the zebra from its background. T-junctions between the zebra and the background can help to push the background behind the zebra figure.

control surface capture? Our two eyes experience slightly different views of the world that lead to relative displacements, or disparities, on their retinas of observed scenes (Fig. 8; ►Binocular vision). These



**Form Perception. Figure 6** (a) A Kanizsa stratification figure. The percept usually looks like a white cross in front of a partially occluded white square, but can switch to look like the square in front of a partially occluded cross. The white region that is shared by the square and the cross is "captured" by the surface form that appears to be in front. (b) Bayesian theorists claim that what we see is likelihood statistics. However, this figure causes the highly unlikely percept of a cross both in front of and behind the square. (c) This image of three abutting rectangles is perceived as a horizontal bar that partially occludes a vertical bar just behind it in depth. The occluded vertical surface is invisible [3]. (d) This juxtaposition of three figures generates a bistable percept of a transparent square in front of a background square. What determines when a surface form appears opaque vs. transparent? Stable or bistable [3]?

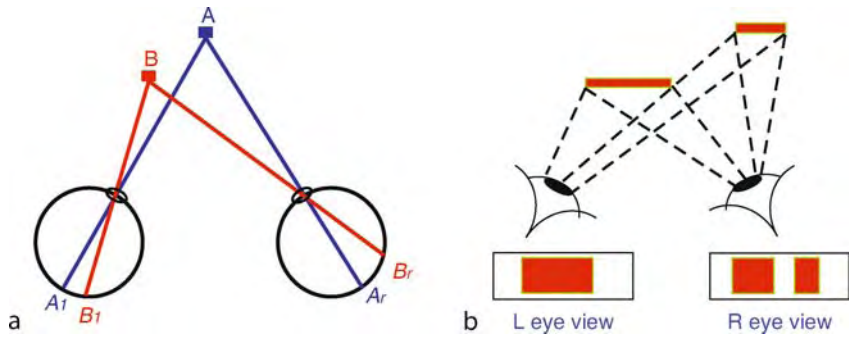


**Form Perception. Figure 7** An example of the watercolor illusion due to Baingio Pinna. The spatial juxtaposition of the more-contrastive thin blue curves abutting less-contrastive light blue curves enables the more contrastive boundaries to inhibit the less contrastive boundaries and thus release surface filling-in of the lighter blue color.

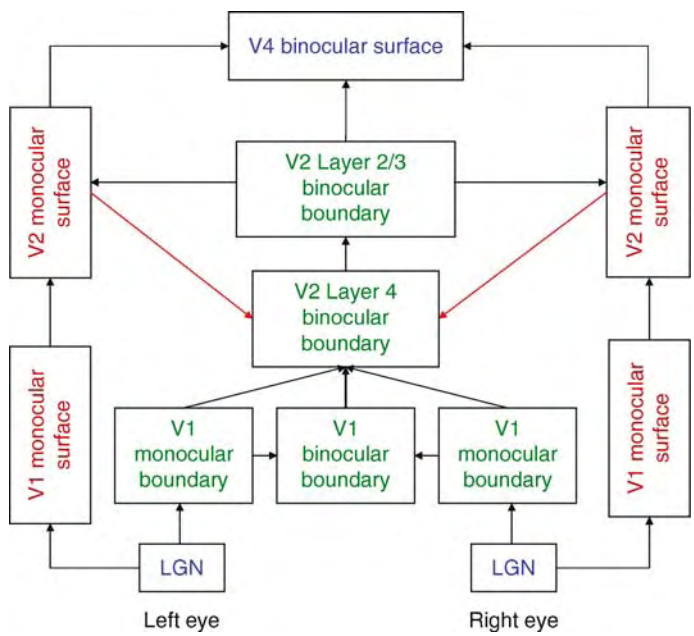
F

disparate retinal images are binocularly matched and fused at disparity-sensitive simple cells in area V1. Simple cell outputs combine at complex cells whose outputs to area V2 activate grouping cells that form depth-selective boundaries, which capture feature contour signals at the corresponding depth-selective surface filling-in domains (Fig. 9).

*Multiple Scales into Multiple Boundary Depths*. When a single eye views an object in depth, the same retinal image may be due to either a large object far away or to a small object nearby. How is this ambiguity overcome to activate the correct disparity-sensitive cells? The brain uses multiple ▶receptive field sizes (Visual subcortical and cortical receptive fields), or



**Form Perception. Figure 8** (a) When the two eyes foveate an object such as A, an object such as B activates the two retinas at displaced positions $B_l$ and $B_r$, leading to a binocular disparity that helps us see objects in depth. (b) Sometimes only one eye can see part of an object in depth when it is occluded by another object, thereby eliminating some disparity clues to depth. This sort of daVinci stereopsis is nonetheless solved by the brain [3].

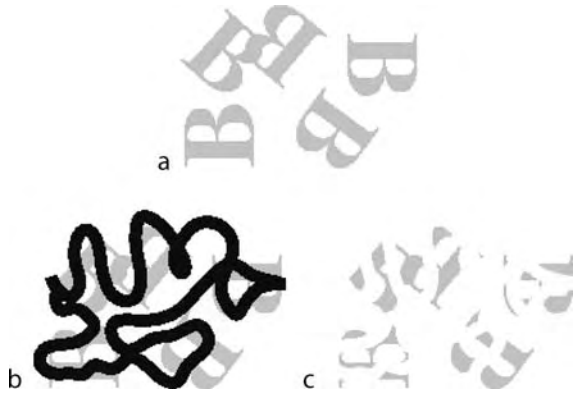


**Form Perception. Figure 9** Macrocircuit diagram of some processing stages whereby the boundary stream (*green*) and the surface stream (*red*) interact to form a visible percept of binocular form. Simple cells form the area V1 monocular boundaries. Both simple and complex cells form area V1 binocular boundaries. Area V2 layer 2/3 cells carry out long-range boundary completion, as in Fig. 5. Their signals contain filling-in within the area V2 monocular surfaces. The area V2 monocular surfaces combine to form area V4 binocular surfaces, constrained by boundary signals from area V2 layer 2/3. These binocular surfaces are predicted to give rise to visible percepts of surface form. see [3].

scales, that compute a "size-disparity correlation" between retinal size and binocular disparity (Binocular vision). Each scale can fuse multiple disparities, although larger scales can fuse a wider range of disparities [9]. Multiple boundary scales react differently to different regions of texture or shading, leading to a multiple-depth form-sensitive "boundary web" of small boundary compartments. Each depth's boundary web captures different feature contours, whose filling-in can lead to a curved surface percept (Fig. 5b).

*Recognizing Objects vs. Seeing Their Unoccluded Parts*. In most scenes, some objects partially occlude others. How do we know which features belong to which objects? Figure 10 clarifies some issues [10]. In the lower left, gray B shapes can be recognized despite partial occlusion by the black snakelike occluder. This happens because the boundaries that are shared by the occluder and the gray shapes are assigned by the brain to the black occluder by a process of "►border ownership," leading to seeing the black occluder as closer. With the shared boundaries removed from the gray shapes, the B boundaries can be completed behind the positions of the black occluder, just like boundaries complete in response to Figs. 3 and 6. In the lower right, the occluder is removed and the B shapes are harder to recognize.

*From Boundary-Surface Complementarity to Consistency*. Given that boundary and surface computations are complementary, how do we see a single percept? How does *complementarity* become *consistency*? Consistency can be realized by feedback that occurs between the boundary and surface streams (Fig. 9). Remarkably, this feedback seems also to initiate the process of separating forms from each other during ►figure-ground perception [3].



**Form Perception. Figure 10** Both Albert Bregman and Gaetano Kanizsa discussed how an occluding form can "own" a shared boundary with an occluded form. Such border ownership influences how the occluded form may be recognized. The black occluder facilitates recognition of the partially occluded B shapes by owning the shared boundaries. This allows the remaining B boundaries to be completed at a farther depth, thereby facilitating their recognition there.

## Fossa Sylvii

### Definition

The fossa (Latin for trench or ditch) Sylvii is (Sylvius was a seventeenth century French anatomist) a very old term referring to the Sylvian fissure, now called the lateral fissure. It separates the temporal and frontal lobes.

## Fourier Transform

### Definition

The mathematical transformation of a time-domain waveform into a frequency-domain representation or vice versa. Any time-domain waveform can be Fourier transformed into a sum (integral) of sinusoidal time domain components, with each component defined by a magnitude, a frequency, and a starting phase term.

►Signals and Systems

## Fourth Ventricle

### Synonyms

►Ventriculus quartus

### Definition

It lies in the center of the rhombencephalon and stretches caudally into the central canal of the spinal cord. Via the apertures of the fourth ventricle, it releases CSF into the subarachnoid system. The latter is formed by the subarachnoid space and is subdivided into various cisterns. The CSF is reabsorbed by venous blood at the arachnoid granulations of the cranium and at the spinal roots.

►Meninges & Cisterns

## Fovea (Fovea Centralis)

### Definition

Region of ~1 mm diameter in the temporal retina of haplorhine primates, located in the centre of the area centralis. Anatomically, the fovea is an indentation of the retina, where all cell layers, except the photoreceptor layer, are shifted aside to give light unscattered

access to the photoreceptors. The foveal pit (= foveola; ~300 µm diameter) contains only cones, no rods. The foveal cones are connected to the central-most bipolar and ganglion cells, positioned at the foveal rim. In primates, the fovea provides highest acuity and is used for the fixation of objects. Nonprimate mammals have no fovea, whereas a number of non-mammalian vertebrates (e.g. some fish, reptiles and birds) have foveae.

►Inherited Retinal Degenerations
►Photoreceptors
►Retinal Bipolar Cells
►Retinal Ganglion Cells
►Vision

## Foveal Magnification

### Definition

The primate retina shows variable resolution (unlike digital cameras) with the highest acuity at the center of the fovea and a continuous falloff of approximately 30-fold to the far periphery of the retina. The enhanced vision closer to the fovea is reflected in higher density of near-foveal neurons in retina and throughout the visual system.

►Fovea (Fovea Centralis)
►VisualAcuity, Hyperacuity

## Foveation

### Definition

The retina of primates is highly anisotropic, and the highest density of visual photoreceptors is found in a small, central area (fovea) which provides the best resolution and chromatic visual analysis in the central 2°–3° of the visual field. Thus foveation, which is the centering of the retinal image of an object of interest onto fovea, yields an updated visual analysis and localization of the newly-fixated point of interest.

Foveation is achieved by different types of eye (or gaze) movements to realign or maintain the point of interest onto the visual axes of the two eyes (saccadic, vergence and pursuit eye movements).

►Eye Movements Field

## Foveation Hypothesis

Adonis Moschovakis
Institute of Applied and Computational Mathematics, FO.R.T.H., and Department of Basic Sciences, Faculty of Medicine, University of Crete, Heraklion, Crete, Greece

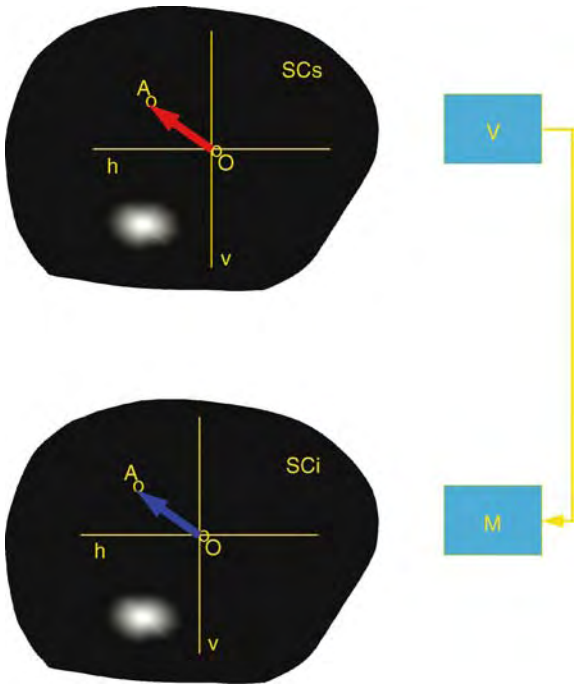
### Definition

An early attempt [1] to explain how information flow through the superior colliculus (SC) leads to the generation of accurate (foveating) saccades towards visual targets.

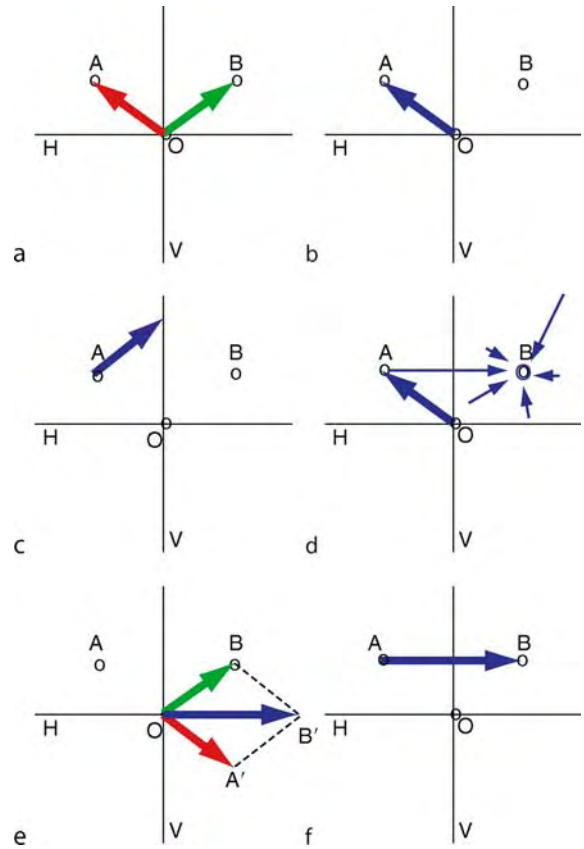
### Description of the Theory

The "foveation hypothesis" (schematically illustrated in Fig. 1), takes advantage of the fact that the input to the SC is a retinal error signal (Re; the vector in red) represented in the superficial layers of the SC not in terms of firing rate, but in terms of the location of active cells (V) along the topographic representation of visual space in the SC (►SC – sensory maps). Due to the spatial distribution of their projections to the deeper tectal layers (►SC – interlayer neurons), the discharge of these superficial SC neurons in turn activates presaccadic neurons (M) that are located underneath the visual cells. As the motor map of the deeper SC is in register with the visual map of the superficial layers (►SC – tectal long lead burst neurons), the M cells engaged have movement fields such that the eyes are displaced by the vector in blue. As the latter is equal to the retinal error vector (in red), the eyes move accurately to the target which ends up being projected onto the fovea.

Acceptance of the "foveation hypothesis" in part depended on the existence of anatomical projections of the superficial to the deeper tectal layers. By the time supporting evidence had been documented (with the demonstration of the axonal trajectory and projections of L neurons considered in the entry devoted to SC – interlayer neurons), in particular in a higher mammal such as the monkey, a considerable number of psychophysical, and neurophysiological objections to the "foveation hypothesis" had been amassed [2]. An example of a relevant argument is illustrated in Fig. 2. While the subject fixates point O, targets A and B appear and their retinal error vectors (Fig. 2a) are represented in the superficial SC. Then the first saccade, to A, is executed as soon as both targets disappear (Fig. 2b). If the second saccade corresponded to vector OB (from the retinal error vector of target B initially represented in the SC), the eyes would end up in the wrong place (Fig. 2c). Instead, the eyes execute the



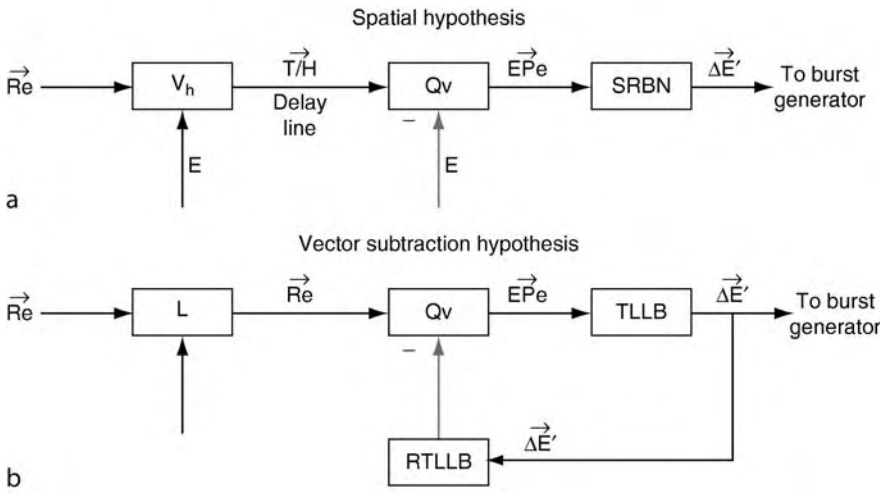
**Foveation Hypothesis. Figure 1** Information flow from the superficial (SCs) to the intermediate (SCi) SC layers according to the foveation hypothesis. Regions in black and gray demarcate the borders of the nucleus and of the activated areas as seen from above. Abbreviations: *h*, horizontal saccade size; *v*, vertical saccade size; *M*, movement cells (of the SCi); *V*, visual cells (of the SCs).



**Foveation Hypothesis. Figure 2** Sequence of saccades executed in response to two targets which appear simultaneously at the points A and B, and are extinguished before the first saccade. (a) Retinal error vectors immediately after target presentation. (b) Vector of eye displacement due to the first saccade executed. (c) Prediction of the "foveation" hypothesis regarding the eye displacement due to the second saccade executed (from point A). (d) Prediction of the "spatial" hypothesis regarding the eye displacement due to the second saccade executed (from any point, including A). (e) The vector of eye displacement due to the first saccade is subtracted (equivalent to adding its opposite, in stippled red) from the Re vector of target B (green) to obtain the vector of desired eye displacement for the second saccade to be executed from point A. (f) Prediction of the "vector subtraction" hypothesis regarding the eye displacement due to the second saccade executed (from point A).

correct saccade (to B) thus falsifying the "foveation hypothesis." Several experiments following this line of reasoning were described in the last quarter of the previous century (collectively called ►double-step stimulation experiments). Probably the most dramatic of these was the demonstration that subjects are able to saccade to a target briefly flashed during the execution of a previous saccade [3]. As the target in this experiment was sometimes flashed onto the fovea, retinal error (Re) must equal zero and, therefore, the metrics of the foveating saccades cannot be computed from Re alone. Similarly, the foveation hypothesis cannot account for the ability of monkeys to compensate for the perturbations of orbital position that result from the electrical stimulation of the SC (this is equivalent to the presentation of target B only, in Fig. 2a, followed by an electrically evoked saccade OA), by executing saccades to the approximate location of a visual target extinguished before the electrical stimulation [4].

To explain the performance of monkeys and humans in double-step stimulation experiments, one might think that the saccadic system is built in such a way that it represents targets (e.g. point B) as movement goals (Fig. 2d), obliging the eyes to move to them from any initial position (including point A). An assumption of this form is implied in certain models that rely on non-retinotopic encoding of a target location, such as the "spatial hypothesis" illustrated in Fig. 3a. To see how it works, consider that a target (with a retinal error Re) is presented when the eyes are at position $E_1$. The location of the target is first computed in head centered



**Foveation Hypothesis. Figure 3** (a) "Spatial" hypothesis (adapted from ref. [5]). (b) "Vector subtraction" hypothesis (adapted from ref. [6]). Vector notation indicates place coding of relevant signals. Arrows indicate excitatory (solid) and inhibitory (stippled) connections. Abbreviations: $\Delta E'$, desired eye displacement; *E*, eye position; *EPe*, eye position error; *L*, interlayer neuron of the SC; *Qv*, quasivisual neuron; *Re*, retinal error; *RTLLB*, reticulotectal long lead burst neuron; *SRBN*, saccade related burst neuron; *T/H*, target location with respect to the head; *TLLB*, tectal long lead burst neuron; *T/R*, target location with respect to the retina, *Vh*, visual cell encoding target location in head centered coordinates.

coordinates (T/H = Re + $E_1$). After a certain delay (i.e. just before saccade launching, indicated by the DELAY LINE), and while the eyes may have been deviated (naturally or electrically) to a new position ($E_2$), the new eye position signal $E_2$ is subtracted from T/H. The result of this subtraction (eye position error, EPe = Re + $E_1$−$E_2$) is carried by a particular class of tectal cells, the quasivisual neurons (Qv; see SC – quasivisual neurons), in such a way that different amounts of EPe are coded by different populations of Qv cells, arranged over the mediolateral and anteroposterior extent of the SC in an organized fashion. This signal is then relayed to presaccadic SC cells which generate the desired eye displacement command that leaves the SC [5]. This will produce an accurate saccade from point A to point B, because EPe is equal to the sum of Re and $E_1$−$E_2$ (in other words, equal to Re corrected by the amount of eye displacement due to the first saccade, $E_1$−$E_2$).

It is possible to account for the whole evidential basis of the "spatial hypothesis" without adding and then subtracting the same signal (eye-position) to calculate target coordinates in a spatial and then again in an oculocentric frame of reference. Such a scheme is illustrated in Fig. 3b. As in the "foveation hypothesis," the input to its SC units is Re. As with the "spatial" hypothesis, instead of using this signal directly, its presaccadic SC units use the EPe vector to compute the vector of desired eye displacement ($\Delta E'$). However, in contrast to the "spatial" hypothesis, a neural replica of $\Delta E'$ is fed back to the SC where it is vectorially subtracted (equivalent to adding its opposite; Fig. 2e, red) from the Re signal (Fig. 2e, green) to obtain the EPe signal (Fig. 2e, blue). When executed from point A, the saccade that corresponds to this EPe vector sends the eyes correctly to point B (Fig. 2f ). As it assumes the implementation of vector subtraction to compute the requisite eye displacement commands, this scheme is known as the "vector subtraction hypothesis" [6]. With straightforward extensions to take into account intervening joint angles, the same model can explain the accuracy of saccades to targets of other modalities such as auditory or somatosensory. For example, the location of auditory stimuli is coded in a head centered (T/H) frame of reference (e.g. by inferior colliculus neurons [7]). Subtraction of a signal proportional to eye position from the signal specifying the location of the auditory target with respect to the head suffices to extract the EPe of auditory targets (equivalent to remapping auditory fields in retinotopic coordinates). A neural network that could implement this process in the SC has been formulated [8], and there is experimental evidence consistent with eye position dependent shifts of the auditory receptive fields of SC neurons [7]. The same is true of the somatosensory receptive fields of SC neurons ([9]). After its extraction, the EPe signal to auditory targets is handled in the "vector subtraction hypothesis" just like the EPe signal to visual targets.

Since both the "spatial" and the "vector subtraction" hypotheses are consistent with it, psychophysical

evidence cannot be used to test their verisimilitude. Instead, to understand which of the two, if any, is implemented in the brain one should rely on neurophysiology. In principle, this should not be too difficult because the "vector subtraction" and the "spatial" hypotheses differ considerably in terms of the signals they manipulate. For example, a signal proportional to target location in head centered coordinates is important for the "spatial" but not for the "vector subtraction" hypothesis, which instead relies on an efference copy of intended saccadic eye displacement. Which of the two hypotheses is more consistent with known neuroanatomy and neurophysiology? Neurons encoding target location in head centered coordinates have been found in some cortical areas, but it is not known if their output is sent to the SC as required by the spatial hypothesis. In contrast, if a vector subtraction scheme is implemented in the brain, it should be possible to demonstrate the existence of neurons that carry a signal proportional to eye displacement, and (i) are located in a region of the brain where axons of tectal long lead burst neurons terminate, while (ii) their axonal terminations include the SC. The existence of such neurons has indeed been demonstrated (described in the entry ►Reticulotectal long lead burst neurons – RTLLBs). It is possible to connect the RTLLBs with the collicular machinery such that the resulting distributed network implements the "vector subtraction hypothesis," as shown by Bozis and Moschovakis [10] who presented a model of the SC consistent with known anatomy and physiology.

The advantages of the "vector subtraction" over the "foveation" hypothesis are evident only if the eyes move in the interval that elapses between target presentation and acquisition. It is unlikely that a neural system would have developed if its only function were to generate saccades in such artificial circumstances. Instead, it may have developed under the evolutionary pressure for a system that programs complicated sequences of saccades. Thus, the line of sight can serially visit important features of a complicated image without the need to reprocess visual information after each saccade. To see how implementations of the "vector subtraction" hypothesis would work in circumstances such as this, consider that several targets appear simultaneously, each of them represented by a mound of excitation in the SC. The model predicts that each time the eyes make a saccade to a target the mound that corresponds to it is destroyed, while those that correspond to all other targets are moved inside the SC, to new positions defining a new EPe signal. Saccades corresponding to these EPe signals are serially executed one after another (while the mounds of excitation that correspond to the remaining targets are appropriately re-positioned in the SC) until all targets are visited by the eyes.

# Fractal

## Definition

Technically, a fragmented geometric shape that can be subdivided into parts, each of which is a reduced-size copy of the whole, a property called self-similarity.

►Evolution and Brain-Body Allometry

# Fractal Dimension

## Definition

A statistical quantity that gives an indication of how completely a fractal appears to fill space, as one zooms down to finer and finer scales.

►Evolution and Brain-Body Allometry

## Fractal Process

### Definition

The term "fractal process" denotes statistical self-similarity of a process in time (e.g. a neuronal spike train) leading to time-scale invariant, long-range correlations among events. In contrast to a random series of events, a fractal time series is characterized by long-term memory resulting from nonlinear interactions of processes occurring on different time scales; the product of a complex, deterministic system.

## Fractured Somatotopy

### Definition

Non-adjacent representation of adjacent parts of the body, as if an orderly somatotopic map had been fractured into many pieces and then reassembled in a new arrangement, for example with the index finger represented between the middle and ring fingers.

►Motor Cortex – Hand Movements and Plasticity

## Fragile X Syndrome

### Definition

A syndrome of X-linked mental retardation.

## Frames of Reference (FRs)

### Definition

Systems of coordinates in which muscles and neurons, including motoneurons, function or, at the level of the organism or its subsystems, action and perception are accomplished; FR parameters (origins, metrics, geometry, and the orientation of one FR in another FR) are defined by control variables, changes in which influence perception and action; are called actionproducing or physical in the λ model in order to distinguish them from formal, mathematical FRs for which changing parameters modifies the description of the system's behavior but not the behavior itself.

►Equilibrium Point Control

## Free Energy (of Helmholtz)

### Definition

The free energy density is defined as the internal energy density minus the product of the absolute temperature times the entropy density.

►Mechanics

## Free Nerve Endings

### Definition

Neural receptor elements without end-organ structures, located ubiquitously within and in the cutaneous covering of the body.

## Freedom of Will

Alfred R. Mele
Department of Philosophy, Florida State University, Tallahassee, FL, USA

### Definitions

Freedom of will may be defined as the power to act freely. But what is it to act freely? Standard answers fall into two groups: compatibilist and incompatibilist. ►Compatibilism and ►incompatibilism are positions on the relationship between free action and ►determinism. Determinism is the thesis that a complete statement of the laws of nature together with a complete description of the condition of the entire universe at any point in time logically entails a complete description of the condition of the entire universe at any other point in time. Compatibilism is the thesis that acting freely is

compatible with the truth of determinism. Paying due heed to what contemporary physics tells us, the overwhelming majority of compatibilists do not believe that determinism is true, but they do believe that even if it were true, we would be able to act freely. Their identifying themselves as compatibilists is explained by a lengthy tradition of framing the issue in these terms. (Incidentally, because very few contemporary philosophers believe that determinism is true, one rarely sees the once familiar expressions ►soft determinism and ►hard determinism in recent work on freedom of will. Soft determinism is the thesis that determinism is true and is compatible with free action. Hard determinism is the thesis that determinism is true and is incompatible with free action.) Incompatibilism is the thesis that acting freely is incompatible with the truth of determinism. In the incompatibilist group, most answers to the question what it is to act freely come from libertarians. ►Libertarianism is the conjunction of incompatibilism and the thesis that some people act freely. Some incompatibilists argue that no one acts freely [1]. They argue that even the falsity of determinism creates no place for free action.

## Description of the Theories

The compatibilist thesis typically sounds strange to nonspecialists. That is explained partly by the fact that when people first encounter the pair of expressions "free will" – or "freedom of will" – and "determinism" they tend to get the impression that the two ideas are defined in opposition to each other, that they are mutually exclusive by definition. This is one reason that it is useful to think of freedom of will as the power to act freely and to regard acting freely as the more basic notion – that is, as a notion in terms of which freedom of will is to be defined. Consider the following conversation in ordinary, nontechnical English between two inner-city Chicago police officers who know a stingy man named Sam. Ann: "Sam gave $20 to a street person today." Bob: "Why? Did he hold a gun to Sam's head?" Ann: "No, Sam gave him the money freely." Surely, Ann and Bob do not need to have an opinion about whether determinism (as defined above) is true to have this conversation. If what Ann says is true – that is, if Sam freely gave the person $20 – and freedom of will is the power to act freely, then Sam has freedom of will (or, at least, he had it at that time). Even if "free will" and "freedom of will" are typically opposed to "determinism" in ordinary speech, "he did it freely" seems not to be. And even if "he did it freely" were typically opposed to determinism in ordinary speech, that would settle nothing. After all, in ordinary speech, deductive reasoning seems to be defined as reasoning from the general to the particular, and that certainly would only jokingly be said to constitute an objection to a logician's definition of deduction (according to which "Ann is here; Bob is here; therefore Ann and Bob are here" is a valid deductive argument).

Compatibilist theories of free action emphasize a distinction between ►deterministic causation and compulsion [2,3]. If determinism is true, then this author's driving to work today, working on this article, eating dinner after work, and so on, were deterministically caused; and so were a certain compulsive hand-washer's washing his hands dozens of times today, a certain delusional person's spending the day trying to contact Martians with his ham radio, a certain crack addict's smoking crack today while in the grip of an irresistible craving for the drug, and a certain person's handing over the money in his pocket to gunmen who made it clear that they would kill him if he refused. But there is an apparent difference. This author is sane, suffers from no uncontrollable addictions, and received no death threats today. The basic compatibilist idea is that when mentally healthy people act intentionally in the absence of compulsion and coercion they act freely, and an action's being deterministically caused does not suffice for its being compelled or coerced.

Many compatibilists have been concerned to accommodate the idea that, for example, if this author freely drove to work this morning, he could have done something other than drive to work this morning. They grant that, if determinism is true, then there is a sense in which people could never have done otherwise than they did: they could not have done otherwise in the sense that their doing otherwise is inconsistent with the combination of the past and the laws of nature. But, these compatibilists say, the fact that a person never could have done otherwise in that sense is irrelevant to free action. What is relevant is that people who act freely are exercising a rational capacity of such a kind that if their situation had been different in any one of a variety of important ways, they would have responded to the difference with a different suitable action [3]. For example, although this author drove to his office today, he would not have done so if someone had bet him $1,000 that he would not stay away from his office all day. This truth is consistent with determinism. (Notice that if someone had made this bet with the author, the past would have been different from what it actually was.) And it reinforces the distinction between deterministic causation and compulsion. Offer a compulsive hand-washer $1,000 not to wash his hands all day and see what happens.

Some compatibilists claim that what matters for freedom is the exercising of a rational capacity that is appropriately responsive to reasons even if it is agreed that an agent's exercising a capacity of this kind is not sufficient for its being true that the agent "could have done otherwise." Such compatibilists call themselves semicompatibilists (►Semicompatibilism) [4]. Unlike traditional compatibilists, they do not insist that acting freely entails that one could have done something

else; but like traditional compatibilists, they claim that determinism is compatible with free action.

Libertarian theories of free action divide into three kinds: noncausal, event-causal, and agent-causal. Most theories about what intentional actions are include a causal condition. Roughly speaking, according to these theories, all intentional actions are events that are caused in a certain distinctive range of ways – either deterministically or indeterministically. For example, it may be claimed that what it is to be an intentional action is to be an event that is suitably caused by motivational and representational states. Noncausal libertarian theories of free action reject this idea [5,6]. Like compatibilists, noncausal libertarians tend to maintain that when mentally healthy people act intentionally in the absence of compulsion and coercion they act freely, but they insist that the deterministic causation of an action is incompatible with the action's being freely performed and that uncaused events can be intentional actions.

Typical event-causal libertarian theories of free action assert that agents never act freely unless some of their actions are indeterministically caused by immediate antecedents that are events, broadly construed, in the agents [7]. Whereas the laws of nature that apply to deterministic causation are exceptionless, those that apply most directly to ►indeterministic causation are instead probabilistic. Typically, events like deciding to help a stranded motorist – as distinct from the physical actions involved in actually helping – are counted as mental actions. Suppose that Aida's decision to help a stranded motorist is indeterministically caused by, among other things, her thinking that she should help. Given that the causation is indeterministic, she might not have decided to help given exactly the same internal and external conditions. In this way, event-causal libertarians seek to secure the possibility of doing otherwise that they require for free action, or for fundamentally free action (free action that does not derive its freedom solely from earlier free actions the agent performed).

Agent-causal libertarian theories of free action assert that agents themselves – as opposed, for example, to agents' motivational and representational states – are causes of free actions. Think of causation as a relation between cause and effect. In ordinary event causation – for example, a lightning strike's causing a tree to crack – both the cause and the effect are events. These events are connected by the relation causation. In ►agent causation, an agent is connected by the relation causation to an action. Whereas most agent-causal libertarians prefer their agent causation straight [8], some mix it with event causation in a theory of the production of free actions [9].

Each of the theories of free action described above has its detractors. Some theorists view determinism as precluding a kind of flexibility that they take to be required for free action and therefore reject all compatibilist views [7]. Even if they accept the compatibilist distinction between deterministic causation and compulsion, they contend that each of the two elements of the distinction precludes the required flexibility in its own way. Other theorists regard uncaused actions as impossible and therefore reject noncausal libertarianism [9,10]. Yet others maintain that although event-causal libertarianism introduces a chance of acting otherwise that is absent in deterministic universes (►indeterministic universe), it does not give agents the sort of control over their actions that free action requires [1,8,9]. They argue, for example, that event-causal libertarianism has the undesirable result that it is just a matter of chance that an agent decides on a particular course of action at a given moment rather than deciding on an alternative course of action then [8]. And some theorists find it very unlikely that agent causation has a place in the natural order of our universe [1,7].

If a typical compatibilist theory of what it is to act freely is correct, then it is very likely that people often act freely [10]. After all, there are a great many mentally healthy people, and it is difficult to deny that they often act intentionally in the absence of compulsion and coercion. Also, of course, if freedom of will is simply the power to act freely, anyone who acts freely has that power. If any of the libertarian theories of what it is to act freely are correct, it may reasonably be doubted that anyone ever acts freely. If there are, in fact, no uncaused actions, then no theory that requires that free – or fundamentally free – actions be uncaused permits us to act freely. If the brain, in fact, does not work indeterministically in a way required by event-causal libertarianism, then if that theory of what it is to act freely is correct, no one acts freely. And if there is no agent causation in the real world, agent-causal libertarianism has the same upshot.

Often, theorists who disagree about what it is to act freely attempt to find support for their view in the closely related sphere of moral responsibility. A common claim about the power to act freely – that is, freedom of will – is that it is a necessary condition for being morally responsible for one's actions, where moral responsibility is understood as a necessary condition for such things as deserved punishment, deserved moral blame, and deserved moral praise or credit. The various theories of free action described here have readily recognizable counterparts in the sphere of moral responsibility.

## Free Run

### Definition

The state of a rhythm or oscillator in the absence of time cues (zeitgebers) that can control their phase and period.

## Free-running Period

### Definition

Period length of the circadian oscillator in the absence of external timing cues (about 24 hrs). In mammals, normally determined under constant dim light or complete darkness conditions.

►Clock-Controlled Genes

## Free-running Rhythms

### Definition

Free running rhythms are rhythms with a period length (Greek symbol τ) which systematically deviates from the period length (Greek symbol T) of synchronizing environmental cycles, like light-dark or temperature cycles.

## Freeze-fracture Technique

### Definition

This is a method for preparing tissue for viewing in an electron microscope. Tissue is frozen very quickly, e.g., with liquid nitrogen, and then broken. A replica of the surface of the break is created by coating it with metal vaporized in a vacuum. The tissue is dissolved leaving the metal replica which is viewed with an electron microscope.

## Frequency

### Definition

Measured in Hertz (Hz), a frequency of "n" Hz indicates that a periodic cycle has repeated itself "n" times per second.

## Frequency-band Lamina

### Definition

The main anatomical structure of the tonotopy in the central nucleus of the midbrain inferior colliculus. A frequency-band lamina is a sheet-like structure consisting of the main cells (disk-shaped neurons) in this nucleus. These cells together cover with their characteristic frequencies a narrow frequency range. The characteristic frequencies of the neurons of a frequencyband lamina depend on the position of the neurons in the lamina.

►Inferior Colliculus
►Tonotopic Organization (Maps)

## Frequency Domain

### Definition

A description of the signal as a sum of (a possibly infinite number of) sines in different frequencies and

phases. The actual description is the phase and amplitude of each sine.

►Signals and Systems

## Frequency-following Response (FFR)

### Definition

An auditory evoked response that involves phase locking to periodic signals. This phase-locked response has been recorded in a number of structures along the auditory pathway, with more central structures systematically following at lower maximal frequencies.

Measured from the scalp, it likely is a volume conducted response from rostral brainstem structures.

►Auditory Evoked Potentials

## Frequency Response

### Definition

The description of a system using a function, which specifies the change in amplitude and phase, which will be effected to a sine input at a given frequency.

►Signals and Systems

## Frequency Tuning

### Definition

Sensory cells and neurons of the auditory system respond like frequency filters, i.e. they respond only to a certain bandwidth of the total frequency range of hearing of a species. They are tuned to a certain frequency range. The frequency tuning curve of a neuron is the curve in a frequency-amplitude-plot following the minimum tone amplitude (threshold) for a neuron's response as a function to tone frequency.

►Tonotopic Organization (Maps)

## Friedreich's Ataxia

### Definition

Genetic disorder with combined degeneration, at the ►spinal cord level, of the ►corticospinal tracts and ►spinocerebellar tracts, and the ►dorsal columns. In adolescence, the disease usually starts with loss of ►proprioception, weakness of the legs and ►ataxia in walking. While ankle and knee ►tendon reflexes are lost, the ►Babinski sign may be present. Due to ►cerebellar involvement, ►tremor of arms and ►nystagmus may appear later.

## Frontal Cortex

►Prefrontal Cortex

## Frontal Cortex (Areas 6 + 8)

### Definition

Premotor cortex. It plays a decisive role in the initiation of movements and comprises the frontal eye field (area 8).

►Telencephalon

## Frontal Eye Fields

Jeffrey D. Schall
Center for Integrative and Cognitive Neuroscience, Vanderbilt Vision Research Center, Department of Psychology, Vanderbilt University, Nashville, TN, USA

### Definition

Frontal eye field (FEF) is the area in dorsolateral prefrontal cortex that signals the location of targets and controls the execution of goal-directed movements of the eyes.

## Characteristics

### Higher Level Structures

FEF influences *saccade* production through three pathways – a projection to the ipsilateral superior colliculus concentrated in the intermediate layers, a pathway through the basal ganglia via the ipsilateral striatum and subthalamic nucleus, and a projection to mesencephalic and pontine nuclei [1].

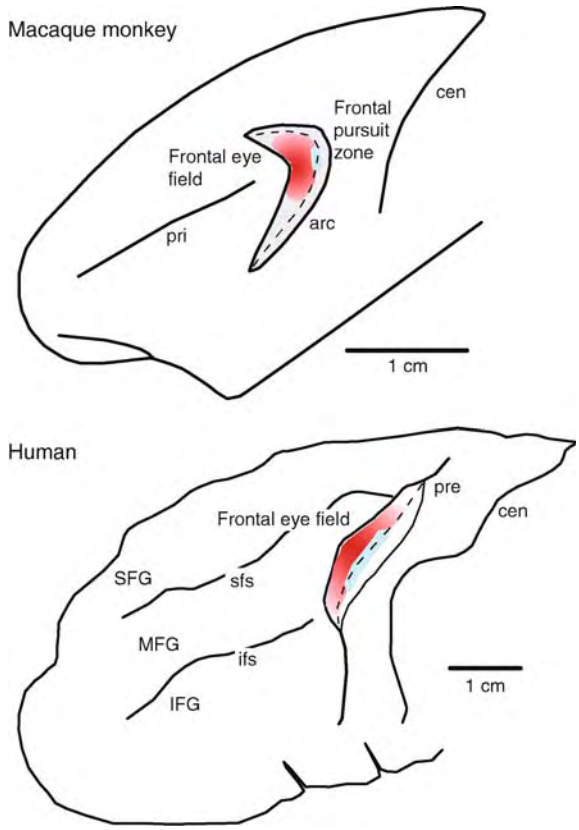
FEF is innervated by nuclei in the thalamus bordering the internal medullary lamina, mainly the lateral part of the mediodorsal nucleus and the medial part of the ventroanterior nucleus. The thalamic zones most heavily connected with FEF are themselves innervated by oculomotor afferents from the intermediate layer of the superior colliculus, the substantia nigra pars reticulate, and the dentate nucleus of the cerebellum.

FEF is connected with diverse cortical areas. Within the frontal lobe FEF is interconnected with SEF, with prefrontal areas 46 and 12, and weakly with anterior cingulate area 24 and postarcuate premotor cortex. FEF also receives abundant inputs from a multitude of visual cortical areas in both the dorsal and ventral streams [2]. In fact, FEF is unique in the extent of its connectivity with extrastriate visual cortex, and it should not be overlooked that FEF provides reciprocal connections to equally many extrastriate visual areas. Thus, FEF can influence the activation of neurons in extrastriate visual cortex.

The connectivity of FEF with visual areas caudal to the central sulcus is topographically organized. The more ventrolateral portion of FEF, which is responsible for generating shorter saccades, is interconnected with the perifoveal representation in retinotopically organized areas, from areas that represent central vision in inferotemporal cortex and from other areas having no retinotopic order. In contrast, mediodorsal FEF, which is responsible for generating longer saccades, is interconnected with the peripheral visual field representation of retinotopically organized areas, from areas that emphasize peripheral vision or are multimodal and from other areas that have no retinotopic order.

### Lower Level Components

In macaque monkeys, FEF occupies the rostral bank of the arcuate sulcus in Brodman's area 8 (Fig. 1). At a more refined level, the dorsal part of the rostral bank is designated area 8Ac and is distinguished from area 45 in the lower limb of the arcuate sulcus. The lip and convexity of the rostral bank of the arcuate sulcus is designated area 8Ar which borders rostrally with area 46. In humans, FEF is located in the rostral bank of the precentral sulcus at the caudal end of the middle frontal gyrus (Fig. 1). However, human FEF has been described as being in Brodman's area 6. The apparent difference between species seems to be more a difference of labels than of cortical architecture.



**Frontal Eye Fields. Figure 1** Stylized, lateral view of frontal cortex of macaque monkey (*top*) and human (*bottom*). The macaque arcuate sulcus is opened to expose the frontal eye field (red) on the rostral bank and the frontal pursuit zone (blue) on the fundus. The human precentral sulcus is opened to expose the frontal eye field (red) on the caudal end of the middle frontal gyrus with the pursuit zone (blue) in the fundus. Abbreviations: *arc*, arcuate sulcus; *cen*, central sulcus; *IFG*, inferior frontal gyrus; *ifs*, inferior frontal sulcus; *MFG*, middle frontal gyrus; *pre*, precentral sulcus; *pri*, principal sulcus; *SFG*, superior frontal gyrus; *sfs*, superior frontal sulcus.

### Higher Level Processes and Lower Level Processes

#### *Role in Eye Movement Generation*

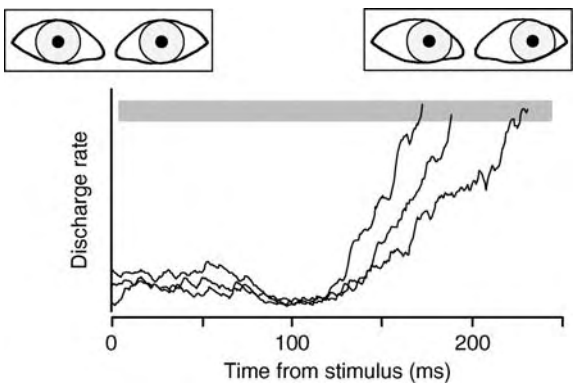
The FEF has been regarded most commonly as part of the ocular motor system; the evidence for this is beyond dispute [1]. Most evidence has been obtained through invasive studies with nonhuman primates, but the human FEF has been located through brain imaging [3], transdural recording and stimulation [4], and transcranial magnetic stimulation [5]. FEF contributes to the generation of rapid saccadic gaze shifts as well as slow pursuit eye movements. The zone involved in pursuit is located at the fundus of the sulcus, separate from the area of frontal eye field that is involved in saccade production (Fig. 1).

Low intensity electrical stimulation of FEF in monkeys elicits saccadic eye movements, while stimulation of the ►frontal pursuit area elicits pursuit eye movements. Reversible inactivation of FEF prevents saccade production, complementing earlier observations that ablation of FEF causes an initially severe impairment in saccade production that recovers in some but not all respects over time. If the fundus of the arcuate sulcus is ablated, pursuit deficits occur.

The direct influence of FEF on saccade production seems to be mediated by neurons in FEF that are activated specifically before and during saccades [6,7]. Two kinds of neurons that control gaze have been distinguished. In general, *movement* neurons contribute to gaze shifting, and *fixation* neurons contribute to gaze holding. Neurons in FEF that generate movement-related or fixation-related activity are located in layer 5 and innervate the superior colliculus and parts of the neural circuit in the brainstem that generate saccades. Physiological recordings indicate that these neurons, in concert with a network including the superior colliculus, produce signals necessary to produce saccadic eye movements. Saccades are initiated when the activity of movement-related neurons reaches a threshold (Fig. 2). Variability in saccade latency can be accounted for by the time taken to reach this threshold. If an interrupting stimulus occurs, saccade preparation is canceled if, and only if, the activity of these neurons is reduced and prevented from reaching the threshold.

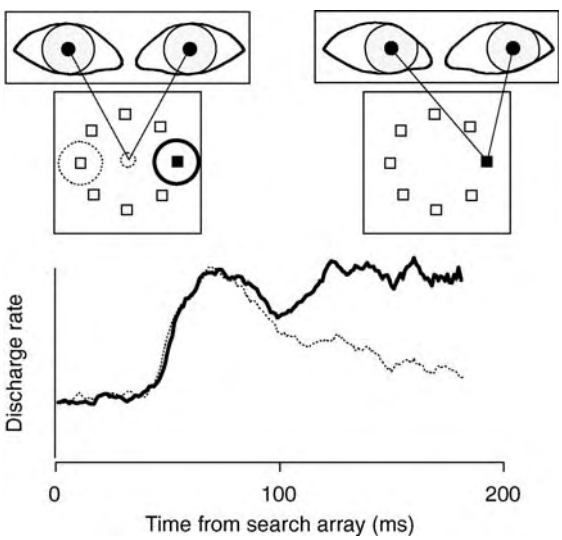
### Role in Target Selection

FEF contributes to selecting the target and shifting attention before gaze shifts, both saccadic and pursuit [8].



**Frontal Eye Fields. Figure 2** Saccades are produced when the activity of movement-related neurons in frontal eye field, as part of a network, reach a fixed threshold. Variability in the time of initiation of the saccade originates in the variable time taken for the activity to increase to the threshold.

It is also crucial to note that the neural signals occurring in FEF coincide with identical signals occurring in a network of interconnected structures including the superior colliculus and posterior parietal cortex. In macaque monkeys trained to shift gaze to the oddball target in visual search arrays, most visually responsive cells in FEF responded initially indiscriminately to the target or the distractor of the search array in their receptive field because neurons in FEF are not feature selective (Fig. 3). However, before gaze shifts, a selection process transpires by which most visually responsive cells in FEF signal the location of the target stimulus through suppression of the response to non-target stimuli, leaving only the response to the target. This selection process occurs if no saccade is made or if the saccade is directed to a non-target stimulus. The selection process is influenced by the similarity of the target and non-target stimuli, taking longer the more similar the stimuli. The selection process is also influenced by knowledge of target properties acquired over preceding trials or sessions. These properties of the target selection process observed in FEF indicate that it can be identified with the allocation of visual



**Frontal Eye Fields. Figure 3** Targets for saccades are selected by the pattern of activity of visual neurons in frontal eye field, as part of a network. The activity of a visual neuron of a monkey shifting gaze to a single conspicuous stimulus. The response to the target (solid line), and the response to a distractor (dotted line), are superimposed for comparison. The stimulus array is shown at the top with superimposed receptive fields mapping onto the corresponding activation. After around 100 ms a selection process transpires that results in an accurate representation of the location of the target that can be used to guide the saccade.

spatial attention. The contribution of FEF and surrounding cortex to the allocation of spatial attention has been described in human studies using functional brain imaging [9] and transcranial magnetic stimulation [10]. All of these data can be organized under the framework that FEF is a salience map.

### Function

The FEF as part of a network samples the outcome of sensory processing to orient toward conspicuous and important elements in the environment.

### Pathology

Damage to the area of cortex including the FEF in humans results in deficits in controlling gaze in response to arbitrary cues while leaving visually guided eye movement control largely intact.

## Frontal Gyri

### Synonyms

►Gyri frontales

### Definition

The frontal gyri form three groups:

– Superior frontal gyrus
– Medial frontal gyrus
– Inferior frontal gyrus

Located in the gyri are also, inter alia, the premotor cortex and the motor speech center (Broca). The prefrontal cortex features additionally areas with pronounced associative functions.

►Telencephalon

## Frontal Lobe

### Synonyms

►Lobus front

### Definition

The frontal lobe extends from the frontal pole to the central sulcus.

►Telencephalon

## Frontal Pursuit Area

### Definition

A small region of the frontal lobe that contributes to the production of slow visual pursuit eye movements. In macaque monkeys it is located at the fundus of the arcuate sulcus. In humans it is located in the precentral sulcus. It contains neurons discharging in relation to pursuit and not saccadic eye movements. Its electrical stimulation elicits smooth, ipsiversive eye movements and its ablation results in pursuit deficits.

►Frontal Eye Fields

## Frontotemporal Dementia

### Definition

Uncommon but important degenerative disease accounting for up to 50% of dementia before age 60. While most cases are sporadic, some have a genetic basis (one mutation affecting the microtubule-associated protein (MAP) tau on chromosome 17, but there are others). Most often, frontotemporal degeneration is associated with ubiquitin inclusions. Frontotemporal dementia is characterized by personality alterations, often starting with disinterest and apathy, and behavioral changes such as disinhibition and perseverative, compulsive behavior, as well as corticobasal degeneration and ►primary progressive aphasia, and occasionally semantic dementia (loss of the meaning of nouns and objects).

## FST

### Definition

Relative to neuroscience a "functional-anatomical system" encompasses the interconnected neuronal circuits and end organs serving identified or presumed core functions of animals including humans.

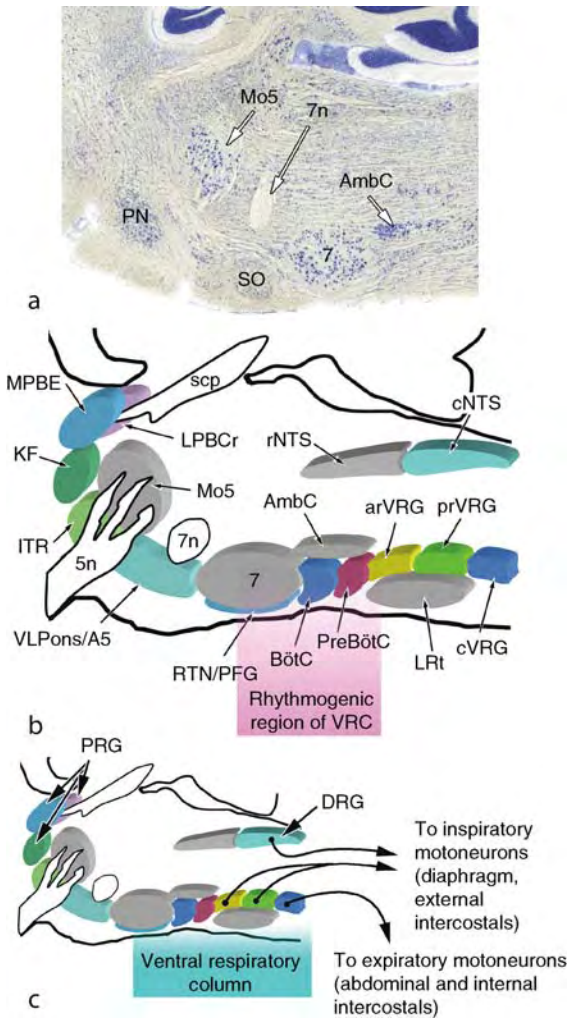
### Characteristics

Neuroscience research confronts the nervous system at a variety of levels ranging from the molecular biology and biophysics of the constituent neurons and glia to the overall physiological and structural organization of cellular networks serving the phenotypic behaviors of the organism. The latter include maintenance of internal and overt behaviors necessary for individual survival (respiration, food and water intake; cardiovascular/autonomic regulation e.g. [1]), and the persistence of individual species (e.g. social behaviors, including pair bonding, copulation, parenting, and territoriality, e.g. [2]). Functional-anatomical systems encompass most levels of organization included between molecular biology and organized overt behaviors. Functional anatomical systems are both modular and interactive. That is, functional specificity may be demonstrated for many regulatory and overt behavioral systems at least for broad portions of their underlying neural circuits. On the other hand, various classes of behaviors often interact, reinforcing or inhibiting one another. Prioritizing the activity for competing specific functional systems, however, do not invariably represent a static hierarchy; specific behaviors are expressed appropriate to the environmental context and according to varying levels of homeostatic demand.

One example of a modular functional-anatomical system is the neural circuitry controlling breathing (Fig. 1) along with its related central and peripheral sensors and the end organs in the lungs and the muscles of the respiratory pump.

Premotor neurons responsible for the regular and persistent (lifetime) oscillation between inspiration and expiration as well as for most adjustments in rate and amplitude of contraction on the "pump muscles" (diaphragm, intercostal, and abdominal muscles in mammals), are located entirely within the rhombencephalon. Following mid-collicular decerebrations, breathing persists practically unaltered from baseline rates and remains responsive to various homeostatic demands (e.g. hypoxia or ►hypercapnea) despite the absence of forebrain inputs. In the normal intact animal, however, breathing is a voluntary, albeit highly motivated behavior, which may be stopped and started at will.

The respiratory network is also interactive, in that a variety of behavioral systems may access and modify the activity of brainstem respiratory premotor and motor neurons for purposes other than gaseous (►$PO_2$, $PCO_2$) homeostasis. These include modulation of expiratory and airway muscles during vocalizations, co-activation of inspiratory and expiratory muscles during vomiting, and modification of breathing in response to orientation and defense responses, and modification of breathing in response to strong emotional stimuli including painful stimuli. Breathing is also inhibited by a variety of behaviors for example



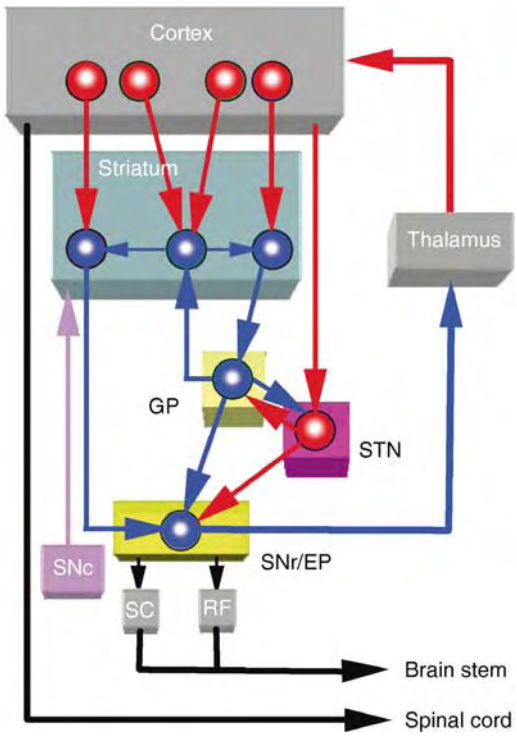
**Functional-anatomical System. Figure 1** Respiratory related compartments of the rhombencephalon of the rat. Adapted from Figure 1 in Alheid et al. (2004) [3] (with permission from Elsevier) (a) Nissl stained sagittal section through the lateral rhombencephalon of the rat brain at the level of the ventral respiratory column of the medulla. (b) Schematic of respiratory related compartments of the rhombencephalon. (c) Main brainstem respiratory outputs to spinal motoneurons activating the pump muscles for breathing. Generation of respiratory rhythm and pattern are controlled by a series of neuronal compartments found mainly in the lateral rhombencephalon (color coded regions in b). Respiratory neurons, whose firing pattern is more or less phase-locked to the respiratory cycle, are found in the dorsolateral pons in an area termed the pontine respiratory group (PRG), in the dorsal respiratory group, and most prominently in the ventral respiratory column of the medulla (VRC; blue bar in c), particularly by neurons within the ►preBötzinger complex (preBötC) and likely within the parafacial respiratory group (PFG) located ventral to the facial nucleus. The PRG encompasses subsets of neurons in the medial and lateral parabrachial complex and in the ►Kölliker-Fuse nucleus (KF), while the DRG is composed of respiratory related neurons in caudal portions of the nucleus of the solitary tract (cNTS). It is generally agreed that neurons in the rostral half of the VRC are responsible for the generation of the respiratory rhythm (pink bar in b), while neurons in the DRG (within caudal portions of the nucleus of the solitary tract; cNTS) and in the caudal half of the VRC (c) represent the most prominent source of premotor input to spinal motoneurons controlling the respiratory pump. Neurons in the ►rostral ventral respiratory group (VRG) are mainly inspiratory premotor neurons, while neurons in the ►caudal ventral respiratory group (cVRG) are mainly expiratory premotor neurons. The rVRG may be further subdivided, in that interneurons in the anterior part of the rostral ventral respiratory group (aVRG) also appear to contribute to respiratory rhythm generation [4], while stimulation of cells in the posterior portion of the VRG (pVRG) have little effect on respiratory frequency. Cranial motoneurons innervating airway muscles are also located within the VRC and are generally modulated by respiratory premotor neurons, as are motoneurons in the hypoglossal nucleus (not shown).

during swallowing, and (in amphibious animals) as an element in the diving reflex. Interestingly, in the latter instance, breathing is suspended both before and during submergence implying involvement of anticipatory cognitive processes.

The known functions (e.g. for homeostasis or sensory processing) of many systems motivate the research aimed at understanding their neural basis. However, the precise functions of some anatomical systems are not initially clear. Investigations of such systems were undertaken because of the obvious coherence in their neural circuitry and/or their likely involvement in neurological disorders. For some of the latter, functional roles have been postulated only after much study and often remain a topic of debate.

Significant examples include the "cortico-striatopallido-system" (Fig. 2) and the "cerebellar systems." In the past, these were characterized as parallel components of the so-called "►extrapyramidal motor system." The latter term, however, was merely one of exclusion from the presumed more direct motor activation effects of stimulation in primary motor cortex. Despite the initial lack of a functional focus, the physiology and neuroanatomy of the circuits centered on the striatum or cerebellum have been described in great detail. Both of these systems have profound effects on motor function, but with apparently limited direct interactions with one another except at the level of motor output. Moreover, evidence has been offered to suggest that each of these systems interacts with functions beyond the scope of direct motor control.

Cerebellar efferents interact relatively directly with motor cortex via cerebello-thalamo-cortical axons and



**Functional-anatomical System. Figure 2** Schematic of principal basal ganglia pathways. Redrawn from Figure 1 in Bolam et al. (2000) [5] (with permission from Blackwell publising and the Author). In this simplified schematic excitatory connections are shown in red and inhibitory connections in blue. The dopaminergic input from the pars compacta is shown in purple since it may be potentially inhibitory or excitatory depending on the current activity of the targeted striatal neurons. The basal ganglia receive a broad pattern of input from cortical areas including cortical like regions in the lateral-basolateral complex of the amygdala. The rostral thalamus provides an ascending feedback loop to the cortex, but also afferent input from the ►intralaminar thalamic nuclei (not shown). Generally a *direct and indirect pathway* are described for basal ganglia circuits. In the first, the striatum sends and inhibitory projection directly to the entopeduncular nucleus (medial pallidal segment of primates) and or to the pars reticulata of substantia nigra, which are the principal output nuclei for basal ganglia. In the second, the striatum projects indirectly to the output nuclei via inhibitory projections to the globus pallidus (external pallidal segment of primates) which then send inhibitory projections to the substantia nigra and subthalamic nucleus. The subthalamic nucleus provides excitatory afferents to the output nuclei but also provides excitatory feedback to the globus pallidus. Note that the cortex may excite the subthalamic nucleus via two inhibitory steps or via a single step direct excitatory projection to the subthalamic nucleus. The dopaminergic neurons in the pars compacta, substantia nigra receive afferents from the basal ganglia and from the brainstem (not shown) and provide a massive input to the striatum that modulates

with the ventral horn of the spinal cord via cerebello-rubro-spinal axons to provide refinement of motor control (predictive, strength and timing of motoneuron activation). Human functional imaging data, however, also suggests that the cerebellum is also activated by a variety of non-motor behaviors, including during cognition and emotions. "Associative" regions of cortex also appear to be reciprocally linked to portions of the cerebellum and its output from the deep cerebellar nuclei. These interconnections are topographically distinct from those areas most closely connected with motor and premotor cortical areas. The cerebellum, when damaged, leads to clear disruption of movement (ataxia), however, pathological changes in the cerebellum have also been noted in the brains of schizophrenic patients.

The striatopallidal system when damaged, is the source of profound motor impairment in humans including hypokinesia, rigidity, and tremor consequent to the loss of neurons in the pars compacta of substantia nigra that provide the dopamine innervation of striatum (in Parkinson's disease), or hyperkinesias following selective deterioration in subsets of striatal neurons (in Huntington's chorea). Earlier theories postulated that the striatopallidal system was responsible for postural adjustments or alternatively, for the initiation of movements. More recent evidence, however, suggests that initial neural activity preceding movement occurs in cortical regions projecting to striatum and that the striatopallidal system may be responsible for the sequencing of motor activity subsequent to movement activation. In addition, the striatopallidal system is

information flow through this structure. In addition to output via the rostral thalamus, the substantia nigra, pars reticulata and entopeduncular nucleus send efferents to the brainstem and reticular formation that provide direct modulation of motor output. *5n* trigeminal nerve; *7* facial nucleus; *7n* facial nerve; *A5* A5 noradrenergic neuron in the ventrolateral pons; *AmbC* compact part of nucleus ambiguus; *arVRG* anterior rostral VRG; *BötC* Bötzinger complex; *cVRG* caudal ventral respiratory group; *DRG* dorsal respitory group; *EP* entopeduncular nucleus; *ITR* intertrigeminal nucleus; *KF* Kölliker-Fuse nucleus; *GP* globus pallidus; *LPBCr* lateral parabrachial complex, crescent subnucleus; *LRt* lateral reticular nucleus; *Mo5* motor nucleus of the trigeminal nerve; *MPBE* medial parabrachial complex external subnucleus; *PFG* parafacial respiratory group; *PN* basilar pontine nuclei; *preBötC* preBötzinger complex; *PRG* pontine respiratory group; *prVRG* posterior rostral VRG; *RF* reticular formation; *RTN* retrotrapezoid nucleus; *SC* superior colliculus; *scp* superior cerebellar peduncle; *SNc* substantia nigra pars compacta; *SNr* substantia nigra pars reticulata; *STN* subthalamic nucleus; *VLPONS* ventrolateral pons.

postulated to function as a substrate for procedural learning (e.g. automatization of behaviors).

The striatopallidal system [5], on the other hand, receives input from nearly all cortical areas and has been implicated in a variety of behaviors that are not limited to motor activity or procedural sequences. Caudal striatal regions, for example, receive input from sensory regions of cortex and relay this input via globus pallidus to posterior (sensory) thalamus and to caudal brainstem. Absent from this "sensory striatal" circuit are the terminations in the subthalamic nucleus that characterizes portions of the striatopallidal system that serve motor and premotor cortices [6]. Increases in striatal dopamine release, and particularly increases in dopamine within "ventral striatum" (nucleus accumbens and olfactory tubercle), appear to be a general component of naturally rewarding stimuli [7], including the response to addictive drugs. Disturbances in the function of the striatopallidal system have also been implicated in the etiology of schizophrenia as well as in obsessive compulsive disorders and even disrupted memory [8].

The functions of some neuroanatomical systems remain elusive despite their intense scrutiny. One such region is the amygdala. This forebrain area is involved in a wide variety of behaviors such as the influences of learned emotional responses, including conditioned fear, on autonomic behaviors such as blood pressure and gastrointestinal motility. Reproductive behaviors such as copulation and parenting are mediated in part by subnuclei of the amygdala, including the extended amygdala, and neurons are observed that respond to familiarity in general, and to face recognition in particular. While studies often still refer to the amygdala as an anatomical entity, modern neuroanatomical, physiological, and psychopharmacological experiments relate sub groups of the numerous nuclei composing the amygdala to a variety of distinct functional anatomical systems. These include the modulation of reproductive and defensive behaviors by medial amygdaloid nuclei (e.g. [9]), and modulation of autonomic and neuroendocrine responses to emotional stimuli including stress, by the central amygdaloid complex. The cortical-like nuclei of the amygdala, including the lateral-basolateral complex, relay afferent input from the thalamus and cortex to medial and central amygdala and basal forebrain including the basal ganglia [10]. Prominent afferents from the main and accessory olfactory bulbs also provide direct afferents to medial amygdala and specific cortical amygdaloid nuclei.

## Functional Anatomical Systems are Genetically Determined

Functional anatomical systems are, to varying degrees, adaptive and modified by environmental demands during development, including the physical and social challenges confronting individual organisms. Nonetheless, all functional anatomical systems are based on circuitry and structures defined by the genetic code. This is clear from the intraspecific homogeneity in the neural circuits and end organs serving particular functions, and the increasing discovery of related genes serving homologous functions across varieties of species spanning nearly entire phylogenetic orders. At one extreme this is represented by more or less hard wired systems resulting in stereotypic behaviors (fixed action patterns), with modest modifications by environmental interactions such as for the social and parental behaviors of birds, or for the development of synaptic refinement during critical developmental epochs for sensory and motor systems. At the other extreme is the life long modification of cognitive and verbal behaviors characterizing humans. The latter, of course, operate through genetically specified modules for the execution of overt behaviors such as vocalization, and through the genetically established neurological substrates of learning and memory.

All functional anatomical systems are composed of multiple modules each of which are specified by large arrays of interacting genes. Some of these specify basic developmental/neurochemical elements common to many different functional modules such as for cell metabolism, ion channels, neurotransmitter receptors, and differentiation of stem cells into neurons or glia. Other genes evince regional or system specific expression such as those controlling the development of rhombomeres in the brainstem, in specific amygdalar pathways related to reproductive or defensive behaviors [9], or genes specifically associated with the olfactory system. Since in the broadest sense, most functional anatomical systems are integrated across the entire neuroaxis, including the sensory and motor innervation of end organs, an important long term objective is identifying the various genetic determinants specifying the vertical integration of complex functional anatomical systems.

# Functional and Neurochemical Organization of Vestibulo-Motor Pathways

H. Straka[1], M. B. Dutia[2]
[1]Laboratoire de Neurobiologie des Réseaux Sensorimoteurs, Université Paris 5, Paris, France
[2]Centre for Integrative Physiology, Edinburgh University, Edinburgh, Scotland

## Definition

Linear and angular head acceleration in three dimensions is detected and decomposed into individual acceleration vectors by the vestibular receptors located in the inner ears on both sides (the semicircular canal and macula organs) [8]. The three semicircular canals are oriented roughly perpendicularly to each other and sense angular head acceleration in their respective anatomical planes. Based on their mirror image like position on both sides of the head, the anterior vertical canal on one side and the posterior vertical canal on the other side as well as the horizontal semicircular canals on both sides form functional co-planar canal pairs respectively. The two macula organs detect static changes in the head position relative to gravity as well as linear acceleration of the head. In general, the utricle detects linear head acceleration in the horizontal plane and changes of the head with respect to gravity, whereas in mammals including humans the saccule detects vertical linear head acceleration. In non-mammalian species, vertical linear head acceleration is largely detected by the lagena, a third macula organ, whereas the saccule in these latter species is sensitive to bone-conducted sound or vibrations.

## Characteristics

### Functional Organization of the Peripheral Vestibular Receptors

The functional organization of the sensory epithelium of semicircular canal and macular organs is very similar across different vertebrate species [4]. The sensory cells are embedded into the epithelium of the semicircular canal (cupula) and of the macula organs and consist, in mammals, of two different types called type I and type II hair cells. These differ in their cell morphology, in the synaptic structures of the afferent nerve fibers that innervate them and in the termination of efferent vestibular fibers. Particularly prominent are type I hair cells which are "bottle-shaped", have calyx-like afferent terminals surrounding a large part of the cell body and originate from the thickest afferent nerve fibers. These hair cells are located mainly in the center of the semicircular canal cupula and the striola of the macula organs. In contrast, type II hair cells are cylindrical with multiple bouton-like afferent terminals. Based on the morphology of their synapse onto the hair cells, afferent fibers in mammals are subdivided into three classes, calyx fibers, bouton fibers and dimorphic fibers.

All present evidence suggests that glutamate is the putative neurotransmitter at the hair cell-afferent axon synapse in the mammalian as well as the non-mammalian inner ear [4,8]. Bath application of glutamate, aspartate or N-methyl-D-aspartate (NMDA) evokes a dose-dependent depolarization in semicircular canal afferent nerve fibers *in vitro* or an increase in the resting rate of afferent fibers. Postsynaptically, the amplitude of synaptic depolarizations is reduced by various glutamate receptor antagonists such as kynurenic acid or 2-amino-5-phosphono valeric acid (APV). A presynaptic effect of glutamate on hair cells, mediated by metabotropic receptors, might be related to an enhancement of signal discrimination. In a subpopulation of hair cells in toadfish and pigeon, GABA has been found to be colocalized with glutamate. Based on physiological evidence, a combined postsynaptic effect of both excitatory and inhibitory transmitters might be involved in shaping vestibular afferent responses.

### Synaptic Transmission Between Vestibular Nerve Afferent Fibers and Second-Order Vestibular Neurons

Vestibular nerve afferent fibers from individual labyrinthine endorgans terminate in all major vestibular nuclei, the adjacent reticular formation and the cerebellum [3,6]. Although the termination of fibers from individual endorgans predominates in certain areas of the vestibular nuclei, there is neither a clear spatial segregation of signals from particular semicircular canals nor of signals from particular macula organs. However, at variance

with the general overlap of afferent fiber terminations, the ipsilateral convergence of afferent input at the single cell level of second-order vestibular neurons is rather specific and very similar in different species [8]. As a rule, signals from individual semicircular canals remain largely separate at the level of second-order vestibular neurons, whereas horizontal canal signals converge largely with signals from the horizontally oriented macula organ (utricle), and signals from the two vertical canals converge predominantly with those from the vertically oriented macula organ (saccule in mammals, lagena in frogs).

All vestibular nerve afferent fibers mediate their signals to second-order neurons mainly by chemical transmission [4,8,10]. As it is the case for most excitatory synapses in the vertebrate central nervous system, glutamate is the putative transmitter of vestibular nerve afferent fibers. Postsynaptically different subtypes of glutamate receptors are activated in second-order vestibular neurons. The presence and the activation of multiple glutamate receptor subtypes as well as a number of additional, differentially distributed neuroactive substances in vestibular nerve afferent fibers such as glycine or substance P suggest that this chemical transmission is not however uniform. In fact, different response components might be mediated by different subsets of vestibular nerve afferent fibers that use different combinations of presynaptic neuroactive substances and postsynaptic receptors.

## The Putative Transmitter of Vestibular Nerve Afferent Fiber Is Glutamate

Even though not all the criteria that are necessary to consider a substance as the neurotransmitter at a particular synapse are determined yet, glutamate meets a large number of these conditions in vestibular nerve afferent fibers [8]. Thus, it is very likely that this amino acid or a closely related analog is the excitatory transmitter between vestibular nerve afferent fibers and second-order vestibular neurons. Immunocytochemical studies have shown that glutamate is present in afferent fibers and ganglion cells in frog, mouse, rat and cat. However, the intensity of the glutamate immunoreactivity is not uniform across afferent fibers but decreases with increasing diameter of the ganglion cell. The role of glutamate as transmitter is supported by the presence in mouse vestibular ganglion cells of mitochondrial or cytosolic aspartate aminotransferase, an enzyme involved in the synthesis of glutamate and aspartate.

## Glycine and Substance P as Possible Cotransmitters

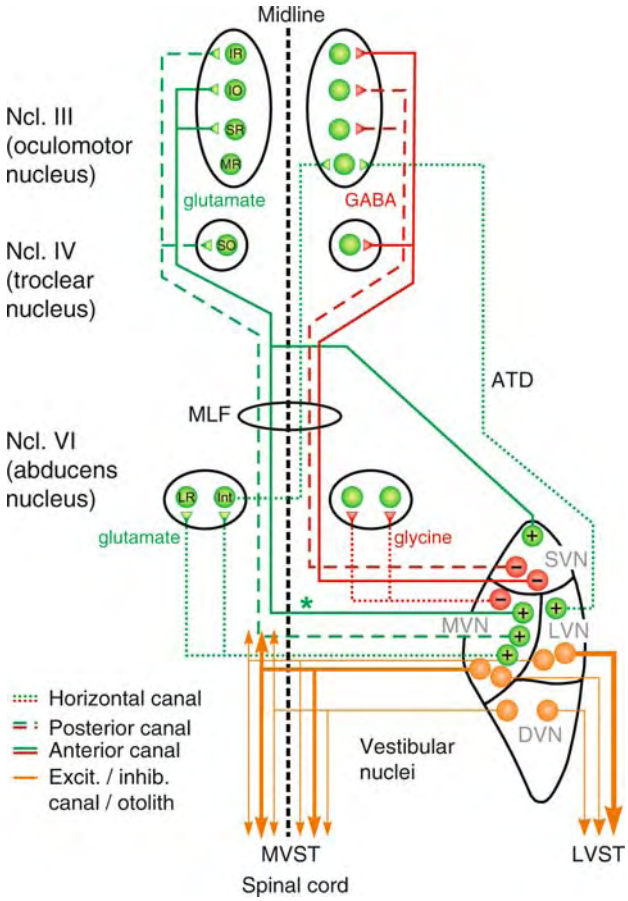
In addition to the presence of glutamate in the ganglion cells of vestibular nerve afferent fibers a population of particularly large vestibular ganglion cells exhibits an intense glycine immunoreactivity. Thus, glycine and glutamate are colocalized in the largest ganglion cells, their afferent nerve fibers and their terminal-like structures. The differential distribution of glycine in vestibular nerve afferent fibers is complemented by the presence and differential distribution of substance P in these fibers. Using antibodies against substance P, about 85% of the vestibular ganglion cells were immunopositive in guinea pig; these were significantly smaller in diameter than the unlabelled ganglion cells. The presence of substance P in particularly small ganglion cells, although they were fewer in number was corroborated in rabbit, cat and monkey. These data suggest that small vestibular nerve afferent fibers colocalize glutamate and substance P, whereas large vestibular nerve afferent fibers colocalize glutamate and glycine. If glycine and substance P were also released from vestibular nerve afferent fibers both substances might have a possible functional role as cotransmitter or neuromodulator of the synaptic transmission onto second-order vestibular neurons.

## Postsynaptic Glutamate Receptors in Second-Order Vestibular Neurons

Electrophysiological and pharmacological studies in a variety of vertebrate species support the hypothesis that vestibular nerve afferent fibers use glutamate as the excitatory neurotransmitter to activate second-order vestibular neurons [8,10]. Electrical stimulation of vestibular nerve afferent fibers and recording of second-order vestibular neurons in fact activates different subtypes of postsynaptic glutamate receptors. These receptors subdivide into NMDA and non-NMDA or α-amino-3-hydroxy-5-methyl-4-isoxalone (AMPA)/kainate receptors (Fig. 1).

The multitude of glutamate receptor subtypes opens the possibility that they might be activated by different subsets of vestibular nerve afferent fibers. Since vestibular nerve afferent fibers differ from each other in a number of interrelated physiological and pharmacological properties, different glutamate receptors might be activated and transmit different dynamic components of the sensory signals (Fig. 1).

Assuming that glycine is in fact localized in and released from thick vestibular nerve afferent fibers, it could theoretically activate the strychnine-sensitive inhibitory glycine receptor. However, all electrophysiological data preclude a possible role of glycine as an inhibitory transmitter at this synapse. Alternatively, glycine might bind to the glycine-binding site of the NMDA receptor on second-order vestibular neurons and act as a cotransmitter in conjunction with glutamate. The binding of glycine to the respective site of the NMDA receptor in addition to the binding of glutamate is a necessary requirement to activate this glutamate receptor subtype. Given the fact that glycine is only present in the thickest vestibular nerve afferent fibers, only the latter type of neurons but not thin



**Functional and Neurochemical Organization of Vestibulo-Motor Pathways. afferent fibers would activate NMDA receptors on second-order vestibular neurons.

### AMPA/Kainate Receptors

Subunits of the AMPA/kainate receptor are differentially distributed in almost all parts of the vestibular nuclei in gerbil, chinchilla and rat [6]. Bath application of glutamate, aspartate, kainate or quisqualate evokes pronounced depolarizations in frog, rat and guinea pig central vestibular neurons [10]. Part of these responses as well as vestibular nerve afferent-evoked monosynaptic EPSPs in central vestibular neurons are blocked by different glutamate receptor antagonists among which the relatively unspecific kynurenic acid is the most effective. More specific antagonists such as the AMPA/kainate antagonists CNQX or DNQX reduce the monosynaptic responses in central vestibular nucleus neurons at very low concentrations. However, monosynaptic vestibular nerve afferent fiber-evoked responses were not blocked completely by these antagonists, but were only abolished by adding the NMDA antagonist D-(-)-2-amino-5-phosphonovaleric acid (D-APV) or 7-chloro-kynurenic acid. This indicates that the responses are mediated in part by AMPA/kainate receptors and in part by NMDA receptors.

### NMDA Receptors

The NMDA receptor subunit NMDAR1, the major subunit of this glutamate receptor subtype, is found in neurons in all four major vestibular nuclei, although

in differential densities [6,10]. Glutamate agonists like L-homocysteate or NMDA evoke pronounced depolarizations in frog, rat and guinea pig central vestibular neurons that can be reversibly blocked by the specific NMDA antagonist D-APV. Similarly, vestibular nerve afferent-evoked responses in second-order vestibular neurons are blocked by specific NMDA antagonists, indicating in fact an activation of these glutamate receptor subtypes during natural stimulation. Given the voltage-dependent $Mg^{2+}$ block of these receptors, the discrepancies in the different studies concerning the respective magnitude of the NMDA responses relative to the total response are probably related to the level of $Mg^{2+}$ in the Ringer solution used. Under these conditions, strong electrical stimuli applied to vestibular afferent nerve fibers are more likely to facilitate a release from the voltage-dependent $Mg^{2+}$ block and to trigger an NMDA response.

### Afferent Nerve Fibers with Different Dynamics Activate Different Glutamate Receptors

Selective electrical activation of thick and thin vestibular nerve afferent fibers in the isolated adult frog brain indicates that second-order vestibular neurons are activated by variable contributions of thick and thin vestibular nerve afferent fibers [8]. Thick vestibular nerve afferent fibers activate these neurons via NMDA as well as AMPA receptors, whereas thinner vestibular nerve afferent fibers activate predominantly non-NMDA receptors. The specific contribution of NMDA receptors to the afferent nerve-evoked excitatory response thus depends on the relative amount of convergence of thick and thin afferent fibers. The activation of NMDA receptors could be facilitated by glycine if the latter amino acid is coreleased together with glutamate from thick afferents and binds to the glycine-binding site of NMDA receptors. In fact, the binding of glycine to this site is a prerequisite for the NMDA receptor activation. Given the fact that the thickest vestibular nerve afferent fibers contain glycine and glutamate and assuming that both substances are released upon stimulation, the evoked responses are in fact facilitated by the colocalization and the possible corealease of the two amino acids. In fact, perfusion of specific agonists and antagonists of this glycine-binding site into the guinea pig vestibular nuclei indicated that vestibular responses can be modulated through this glycine-binding site [10].

### Neuromodulatory Substances Acting on Second-Order Vestibular Neurons

Apart from vestibular nerve afferent inputs, most second-order vestibular neurons are endowed with a spectrum of neurotransmitter receptors of various subtypes that differ between vestibular neurons with different functional properties. Cholinergic, serotoninergic, histaminergic, dopaminergic and noradrenergic receptors are present as well as $GABA_A$, $GABA_B$ and glycinergic receptors [2,9,10]. Of particular interest have been the actions of histamine and histaminergic agents on vestibular neurons, because of the mitigatory effects of histamine in vestibular dysfunction or during vestibular compensation. Current literature implicates pre-synaptic control of heterosynaptic neurotransmitter release by H3 histaminergic receptors as well as post-synaptic excitatory effects of H1 and H2 receptors in the actions of histamine [2]. Also of interest have been the effects of serotonin, which has either net excitatory effects through 5-HT2 receptors or inhibitory effects via 5-HT1A receptors or, in some cells, a biphasic action involving both subtypes. Opioids and neuroactive steroids also modulate neurotransmission in the vestibular nuclei [10].

## Functional and Neurochemical Organization of the Vestibular Nuclei

Excitatory and inhibitory central vestibular neurons that relay particular semicircular canal signals are highly organized and project via distinct fiber tracts to individual populations of oculomotor, trochlear and abducens motoneurons (Fig. 1). The different functional subgroups develop ontogenetically from distinct hindbrain segments and are highly conserved among vertebrates [1,5].

The medial vestibular nucleus (MVN) is generally assumed to be the major vestibular relay nucleus for the VOR, particularly for horizontal canal and utricular signals [3,6]. It contains several functional subgroups that project to distinct pools of extraocular motoneurons and internuclear neurons mediating afferent inputs from semicircular canals to specific extraocular motoneurons (Fig. 1). These vestibular neurons thus form the central part of the classical three-neuronal vestibulo-ocular reflex pathway. Two subsets of MVN neurons are activated by afferent inputs from the horizontal canal and provide uncrossed, inhibitory projections and crossed, excitatory projections to lateral rectus (LR) motoneurons and abducens internuclear neurons respectively to generate the horizontal VOR (Fig. 1). Another subset of MVN neurons located in the magnocellular part of the caudal MVN are activated by posterior vertical canal inputs and excite contralateral inferior rectus (IR) and superior oblique (SO) motoneurons in the oculomotor and trochlear nucleus (Fig. 1). Whether neurons in the MVN contribute to an anterior vertical canal-activated excitatory pathway to contralateral inferior oblique (IO) and superior rectus (SR) motoneurons (* in Fig. 1) still remains open.

Additional subgroups in the lateral (LVN) and superior (SVN) vestibular nuclei supplement the vestibulo-ocular projections from the MVN. A subgroup of neurons in the rostral LVN gives rise to the ascending

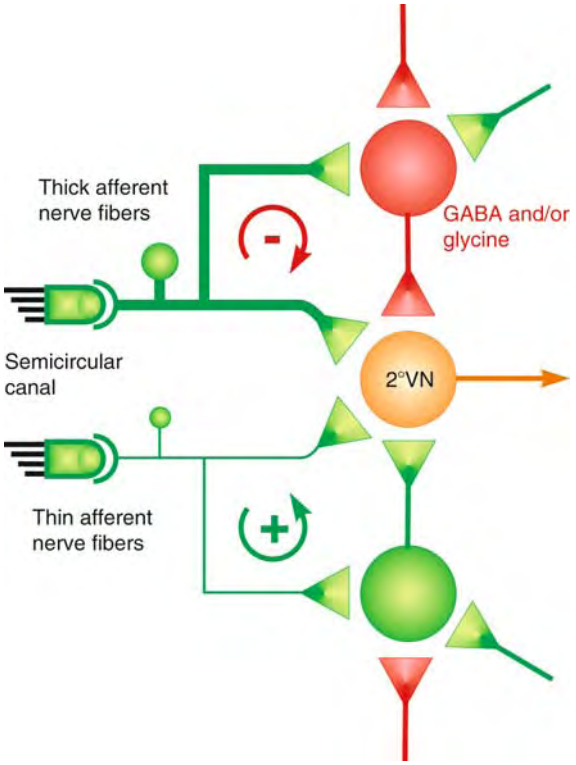
tract of Deiter's (ATD), which relays horizontal canal signals and excites ipsilateral medial rectus motoneurons (MR; Fig. 1). The SVN contains two inhibitory and one excitatory subgroup that mediate anterior and posterior vertical canal-related signals, respectively, and project to ipsi- (IR, SR, IO, SO) and contralateral (IO and SR) oculomotor/trochlear motoneurons controlling vertical and oblique eye muscles (Fig. 1).

Additional neuronal subgroups in the MVN, LVN and descending vestibular nucleus (DVN) project to spinal targets and transmit semicircular canal and macula signals for postural control (Fig. 1). Vestibular signals to the spinal cord are relayed by two major pathways, the uncrossed lateral vestibulo-spinal tract (LVST) that projects to all spinal levels and the bilateral medial vestibulo-spinal tract (MVST) that projects mainly to the cervical spinal cord. The LVST originates mainly from the LVN, the DVN and the magnocellular part of the MVN and the MVST largely from the MVN (Fig. 2). In different species a variable number of vestibular neurons have axon collaterals that project to both spinal and to extraocular motor nuclei, thus coupling the activation of motor targets for gaze and posture control. Both excitatory and inhibitory neuronal populations contribute to the different fiber tracts.

The pharmacological organization of the reciprocal inhibitory and excitatory canal connections is remarkably conserved among vertebrates [8,10]. All excitatory synapses in the VOR pathway use glutamate as a transmitter and activate NMDA as well as non-NMDA glutamate receptors. In contrast, inhibitory vestibulo-ocular connections use different transmitters for vertical/oblique as opposed to horizontal extraocular motoneurons, respectively. The vestibular inhibition of vertical and oblique extraocular motoneurons in the oculomotor and trochlear nucleus is mediated by GABA and an activation of postsynaptic $GABA_A$ receptors, whereas the vestibular inhibition of abducens motoneurons and internuclear neurons is mediated by glycine. This differential profile is most probably due to the different developmental origins of the different pools of inhibitory vestibulo-ocular neurons from particular hindbrain segments in which either GABAergic or glycinergic neurons predominate in the vestibular nuclear area [1].

## Control of Vestibular Neuron Activity by Inhibition

Sensory signal processing in second-order vestibular neurons is modified by several inhibitory side-loops that are hypothesized to control different response parameters such as gain (cerebellar loop), dynamics (uncrossed vestibular loop) and response sensitivity (commissural loop) [8]. The presence of these multiple control loops in different vertebrate species, suggests that these connections are a fundamental organizational property of vestibular signal processing.



**Functional and Neurochemical Organization of Vestibulo-Motor Pathways. Figure 2** Schematic diagram illustrating the interaction between the disynaptic inhibitory (*red*) and the disynaptic excitatory (*green*) feed-forward side-loop with the monosynaptic semicircular canal excitation in second-order vestibular neurons. The differential activation of the inhibitory (–) and excitatory (+) side-loop by afferent nerve fibers with different response dynamics (*marked here as thick and thin fibers*) and their graded control (additional excitatory and inhibitory synapses on these neurons) allows an adjustment and fine tuning of the response dynamics of second-order vestibular neurons.

## Uncrossed Vestibular Side-Loops

Monosynaptic EPSPs in second-order vestibular neurons evoked by electrical stimulation of vestibular nerve afferent fibers are superimposed by additional inhibitory and excitatory responses with a disynaptic onset (Fig. 2) [4,8].

Both response components are relayed by neurons located in the ipsilateral vestibular nuclei that are either local vestibular interneurons or projection neurons with local axon collaterals. The disynaptic IPSPs are mediated by GABA, by glycine or by a combination of GABA and glycine. In frog, both the disynaptic EPSPs as well as the IPSPs originate from the same semicircular canal that gives rise to the monosynaptic excitation (Fig. 2). More specifically, the vestibular

F

neurons mediating a disynaptic inhibition are activated predominantly by thicker vestibular nerve afferent fibers, whereas those mediating a disynaptic excitation are activated by vestibular nerve afferent fibers with intermediate or thin diameters (Fig. 2). This neuronal arrangement is highly suitable for a feed-forward control of the response dynamics of second-order vestibular projection neurons without changing their spatial response vector.

With this uncrossed vestibular side-loop, thick afferent nerve fiber-mediated responses of second-order vestibular neurons can be disfacilitated, thus allowing adjustment of the response dynamics in these neurons (Fig. 2). The inhibitory control is based on both cellular and network mechanisms. On a cellular level, the disynaptic IPSPs from thick vestibular nerve afferent fibers will restrict the monosynaptic, voltage-dependent activation of the NMDA receptors mediated by these fibers. On a network level, the disynaptic inhibition will reduce the phasic response components mediated by the thick vestibular nerve afferent fibers. This modifiable control loop involving excitatory and inhibitory neurotransmission within the vestibular nucleus seems to be a basic vertebrate design, appropriate for a graded control of tonic and phasic components and suitable for a continuous and adaptive fine-tuning of response dynamics.

### Commissural Vestibular Connections

Vestibular commissural fibers mediating semicircular canal and macular signals cross the brainstem and interconnect central vestibular neurons on both sides [3,6]. In the case of semicircular canal signals, brainstem vestibular commissural fibers relay a canal plane-specific inhibition that is supplemented to a variable degree by spatially unspecific, commissural excitatory connections [8]. The inhibitory canal-commissural pathway connects vestibular neurons related to co-planar semicircular canal pairs on both sides of the brainstem. This connectivity is present in all vertebrates and thus represents a phylogenetically conserved property of the vestibular network. The commissural inhibition is mediated either by an inhibitory neuron that crosses the brainstem (disynaptic) or by an inhibitory neuron on the contralateral side that is activated by an excitatory neuron that crosses the brainstem (trisynaptic) [3]. Whether the vestibular commissural inhibition is mediated by GABA as well as by glycine or only by GABA is still unclear. Functionally, the commissural inhibitory system increases the sensitivity of vestibular neurons for angular acceleration with respect to the activity of canal nerve afferent fibers by a factor of about two. During vestibular compensation vestibular commissural inhibition has been proposed to be modified by cellular mechanisms involving changes in the functional efficacy of GABA and glycine receptors, so as to re-balance the activity of vestibular neurons on the two sides of the brainstem [9].

### Cerebellar Inhibitory Loop

Purkinje cells exert a GABAergic inhibition onto second-order vestibular neurons. Depending on the somatotopic location of the Purkinje cells in the cerebellum, this inhibition is mediated onto vestibulo-spinal or onto vestibulo-ocular neurons and is thus involved in the control of gaze as well as posture. In mammals, the flocculus has been shown to be particularly important for the control of specific subsets of VOR neurons and is implicated in adaptive control of the gain of the VOR. Moreover, floccular target neurons in the vestibular nuclei form a distinct subpopulation of type B vestibular neurons and are thought to play an important role in VOR plasticity [7,9]. Neuroactive steroids, as well as histamine have been shown to modulate cerebellar inhibition of vestibular nucleus neurons.

## Definition

A technique that records neural activity in many places in parallel, generally using light. Activity patterns can be visualized as images that reflect both anatomy in space and activity in time. Subtechniques include optical imaging (e.g. using intrinsic signals or voltage sensitive dyes), calcium imaging (using fluorescent dyes, ►ratiometric dyes, measure of ►deltaF/F), and functional magnetic resonance tomography (fMRT), among others.

## Characteristics

### Imaging Techniques

Brains consist of a high number of neurons that are interconnected and work as an ensemble. For example, the human brain has 10 billion neurons, and even the brain of a humble honeybee has 1 million neurons. Understanding their function requires recording from these neurons under physiologically controlled conditions. Single-cell electrophysiology gives information about neural activity in individual cells as a whole. Functional imaging techniques have been developed in order to record neural activity both in space and in time simultaneously. Space can include the analysis of activity along the branching pattern of a single neuron, or across large neuron populations. As a consequence, functional imaging has gained an important role in understanding the relationship between the morphology of neurons and their function, and in understanding combinatorial information processing in the brain.

In the following, I will review the major techniques that have been used in recent years, first from the point of view of the signal that is measured (intrinsic signals, dyes, reporter proteins), next from the point of view of the neurons measured (from single neurons to entire brains), including examples from the analysis of olfactory systems.

#### *Optical Imaging: Intrinsic Signals*

Neurons change their light properties when they are active, though the exact physics of this phenomenon is as yet unknown. While these changes were used in the very early days of optical imaging, today intrinsic signals are used mostly for *in vivo* studies of mammalian brains. Here, the main signal derives from blood, which changes its color in its transition from the oxygenated to the deoxygenated state. Therefore, the brain is illuminated with a red light, and the reflectance is measured. While the skull has to be removed in order to gain optical access to the brain in most cases, in small mammals, notably rodents, successful measurements have been done through the thinned skull bone layer. The advantage of this technique is its independence from dyes, and therefore the brain is measured with very little interference. However, the signal is only an indirect measure of neural activity, since it consists of a blood oxygenation response, and therefore it is relatively slow and has a limited spatial resolution. Hence the strength of this technique to map spatial activity patterns.

#### *Optical Imaging: Voltage Sensitive Dyes*

Much faster measurements are possible with voltage sensitive dyes (VSD), and when only neurons are stained with these dyes, the signal is exquisitely neuronal. VSDs are generally fluorescent dyes, with a charged chromophore attached to a lipophilic moiety that integrates into the cell membrane. As the voltage across the membrane changes, the charged chromophore moves with respect to the membrane, and the fluorescent spectrum shifts. When using a ►fluorescence excitation and emission setting that hits the dye's maximum, a shift in fluorescent spectrum of the dye results in a fluorescence decrease. This decrease is proportional to the membrane's voltage change. VSDs are generally fast, which is their greatest advantage. In suitable preparations it is possible to resolve single spike events. However, changes in fluorescence are small, often resulting in a poor ►signal to noise ratio. Dyes can be applied by soaking the brain in it, or by selective staining (see below). Because optical access to the brain is necessary, these techniques are always invasive.

#### *Optical Imaging: Calcium Signals*

Most studies done with animals as opposed to humans have used calcium as an indicator for cellular activity. This has specific reasons: calcium is the ion that has the greatest concentration change when a neuron is active. Within cells, calcium concentration is in the range of 200 nm, while outside concentration can easily reach millimolar concentrations, giving a concentration difference of up to 10,000-fold. This enormous gradient is actively created by the cells with calcium pumps that keep intracellular concentration low, and is used for intracellular messaging: calcium plays an important role in many intracellular information cascades, ranging

from neurotransmitter release to second messenger cascades, including sensory transduction cascades. Most cells express voltage sensitive calcium channels, so that intracellular calcium concentration increases when the neuron depolarizes. However, although in most cases the correlation between calcium concentration and depolarization and/or spiking activity is very good, this relationship is not one-to-one, given that calcium fulfils many more tasks within the cell.

Calcium dyes are generally modified ►calcium chelators with a fluorescent chromophore attached to it. The calcium chelator has a predominance of negative charges that are compensated when the positive calcium ion is trapped in it. Thus, the fluorescence chromophore is modified, with a resulting change in fluorescent properties. In some dyes, such as *calcium green* or *fluo-4*, fluorescent intensity increases with increasing calcium concentration. In other dyes, such as *fura*, increase or decrease depend on the excitation wavelength. Specifically, in *fura* measurements, fluorescence with excitation light of 340 nm increases, and with excitation light of 380 nm it decreases (at approx. 360 nm there is an isosbestic point, i.e. a point where fluorescence is calcium-concentration independent).

### Optical Imaging: Other Dyes

There are a variety of other dyes to monitor cell activity, including dyes for ions such as chloride and potassium, pH-sensitive dyes, or more sophisticated variants that monitor transmitter vesicle release. It is beyond the scope of this chapter to list them all.

### Optical Imaging: Genetically Engineered Dyes

An area of fast and important growth is the development of genetically engineered reporter proteins. The basic concept is easy: a fluorescent protein is linked to another protein that is sensitive to the metabolic status of a cell in such a way that changes in metabolism result in fluorescent changes. Then, the gene for this artificial protein is inserted into an animal under the control of a cell-specific promotor creating a transgenic organism. As a result, a genetically defined population of cells will express the reporter gene, and measurements of these cells can be done with optical methods.

Take, as an example, the calcium sensitive G-CaMP. One component of this protein is a modified GFP-protein (GFP – green fluorescent protein – was the first of what is now a large family of proteins that are fluorescent. Several animals naturally express fluorescent proteins. GFP was isolated from the jellyfish *Aequorea victoria* that uses it together with a bioluminescent protein to produce light of controlled wavelength). The other component of G-CaMP is derived from the calcium-sensitive natural protein calmodulin. Thus, borrowing from natural proteins as if it were building blocks in a child's game, a new calcium-sensitive fluorescent protein was created (of course, the technical details make the process much more complex). Finally, in order to use these proteins for functional imaging, their genes have to be inserted into the genome under the control of a promotor. It is the choice of the promotor that will lead to expression in neurons rather than in other cells, or even in genetically defined specific populations of neurons, e.g. only receptor cells, or only inhibitory cells – in fact, any cell populations for which a specific promotor is known. Alternative approaches include a random gene expression using a gene-gun, where gold particles are coated with the genetic material, shot into the tissue, taken up by some but not all cells, and then expressed, resulting in a situation where some but not all cells are labeled with the reporter protein.

Once the cells of interest have been labeled, recording follows the same procedures as for synthetic dyes. Being fluorescent dyes, it is necessary to gain optical access to these neurons (e.g. by removing the skull in the case of in-vivo measurements), then an excitation light is shone on the neurons, and the fluorescent light is measured using a light sensitive device, e.g. a photomultiplier or a CCD-Camera.

Just as calcium sensitive proteins have been created from calcium-sensitive cell constituents, proteins sensitive to other cell properties have been and/or are being developed. These include probes for membrane potential, for pH value, for synaptic transmission, and for second messengers such as cAMP. A further development is to create probes that interfere with cellular events: here we leave functional imaging, and enter the realm of targeted functional manipulation.

### fMRT: BOLD Signal

An increasingly important technique in biomedical imaging measures the BOLD signal (Blood Oxygen Level Dependency) with fMRT (functional Magnetic Resonance Tomography). This is a technique that uses intrinsic signals (see above), but does not involve light. Rather, a strong magnetic field is applied as a pulse, and the magnetic relaxation is measured. The BOLD-signal is related to blood flow, and therefore also to neuronal activity. Just as for other intrinsic signals, this is an indirect measure of neuronal activity, and therefore intrinsically slow. Furthermore, the spatial resolution is limited by the strength of the magnetic fields used, and by the volume of blood affected by neural activity. Therefore, single cell analysis will never be possible with this technique. However, brain areas can be investigated. For example, in the olfactory system, the analysis of individual olfactory glomeruli is already possible. The greatest advantage of this technique is that the animals remain intact: no chirurgical manipulation is necessary, and no dye or contrast agent needs to be administered. As a consequence, fMRT gains increasing importance in studying brain activity in humans.

Most importantly, results from invasive experiments on animals can in many cases be verified for their relevance to the human system by using fMRT.

## Imaged Structures

Functional imaging studies play an important role in neuroscience research, because they allow measuring neuronal activity over time and space. However, the kind of results that can be obtained depend strongly on the technique used, and on the structures that are imaged. It is the combination of different staining techniques that is allowing scientist to study brain function just as putting together a jigsaw-puzzle.

### *Single Neurons: Selective Loadings*

The unit of brain activity is the individual neuron. After loading a single neuron with dye using a microelectrode (effectively a hollow glass tube with a microscopic tip that penetrates into the cell), functional imaging allows to analyze how the neuron itself is substructured into functional domains. A textbook neuron consists of an input branch (the dendrites) and an output site (the axon), joined by the cell body. Using functional imaging, these compartments can be characterized: their electrical and biochemical properties can be analyzed separately. For example, many cells have spines on their dendrites, small protuberances that are the sites of synaptic input. Imaging studies showed that each spine constitutes a compartment on its own, acting in concert with the rest of the cell, but independently to a great extent. In more complex neurons, where the input and the output regions are not separated so clearly, functional imaging is used to map input and output sites, and characterize their properties. For example, local neurons within the olfactory bulb create microcircuits mediating activity of neighboring mitral cell dendrites. Thus, these neurons do not really act as a unit, but themselves as a complex of many, interconnected units.

### *Neuron Populations: Selective Staining*

Neural processing occurs in neural networks of interconnected units and networks. By selectively staining particular populations of neurons it is possible to follow neural processing along its steps. For example, in the olfactory system odor coding can be followed from receptor neurons, to populations of local neurons in the first olfactory epithelium (the mammalian olfactory bulb, or the insect antennal lobe), to higher order brain centers, including the mammalian cortex. Such studies are only possible by selectively staining specific populations of neurons, because in any one brain area there are many neurons that contribute in different ways to processing in that area. Techniques for selective staining include filling many neurons by injecting a bolus of highly concentrated dye or dye crystals into a brain region, with the result that many neurons in that region will pick up the dye. As a result, in other areas of the brain neurons will not be stained, unless they have a projection (e.g. an axon) into the treated area – with other words, here the staining is selective for those neurons that have specific connections to the injected area.

### *Neuron Populations: Genetic Labeling*

Many neurons that work in groups are not easy to label by dye injection. For example, in all brain regions there are local neurons that do not project to other areas. These neurons cannot be stained by dye injection without incurring into unspecific staining of other neuron populations. In many cases, however, it has been possible to find genetic promotors that are specific to local neurons, and to use these for expressing reporter genes in these neurons. The fruit fly *Drosophila melanogaster*, for example, is among the animals with the best genetic tractability. Here, it was possible to characterize at least three distinct populations of local neurons in the first olfactory processing area, the antennal lobe, and to show that they all have a distinct role in odor processing, and different functional properties.

As another example, many olfactory sensory cells express the same olfactory receptors, and consequently respond to the same odors. This is a property that derives from their genetic instruction, and has been used to create animals were only neurons expressing a particular receptor type express a reporter gene. Such preparations can be used to characterize the molecular response profiles of olfactory receptors, i.e. the entire description of the odors that bind to a particular receptor.

### *Neuron Populations: Non-Selective Staining*

Non-selective stainings are those that make no distinction of different cell types. One technique is to bath the brain tissue in dissolved dye, and to allow all neurons to incorporate the dye. These studies do not allow dissecting the cellular steps of neural processing. However, they allow investigating the spatial arrangement of information processing in the brain. For example, the olfactory system creates a functional map of activated glomeruli in the antennal lobe (insects) or the olfactory bulb (mammals). These maps can be directly measured using non-selective staining techniques. Such measurements have revealed the basic principles of olfactory coding: a combinatorial scheme, where each odor evokes activity not in one, but in many glomeruli, and the information about the odor resides not in any single glomerulus, but in its combinatorial arrangement. Thus, a single glomerulus will contribute to the code of very different odors, and the task of the brain is to extract the olfactory significance in each combinatorial pattern.

## Functional Magnetic Resonance Imaging (fMRI)

### Definition

Functional magnetic resonance imaging (fMRI) is used to monitor hemodynamic events related to changes in neuronal activation in the brain. This is accomplished by a sensitization to the effect from microscopic inhomogenieties in the magnetic field caused by the magnetic properties of hemoglobin.

►Magnetic Resonance Imaging

## Functional Muscle Synergies

## Functional Neuroimaging Methods

### Definition

Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are two main functional imaging techniques used to study brainbehavior relationships. PET techniques involve intravenously injecting different short-lived radioactive agents and then imaging people in a specialized detector system to examine biochemical or physiological processes involved in cerebral blood flow and metabolism.

FMRI techniques produce images of brain activation by detecting the indirect effects of neural activity on local blood volume, flow, and oxygenation.

The most common fMRI technique involves blood oxygen dependent-level contrast, which detects endogenous changes in local concentrations of paramagnetic deoxyhemoglobin associated with local increases/decreases in neural activity.

►Functional Magnetic Resonance Imaging (fMRI)
►Positron Emission Tomography (PET)

## Functional Role

### Definition

Specifies the relation between inputs, outputs, and internal roles of a system; it is used to characterize states, particularly mental states in the philosophy of mind.

►Emergence

## Functional Stretch Reflex

### Definition

Term referring to stretch evoked increases in EMG in the triceps surae muscles. These responses occur at latencies similar to those of volitional responses to an unexpected perturbation, so it is inappropriate to consider these responses to be long loop (long-latency) reflexes.

►Electric Fish
►Long Loop Reflexes

## Functionalism

### Definition

The view that the physical realization of a component is not its essence. Rather, what individuates a functional component of a special type is characterized in terms of its role in relating inputs to outputs and in terms of its relations to other (functional) components.

►Causality
►Mental Models
►Reductionism (Anti-Reductionism, Reductive Explanation)

## Fungiform Papillae

### Definition

(Papilla: small protuberance, Fungus: mushroom) These are small "mushroom shaped" structures of diameter up to 15 mm protruding slightly from the dorsal surface of the tongue. Fungiform papillae are disseminated between the filiform papillae all over the anterior two-third of the tongue with a higher density towards the tip. They can contain up to 20 taste buds (human) from which the pores emerge at the top however it is estimated that up to 60% of fungiform papillae lack taste buds. The average number of fungiform papillae on the tongue is around 200 for a density of taste buds at the tip of the tongue of about 150 taste buds/cm2.

►Taste

## Fusiform Cells

### Definition

Principal cell type in the dorsal cochlear nucleus.

►Cochlear Nucleus

## Fusiform Face Area

### Definition

►Face Processing in Different Brain Areas

## Fusimotor Neurons

### Definition

Small diameter motoneurons that innervate the intrafusal fibers of the muscle spindles. Firing of fusimotor neurons causes the ends of the intrafusal fibers to contract. This stretches their central regions and stimulates the spindle afferent fibers.

►Proprioception: Roles of Muscle Receptors

## Fusimotor Reflexes

### Definition

Responses of fusimotor neurons to sensory inputs.

Fusimotor neurons control the background firing rate and stretch-sensitivity of muscle spindle afferents by activating intrafusal muscle fibers.

## Fusion Pore

### Definition

The initial connection between the lumen of a vesicle and the extracellular space during the process of exocytosis.

►Non-synaptic Release

## F-Wave Method

### Definition

A method used to estimate the peripheral conduction time from spinal motoneurons to muscle(s). It is based

on electrical stimulation of the peripheral nerve with supra-maximal intensity and recording evoked muscle potentials. It is calculated as (F + M-1)/2, where F is the shortest F-wave latency, M the onset of the direct muscle response and 1 ms allowed for neuron activation.

►Transcranial Magnetic Stimulation

# Fyn

## Definition

A non-receptor tyrosine cytoplasmic kinase that can transfer a phosphate group from ATP to tyrosine residues of target proteins.

## G Protein-activated Potassium Channels

### Definition

A family of inwardly-rectifying potassium channels that are activated by the βγ subunits of G proteins of the Gi/o family.

►Neuronal Potassium Channels

Metabotropic Receptor

### Definition

►G protein-coupled receptors (►GPCR) constitute the largest family of cell-surface receptors. GPCRs share a common architecture of seven membrane-spanning α-helices and transduce the messages mediated by a diverse range of signaling molecules, including acetylcholine, adrenaline, dopamine, serotonin, glutamic acid, γ aminobutyric acid, proton, $Ca^{2+}$, adenosine, ATP, prostaglandins and other lipids, opioids and other peptides, and various proteins, as well as various kinds of odorants and taste substances, leading to alterations of cellular function. Targets for 30–60% of medicines and opsins (receptors for light) are also GPCRs. This superfamily of receptors contains approximately 900 members in the mammalian genome. Moreover, GPCRs are roughly estimated to account for 4 and 1% of the total genes in the genomes of *Caenorhabditis elegance* and *Drosophila melanogaster*, respectively, demonstrating that these receptors have been well conserved throughout evolution.

Upon binding of an extracellular ligand, GPCR is activated, and the activated receptor facilitates the release of GDP from heterotrimeric GTP-binding regulatory proteins (G proteins; Gα/Gβγ), resulting in the binding of GTP to Gα/Gβγ, followed by its dissociation into GTP-bound Gα (Gα-GTP) and Gβγ. Gα-GTP and Gβγ then activate or inhibit several effector proteins such as adenylyl cyclases, phospholipase Cβs, phosphodiesterases, phosphoinositide 3-kinases, and ion channels, resulting in a variety of cellular responses. Upon GTP hydrolysis, Gα-GDP and Gβγ reassociate into inactive G protein trimer, terminating activation of effector proteins. Gα itself has GTPase activity, which is stimulated by effectors themselves or specific GTPase-activating proteins referred to as regulators of G protein signaling (RGS) proteins. Thus, G proteins generally mediate GPCR signaling, although several reports have claimed recently that some GPCRs can mediate the signal by interacting with proteins other than G proteins, such as arrestin [1].

### Characteristics

#### Classification of GPCRs

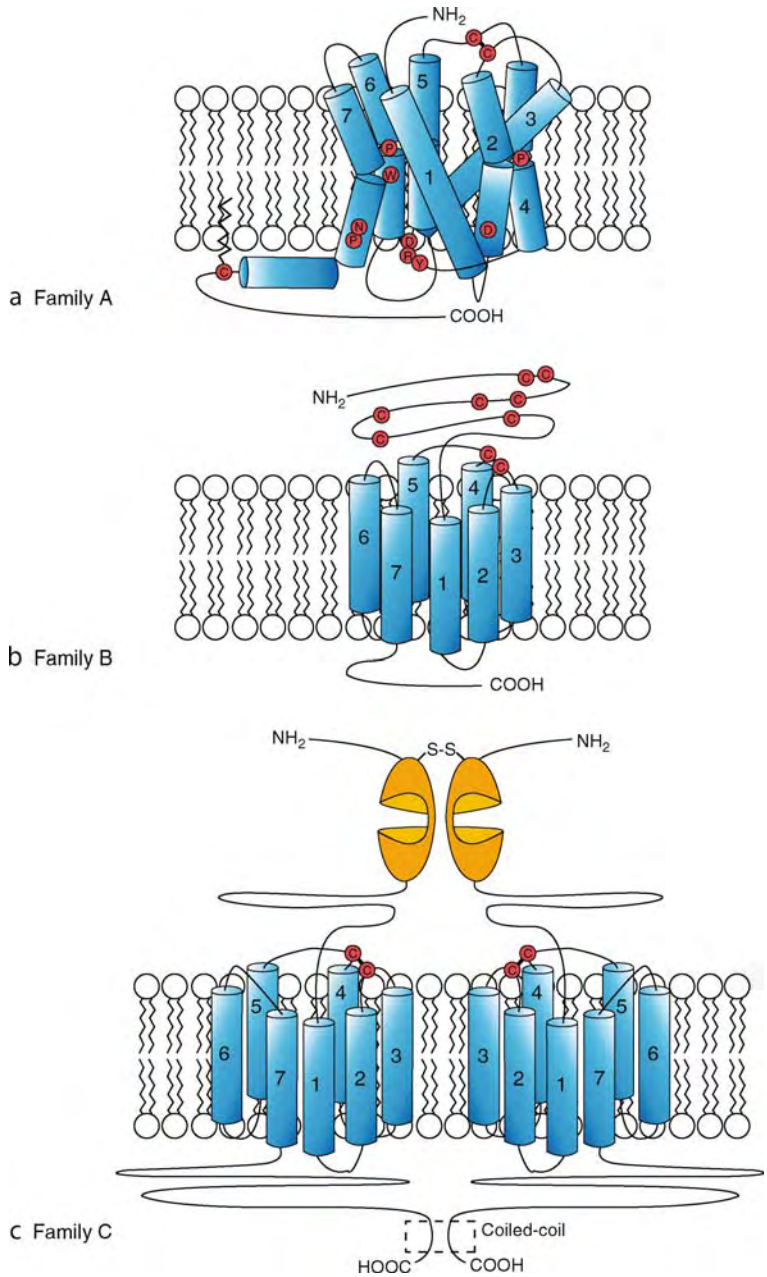
The superfamily of GPCRs can be divided into several subfamilies based on sequence similarities. GPCRs in one subfamily do not share significant sequence similarity with those in another subfamily, although they all have a central core domain made up of seven transmembrane domains (TM1-TM7). TM1-TM7 are α helices connected by three extracellular loops (e1-e3) and three intracellular loops (i1-i3). Aside from sequence variations, GPCRs differ in the length and function of their N-terminal extracellular domain, their C-terminal intracellular domain and their intracellular loops.

In one of the most frequently used classification, GPCRs are grouped into families A, B, C, D, E, and F [2]. Mammalian GPCRs are found only in family A, B and C.

##### *Family A (Rhodopsin Family)*

This family includes the most extensively studied GPCRs, such as rhodopsin, adrenergic receptors, and muscarinic acetylcholine receptors, and the majority of GPCRs identified to date. Small ligands like catecholamines bind in a cavity formed by seven TMs, while short peptides interact with the extracellular loops and

the N-terminal domain as well as with TMs. Receptors in the Family A are characterized by some highly conserved amino acids (Fig. 1a). For instance, an Asp in TM2 is essential for coupling to G proteins, and is known to form a hydrogen bond with the side chain of a conserved Asn in TM1 and Ala in TM7 in rhodopsin. The Asp-Arg-Tyr (DRY), Glu-Arg-Tyr (ERY), or Glu-Arg-Tryp (ERW) sequences at the N-terminus of i2 are highly conserved and are directly involved in G protein activation. Furthermore, a disulphide bridge



**G Protein-coupled Receptor. Figure 1** Structural models of G protein-coupled receptor (GPCR) families. (a) Familiy A of GPCRs such as rhodopsin, muscarinic acetylcholine receptors, and adrenergic receptors. The GPCR structure is depicted according to the structure of rhodopsin. Cysteine and other residues common to family A GPCRs are shown with *red circle*. (b) Familiy B of GPCRs that are represented by secretin receptor. (c) Family C of GPCRs such as metabotropic glutamate receptors and $GABA_B$ receptor. As no structural information is available for TM regions of GPCRs in family B and C, 7 TMs are shown with *straight rods*. Coiled-coil structure is formed at the C-terminal tail in $GABA_B$ receptor (*enclosed in broken line*).

that connects e1 and e2 is conserved in most GPCRs in this family (Fig. 1a). Most of these receptors have the palmitoylated cysteine in the C-terminal tail, which serves as the membrane anchor (Fig. 1a).

### *Family B (Secretin Receptor Family)*

This family includes receptors for secretin, calcitonin, parathyroid hormone, glucagon, corticotropin-releasing factor, vasoactive intestinal peptide, and pituitary adenylyl cyclase-activating protein. The secretin receptor was the first one cloned among those in this family. The ligand-binding site of these receptors is mostly composed of extracellular domains, although TMs may be partly involved. GPCRs in this family are characterized by a relatively long N-terminus, which contains several cysteines that form a network of disulphide bridges (Fig. 1b). Conserved residues and motifs of the family B receptors are different from those of the family A receptors, and the palmitoylation site is missing in the former.

### *Family C (Glutamate Receptor Family)*

Family C contains at least eight metabotropic glutamate receptors (mGluRs), calcium-sensing receptors, and $GABA_B$ (γ aminobutyric acid, type B) receptors. These receptors are characterized by long N- and C-terminal tails (Fig. 1c). The ligand recognition domain in the mGluR is found in the N-terminus (Fig. 1c), which has been shown to form a disulphide-linked dimer by X-ray crystallographic analysis. The structure appears to resemble a "Venus fly trap," which could open and close with the agonist bound inside. Receptors in this family do not have features common to those in family A and B receptors, except for two cystine residues in e1 and e2 that are supposed to form a disulphide bridge (Fig. 1c). A unique feature of family C receptors is that i3 is short and highly conserved.

Family D represents the fungal pheromone A receptors.

Family E contains the cAMP (►cAMP system) receptors of *Dictyostelium discoideum*.

Family F contains archaebacterial opsins.

## Structure of GPCRs

In 2000, Okada et al. succeeded in crystallizing bovine rhodopsin, and reported its three-dimensional structure at the resolution of 2.8 Å [3]. This provided direct evidence that seven hydrophobic regions (20–25 amino acid residues each) form α helices and transverse the membrane, and the N- and C-terminal tails are located in the outside and inside of cells, respectively. Although the mass of TM bundles for rhodopsin does not differ significantly from the mass of those for bacterial rhodopsin, the arrangement of seven helices is different. As expected from previous electron diffraction studies of rhodopsin, TM1, 4, 6, and 7 are bent at proline residues, although the bending is not apparent in TM1 and is present at the extracellular end in TM4 (Fig. 1a). Proline residues are conserved in all members of family A GPCRs and are thought to be critical for their functions. TM5 is almost straight in spite of the presence of a proline residue in the middle, whereas TM2 is bent at the Gly-Gly doublet in the middle. TM4 and 7 are shorter than the other TMs. Moreover, the eighth α helix was found to be present parallel to the membrane surface, between the end of TM7 and the palmitoylated cysteine residues in the C-terminal region (Fig. 1a). The highly conserved E-R-Y sequence at the N-terminus of i2 was found to be surrounded by hydrophobic residues from TM2, i2, TM5, and TM6. This region is likely to form a contact surface with G proteins. Retinal forms a Shiff base with $Lys^{296}$ of TM7 (retinal-CHO + $NH_3^+$-Lys = retinal-CH = $NH^+$-Lys). This protonated Schiff base interacts with the carboxyl anion of $Glu^{113}$ in TM3. A disulphide bridge between e1 and e2 was confirmed in rhodopsin and is supposed to be present in GPCRs of family A. The N-terminal domain of rhodopsin contains two anti-parallel β sheets that are located just below the e2, which also contains two anti-parallel β sheets. These four β sheets, as well as most of e2, appear to make an extracellular plug, which might serve to prevent the all-trans retinal from projecting out of the pocket during activation. It remains to be determined if such plugs are present in other GPCRs of family A. Recently, Okada et al. succeeded in improving the quality of rhodopsin crystals, and a higher resolution (2.2 Å) structure was reported. This revealed a complete structure of a cytoplasmic region of rhodopsin, which was missing in the previous structure.

The structure of rhodopsin is so far the one and only model for GPCRs. The determined structure, however, is that of rhodopsin in its inactive state, and this structure might not be an appropriate model for the active state of GPCRs and for the design of specific drugs. Several researchers have used this structure as a starting point to make a structural model for the active state of rhodopsin and other GPCRs in family A.

## Dimerization of GPCRs

For many years, GPCR and G protein were supposed to couple with one to one stoichiometry. The growing body of evidence, however, has suggested the dimerization or oligomerization of GPCRs. In the following, we refer to this as dimer for simplicity, although some might be tetramer or other oligomers.

The first convincing evidence came from studies on $GABA_B$ receptors. Heterodimerization of $GABA_B$ receptor subunits, $GABA_BR1$ and $GABA_BR2$, was demonstrated to be indispensable for cell surface expression and their functional coupling with G proteins. The $GABA_BR1$ is retained in the endoplasmic reticulum through a C-terminal retention motif, and can be

translocated into the cell surface only after interaction with $GABA_BR2$ through their C-terminal coiled-coil α helical structures. It has been suggested that each subunit of the $GABA_BR1/R2$ heterodimer share the respective role, the ligand binding activity by R1 and the G protein activation by R2. In addition, some taste receptors with the long N-terminus have been shown to form heterodimers with high affinity for amino acids and other substances. Furthermore, the tertiary structure of the extracellular domain of mGluR1a was determined by X-ray crystallography, demonstrating that they form a constitutive dimer. These results indicate that GPCRs in family C form the dimer.

Besides GPCRs in family C, a number of reports have indicated the functional significance of dimerization of GPCRs in family A. One of the striking examples is the change in pharmacological properties of δ- and κ-opioid receptors. These receptors showed a high affinity for their respective selective ligands when expressed alone, but did have a very low affinity for them when expressed together. When a combination of two ligands was applied to cells that express both receptors, however, both receptors exhibited a high affinity for either of the ligands. This result indicates that the two receptors form a heterodimer that binds two ligands in a highly positive cooperative manner. Another example is chimeric receptors between the α2 adrenergic receptor (α2AR) and $M_3$ muscarinic receptor ($M_3$), which are composed of the first five TMs of one receptor and the last two TMs of the other receptor. Neither chimera, α2(TM1–5)·$M_3$(TM5,6) or $M_3$(TM1–5)· α2 (TM5,6), binds ligands nor activates G protein when expressed alone, but the binding activity for both α2AR and $M_3$ agonists and the G protein-activating activity are recovered when both chimeras are co-expressed. This result suggests that the two chimeras form the dimer, in which the ligand binding activity is retained complementarily by TM1–5 from one receptor and TM6,7 from the other. A number of other receptors have also been suggested to form heterodimers by analysis of ligand binding characteristics or of downstream signaling. In addition, other lines of evidence have suggested that dimerization is necessary for receptors to be translocated from the endoplasmic reticulum to the cell surface, and that an agonist for one receptor facilitates the internalization of the other receptor, or the agonist-induced internalization of one receptor is inhibited by coexpression of the other receptor (see review by Terrillon and Bouvier [4]). Some of these phenomena may be artifacts derived from high-level expression of receptors in the heterologous cell system. In fact, the β2 adrenergic receptor is reported to form a heterodimer with δ-opioid receptor only when expressed at a high level. On the other hand, some reports have shown that the synergistic binding or signaling between two types of receptors have been observed in native tissues as well as in the heterologous expression system.

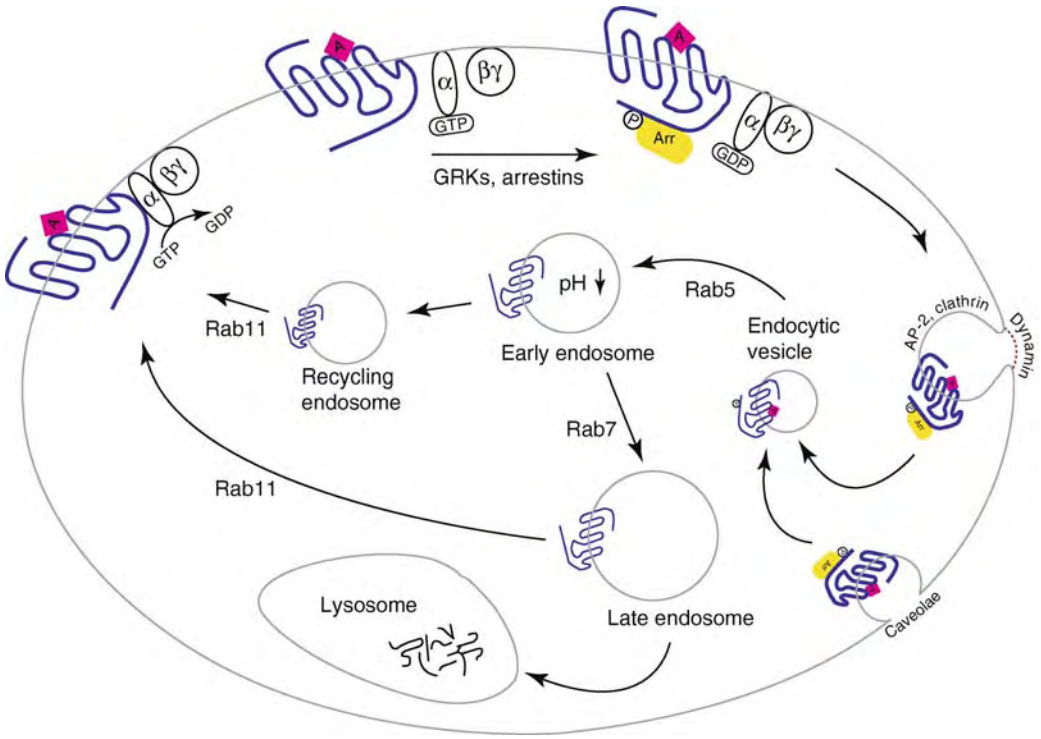
Interestingly, rhodopsin has been reported to exist as homodimers in dark-adapted retinal membranes based on observation by atomic force microscopy [5]: it should be noted that critical comment was also made on the possibility for artificial segregation of rhodopsin from lipid layers during the sample preparation [6]. Recently, Baneres et al. [7] showed, by using reconstitution of solubilized receptors, G proteins and chemical cross-linking, that leukotriene B4 receptors form a dimer in the presence of leukotriene B4 and that the dimer interacts with one heterotrimeric G protein, forming a pentamer complex $(B4\ Receptor)_2/Gi2\alpha/G\beta1\gamma2$. These results indicate that GPCRs may form homodimers as well as heterodimers, raising questions as to whether GPCRs are intrinsically dimers and if dimerization of GPCRs is prerequisite for their function. In this context, it is interesting to note that solubilized rhodopsin may exist either as a monomer or a dimer, depending on detergent concentrations, and that the monomeric rhodopsin appears to interact with and activate G protein [8]. If GPCRs can exist as either monomers or dimers on the cell surface, the question is raised as to what is the physiological function for GPCR to be a dimer in native tissues (see reviews Bouvie [4], Milligan [9]).

Some GPCRs have been reported to form dimers with other proteins. For example, calcitonin receptor-like receptor interacts with a protein called RAMP (receptor-activity-modifying protein) that has a single TM domain. The dopamine D5 receptor interacts with the C-terminal domain of $GABA_A$ ionotropic receptor, which is a member of the ligand-gated channels.

## Desensitization of GPCRs

Desensitization of GPCRs refers to a progressive attenuation of the effector activity and the loss of the physiological response, despite the continued presence of agonist stimulation. Two types of desensitization, homologous and heterologous, have been described. Both desensitizations are initiated by activation of GPCRs, but only agonist-bound GPCRs are desensitized in homologous desensitization, whilst any GPCRs may be desensitized in heterologous desensitization. Desensitization is generally thought to occur in three phases. The most rapid phase (seconds to minutes) involves uncoupling of the receptors from its G proteins, which is induced by agonist-stimulated GPCR phosphorylation (Fig. 2; [10]).

Sequestration/internalization is the second phase that commonly occurs with a slightly slower time course. In the third phase, internalized receptors can be recycled back to the cell surface (receptor recycling/resensitization) for further duty or targeted to lysosomes for degradation (down-regulation; Fig. 2). The extent to which each of these phases is responsible for desensitization depends on the types of receptors or cells expressing receptors.



**G Protein-coupled Receptor. Figure 2** A model for internalization and recycling of GPCRs. Some GPCRs internalize in clathrin-mediated pathway that is dependent on phosphorylation of C-terminal tail or i3 by GRKs and the subsequent binding with arrestins, whereas some other GPCRs internalize in caveolae-mediated pathway. Some GPCRs can be recycled back to the cell surface for further obligation. A agonist; Arr arrestins; Rab small molecular weight GTP-binding protein.

In heterologous desensitization, second messenger-dependent kinases [protein kinase C (PKC) and protein kinase A (PKA)] are supposed to be involved. These kinases are activated by second messengers that are increased by the action of agonist-bound GPCR, but the substrates of these kinases may include not only the agonist-bound receptor, but also other receptors and other down-stream proteins. β2 Adrenergic receptors (β2ARs) are good substrates for PKA, and their phosphorylation on the i3 leads to an uncoupling from Gs. The PKA-mediated phosphorylation can increase β2AR coupling to Gi and promote MAP kinase cascade activation. It remains to be determined if this is a general mechanism applicable for other GPCRs. PKC-mediated heterologous desensitization has also been reported.

G protein-coupled receptor kinase (GRK)- and arrestin-mediated processes are involved in homologous desensitization of many GPCRs. GRKs can discriminate between inactive receptors and agonist-activated ones, partly because GRKs are activated by agonist-stimulated receptors including light-activated rhodopsin. Phosphorylation by GRKs occurs either in the C-terminal domain (β2AR and rhodopsin) or i3 (α2AR and muscarinic $M_2$). Phosphorylation does not necessarily mean uncoupling. After GRK-mediated phosphorylation of rhodopsin and β2AR, uncoupling occurs when arrestins bind to the phosphorylated receptors. The classical pathway for β2AR endocytosis involves its targeting to clathrin-coated pits, although it can also be targeted to caveolae, as are some other GPCRs (Fig. 2). The targeting to clathrin-coated pits means the binding of arrestin-bound receptors with several proteins such as AP-2 (adapter protein 2) and Src as well as with clathrin. The clathrin-coated vesicle containing the receptor complex is pinched off from the plasma membrane by action of dynamin, and the receptor is transferred to other vesicles referred to as endosomes. Receptors in endosomes are recycled back to the cell surface or translocated to lysosomes (Fig. 2). Recently, ubiquitination has been suggested to be involved in the down-regulation of GPCRs [10]. Recycling of some GPCRs appears to require specific recycling-signal sequences at their C-terminal regions, but the molecular mechanisms remain to be elucidated.

## G Proteins (Guanine Nucleotide Binding Proteins)

### Definition

A family of proteins that act as the principal intermediaries in the regulation of second messenger pathways by G protein-coupled receptors. Each G protein is made up of three distinct subunits, α, β and γ.

Upon binding of a G protein-coupled receptor by its ligand, G proteins switch from an inactive state bound to guanosine diphosphate to an active state bound to guanosine triphosphate. This results in the separation of the α subunit from the tightly bound βγ moiety and from the receptor. Both α and βγ are then available to regulate second messenger pathways. Termination of the signal occurs by hydrolysis of the guanosine triphosphate to guanosine diphosphate.

## GABA

### Definition

γ-Aminobutyric acid (GABA) is the major inhibitory transmitter in the adult brain. GABA is recognized as being part of the amino acid family of classical neurotransmitters. GABA is formed from L-glutamic acid and the reaction is catalyzed by glutamic acid decarboxylase (GAD). After synaptic release the actions of GABA are terminated by active reuptake into glia and not into the presynaptic terminal.

## $GABA_A$ Receptor

### Definition

A ligand-gated ion channel (ionotropic receptor) located on sub-synaptic neuronal membranes, and also extra-synaptically. The major inhibitory neurotransmitter in the brain, γ-aminobutyric acid (GABA), opens the receptor ion channel to allow the influx of anions (chloride ions). This hyperpolarizes the neuronal membrane, thus reducing the ability of excitatory inputs to the neuron to generate an action potential.

## Gain in Optokinetic System

### Definition

A measure of the performance of a system or behavior.

It is the ratio of the output of the system divided by the input to the system. For the optokinetic system, this is the angular velocity of the eye movements divided by the angular velocity of the optokinetic drum. If the optokinetic system produced eye velocity equal to the velocity of the drum, there would be no retinal slip, and the gain would be 1.0. But because some retinal slip is necessary to stimulate the optokinetic system, perfect tracking is not possible and the gain will always be less than one. Similarly, retinal slip in the opposite direction of the eye movements will force the optokinetic system to reduce the eye velocity, so gains greater than one are always short-lived.

►Rerinal Slip

## Gain Modulation (Gain Field)

### Definition

Modulation of a neuronal activity evoked by visual stimulation or related to the associated motor response, as a function of the direction of the visual axis. In most instances, the gain field exhibits a linear relationship between the neuronal discharge rate and eye position and has been assumed to result from a multiplicative (gain modulation) effect of eye position on the neuron's visual or motor sensitivity. The distribution over large neuronal populations of gain fields of visual responses has been thought to be the signature of a coordinate transformation from an initial retinal frame of reference to a head-centered frame of reference. Indeed, whereas the visual response of most neurons is retinotopically organized, the explicit encoding of visual target position in a head-centered frame of reference has been rarely found at the individual neuronal level. Thus, head-centered encoding of visual space is thought to derive from the combined activity of a large population of neurons with gain fields.

G

# Galectin-1

## Definition

Galectin-1, which was the first β-galactoside-binding animal lectin to be discovered, has a molecular weight of 14.5 kDa. Galectin-1's 134 amino acid sequence includes six cysteine residues and is highly conserved evolutionarily, especially between humans and rats/mice. Galectin-1 is expressed in many tissues. The expression of galectin-1 in the nervous system changes as development progresses: it is localized in central nervous system (CNS) as well as peripheral nervous system (PNS) during development and becomes restricted to the PNS with maturation. The β-galactoside- binding activity of galectin-1 is evident only in the presence of a reducing agent, and this lectin (carbohydrate- binding) activity plays a role in cell adhesion, cell proliferation, and apoptosis in various cell types. The molecular structure of galectin-1 is changed by oxidization under non-reducing conditions, resulting in the loss of the lectin activity. This oxidized form of galectin-1 promotes axonal regeneration in the PNS.

# GAL4/UAS Expression System

Margaret J. Sonnenfeld
Department of Cellular and Molecular Medicine, Faculty of Medicine, University of Ottawa, Ottawa, ON, Canada

## Synonyms

Bipartite GAL4/UAS expression system

## Definition

The GAL4/UAS system refers to the use of yeast proteins which interact to induce the expression of genes from any organism in a tissue and temporal-specific manner.

## Characteristics

### The GAL4/UAS System

There are many tools available when using the fruitfly, *Drosophila melanogaster*, a model organism highly amenable to genetic analysis. One particular tool is the GAL4/UAS system that allows for the expression of genes from any organism in a tissue and temporal-specific manner. This has led to the identification of conserved genes involved in apoptosis [1], tyrosine kinase signaling [2] and neurodegenerative diseases.

GAL4 is a yeast protein that regulates genes induced by galactose. GAL4 binds to 17 basepair sites referred to as the Upstream Activating Sequences (UAS) in order to activate the *GAL10* and *GAL1* target genes. In 1993, Brand and Perrimon used the ability of GAL4 to activate transcription from the UAS element in *Drosophila* to show its use in tissue and temporal control over expression of any gene. As shown in Fig. 1, GAL4 can be placed under control of any promoter to generate the tissue specificity driving expression of the gene of interest.

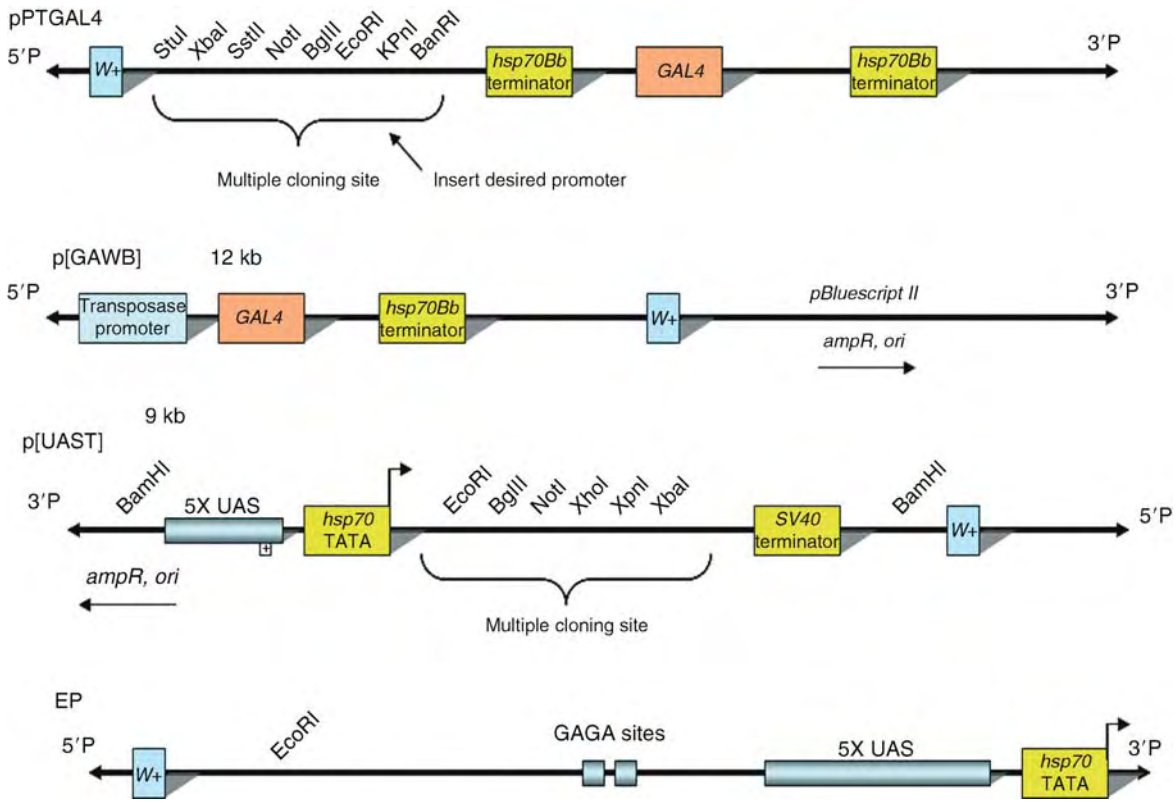
There are two vectors which allow one to clone in the chosen promoter to direct GAL4 expression, which include pGATB and pGATN. Chosen regulatory elements are placed upstream of GAL4 in pGATB and pGATN and then the fusions are excised and placed in a ►P element transformation vector. Alternatively, there is a P transformation vector, pPT-GAL, in which regulatory sequences can be placed directly upstream of GAL4 (Fig. 1). These vectors contain P element inverted repeats at the ends, designated 5′ P and 3′ P, which allow for integration into the genome to make transgenic flies.

Many GAL4 fly lines are housed in the Bloomington stock centre which can be accessed at http://flystocks.bio.indiana.edu/Browse/misc-browse/gal4.htm. An additional GAL4 vector, called pGAWB, acts as an ►enhancer trap because it contains P transposase promoter sequences upstream of GAL4 (Fig. 1). P transposase is the enzyme required to allow P elements to hop. This means that the GAL4 vector can insert into random genomic sites and come under control of a particular promoter. GAL4 strains driving expression in almost every tissue exist and their expression patterns can be verified by activating a UAS-*lacZ* fusion and staining with an antibody to the *lacZ* product, β-Galactosidase (β-Gal).

The plasmid pUAST is used for GAL4-inducible expression of transgenes in flies (Fig. 1) [3,4]. pUAST is a vector containing P-element sequences, the basal promoter *heat shock protein 70* (*hsp70*), a multiple cloning site, the SV40 small t intron and a polyadenylation signal. The multiple cloning site contains a range of convenient restriction sites to allow for directional cloning of the gene of interest.

Transgenic flies carrying GAL4 and pUAST constructs are generated by injecting early syncytial *Drosophila* embryos with the DNA which will incorporate into the genome by P element-mediated transformation [5]. Fly strains carrying GAL4 and UAS are transcriptionally inactive until combined avoiding any potential lethal effects as shown in Fig. 2.

Once combined, the progeny express the UAS fusion protein in the pattern activated by the promoter fused to GAL4 (Fig. 2). Illustrated in Fig. 2 is the ectopic expression of the *Drosophila* UAS-*D*ATR-X gene in a pair-rule pattern of seven stripes as driven by the *paired*-GAL4 driver.



**GAL4/UAS Expression System. Figure 1** Illustrations of various GAL4/UAS vectors. The top diagram shows a variation of the GAL4 vector called pPTGAL4. The second diagram shows an example of a GAL4 vector called p[GAWB] which allows for inserting the desired promoter to drive expression. The third diagram shows the pUAST vector and its size. The last diagram shows a variation of the pUAST vector called the EP (enhancer/promoter) element. Adapted from Duffy, 2002.

## Variations of the GAL4/UAS system

### *Enhancer-Promoter (EP)-transposable elements*

The EP element contains five tandem repeats of UAS sites (5XUAS) next to a basal promoter (hsp70) which are adjacent to the 3′ inverted repeat (3′ P) (Fig. 1). In the presence of transposase enzyme, this element can be randomly hopped around the genome to allow for expression of any gene under control of GAL4. When the EP element is inserted proximal to a gene and in the same orientation it results in ectopic expression of the gene under control of GAL4. When the EP element is inserted in the opposite orientation the gene will be inactivated. This technique is limited by the insertion specificity of the P element. Overexpression or downregulation of the predicted downstream gene under the control of GAL4 can be confirmed by in situ hybridization. EP elements can be obtained from the *Drosophila* Szeged Stock Centre and from Exelixis. The EP insertion position and orientation can be determined using the online database of FlyBase. The Berkeley *Drosophila* Genome Project (BDGP) has used EP elements to create insertion mutations in genes found throughout the genome. These insertions have been characterized and the adjacent gene identified.

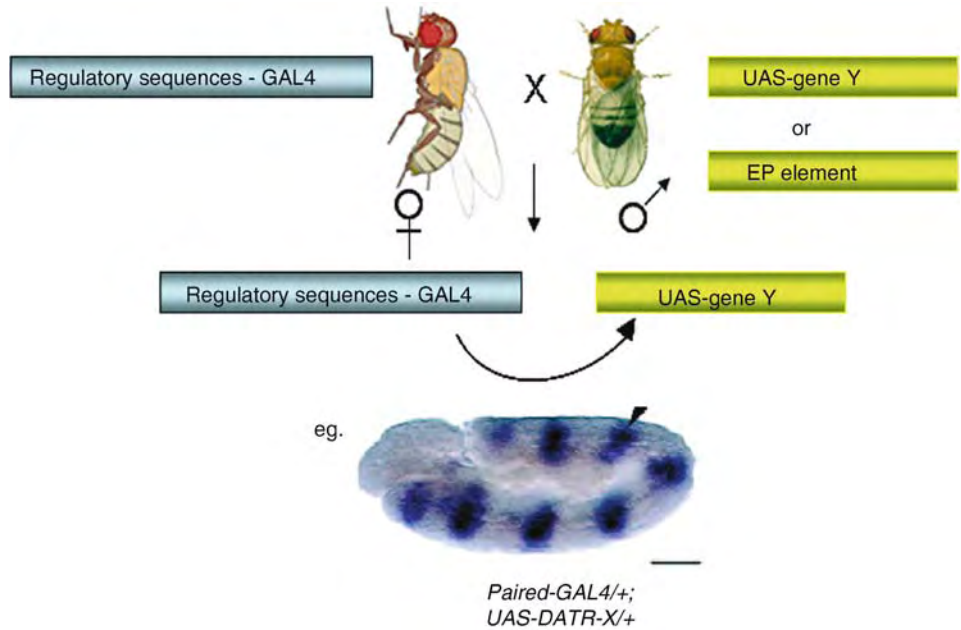
### *The Nova method*

This stands for "novel overexpression activity" and was used to generate ►dominant alleles of genes in the *Drosophila* epidermal growth factor receptor (EGFR) pathway [2]. A UAS transgene is exposed to mutagenesis and its expression is targeted using a GAL4 driver and then progeny are screened for novel visible phenotypes [2]. This technique resulted in new alleles that produce ►RNA interference-like transcripts as well as other genetic rearrangements in the locus.

## Use of the GAL4/UAS System for Neurobiological Research

The analysis of disease mechanisms has traditionally been carried out using transgenic animal models such as the mouse. However, this system is costly and time consuming.

The creation of the GAL4/UAS system for targeted gene expression in *Drosophila* has opened the possibilities of investigating the role of genes from any organism



**GAL4/UAS Expression System. Figure 2** The bipartite GAL4/UAS system in *Drosophila*. Illustrated is the expression of the UAS-*DATRX* gene in a pair-rule pattern of stripes (arrowhead) driven by *paired*-GAL4.

with relevance to medical processes. Targeted misexpression, using the GAL4/UAS system, of the products of human disease genes in flies has created models for trinucleotide repeat expansion disorders, Alzheimer's disease and Parkinson's disease.

### *Targeted RNA Interference (RNAi)*

Homologs of human neurodegenerative disease genes are found in the *Drosophila* genome (http://superfly.ucsd.edu/homophila/). The function of these genes can be determined by creating mutations and studying the effects in flies. This genetic approach has been used to study ataxin-2 and parkin which are involved in spinocerebellar ataxia 2 and with autosomal recessive juvenile parkinsonism, respectively [6]. Generating endogenous point mutations in a gene can be time-consuming and therefore the use of RNA interference-mediated knock down of gene expression has become more popular. Since it uses the GAL4/UAS system, it has the distinct advantage that a mutation of the gene of interest can be targeted in time and space. RNA interference (RNAi) has been used to knock down the fly homolog of *huntingtin* and reveal its role in regulation of axonal transport and cell death [7]. In addition, targeted RNAi-induced knock down of the fly homolog of a human gene that causes X-linked mental retardation (*D*ATRX) revealed a critical neuronal and glial role for this protein in axon guidance [8].

A vector exists that is designed to express double-stranded RNA as a ►snapback hairpin and is derived from the pUAST transformation plasmid [9]. This plasmid is called pWIZ (*W*hite *I*ntron *Z*ipper). A fragment of the chosen gene is cloned into pWIZ to form an inverted repeat and the repeats are placed upstream and downstream of the intron of the *white* gene. The fragments are sequentially cloned in opposite directions using a number of restriction sites on either side of the intron. The optimal size of the fragment should be 500 and 1000 base pairs in length which causes stronger silencing than shorter fragments. A library of transgenic RNAi flies exists at VDRC (Vienna Drosophila).

### *Parkinson's Disease (PD)*

Mutation as well as triplication of the α-synuclein locus is associated with dominant parkinsonism. A *Drosophila* model using this gene has been developed to investigate its role in Parkinson's disease [6]. By expressing normal and mutant forms of α-synuclein in *Drosophila,* the adult-onset loss of dopaminergic neurons in the brain, as found in human cases, was reproduced. Using this model, a role for the chaperone, heat shock protein 70 (Hsp70), in preventing dopaminergic neuron loss was shown by transgenic expression. This led to pharmacological tests altering chaperone levels to delay the progressive degeneration of dopaminergic neurons. Feeding flies geldanamycin, which upregulates chaperonins, protected against α-synuclein-induced dopaminergic neuron loss.

The GAL4/UAS system was used to target *Drosophila* PINK1 (PTEN-Induced Kinase 1) (*D*PINK1) RNAi ubiquitously in flies to reveal that mitochondrial

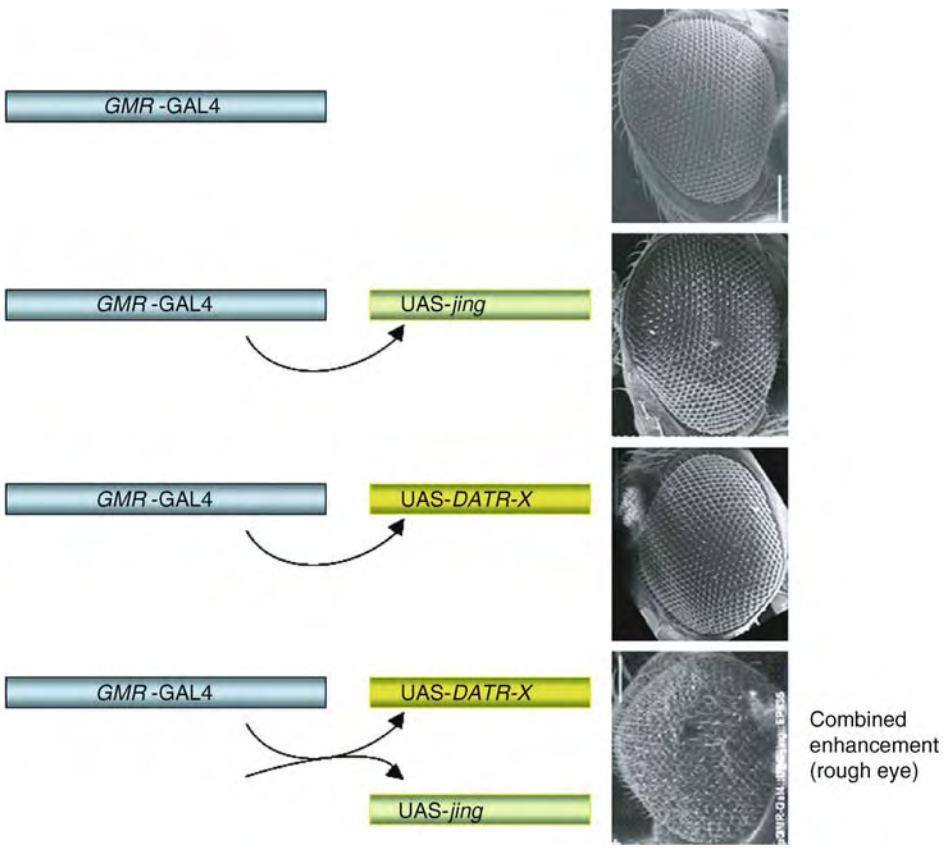
pathology and muscle and dopaminergic neuron degeneration are associated with parkinsonism. This technology was also used to show that *D*Parkin could rescue dopaminergic and muscle pathologies in *D*PINK1 RNAi flies. Therefore, by using the power of *Drosophila* genetics and transgenic technology the evolutionary conservation of disease gene pathways can be revealed.

### *Alzheimer's Disease (AD)*

A pathological hallmark of AD is the hyperphosphorylation of tau protein which then forms insoluble aggregates. Fly models of tau toxicity have been developed using the GAL4/UAS system to determine how generation of β-amyloid peptides affects tau phosphorylation and aggregation. The entire human APP/secretase system, which processes the amyloid protein, has been recreated in the fly using the GAL4/UAS system [6]. Axonal transport and behavioral defects are observed when wild-type human tau is expressed in *Drosophila* motor axons. Targeted expression of a tauopathy-associated mutant of human tau throughout the fly nervous system (using *elav*-GAL4) resulted in a rough eye, tau phosphorylation and neurodegeneration. A number of quick assays have been developed to determine the consequences of AD transgene expression in flies including longevity assays, locomotor assays, olfactory learning assays and rough eye phenotypes. Therapeutic agents that interfere with the generation of toxic aggregates of β-amyloid peptides can rescue AD flies. Therefore, the power and speed of the GAL4/UAS system and genetic screens (see below) in flies are being used to discover new therapeutic agents to treat AD.

## GAL4-UAS-based Genetic Screens

*Drosophila* geneticists have long used the adult eye, a system of 800 photoreceptor cells, as an ideal expression system to identify genes functioning in particular pathways in neural cells. Using a ▶genetic modifier screen (Fig. 3), enhancers of *grim(grm)-reaper*



**GAL4/UAS Expression System. Figure 3** Screening for modifiers using the GAL4/UAS system. Shown is a screen for enhancers of misexpression of the transcription factor, *jing*, in the adult eye. Expression of UAS-*jing* under control of *GMR*-GAL4 has no effect on eye development when observed by scanning electron microscopy (SEM). Similar expression of the *Drosophila* homolog of human α-thalasemia mental retardation on X (ATR-X) has no effect on eye development. Co-expression of UAS-*jing* and UAS-*DATR-X* under *GMR*-GAL4 control results in a rough eye phenotype signifying a disruption of ommatidial development.

*(rpr)*-induced cell death were identified including the F box/ubiquitin conjugase protein Morgue [1]. Using an eye-specific promoter called the glass multiple promoter (GMR) fused to Gal4, UAS-*grm*/*rpr* could be expressed in the larval photoreceptor cells. Flies carrying both elements were then combined with those containing EP elements upstream of 1200 different genes. Any enhancement of UAS-*grm*/*rpr*-induced cell death could be detected by a more severe disruption of eye morphology.

The modifier approach is also being used to identify genes involved in human disease [6]. Tau expression was targeted to the eye using the GMR-GAL4 driver causing a rough eye phenotype. Enhancers and suppressors of the Tau-induced rough eye phenotype were found by individually combining 2276 EP lines with the GMR-GAL4/ +;UAS-Tau/ + flies [10]. 16 enhancers and 8 suppressors were found that encode mediators of apoptosis, kinases and phosphatases which are known to phosphorylate or dephosphorylate Tau. Many of the kinases and phosphatases regulating Tau toxicity in flies have been implicated in Alzheimer's disease. This suggests that these proteins may act as key therapeutic targets in Alzheimer's disease and other related disorders.

# Galvanic Skin Response

## Definition

"Galvanic skin response" (GSR) proposed by Landis (1932) is now used to mean changes in electrical skin resistance (ESR). The electric resistance between two electrodes applied to the skin surface in humans may be recorded with a Wheatstone bridge circuit. To a large extent, the ESR is determined by the amount of sweat in the sweat ducts and its concentration of electrolytes.

The resistance of the corneal layer of the skin itself is high but may be reduced by infiltration of sweat.

►Sweat Gland Control

# Galvanic Stimulation of the Labyrinth

## Definition

Electrical stimulation of the labyrinth performed by using constant amplitude, long duration pulses of current or continuous currents applied through the mastoid bone(s). In bipolar stimulation, the negative (cathode) pole of the stimulator is connected to the mastoid bone of one side, while the positive (anode) pole is connected to the opposite mastoid, so that both electrodes may modify the activity of the vestibular nerve fibers, leading to an increase at the cathode and to a depression at the anode. In unipolar stimulation the anode is over the skin and does not affect the labyrinthine activity of the corresponding side.

### Synonyms

Galvanic vestibulopostural responses; GVS; Galvanic vestibular balance responses

### Definition

Galvanic vestibulospinal responses refer to postural responses or muscle electromyographic responses elicited by direct current stimulation to the vestibular afferents.

### Description of the Theory

#### Method of the Galvanic Vestibular Stimulation

Galvanic vestibular stimulation (GVS) is a technique in which a low intensity current is transcutaneously delivered to the afferent nerve endings of the vestibular system through electrodes placed over the mastoid bones [1]. The applied current alters the firing rates of the peripheral vestibular afferents, causing a shift in a standing subject's vestibular perception and a corresponding postural sway. If the anodal electrode is placed on the mastoid, sustained positive currents decrease the firing rate of the vestibular nerve fibers, whereas sustained cathodal negative currents increase vestibular activity. GVS is well tolerated by subjects with current ranges up to 2 mA.

#### Postural Responses to GVS

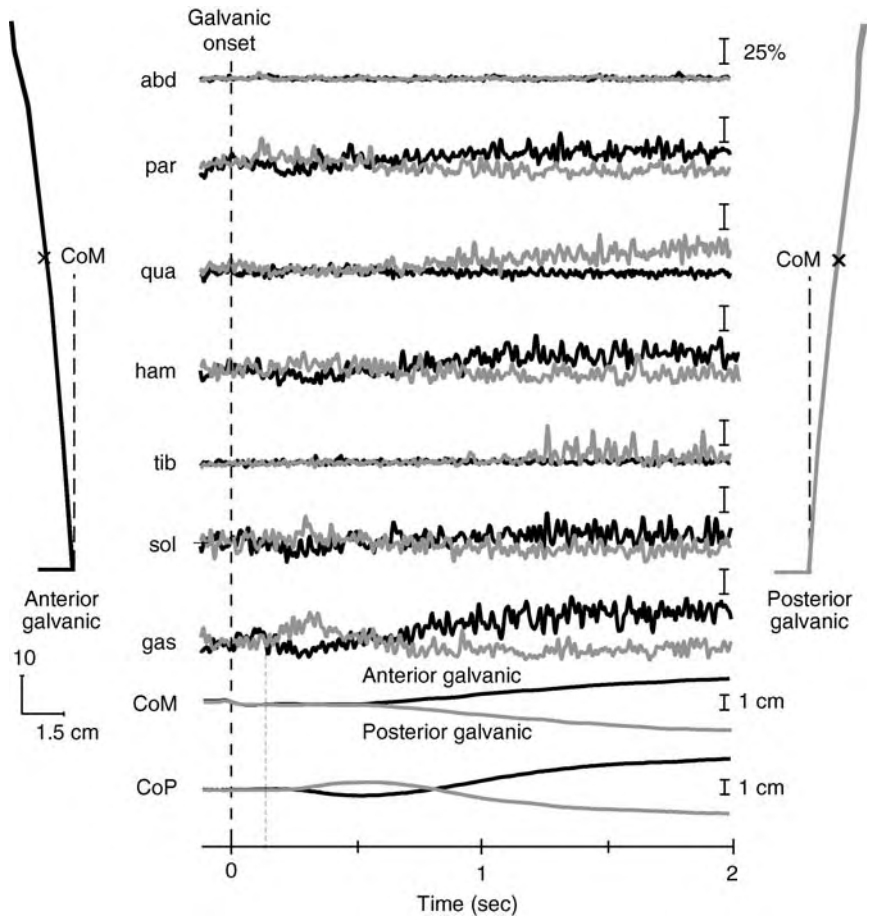
GVS causes an asymmetry of vestibular activity, resulting in postural sway with head, trunk and body leaning toward the vestibular apparatus with the reduced level of afferent activity (i.e., toward the anodal current). GVS induces a postural response that depends on the position of the head and trunk with respect to the feet. If the subject is standing with the head facing forward, GVS with electrodes of different polarity placed over each mastoid (bipolar binaural stimulation) induces a lateral body tilt parallel to the ►inter-labyrinthine line. If the head or the trunk is turned to the side in the horizontal plane, the postural response will again be with direction parallel to the inter-labyrinth line, in this case sway is in the anteroposterior direction. Postural responses to GVS recorded by a force platform as the centre of pressure (CoP) or by kinematic sensors as the centre of body mass (CoM) are presented in Fig. 1. Sinusoidally varying bipolar binaural GVS with frequencies ranging from 0.01–1 Hz, the body tends to sway sinusoidally with the frequency of stimulating current.

Monoaural GVS activates one side of the vestibular apparatus and induces reproducible, stereotyped deviations of the centre of pressure (CoP) in both the anteroposterior and lateral plane [2]. With monopolar, binaural GVS, also called double monopolar GVS, electrodes of the same polarity are placed over both mastoids and indifferent electrodes are placed on the forehead. If anodal electrodes are placed on the mastoids, the stimulating current decreases the firing rates of the peripheral vestibular afferents on both sides. Cathodal electrodes placed on mastoids produces an increase of firing rate. This change in the firing rates of the vestibular afferents results in postural sway perpendicular to the inter-labyrinths line. A cathodal stimulation over both mastoids results in a larger sway in the forward direction than the backward sway induced by anodal stimulation over both mastoids.

Kinematic records of body segment responses to GVS showed that the head tilted more than the trunk and the trunk tilted more than the pelvis, resulting in a bending of the body towards the anodal ear. Trunk movement begins at a latency of 150–180 ms. The tilt of all three segments is reduced by increasing stance width. The results indicate that the response is organized to stabilize the body, rather than the head, in space.

When visual input about body sway is available, the whole body GVS sway responses are reduced or absent. Loss or alteration of somatosensory input leads to an increase in the GVS response. For example, stance on a compliant surface and somatosensory loss due to neuropathy results in larger GVS responses [3]. Thus, GVS responses include integration of vestibular, visual and somatosensory inputs for postural control.

GVS with a very small current (0.5 mA) before and during postural responses to platform translation alters automatic postural muscle activation and center of pressure responses and the final equilibrium position



**Galvanic Vestibulospinal Responses. Figure 1** Comparision of anterior (black lines when anode is on forward ear) and posterior (gray lines when anode is on backward ear) galvanic stimulation during quiet stance with head turned to the right and eyes closed. Normalized EMGs, center of mass (CoM), center of pressure (CoP), and sagittal stick figures are group-averaged responses to 0.4 mA bipolar, galvanic stimulation. Sticks show difference from initial stance at 4 s following the onset of stimulation with x showing calculated CoM position. abd-rectus abdominis, par-paraspinals, qua-quadriceps, ham-hamstrings, tib-tibialis, sol-soleus, gas-gastrocnemius EMG responses. (From Horak, Hlavacka Exp Brain Res 2002).

[4,5]. The tonic vestibular asymmetry induced by bipolar galvanic current alters the sensory estimate of verticality to a new position. Subjects appear to alter the magnitude of their automatic postural response to realign their centre of mass (CoM) and CoP with a newly established equilibrium position.

## Muscle Responses to GVS

After the onset of a GVS current, short and medium latency electromyographic responses can be observed in muscles of the upper limbs, the trunk and the lower limbs, which result in well organized body movement. In ankle muscles, the short latency muscle responses to GVS occur at 55–65 ms and the medium latency muscle responses occur at 105–120 ms [1,6]. The muscle responses to GVS are biphasic: a small, short latency component is followed by a larger, medium latency component with opposite sign (see Fig. 1, Gas). Both responses increase with stimulus intensity, but the short latency response has a higher threshold [6]. The early response has a similar latency to muscle responses evoked by rapid postural perturbations. Cathodal and anodal stimulation produce opposite effects on short and medium latency responses in the soleus muscles.

Both short and medium latency responses are larger when the eyes are closed. When the support platform is unstable and in subjects with neuropathy, both muscle responses to GVS are larger. Galvanic vestibulospinal stimulation can alter medium latency automatic postural muscle response triggered 100 ms after surface translation [7].

Monopolar, monaural GVS can modify the amplitude of the ipsilateral soleus H-reflex and bipolar, binaural GVS significantly alters the onset of activation

and the initial firing frequency of gastrocnemius motor units. This suggests that in certain situations, it may be possible to use vestibular stimulation to examine the integrity of descending vestibulospinal pathways in human subjects.

The initial firing frequencies of motor units can be significantly altered by GVS. The changes in the initial firing frequencies and alterations in onset of motor unit activity with GVS suggest that vestibulospinal mechanisms can influence the force output of individual motoneurons.

### Interpretation of Motor Response to GVS

Galvanic vestibulospinal responses are elicited by modification of vestibular outputs from both canals and otoliths. Recent data indicates that the canal and otolith system exert their effects on balance through different pathways [8]. The GVS evoked canal signal indicates lateral head rotation while the otolith signal indicates lateral tilt or head acceleration. Galvanic vestibular stimulation induces a vestibular signal of head motion, which has reproducible effects on the human balance system. This virtual signal of head movement produced by GVS has an effect on the whole body postural control, evoking electromyographic responses and a highly organized balance response involving the entire body. The postural responses to GVS are highly sensitive to information coming from all other sensory sources.

## Ganglia

### Definition

Ganglia are collections of neuron somata that aggregate during development, often in a segmental arrangement, and include autonomic ganglia and the primary afferent neurones in dorsal root ganglia and cranial nerve ganglia.

►Autonomic Ganglia
►Dorsal Root Ganglion (DRG)

## Ganglion

### Definition

A ganglion (Greek for knot) is a collection of nerve cell bodies, usually referring to such collections outside the CNS, e.g., collections of primary afferent neuron cell bodies located in the dorsal root ganglia or those associated with cranial nerve afferents. There is also a large group of neurons inside the CNS in the forebrain also referred with the same term, i.e., the basal ganglia (the caudate, putamen, and globus pallidus).

## Ganglion Cell Layer (GCL)

### Definition

The innermost cellular layer of the retina. It is comprised of the cell bodies of retinal ganglion cells and amacrine cells.

## Ganglionic Eminences

### Definition

Regions of the basal forebrain (telencephalon) also know as sub-pallium that give rise to the striatum and basal ganglia. However, many interneurons that express GABA generated in the ganglionic eminences migrate tangentially to the neocortex/pallium.

## Ganglioside

### Definition

A glycolipid with one or more sialic acid residues. Glycocalix – to be defined elsewhere.

►Membrane Components

## GAP-43

### Definition

GAP-43 is a membrane-anchored neuronal growth associated protein (also known as neuromodulin or B50) expressed at high levels in actively motile growth cones and plastic presynaptic terminals. It has been implicated in the formation of novel neuronal connections, synaptic remodeling and in regeneration and sprouting after injury. GAP-43 is a substrate for calcium-dependent and phospholipid-dependent protein kinase C. In addition, it directly binds calmodulin, the α subunits of Go and Gi proteins and PI(4,5)P2.

GAP-43 activity can also induce a transient rise in intracellular calcium that can affect cytoskeletal dynamics.

►Growth Cones

## Gap Junctions

### Definition

Gap junctions are clusters of channels that connect the interiors of adjoining cells and mediate the exchange of ions and small molecules between the coupled cells.

Gap junctions are formed by members of the connexin, innexin, and pannexin families, structurally related transmembrane proteins that assemble in sextamers to form a gap junction hemi-channel. Each of the adjoining cells contributes one hemi-channel to a complete gap junction channel.

►Electrical Synapses

## Gap-Saccade Paradigm

### Definition

The gap-saccade paradigm is an experimental eye movement task in which a central fixation point to which a subject is attending is extinguished before an eccentric target that is the goal for a saccade is turned on. The temporal period between the time of fixation offset and target onset is called the gap period.

The gap saccade paradigm produces saccades with short latencies.

## Gastric Mill

### Definition

In general muscular pouch for grinding food; specifically part of the digestive system of crabs.

## Gastrin-releasing Peptide (GRP)

### Definition

Contains 27 amino acids and is thought to be the mammalian equivalent of the anuran peptide bombesin.

In the periphery, GRP is released by fibers of the vagus nerve and stimulates cells of the stomach to release gastrin. GRP is also involved in the circadian system, playing a role in the signaling of light to the master circadian oscillator of the brain, in the suprachiasmatic nuclei (SCN). In the SCN, GRP is localized to the ventral retinorecipient zone, from where it communicates photic resetting signals to the rest of the nucleus.

After exposure to light, upregulation of the Per clock genes in the SCN is first apparent in ventrally located neurons, including GRP- or vasoactive intestinal peptide- (VIP)-containing cells, and later in the rest of the SCN.Within the SCN, GRP exerts its cellular actions through the BB2 receptor. In contrast to ariginine vasopressin (AVP), it appears that neither VIP nor GRP is rhythmically expressed in the SCN under constant conditions, although in light/dark cycles, GRP is elevated in the day and VIP is elevated at night.

## Definition

Time-dependent sensitivity to environmental cues is determined by a process called gating, in which a predetermined set of conditions must be established to permit a second process to occur. Gated processes are those in which signals are selected only under specific conditions, acting as a control for further flow of information. In electrophysiological studies of the nervous system, the term gating generally refers to the opening or closing of ion channels.

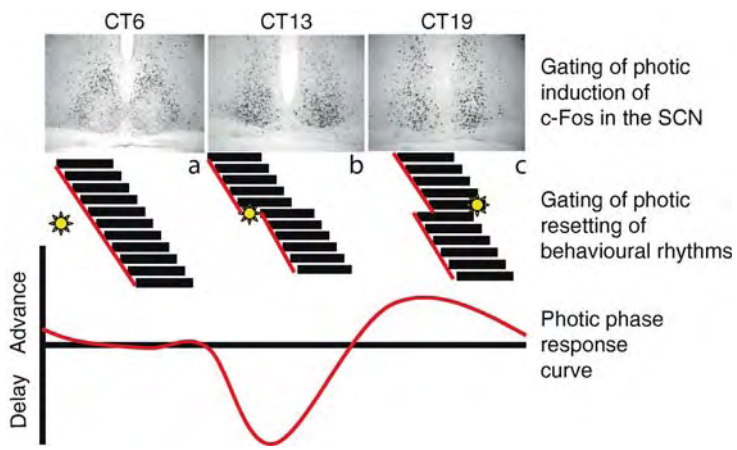
## Characteristics

### The SCN Circadian Clock Regulates Temporal Sensitivity to Internal and External Signals

The ►suprachiasmatic nucleus (►SCN) not only sustains daily rhythms in behavior and physiology so that the clock can be reset only at particular phases of the circadian cycle (►circadian activity), it also "gates" its own response to environmental time cues. That is, the phasing of SCN pacemaker activity is tightly regulated by photic input from the retina. Thus, light can reset behavioral and physiological rhythms only during the night (or ►subjective night) time. During the ►subjective day, light does not reset behavioral rhythms. On the other hand, resetting to light during the subjective night occurs very quickly (within 2 h, in mice) such that repeated exposure to light cannot cause further shifts within this temporal window [1–3]. Hence, the SCN controls if and how light can reset the clock (Fig. 1). In a parallel manner, stimuli such as exercise or social interactions that promote ►arousal (so-called "non-photic" cues) can only reset behavioral and physiological rhythms of nocturnal rodents during the subjective day [4]. During subjective night, non-photic cues do not cause ►phase shifts. Therefore, the SCN clock controls if and how it responds to time cues that promote arousal. This ►gating by the SCN is the basis of a brain clock that is primarily sensitive to non-photic stimuli during the day/subjective day, and photic stimuli during the night/subjective night.

### Gating Occurs Within Clock Cells

Gating does not appear to be due alterations in the strength of either sensory signals that reach the SCN or of brain pathways terminating in the SCN, but rather to changes in the sensitivity of SCN clock cells to inputs. This has been best characterized for the phase-dependent resetting actions of light. SCN neurons show enhanced responsiveness to ►glutamate (the major transmitter of the ►retina's input to the SCN) during the subjective night and this appears to be due in part to increases in the numbers or sensitivity (or both) of receptors for glutamate on clock cells. During



**Gating. Figure 1** The suprachiasmatic nuclei (SCN) circadian clock gates its response to light (photic) stimuli. a. In constant dark, at circadian time (CT) 6, a 15 min light pulse has no effect on the expression of c-Fos protein in the rodent SCN and has no overt effect on the onsets (fitted red lines) of the wheel-running activity rhythm to yieldno measurable phase shift. b. One hour after the onset of activity (CT13), a 15 min light pulse slows the onsets of the behavioral rhythm to cause a phase delay in the SCN clock. c. Seven hours after activity onset (CT19), a 15 min light pulse, accelerates the onsets of wheel-running activity to give a phase advance in the SCN clock.

night, stimulation of these receptors augments cellular excitation and increases in calcium in clock cells. Such changes lead to activation of many intracellular signalling systems including the dexamethasone-induced ras protein 1 [2] and extracellular-signal regulated kinases I and II (ERKs) [1,3]. Indeed, retinal illumination evokes substantive increases in activated (phosphorylated) ERK only during subjective night – the phase of the circadian cycle at which light resets the SCN. Consistent with these findings, pre-treatment with pharmacological blockers of ERK activation abolishes light-driven increases in phosphoERK, and attenuates the size of the shifts to light. Interestingly, there is a rhythm in pERK expression in the central region of the SCN in mouse and hamster that is abolished through blinding or exposure to constant to light.

The molecular targets of the light-driven pERK are likely to include increased transcription of immediate early genes such as *c-fos* (whose protein product, c-Fos can itself act as a transcription factor) as well as the transcription factors Elk-1 and cAMP-regulated binding protein (CREB). Response elements for Elk-1 and CREB are present in the promoter regions of the inhibitory elements of the molecular clock, namely the *Per1* and *Per2* genes [1,3,5], and hence activation of the ERK cascade can regulate the molecular clock through at least two pathways Indeed, activation through phosphorylation of CREB and Elk-1 (pCREB and pElk-1 respectively) can only be induced by light or glutamate at the same phases that photic stimuli resets the SCN clock.

It is notable that in nocturnal rodent species light activates these mechanisms when spontaneous neuronal discharge activity, intracellular pERK, and *Per1*/*Per2* mRNA expression are at or near their respective nadirs [6]. This reduced night-time activity of SCN cells is thought to predispose this circadian clock to the excitatory actions of retinal input and hence the resetting actions of light.

The gating of non-photic stimuli is much less well understood. Neural inputs associated with non-photic resetting contain inhibitory neurochemicals such as ►neuropeptide Y, ►serotonin, and GABA, which in contrast to glutamate, suppress SCN neuronal activity [4,6]. In nocturnal species, non-photic stimuli advance behavioral rhythms during the subjective day, when SCN neuronal activity is highest. In vivo neurophysiological recording has demonstrated that elevation of behavioral activities associated with non-photic stimuli suppress SCN activity. This is mirrored in vitro as these neurochemicals can only ►phase advance SCN brain slices during the subjective day. Similarly, it is notable that *Per1* mRNA expression in the SCN reaches its zenith during the subjective day and that non-photic stimuli and exogenously administered NPY suppress *Per1* mRNA in the SCN at this phase of the circadian cycle. The intracellular mechanisms responsible for these actions are thought to involve the suppression of pERK and c-Fos.

## Gating is a Network Property of the SCN

At the tissue level, gating can not be explained by the behavior of a cell, but as a property of SCN circuitry. The mechanism whereby brief light pulses reset the mammalian circadian clock involves acute *Per* induction. The relationship between *Per* gene activity and behavioral phase shifts, can be seen in the effects of light-induced *Per1* and *Per2* expression in the mouse SCN [1,5]. In the (►vasoactive intestinal peptide) VIP-containing (►Vasoactive Intestinal Peptide (VIP)) region of the core SCN (►core and shell SCN), light-induced *Per1* expression occurs at all times of the subjective night, while *Per2* induction is seen only in early subjective night. In the remaining regions of the SCN (i.e., shell), a ►phase delaying light pulse produces no *Per1* but significant *Per2* expression, while a phase-advancing light pulse produces no *Per2* but substantial *Per1* induction. Moreover, following a light pulse during mid-subjective night, neither *Per1* nor *Per2* are induced in the shell (►SCN shell), and produces no behavioral phase shifts.

Gating to resetting stimuli arises through the interplay of influences arising within cells as well through cell-cell interactions [1,7]. For example, within clock cells, the molecular oscillator regulates receptor expression and the coupling of receptor activation to intracellular signalling cascades such that these cells are differentially responsive to photic and non-photic inputs. It also is clear that intercellular communication is important for gating to photic inputs to be achieved across the SCN. For example, in transgenic mice lacking $VPAC_2$ receptor expression, photic stimuli activate the ERK cascade at any phase of the circadian cycle and hence at the tissue level, gating in the SCN has been lost [8]. The SCN of these mice show abnormally low levels of spontaneous cellular activity and clock gene expression and this dampening of clock activities predisposes the SCN to be photic driven. Therefore coordination of synaptic inputs, electrical activity, and clock gene expression is critical for appropriate integration and responses to exogenous time cues in the SCN [6,8].

## Gating as a General Property of Oscillators

The precise underpinnings of gating to photic and non-photic stimuli encompasses a complex interplay of circadian regulation of membrane-bound and intracellular signalling systems linking to transcriptional control of canonical clock genes. In turn the protein products of these clock genes modulate this temporal sensitivity to synaptic events. Ultimately, gating of

inputs must be translated into appropriate SCN output to regulate brain centers controlling behavioral and physiological states. Interestingly, neural circadian oscillators are also found outside of the SCN, and hence gating is a general property of a hierarchical circadian system; each brain sites gates its own response to SCN outputs to ensure appropriate temporal control of behavior and physiology.

Gating is also a property shared by ►oscillators in peripheral tissues, though the mechanisms underlying such gating are yet to be fully elucidated. For example, oscillators in the liver, heart, and kidney are differentially reset by injections of prostaglandin $E_2$ ($PGE_2$). The molecular clocks in these peripheral tissues are phase-advanced by $PGE_2$ early in the day and in the middle to late night, and are phase-delayed by $PGE_2$ early in the night [10]. By contrast, $PGE_2$ has no consistent resetting action during the midday phase. In addition, ►peripheral oscillators are reset by periodic food availability [9] with velocity of resetting determined in part through actions of glucocorticoids [10]. Hence, regulation of phase and presumably gating in peripheral oscillators arise through complex interactions of metabolic and endocrine signals. Intriguingly, the finding that the molecular basis of oscillators in these extra-SCN clocks, appear to be different to that of the SCN [9], indicates that mechanisms for gating arise through different means in different oscillators.

# Gating Current

►Action Potential

# Gating (Ion Channel)

## Definition

Gating (of ion channels) is a property of many ion channels and refers to the active transition between open and closed states in response to specific signals, such as membrane potential changes (voltage-gating) or the presence of neurotransmitters (ligand-gating). In general, ion channels consist of multiple sub-units, which form a central ion-conduction pathway that can be opened, upon impact of the specific eliciting signal, by moving away transmembrane protein helices with a hydrophobic portion, thus allowing ion movement through the pathway. The way these helices are moved differs between different kinds of channels.

►Action Potential

# Gating (Signal)

## Definition

The process through which a signal passes when the gate is open, and fails to pass through when the gate is closed. The notion of gating alludes to the function served by a “gate” in ordinary English usage. Thus, gating is the process through which a signal passes when the gate is open, and fails to pass through when the gate is closed. The suprachiasmatic nucleus response to light is gated, in that a light pulse during the nocturnal animal's subjective night produces a change in gene expression in the nucleus along with a

resetting of rhythmic behavior, while a light pulse during the animal's day produces no response. This is true even when the organism is housed in complete darkness, and the physical conditions at the time of exposure to light is identical at both times points.

►Suprachiasmatic Nucleus (SCN)

## Gaucher's Disease

### Definition

Rare, autosomal recessive defect in the degradation of ►sphingolipids, due to mutations in the lysosomal enzyme acid-β-glucosidase, which leads to accumulation of non-degradable glycosphingolipids in lysosomes of one or more organs (lysosomal storage disorder). The mild form of the disease (Gaucher type 1, GD1) is characterized by affection of visceral organs, with the brain being affected only sub-clinically. The early-onset neuronopathic type 2 (GD2; also with visceral signs: lung disease, hepatosplenomegaly, anemia) is additionally characterized by rapidly progressive ►brainstem degeneration, with ►opisthotonus, ►dysphagia, strabismus, breathing disturbances, with other symptoms occurring less frequently.

## Gaze

### Definition

As a verb it means to look at something attentively. As a noun it denotes the direction of the line of sight in space. In head free tasks, it is defined as the sum of eye position with respect to the head and the head position with respect to the body.

►Eye Movements Field

## Gaze Control

►Eye-Head Coordination

## Gaze Feedback Hypothesis

### Definition

Despite inefficient sensory feedback, the accuracy of saccadic eye movements is maintained against natural and experimentally-induced ocular trajectory perturbations.

Based on this observation, it has long been postulated that the saccadic pulse generator is controlled by an internal feedback loop keeping track of the instantaneous eye-to-target separation. By extension to the head-unrestrained condition, the gaze feedback hypothesis states that head movement information (efference copy and/or vestibular/proprioceptive signals) is added to the efference copy of the saccadic ocular command in the internal feedback loop to yield a feedback signal of current gaze displacement. This gaze feedback loop controls gaze accuracy independently of any head contribution by switching the saccadic pulse generator off as soon as gaze is on target. In turn the vestibuloocular reflex (VOR) gain, which is reduced during the saccade, automatically reaches pre-movement values as soon as the saccadic pulse generator stops discharging. Thus any residual head rotation is compensated by a vestibular-induced ocular counter-rotation.

## Gaze Motor Error (of a Neuron)

### Definition

Gaze motor error is a vector describing the direction and the amplitude of gaze shift required to move the line of sight from the current fixation point to a new target at another position. Saccade- or gaze-related neurons of the superior colliculus, including the tectoreticulospinal neurons, discharge maximally with movements of particular direction and amplitude. Each of them is characterized by its own optimal gaze motor error, i.e., the one for which its discharge is maximal. One can infer the location of the neuron on the motor map from its optimal gaze motor error.

►Gaze Shift
►Saccade, Saccadic Eye Movement
►SC – Motor Map
►SC-Tectoreticulospinal Neurons (TRSNs)
►Superior Colliculus (SC)

## Gaze Motor Error-Static

### Definition

A vector describing the direction and the amplitude of gaze shift required to move the line of sight from the current fixation point to a new target at a different position. It is encoded by neurons such as the saccade- or gaze-related neurons of the superior colliculus, including the tectoreticulospinal neurons, which discharge maximally with movements of particular direction and amplitude. Each of them is characterized by its own optimal gaze motor error, i.e., the one for which its discharge is maximal. One can infer the location of the neuron on the motor map from its optimal gaze motor error.

## Gaze Paretic Nystagmus

### Definition

Nystagmus that develops during eccentric gaze, usually due to problems with gaze-holding mechanisms.

►Central Vestibular Disorders

## Gaze Pursuit

### Definition

Continuous eye-head movements made to track a moving visual target.

►Position-Vestibular-Pause Neurons

## Gaze Shift

### Definition

Literally, the term gaze denotes attentive looking at something (see Gaze). In this narrow sense, a gaze shift is the realignment of the line of sight so as to bring the image of a new object of interest to the central retina where receptor density and hence visual resolution are the highest. Rapid transfer of fixation from one object to another is achieved by eye saccades when the angular distance between the targets is small. When it is large, eye saccades are combined with head saccades. Gaze shifts to very eccentric targets usually require also rotation of the trunk and, eventually, movements of the limbs. In a larger sense, the term "gaze shifting" is also used to describe smooth gaze movements accompanying slowly moving targets, as well as vergence and divergence eye movements in animals endowed with stereoscopic vision. The above classes of gaze shifts are involved in active "looking" at objects of interest. Another class includes compensatory gaze shifts that serve to stabilize the images on the retina during externally induced disturbances.

►Eye-Head Coordination
►Saccade, Saccadic Eye Movement
►Smooth Pursuit Eye Movements

## Gaze-Velocity Neurons

### Definition

Neurons that appear to encode the angular velocity of gaze in space. The firing rate of these neurons is modulated during head-fixed smooth pursuit and during suppression of the vestibuloocular reflex (VOR) by fixating a target that rotates in conjunction with the head. In gaze-velocity neurons, these eye- and head-velocity sensitivities have the same preferred direction (e.g., excitation during rightward movement) and same magnitude. During the VOR in the dark, the eye and head move in opposite directions, so the respective modulations roughly cancel, and there is little net modulation. A gaze velocity signal can be generated by adding an appropriately weighted eye-velocity corollary discharge and a vestibular signal from the vestibular nuclei. It can also be created as a command from the smooth pursuit system to move the eyes. That is, the modulation during head-fixed smooth pursuit would be conveyed to the motoneurons to produce the eye movement. The modulation during suppression of the VOR would be conveyed to the motoneurons to exactly counteract the vestibular signal that arrives at the motoneurons via VOR pathways. During the VOR in the dark, the motoneurons are allowed to respond to their vestibular input and there is no command from

the smooth pursuit system (and no gaze-velocity modulation).

In reality, the VOR in humans and experienced animals is not ideal and the vestibular input to the motoneurons conveyed by VOR interneurons is partially nullified during suppression of the VOR. Therefore, the expected ratio of eye-velocity to head-velocity sensitivity for a smooth pursuit command signal would arguably be greater than 1.0. Correspondingly, true gaze-velocity neurons in most structure are a subpopulation of neurons having varying ratios of eye- and head-velocity sensitivities.

Gaze velocity neurons are found in the oculomotor vermis, the floccular lobe, the vestibular nuclei, the frontal eye fields, and pontine nuclei.

### Synonyms

Sex; Gender and pain; Sex differences in pain

### Definition

Despite substantial individual variability in pain responses, an expanding body of evidence indicates that males and females experience pain differently. ►Sex differences have been widely reported in the epidemiology of clinical pain, sensitivity to experimentally induced pain, endogenous pain modulation, and responses to analgesic compounds.

The terms sex and ►gender are often used interchangeably in research literature; however, their meanings contain important distinctions. To maintain consistency in this review, the term sex is used to classify organisms as male or female according

to genetic composition and consequent anatomic structures and functions [1]. The more inclusive term gender is a social construct describing an individual's self-representation as male or female, which incorporates biological determinants as well as environmental influences such as experience, culture, and ethnicity. As such, gender exclusively references human research, whereas the term sex can be used in reference to human or non-human animal research. This brief overview summarizes clinical and experimental evidence regarding the relationship of sex and gender to pain and analgesia.

## Characteristics

### Human Clinical Pain

Compared to men, women are more likely to acknowledge pain and seek medical care for numerous painful conditions such as migraine and tension-type headaches, fibromyalgia, autoimmune rheumatic disorders, temporomandibular disorder (TMD), and irritable bowel syndrome (IBS) [2]. In community populations, females describe poorer perceived health and well-being, experience a greater number of symptom recurrences, have more intense pain, and report a disproportionately larger number of pain symptoms for which they do not necessarily seek treatment [3]. These trends persist when confounding factors such as differences in prevalence rates of medical conditions, psychiatric disorders, and gynecologic pain, are statistically controlled.

Sex-specific patterns in pain incidence and prevalence vary between clinical conditions and change across the lifespan. Some discrete differences in pain reporting appear in pre-pubertal children and become more apparent during the reproductive years when gonadal hormone levels increase [2]. However, there are certain conditions that are more prevalent in men (e.g. cluster headache), or for which sex differences are negligible (e.g. toothache due to pulpitis) [2,4]. Sex differences have also been reported in the severity of acute clinical pain (e.g. postoperative pain), although negative findings also exist. Whereas the direction of differences is relatively consistent (i.e. women having a higher likelihood of reporting pain), the magnitude of sex differences varies greatly depending on the type of pain (e.g. acute, chronic), population (e.g. hospital, community-based), pain assay (e.g. thermal, pressure, ischemic, chemical irritant), anatomic location (e.g. cutaneous, visceral), pain dimension (e.g. sensory, cognitive, affective) and by the methodology used in a study [1,4].

## Experimental Laboratory Studies

### *Basal Pain (Nociceptive) Sensitivity*

#### *Non-Human Animal*

Non-human animal studies (primarily rodents) yield mixed results concerning sex differences in nociceptive responses. Female rodents tend to exhibit pronounced behavioral and physiological reactions and lower response thresholds for many, but not all, types of noxious stimuli [1,5]. The direction and magnitude of sex differences in nociception depend on many factors such as the genotype or strain of rodent, anatomic site of testing, age, estrus cycle phase, light exposure during testing, husbandry procedures, and assay type [5]. Importantly, rodent studies of sex differences in nociceptive sensitivity have relied almost exclusively on reflex measures, and the presence of sex differences in nociception has not been determined with operant assays.

Current data, while suggestive of sex differences in basal pain sensitivity, should be interpreted with discretion. Even under tightly controlled experimental conditions, the relative contributions of genetics and other factors can be difficult to distinguish. Several covariates have been found to interact with genotype in a sex-dependent fashion. For example, female estrus cycle is a predictor of baseline thermal nociceptive sensitivity for some, but not all, rodent strains. Divergent estrus cycle effects can mask sex differences when female rodents from hormone-sensitive strains are tested as a randomly mixed group (e.g. estrus and diestrus). Thus, when studies fail to note sex differences it is difficult to determine whether differences are indeed absent, or whether methodological issues (e.g. small sample sizes; choice of rodent strain) have prevented their detection. By using inbred rodent strains, as opposed to outbred strains commonly used in laboratories, specific phenotypes can be targeted for study. This method, in conjunction with transgenic and linkage mapping techniques, marks a promising step toward elucidating the mechanisms underlying specific sex dimorphic traits in laboratory animals [see also ►Transgenic Animal; ►Transgenic Techniques].

#### *Human*

Laboratory studies with healthy humans of reproductive age suggest that females have lower pain thresholds and tolerances than males to a variety of noxious stimuli. These differences generally persist after adjusting for disparities in baseline sensory discriminative abilities (e.g. warmth detection threshold). As with rodent research, there is considerable variability in the magnitude of gender differences among humans. Effect sizes for pain threshold and tolerance range from moderate to large, and vary according to pain assay [1,4]. For example, males consistently exhibit substantially higher pressure pain thresholds and tolerances. Thermal, electrical pulses and ischemic pain assays yield comparatively less consistent outcomes. Men generally display higher pain thresholds and tolerances, and lower pain ratings than women during cold pressor stimulation. Intramuscular injections of algesic

substances such as hypertonic saline or glutamate solutions produce more intense, longer lasting, and more widespread pain in women compared to men. Women also tend to experience longer lasting and more intense post-exertion pain and discomfort, and longer recovery to baseline after certain tests of muscular strength and endurance (e.g. jaw muscle fatigue).

Although the exact mechanisms underlying sex differences in pain sensitivity are unclear, several biopsychosocial variables have been suggested, such as: (i) biological factors including genetic, anatomic (e.g. body composition), physiologic (e.g. cardiovascular and central nervous system differences), neurochemical, and hormonal contributions; (ii) developmental factors influencing the manifestation of pain in childhood and adolescence, and (iii) psychosocial factors such as social learning (e.g. culture/ethnicity, gender role identity), experience (e.g. pain history, abuse/trauma history), and psychological variables (e.g. mood, cognitions, coping strategies, expectations) (Fig. 1). It is unlikely that a single factor adequately explains the complex mechanisms driving gender differences in pain sensitivity. Rather, a multidimensional approach is more likely to be fruitful in gaining a comprehensive understanding of pain experiences.

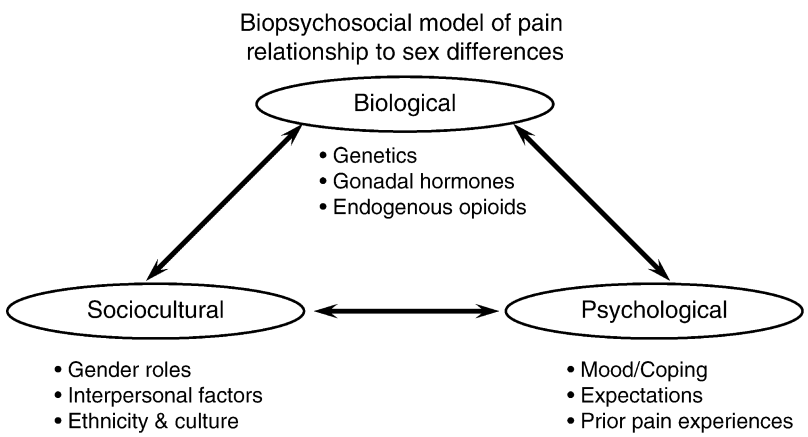
## Clinical Relevance of Experimental Pain Responses

Temporal features of noxious stimuli can influence pain perception differently in males and females. ►Temporal summation refers to a perceived increase in pain created by rapid, identical pulses of noxious stimuli. This perceptual phenomenon presumably occurs when high frequency stimulation of C polymodal nociceptive afferents amplifies second-order neuronal activity in the spinal cord dorsal horn. This series of events has been shown to involve *N*-methyl-D-aspartate (NMDA) glutamate receptors [6]. [see also ►NMDA Receptor] Temporal summation is thought to reflect central neural mechanisms similar to those responsible for the hyperalgesia and allodynia that accompany many forms of clinical pain. Healthy females often exhibit more robust temporal summation than males when given volleys of thermal, electrical, or mechanical stimulation [6]. Within chronic pain populations, robust temporal summation has been associated with greater severity of clinical symptoms and relatively ineffective responses to treatment. Such findings invite speculation that enhanced sensitivity to repetitive or sustained experimental stimuli reflects a predisposition for neuronal hypersensitivity, which may represent a risk factor for developing chronic pain conditions. At present, there is a need for prospective longitudinal studies to investigate further this possibility.

## Endogenous Analgesia (Antinociception)

In laboratory studies, endogenous analgesia can be produced by electrical or chemical stimulation of relevant anatomic sites (e.g. descending neural pathways), or by exposure to environmental stressors such as forced cold-water swims. Effects are assessed by measuring behavioral distress, biomarkers (e.g. plasma cortisol, endorphins in cerebrospinal fluid), and/or measuring neurochemicals extracted from postmortem tissue in laboratory animals. In humans, acupuncture and transcutaneous nerve stimulation (TENS) are examples of procedures used to control pain by stimulating endogenous analgesic mechanisms.

Endogenous pain modulation involves several distinct, but interrelated, systems that involve structures throughout the body [see ►Descending Modulation of Nociception]. In mammals, the opioid system relies heavily on mu, delta, and kappa receptor subtypes located in the central nervous system and peripheral tissue. Endogenous opioids (e.g. endomorphin,



**Gender/Sex Differences in Pain. Figure 1**

endorphin, enkephalin, dynorphin) are released under a variety of naturally occurring conditions involving high arousal states such as physical exertion, sexual activity, or fear [7] [see also ►Endorphins]. Activation of opioid receptors generally inhibits downstream excitatory pathways. The result is temporary pain attenuation and a subjective sense of well being. Certain foods, such as carbohydrates and chocolate, can promote opioid release. Due to their relationship with other neurochemicals such as dopamine and serotonin, opioids have been associated with complex psychological states such as addiction, thrill-seeking behavior or extreme joy. Various chemicals such as ►naloxone can temporarily block opioid receptors [7]. Endogenous opioids play an important role in mediating some types of ►Stress induced analgesia (SIA).

#### *Non-Human Animal*

In response to stressful events such as forced cold-water swims, stress-induced antinociception (SIA) involves both endogenous opioid and non-opioid (i.e. NMDA, naloxone-insensitive) systems. Given identical stressors, female rodents tend to display less opioid and non-opioid mediated SIA than males. It appears that antinociception displayed by females having intact ovaries is neurochemically different from that displayed by males and ovariectomized females. Selectively blocking relevant receptor sites and/or manipulating gonadal hormones can produce divergent effects on SIA in a sex-dependent fashion.

In addition to SIA, pregnancy-induced analgesia and analgesia produced by vaginocervical stimulation are hormonally-mediated endogenous processes unique to females. This suggests that quantitatively and qualitatively different neurochemical mechanisms might support endogenous pain modulation systems for males and females. As with nociceptive sensitivity, sex differences in endogenous antinociception also interact with the genotype of the rodent.

#### *Human*

Relatively little human research has directly addressed sex differences in endogenous pain modulation. Higher resting blood pressure has been associated with lower pain sensitivity, and some evidence suggests that the modulation of pain by resting blood pressure may be more robust among men. In addition, brain-imaging studies have reported sex differences in the magnitude and direction of μ-opioid receptor recruitment during exposure to a sustained painful stimulus [8]. After controlling for female gonadal hormone effects, men tend to demonstrate higher magnitudes of endogenous opioid release in brain regions involved in modulating sensory and affective aspects of pain (i.e. thalamus, nucleus accumbens, amygdala) [8]. It is important to note that opioid receptor availability, binding and/or affinity are dynamic processes that also interact with other variables such as hormonal status, age, and genetics.

Counterirritation [i.e. ►Diffuse noxious inhibitory controls (DNIC)] refers to the process whereby one concurrently applied noxious stimulus inhibits the perception of a second painful stimulus. This phenomenon is thought to reflect descending inhibition of pain signals. DNIC is presumed to operate through activation of descending supraspinal inhibitory pathways initiated by release of endogenous opioids. Several studies have investigated sex differences in the efficacy of DNIC, with mixed results. For example, ischemic arm pain (the DNIC condition) seems to reduce the occurrence of a pain-initiated leg reflex (nociceptive flexion reflex or RIII reflex) equally in men and women. Other studies using variations on the DNIC model have shown that counterirritation is more effective for males. At present, it appears that any sex differences in DNIC are modest and highly variable depending upon the study design.

A variety of psychological factors (e.g. anxiety, anger, coping) are associated with pain responses, which represents another form of endogenous pain modulation. Considerable evidence suggests sex-dependence of some forms of psychological pain modulation. For example, anxiety has consistently been associated with pain responses more strongly among men than women. In addition, the association of anger with pain may differ across genders. Thus, while the precise neurobiological mechanisms underlying psychological pain modulation are not known, these findings provide further evidence of sex differences in the functioning of endogenous pain modulatory systems.

### Exogenous Opioid Analgesia (Antinociception)

#### *Non-Human Animal*

While multiple classes of analgesic drugs exist, research regarding sex differences in analgesic responses has focused primarily on opioids. Numerous studies have shown that male rats exhibit greater antinociception from a variety of opioid receptor (OR) agonists than females [1]. Compared to high-efficacy compounds such as morphine, larger sex differences have been observed with lower-efficacy opioids [1]. Indeed, under some experimental conditions, the same opioid can function as an agonist in males and an antagonist in females.

It is posited that gonadal hormone fluctuations, such as those occurring during the female estrus cycle, are partially responsible for sex differences in exogenous opioid responses, presumably by altering opioid receptor availability and/or binding affinity. For example, adult male rats depleted of hormones via gonadectomy (GDX) have shown unchanged or decreased μ-opioid receptor-mediated antinociception

relative to their baseline, whereas female GDX rats tend to exhibit increased antinociception [1,7]. However, similar studies have failed to replicate these findings or have produced inconsistent results.

In contrast to the unpredictable effects observed with adult hormone changes, manipulation of fetal and neonate hormones typically alters responsiveness to opioids in adulthood. This indicates that early hormone exposure can produce durable effects on the developing central nervous system. As with nociception, sex differences in opioid responses change in accordance with the characteristics of the organism (e.g. genetics, hormonal status, age) in addition to the type of analgesic agent and procedures used to induce antinociception [1].

### *Human*

In contrast to rodent studies, human clinical and experimental pain models show a trend for women to derive superior analgesia from a variety of exogenous opioids compared to men; however, results vary substantially [9]. Clinical studies of patient controlled analgesia have noted that males consume higher doses of morphine compared to women. It is difficult to determine whether disparities in consumption reflect analgesia or other non-specific reasons such as differences in postoperative pain, previous pain experiences, concerns about addiction, or side effects. When differences are found in experimental pain models, they have generally been in the direction of women responding more favorably to μ-opioid receptor agonists such as morphine, meperidine, and hydromorphone. Fairly consistent sex differences have been noted regarding side effects and subjective effects of opioids, with women experiencing more respiratory depression, attenuation of cardiac reactivity, feelings of heaviness, and feeling "spaced out," particularly with μ-opioid receptor agonists [9].

In clinically relevant pain models (e.g. extraction of third molars), women often derive better and longer-lasting analgesia from mixed agonist-antagonist opioids that are agonists at κ-opioid receptors (e.g. butorphanol, pentazocine, nalbuphine). Compared to women, men frequently require larger doses of κ-opioids (adjusted for body weight) to attain equivalent analgesia. It appears that the melanocortin-1 receptor gene (*MC1R*) influences responses to κ-opioids in a sex-dependent manner. Specifically, women with two variant *MC1R* alleles, responsible for the red hair and fair skin phenotype, report significantly better analgesia with κ-opioids. The *MC1R* genotype does not appear to be strongly associated with κ-opioid analgesia for men.

Although a portion of the sex differences observed in responses to analgesic compounds is due to variations in body composition, mounting evidence shows that pharmacodynamic differences exist in opioid receptor binding, as well as in hormonal and other neurochemical influences [10]. Overall, the manifestation of gender differences likely depends on multiple factors including pharmacological characteristics of the opioid, dose administered, pain model employed, and timing of postdrug assessments. Moreover, data suggest that sex-by-genotype interactions may influence opioid responding. It is likely that advances in the field of ►Pharmacogenomics will continue to reveal genetic contributions to sex differences in pain sensitivity and opioid responding.

## Summary

Substantial evidence demonstrates sex differences in responses to pain across multiple pain modalities in both human and non-human species. Specifically, females typically exhibit greater basal pain sensitivity than males, though the magnitude of these differences is variable. Moreover, women are at greater risk than men for many forms of clinical pain. Sex differences in opioid analgesic responses have also been reported, though these data are inconsistent across species, analgesic assays, and specific opioid tested. While sex hormones have been implicated, the nature and extent of their contribution remains undetermined. Findings of sex-dependent genetic associations with pain and analgesia indicate potentially important ►qualitative sex differences in pain and analgesic circuitry. Additional research is needed to elucidate the multiple mechanisms underlying sex differences in pain and analgesia and to determine the implications for sex-dependent tailoring of clinical pain management.

## Definition

►Gene therapy can be defined as the use of therapeutic genetic material for the treatment of a disease.

## Characteristics

►Viral vector-mediated gene transfer in the nervous system is a promising strategy to treat certain neurological diseases including ►neurodegenerative diseases and enzyme deficiencies and in the future may turn out to be of value for the treatment of traumatic injuries of the spinal cord and brain tumors.

## Introduction

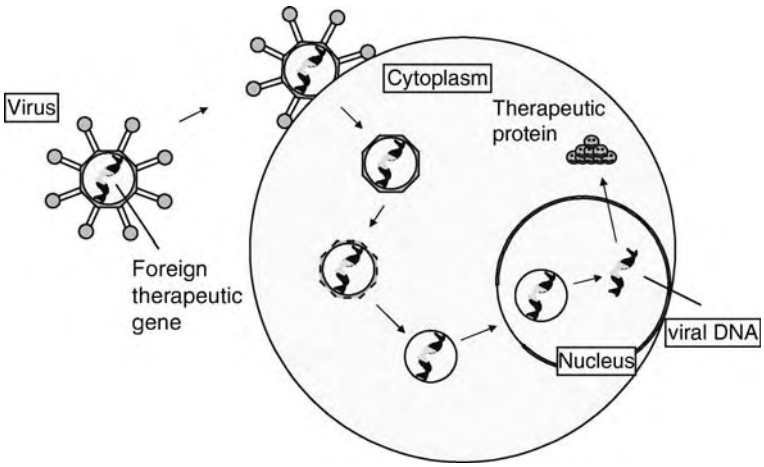
Gene therapy can be defined as the introduction of therapeutic genetic material into cells as a means to treat a disease. Recessive hereditary diseases caused by a defect in a single gene can in theory be treated by gene therapy. Gene therapeutic approaches can also be useful to express a therapeutic protein that is not able to pass the blood brain barrier in the brain or spinal cord. Moreover, in contrast to injection of a therapeutic protein itself, cellular delivery of a gene results in sustained and local expression of a therapeutic protein.

The gene of interest is usually delivered by a viral vector. Viruses have evolved into small genetic delivery systems, as they are able to enter a cell and deliver their RNA or DNA to the host. A viral vector is a genetically modified virus. For gene therapeutic purposes, an expression cassette harboring a promoter in front of a gene encoding a therapeutic protein usually replaces one or more genes in the viral genome. These modifications render a viral vector (in principle) non-pathogenic while the vector maintains its ability to deliver foreign genetic material to the cell nucleus (Fig. 1). We will first discuss the various vectors that are available to the gene therapist. Secondly, we will summarize the state of the art of gene therapy for neurological diseases (we refer to [1] for a comprehensive textbook on CNS gene therapy).

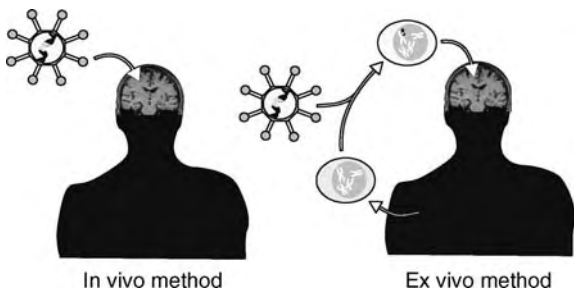
### Vectors for Gene Delivery to the Nervous System

Perhaps one of the most important decisions for gene therapy to be successful is the choice of the viral vector. Because each disease has its unique pathogenesis, each disease requires a vector with the appropriate properties. To make a well informed decision on which vector to use, one has to consider the location, cell type, quantity and duration of ►transgene expression required. During the last 20 years, gene therapy vectors have been created by modifying viruses and by developing non-viral gene delivery systems. Adeno-associated and lentiviral vectors have emerged as the most efficient vectors for gene transfer to the nervous system. Both in vivo as well as ex vivo gene delivery approaches have been developed (Fig. 2).

Using the in vivo approach, the viral vector is directly injected into the brain area of interest. The ex vivo approach entails genetic modification of cultured cells (preferable of the patient itself) prior to implantation into the area of interest. Following implantation in



**Gene Therapy for Neurological Diseases. Figure 1** A viral vector as a carrier of a therapeutic gene. A virus is genetically modified in such a way that it is still able to infect a cell and deliver its genetic material into the nucleus of a cell. After uncoating of the virus and traveling to the nucleus, the genetic information is transcribed and translated into a possible therapeutic protein. The viral vector DNA can be kept episomal (for instance after transduction with an AdV) or can be inserted in the host cell genome (as is the case after transduction by an LV vector).



**Gene Therapy for Neurological Diseases. Figure 2** Principle of gene therapy in the brain. Gene therapy is possible through either direct in vivo injection of a viral vector or indirectly via an ex vivo approach in which cells of a patients are cultured, genetically modified by a viral vectors and transplanted. Using the ex vivo approach, transduced cells serve as a local source of e.g. a growth factor. Using the direct in vivo approach, the viral vector is injected directly into the area of interest and transduces the neural tissue around the injection site.

the brain these cells serve as biological minipumps for e.g. neurotrophic factors.

### Non-viral Vectors

Because humans display (pre-existing) immunity to viruses, a single injection of a recombinant virus into CNS tissue may lead to an inflammatory reaction. In theory therefore, non-viral vectors would be ideal gene delivery vehicles due to their delivery of genetic material without the introduction of immunogenic viral proteins. Non-viral constructs that consists of a DNA molecule, coated with a polymer and a humanized targeting antibody directed transgene expression in the CNS, which lasted for a few days. Thus, when transient gene expression is required, non-viral vectors may be considered. For most applications, however, long term therapeutic gene expression will be a prerequisite.

### Viral Vectors

Whereas non-viral vectors usually are relatively inefficient delivery systems and direct a short period of transgene expression, the use of most viral vectors results in extended periods of transgene expression. Viral vectors have been based on retrovirus (including lentivirus [LV]), herpes simplex virus (HSV), adenovirus (AdV) and adeno-associated virus (AAV). Extensive preclinical data in animal models has documented the advantages and disadvantages of each of these vector systems and has guided the way to the use of specific viral vectors in the clinical setting.

### Retroviral Vectors

The very first viral delivery system was a retroviral moloney murine leukemia vector (MMLV). The retroviridae comprise a family of RNA viruses, that upon infection of a cell, reverse transcribe their RNA into double stranded DNA, which is integrated into the host genome. Since MMLV only transduces dividing cells and most neural cells are post-mitotic, MMLV does not directly transduce nervous tissue. Retroviral vectors have successfully been applied to modify fibroblasts *ex vivo* prior to transplantation in the CNS [2]. In these studies transplanted genetically modified fibroblast served as biological minipumps that locally secreted the neurotrophic factor nerve growth factor

(NGF). These pioneering experiments have recently resulted in a clinical trial for Alzheimer's disease ([3], see below).

### Herpes Simplex Viral Vectors

Herpes simplex virus is a large double stranded DNA virus. HSV was chosen as a potentially interesting vector because it is a neurotropic virus, it maintains a life long state of latency in neurons, and is retrogradely transported along axons allowing peripheral delivery of the vector [4]. Two HSV vector systems exist: recombinant HSV vectors and defective or amplicon HSV vectors. In recombinant vectors deleting or replacing immediate early genes with an expression cassette encoding the gene of interest curtails the lytic cycle of the virus. The amplicon HSV vector is based on the observation that a plasmid containing a transgene and two small elements from the HSV genome (the origin of replication and a cleavage/packaging signal) can be amplified and packaged in the presence of a helper virus. It has been notoriously difficult to produce recombinant HSV vectors that are fully replication defective. The amplicon HSV vectors are contaminated with helper virus and the production of high titer helper free amplicon HSV stocks is extremely difficult. An immunoresponse to herpes virus proteins cuts short transgene expression to a few weeks. HSV vectors are being used in clinical trials for treatment of glioblastoma [5] and clinical trials for the treatment of chronic intractable pain are planned.

### Adenoviral Vectors

Adenovirus has a double stranded DNA genome of 36 kb, consisting of early (E) and late (L) genes. In first generation adenoviral vectors the E1 genes are substituted by a transgene. This renders the vector replication defective. To propagate the vector, E1 is supplied in trans by a cell line with the E1 gene. The adenoviral vector (AdV) genome remains ►episomal and transgene expression can be detected as early as 1 day post-injection in the rodent brain. AdV-mediated transgene expression declines rapidly after 2–3 weeks as a result of an immunological response against the transduced cells. Several strategies have been devised to overcome this problem, including the use of temperature sensitive AdV in combination with immune blockade and the generation of AdV completely devoid of all viral genes, so called "gutless" AdV. Although some successes have been reported, it remains very difficult to produce and purify "gutless" AdV in clinically relevant quantities and it is clear that advances in this area are still required before AdV can be applied in a clinical setting. Despite these problems, AdV have been important tools to show proof of concept in a variety of animal models of neurological disease.

### Adeno-Associated Viral Vectors

The adeno-associated virus (AAV) genome is only 4.7 kb in size and is encapsidated in a simple capsid composed of three viral proteins. AAV is only propagated as a lytic virus in the presence of e.g. adenovirus or HSV. Because the AAV genome is only 4.7 kb in size, a copy of the genome can be easily cloned in a plasmid, with the restriction that the size of the expression cassette should not exceed this limitation. The observation that the wild type AAV genome could be rescued form a plasmid and propagated following transfection into adenovirus infected cells led to the idea that AAV could be developed as a viral vector [6]. To date several plasmid and baculovirus based production systems are available that allow the generation of clinical grade AAV vectors. In addition to AAV2 at least 11 AAV serotypes have been developed into AAV vectors, all with different cellular tropism. Several AAV serotypes, including AAV1, 2 and 5 predominantly transduce neurons. AAV vectors direct transgene expression in rodents and primates for periods of years and so far no immunological response to AAV transduced cells in the brain has been noted. To date AAV vectors are regarded to be safe gene delivery agents and several gene therapy trials for neurological disease use AAV as vector (discussed below).

### Lentiviral Vectors

Lentivirus is a retrovirus that possesses accessory genes that allow these retroviruses to infect non-dividing cells, including neurons. Lentiviral vectors can be divided into two groups: (i) primate vectors, including human immunodeficiency virus [7] and simian immunodeficiency virus based vectors, and (ii) non-primate vectors, including equine infectious anemia virus (EIAV) and feline immunodeficiency virus (FIV) based vectors. EIAV displays a higher ►neuronal tropism compared to the other lentiviral vectors. ►Pseudotyping the capsid of the vector is an important strategy to generate tropism for specific cells. Whereas the commonly used VSV-G coat has a broad host range, pseudotyping EIAV with pseudorabies virus enhances the neuronal specificity and facilitates retrograde transport from nerve terminals in the muscle to spinal motor neurons. Since this vector integrates into the host genome this vector has become the most popular vector for ex vivo gene therapy of dividing cells like primary fibroblast or Schwann cells.

## Gene Therapy for Neurological Diseases

Gene therapy for neurological disease has advanced rapidly in two areas: neurological disorders resulting from enzyme deficiencies and neurodegenerative diseases. In the latter area phase I clinical trails that show

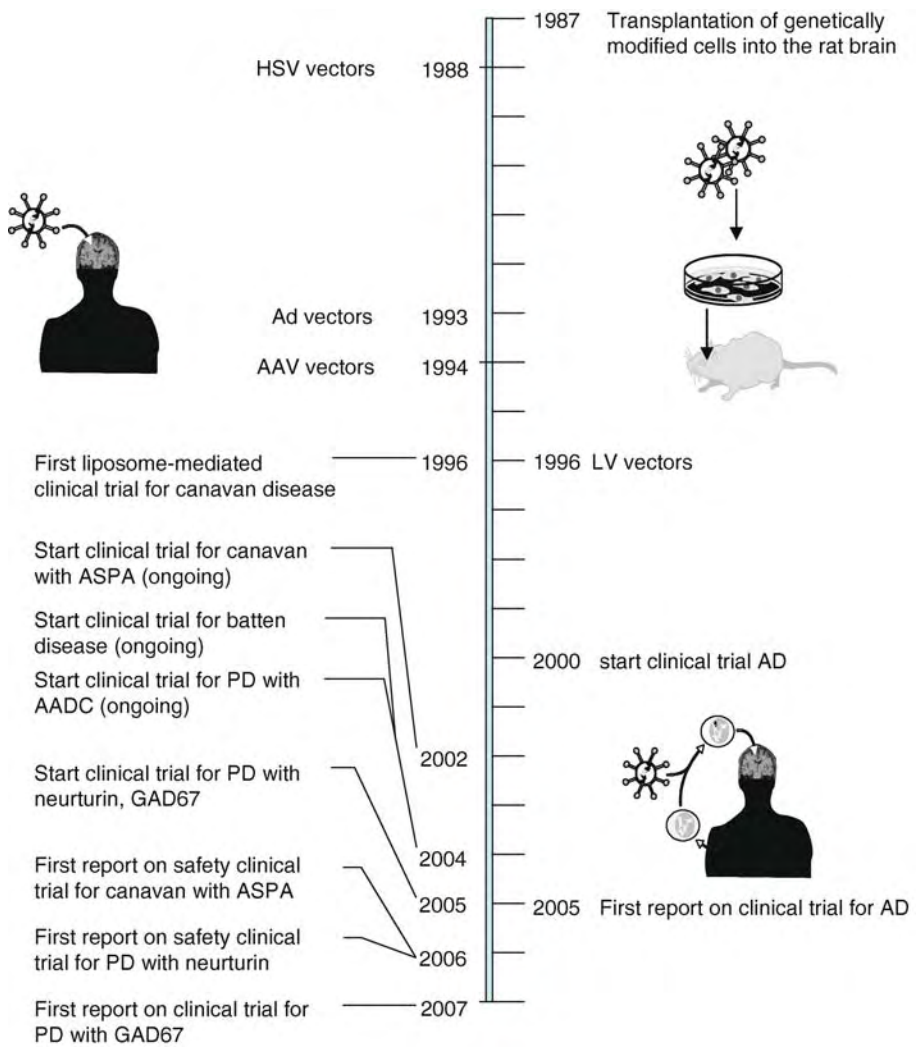
proof of concept have now been completed and phase II/III trails are ongoing (Fig. 3).

### Enzyme Deficiencies

Gene therapy for enzyme deficiencies primarily aims at correction of the compromised activity of the mutated enzyme by intervention with a vector encoding the wild type gene. In these diseases gene therapy has usually to be applied early in life to prevent neurological damage and global transgene expression throughout large areas of the cerebrum is required.

### GM-1 Gangliosidosis

GM1 gangliosidosis is caused by mutations in lysosomal acid beta-galactosidase. In lactase deficient mice, During and colleques were able to introduce the gene into the gut of these mice using AAV-vectors. This resulted in complete correction of the enzymatic deficiency. AAV-mediated expression of acid beta-galactosidase into the brain of neonatal GM-1-gangliosidosis [beta-gal (−/−)] mice resulted in almost complete ▶transduction of the brain and in complete correction of the disease phenotype. For translation



**Gene Therapy for Neurological Diseases. Figure 3** Highlights in gene therapy for neurological diseases. In 1987, a first report on grafting fibroblasts that had been genetically modified to secrete NGF into rat brain was published. In 2000, a clinical trial was initiated for the treatment of Alzheimer's disease using genetically modified cells to secrete NGF of the patient itself. In 2005 the results of a Phase I clinical trial using this treatment strategy were reported. Several vector systems have been developed during the eighties and nineties and were applied in the nervous system, including HSV (1988), Ad (1993), AAV (1994) and LV (1996). The use of AAV in various clinical settings is well underway and AAV gene therapy has been reported to be well-tolerated. For the treatment of Parkinson the results of a Phase I clinical trial recently have been reported [10].

of this gene therapeutic approach into a clinical trial, AAV vectors encoding lysosomal acid galactosidase are further evaluated in larger animal models of GM-1-gangliosidosis.

### Canavan Disease

Canavan disease is autosomal-recessive leukodystrophy caused by mutations in the aspartoacyclase (ASPA) gene. ASPA is enriched in oligodendrocytes and ASPA deficiency results in elevated levels of its substrate molecule, N-acetylaspartate (NAA). The disease is characterized by brain edema, demyelination, motor deficits and seizures. In a knockout mouse model, ASPA activity was normalized following in trathalamic injections of AAV-ASPA, and seizures were reduced but other important clinical parameters where unchanged. Thus, transfer of ASPA to neurons only partially corrects the disease and vectors with tropism for oligodendrocytes will be needed to fully correct the disease. The very first gene therapy trial was conducted to treat Canavan disease in 1996. The gene encoding ASPA was coated with liposomes and injected into the brain. Using this method, a transient expression pattern was achieved, with beneficial results that were linked to the expression pattern (www.canavan.org). Recently, in a phase I clinical trial, a total of 10 patients received six intracranial injections of the AAV vector each in an attempt to ameliorate this neurodegenerative disorder. This was a phase I feasibility study and functional improvements have not been reported. In three out of ten subjects, a low level of AAV-2 neutralizing antibody was detected. Long-term monitoring of subjects and expansion to phase II/III will be necessary to make definitive statements on the efficacy of gene therapy for this disease.

### Batten Disease

Batten disease is a neuronal ceroid lipofucsinosis that arises from autosomal recessive mutations in the cyclin2 (CLN2) gene. Mutations in this gene result in early progressive widespread neurodegeneration and death. Pre-clinical efficacy studies with an AAV2-CLN2 were performed in rats and monkeys. A clinical study that started 2004 is ongoing. (http//www.clinicaltrials.gov/ct/show/NCT00151216).

### Neurodegenerative Diseases

Gene therapy for neurodegenerative diseases involves the local delivery of genes encoding protective or restorative molecules with the primary aim to prevent neuronal loss, promote reestablishment of connections and stimulate or reset the function of the affected neurons.

### Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive motoneuron disease. The cause of the disease is unknown in most patients but dominant mutations in *SOD1*, the gene encoding Cu/Zn-superoxide dismutase, are responsible for the disease in about 5% of cases. The progressive loss of motoneurons was slowed down after viral vector-mediated retrograde delivery of IGF1 [8] or VEGF in a transgenic mouse model of ALS [9]. VEGF is an angiogenic factor and local overexpression of this factor may lead to neovascularization. Several hurdles need to be overcome to translate these results to the clinic. Control over the dose and timing of growth factor expression will be critical in future clinical trial. In ALS the degeneration of motoneurons is widespread. Delivery of the therapeutic gene throughout the ventral spinal motoneuron pool and motor cortex is a challenge for which no solution is as yet on the horizon.

### Alzheimer's Disease

A key feature of AD is cholinergic neuron loss in the basal forebrain. Nerve growth factor (NGF) stimulates cholinergic function, improves memory and prevents cholinergic degeneration in animal models following injury, amyloid overexpression and during aging. A team led by Mark Tuszynski performed a successful phase I clinical trial of *ex vivo* NGF gene delivery in eight individuals with early signs of cognitive impairment [3]. Genetically modified autologous fibroblasts expressing NGF were transplanted in the forebrain. Patients were followed for 22 months and no adverse effects of the treatment were observed. Cognitive decline advanced at a diminished rate and serial PET scans showed significant increases in cortical 18-fluorodeoxyglucose uptake. A second NGF gene therapy trial for AD involves the delivery of AAV-NGF directly to the forebrain (www.ceregene.com).

### Parkinson's Disease

In Parkinson's disease (PD) dopaminergic neurons in the substantia nigra degenerate. This leads to changes in the circuitry of the basal ganglia, including the subthalamic nucleus (STN). At least two distinct gene therapy strategies are being pursued: (i) use of genes that can affect the activity of the remaining neuronal circuitry (e.g. glutamic acid decarboxylase [GAD]), and (ii) transfer of genes encoding neurotrophic factors involved in dopaminergic cell survival.

GAD synthesizes the inhibitory neurotransmitter (gamma)-aminobutyric acid. Dopaminergic cell loss results in disturbances in the circuitry of the basal ganglia; for instance excitatory neurons of the subthalamic nucleus become overactive. AAV-mediated expression of GAD in the STN resulted in silencing of this overactive circuitry in preclinal studies. Based on these results a phase I clinical trial to overexpress GAD in the STN of 12 patients has recently been completed [10]. Following unilateral injections of AAV-GAD into the STN no adverse events related to the gene

therapeutic approach were observed. A limited degree of functional improvement, especially on the side of the body contralateral to the surgery persisted in some patients up to 12 months.

Genzyme has initiated a phase1 open label safety study of intrastriatal infusion of AAV encoding human aromatic L-amino acid decarboxylase (AAV-hAADC-2) in subjects with PD in 2004. AADC is an enzyme that converts L-dopa to dopamine, to restore therapeutic windows of orally administered L-dopa in advanced idiopathic PD. This trial is still ongoing (www.genzyme.com).

Glial cell line-derived neurotrophic factor (GDNF) prevents degeneration of dopaminergic neurons. The neuroprotective effect of GDNF has been studied extensively in animal models for PD. Chronic infusions of GDNF in humans with PD had positive effects in two phase I studies. But the results were disappointing in a subsequent phase II trail and studies on GDNF were terminated. However, recently a phase I gene therapy trail for Neurturin, a naturally occurring member of the GDNF family of neurotrophic factors (www.ceregene.com), reported a 36% reduction in Parkinson symptoms 12 month into the study. Neurturin is delivered to the brain by an AAV vector and a larger phase II clinical trial with more than 50 patients is underway.

## Prospects

Experimental direct viral vector-mediated gene transfer into the rodent nervous system using an HSV vector and the implantation of genetically modified fibroblast were both reported at the end of the eighties of the twentieth century. Since that time enormous progress has been made in the field of gene therapy for neurological diseases (Fig. 3). Gene therapy appears to be safe and well tolerated as suggested by ongoing clinical trails on the delivery of growth factor genes to the afflicted brains of PD and AD patients using AAV vectors. The efficacy in terms of therapeutic benefit for the patient now needs to be addressed in phase II and III clinical trials. These trials are either planned or ongoing. It will be fascinating to witness the progress of gene therapy for various other acquired or inherited disorders, including brain tumors, pain syndromes, spinal cord and peripheral nerve trauma and ophthalmic diseases.

# Gene Therapy in the Central Nervous System: Chronic Pain

Erin D. Milligan[1], Steven F. Maier[2], Linda R. Watkins[2]

[1]University of New Mexico, Albuquerque, NM, USA

[2]University of Colorado at Boulder, Boulder, CO, USA

## Definition

The direct transfer of genes, DNA or RNA sequences directed to/into a specific population of central nervous system cells to correct ongoing pathology and/or disease conditions.

## Characteristics

### Background

Gene therapy for the expression of therapeutic proteins has been applied to clinical conditions that have no effective treatment. As of 2007, greater than 900 clinical trials, worldwide, were ongoing: http://www.

wiley.co.uk/genetherapy/clinical). The development of gene transfer techniques to the central nervous system (CNS) for therapeutic treatment of a variety of debilitating diseases has greatly diversified in the past dozen years and continues to increase with remarkable momentum. Multiple methods have been developed for gene transfer to the CNS: (i) "ex-vivo," where cells are engineered with the therapeutic gene in culture followed by transplantation into the body, (ii) "remote," where the transgene is delivered by either intramuscular or intraneural injection, (iii) "direct," where the vector containing the transgene is injected directly into the brain or spinal cord with the latter two approaches leading to therapeutic gene expression by the recipient's own cells [1], and lastly (iv) ribonucleic acid interference (RNAi) which is used to modulate or silence gene expression and is delivered to the CNS as naked RNA or via vectors [2]. The latter four approaches have been developed to a greater extent to treat neuropathic pain and will be discussed further. With regard to remote and direct vector delivery of genes to the CNS, several viral and non-viral vectors have been exploited for therapeutic gene transfer [1,3]. ►Viral vector therapeutic gene transfer includes the application of recombinant adenovirus (AdV), adeno-associated virus (AAV), herpes simplex virus (HSV), and lentivirus (LV), [1]. Non-viral vectors are fundamentally nucleotide-based therapies (RNA or DNA) in the form of oligonucleotides, plasmids, or ►small interfering RNA (siRNA) that are injected either unmodified, often referred to as naked or free, or after synthetic polymer treatment. In these approaches, the level of gene expression depends on the ►promoter, the design of the expression cassette containing the therapeutic gene, cell-type specific tropism when applying viral vectors, and in some cases, gene regulatory elements [1,4].

A major focus for viral and non-viral mediated gene delivery has been to develop vectors that do not activate the immune system so to maintain healthy, prolonged gene expression for chronic diseases [1]. Thus, an extensive overlap exists for gene therapy strategies to treat neurodegenerative diseases and neuropathic pain because these disorders are chronic, and prolonged treatment is required for successful clinical outcomes. Novel gene therapy development and application to treat neurodegenerative diseases such as Parkinson's disease, Huntington's disease, Alzheimer's disease and amyotrophic lateral sclerosis (ALS) have laid the groundwork for subsequent utility to treat ►chronic neuropathic pain.

## Gene Therapy for Neurodegenerative Diseases can be Applied to Neuropathic Pain

### *Neurodegenerative Diseases*

Parkinson's disease and Huntington's disease are similar in that both involve alterations in basal ganglia function. However, Parkinson's disease (55–65 years; age of onset) is identified by a loss of dopaminergic neurons with concurrent loss of axonal projections within the basal ganglia [1,5], and leads to symptoms of motor abnormalities (i.e. rigidity, tremor) (see Chapter on ►Drug Treatment for Motor Disorders). Dopamine replacement is a standard therapy for treating Parkinson's disease. In Huntington's disease (40–50 years; age of onset), the basal ganglia activity is decreased leading to increasingly greater uncontrollable movements. A progressive and large loss of cholinergic and GABA-ergic neurons ultimately produces pronounced motor dysfunction. Therapeutic gene delivery for neurotransmitter replacement using transfected cells *in vitro* subsequently transplanted *in vivo*, and AAV and Lentiviral viral vectors have been explored in rodent and nonhuman primate models [1]. These approaches have been applied in several ongoing clinical trials. Often, gene therapy approaches are aimed only at neuroprotective effects rather than curative effects because the underlying cause of neuronal death has not been identified [5].

Several gene transfer strategies are being applied in the clinic and to animal models of Alzheimer's disease (5% of people over age 65 are affected) and ALS. Alzheimer's disease is identified by a decline in cognitive function, memory and intellectual skills. The neuropathological features of Alzheimer's disease are senile plaques, neurofibrillary tangles and a high degree of neuronal loss in brain areas related to memory and cognition. This neuronal loss is likely the leading cause of cognitive dysfunction in Alzheimer's disease [5]. A strong link exists between neuroinflammatory processes mediated by ►microglia and ►astrocytes and the formation of senile plaques and neurofibrillary tangles [5]. Results from clinical trials aimed at inhibiting inflammation suggest that anti-inflammatory drugs serve a neuroprotective role in disease progression rather than being therapeutic. However, in terms of gene therapy, several strategies are being developed that target enzymes responsible for producing Alzheimer's-linked peptides, which are not yet known to play a role in inflammatory processes, including delivery of small ►siRNA (discussed further below) that are used to silence disease-causing gene expression [2].

In contrast, ALS is a progressive neurodegenerative disease of motor neurons in the spinal cord, brainstem and cerebral cortex culminating in death within 2–5 years of symptom onset [6]. Several mechanisms are suspected to lead motor neuron degeneration, and thus treatments aimed at motor neuron survival are potentially the best approach. As with several neuropathic pain conditions, activated glia (both astrocytes and microglia; discussed below) are believed to play critical roles in the progression of the ALS [6]. Gene therapy approaches are being applied to animal models of ALS, and several clinical studies are underway (Journal of Gene Medicine

clinical trial site: http://www.wiley.co.uk/genetherapy/clinical). As with Parkinson's, Huntington's, and Alzheimer's disease, novel gene therapeutic approaches for ALS are aimed at neuroprotective strategies. Further, these gene therapeutic approaches are now being applied to several models of neuropathic pain.

### *Neuropathic Pain*

Neuropathic pain is typically associated with either peripheral nerve or CNS damage caused by compression, transection, inflammation and/or altered metabolism [4]. When injured or inflamed tissue endures chronically, this leads to ongoing excitation in primary sensory neurons that communicate to pain transmission neurons in the dorsal horn of the spinal cord (see Chapter on ►Analgesics). Injured or inflamed tissue in the central nervous system can alter activity of spinal or brain neurons as well and, when this occurs in neurons relevant to the pain pathway, chronic pain ensues. Most often, treating such problems resolves pain. However, a number of chronic pain conditions exist where the underlying pathology cannot be treated or cannot be identified. The ongoing excitation leads to a sensitized, pain facilitatory state in the dorsal horn of the spinal cord (central sensitization) due to the ongoing activity of primary sensory neurons, their central nerve terminals and/or dorsal horn pain transmission neurons in the spinal cord [5]. Thus, chronic pathological pain no longer serves the adaptive, protective mechanism that normal pain serves for recuperation and wound healing. Estimates for the prevalence of chronic neuropathic pain in the USA and Europe have been as high as 7%, with most drugs leading to therapeutic efficacy in only ~50% of people [4]. Neuropathic pain, like ►allodynia, is pain associated non-painful stimuli. In rodent models, allodynia is often measured by changes from baseline values in hind paw responses to low threshold mechanical or thermal stimuli, referred to as mechanical or cold allodynia, respectively. Increased sensitivity to normally painful stimuli is often measured by changes from baseline hind paw responses to mechanical or thermal painful (noxious) stimuli, referred to as mechanical or thermal ►hyperalgesia, respectively. Thus, novel strategies using gene therapy to target specific nervous system regions relevant to pain transmission can be examined in a number of animal models of pathological pain. A variety of nerve injury and inflammatory manipulations that produce chronic allodynia and hyperalgesia in rodents have been used to explore gene therapeutic efficacy for the purpose of possible clinical utility. Indeed, the outcome of some of these studies in rodent models are leading to phase I/II clinical trials in patients with cancer pain [7]. Gene therapy strategies to examine pain control in rodents is relatively new, with 55% of pain-related gene therapy studies reported within the past 4 years. The first pain related report, published in 1990, used transplanted cells in the subarachnoid space [4]. Since then, a range of gene therapy strategies has been explored using rodent models of neuropathic pain.

## Viral Vectors for Pain Control

Adenoviral vectors (AdV) have a wide cellular tropism and have been shown to transduce (gene transfer from vector to host cells) neurons and glial cells after direct injection into the CNS and to transduce sensory and motor neurons by axoplasmic transport after intramuscular injection [1]. The underlying mechanism for AdV retrograde gene transfer is poorly understood. Despite the possible clinical application of retrograde transport for gene delivery from the body to the CNS, the immunogenicity of AdV limits its therapeutic efficacy [1]. AdV leads to pronounced immune activation in the CNS that includes glial cell (astrocytes, oligodendrocytes and microglia) activation, increased expression of major histocompatibility complex (MHC) molecules that are critical for efficient antigen presentation, and proinflammatory cytokine expression [1]. Microglia are phagocytic, antigen-presenting cells that are part of the non-specific innate immune response (►Innate immunity), and are classically referred to as the macrophages of the CNS. Astrocytes have similar phagocytic properties, and upon activation, release many of the same immune signals that microglia release in addition to their role as modulators of synaptic transmission [8]. To circumvent the immunogenic properties of AdV, a number of new strategies are being explored that may be promising for future clinical application. For example, nonhuman AdV such as the recombinant, replication defective, canine AdV was examined in human blood cells with a canine AdV-immunological naïve background to assess immune responses [1]. This is an important consideration because >85% of individuals express high circulating antibodies to various serotypes of human AdV, which may lead to robust memory immune responses if given AdV for therapeutic purposes. That is, enhanced and rapid immune responses to previously encountered foreign invaders like human AdV. Thus, immunological responses to canine AdV were predicted to be substantially lower. The nonhuman canine AdV vector produced immune activation, as measured by increased MHC expression, in less than 50% of donors tested [1]. Although canine AdV vectors have not yet been exploited for neuropathic pain treatment, the lower immunogenicity and retrograde transport properties of canine AdV [1] may be useful for gene transfer to discrete regions of the CNS to control pain.

There are few studies examining AdV vectors for gene delivery to treat neuropathic pain. Gene therapy approaches have focused on decreasing the excitability of spinal cord pain transmission neurons, and more recently, has targeted activated spinal cord glia. Our previous

understanding of the creation and maintenance of neuropathic pain has been based primarily on studies focused on neuronal mechanisms of which currently mounting evidence suggests is too narrow. Evidence supports the idea that activated spinal cord glia contribute powerfully to the creation and maintenance of pain facilitation, at least in part, via release of proinflammatory ►cytokines. This may be one reason that drugs only targeting neurons have not proven successful in treating chronic pain in many patients [8]. A number of pain syndromes with widely different etiologies (as discussed above) may involve a common underlying mechanism such as spinal cord glial activation. Glial proinflammatory cytokine involvement in pain facilitation may be alleviated by gene therapy that specifically targets the function of activated glia, rather than neurons. Virally directed, spinal release of the anti-inflammatory cytokines interleukin-10 (IL-10), interleukin-2 (IL-2), interleukin-1 receptor antagonist or soluble receptors for tumor necrosis factor-alpha could achieve this goal. Although AdV can infect a variety of dividing and non-dividing cell types, subarachnoid spinal delivery (►intrathecal; i.t.) of adenovirus primarily infects cells in the ►meninges, both on the spinal and dural surfaces [1]. The meninges is comprised of three membranous layers that surround the spinal cord (dura matter, arachnoid matter, and pia matter). The subarachnoid space cerebrospinal fluid (CSF) [5]. Indeed, i.t. AdV delivery of proteins known to block the actions of proinflammatory cytokines with anti-inflammatory cytokines has proven to be effective by several gene therapeutic strategies. Thus, i.t. delivery of the anti-inflammatory cytokine genes, interleukin-10 (IL-10) or interleukin-2 (IL-2), reversed CCI-induced thermal hyperalgesia and mechanical allodynia from 2 to 4 weeks [4]. Several other studies using AdV delivery methods resulted in therapeutic outcomes in animal models of pain. Delivery of the pro-opiomelanocortin (POMC) gene that encodes beta-endorphin, which effectively blocked thermal hyperalgesia produced by a carrageenan injection into the hind paw, was the first demonstration that i.t. AdV could be a viable strategy for spinal delivery of therapeutic genes. Lastly, the intra-muscular AdV delivery of the neurotrophin-3 gene reduced pain thresholds in diabetic peripheral neuropathy [4,7].

Adeno-associated virus (AAV) is a single-stranded DNA virus that has been developed as a gene transfer vector with up to eleven distinct serotypes that influence cell and tissue specific tropism for gene expression [1]. For example, recombinant AAV serotype 2 has inherent tropism for neurons and glia, whereas recombinant AAV serotype 8 preferentially transduces cells in the liver. In addition, sequences of DNA that facilitate gene expression referred to as promoters, can be selected for more efficient transgene expression. For example, the widely used human cytomegalovirus immediate/early gene promoter and ►enhancer (CMV) to drive the expression of specific transgenes in the brain greatly improved gene expression. The AAV-based vectors lead to long-term gene expression in the brain. Up to eleven promoters have been utilized to drive cell-type specific gene expression mediated by recombinant AAV vectors [1]. Like AdV, only a few studies have applied recombinant AAV vectors for therapeutic gene delivery to pain relevant tissues [4,7]. AAV vector delivery encoding either brain-derived neurotrophic factor or IL-10, by direct spinal or intrathecal injection into the CSF, reversed hyperalgesia and allodynia that lasted from 2 to 8 weeks. Additionally, direct sciatic nerve injection or dorsal root ganglion (DRG) injection of AAV encoding the mu-opioid receptor enhanced morphine analgesia in an acute inflammatory pain model [4,7]. However, to date, AAV as a viable option for pain control is limited because of poor transduction properties, transient effects with a limited gene delivery capacity of a single gene, and can stimulate immune activation leading to viral clearance.

Retrovirus-based vectors, Lentivirus (LV) vectors, can lead to sustained gene expression in specific cell types by using promoter elements that are active only in the target cells. For example, promoter-generated transgene expression can be used to induce transgene expression only in neurons, and not in surrounding glia. Many LV vectors are derived from the human-immunodeficiency virus, exert minimal immunogenic responses, have a large capacity for DNA insertion into the host genome (up to ~10 kb), and are retrogradely transported after intra-muscular injection [1]. Recently, LV vectors encoding nuclear receptor-kB super repressor (sr/kBa) or glial cell-line derived neurotrophic factor (GDNF) reduced allodynia and hyperalgesia from 6 days to 3 weeks [4]. LV vectors preferentially infect glial cells in the dorsal horn of the spinal cord, a property that may be useful for targeting glial cell function involved in neuropathic pain. However, several drawbacks exist for utilizing LV vectors for pain control that include the risk of integration leading to oncogenesis. In addition, LV vector retrograde transport is not efficient, and high titers can be difficult to produce [4].

Recombinant herpes simplex virus (HSV) vectors have been utilized most frequently (~30%) for therapeutic gene delivery to control pain [4]. Some common features between HSV vectors and the naturally occurring "wild-type" parental virus for vector utility are that: (i) infection readily occurs in epithelial cells in the skin, followed by viral envelop glycoprotein interactions with high affinity receptors (herpesvirus entry mediator A, nectin-1 and nectin-2) expressed on sensory nerve terminals, (ii) retrograde axonal transport to sensory neurons in the DRG leads to therapeutic effects by 7 days, (iii) an establishment of a lifelong infection within neurons occurs while viral proteins remain undetectable, (iv) particles do not

integrate into the host genome and remain as intranuclear episomal chromatin structures, (v) large transgenes are a viable option, and (vi) low immunogenicity results; reinoculation leads to continued therapeutic efficacy for weeks [1,4]. Retrogradely transported HSV vectors after cutaneous inoculation have been utilized to elevate preproenkephalin, glutamic acid decarboxylase that enzymatically produces the inhibitory neurotransmitter, gamma-amino butyric acid, the anti-inflammatory cytokine IL-4 and glial cell-line derived neurotrophic. All of these factors expressed in the sensory neurons after HSV inoculation have proven therapeutic for neuropathic and inflammatory pain [4].

## Non-viral Vectors for Pain Control

Several non-viral approaches to deliver potentially therapeutic genes have been utilized primarily because of their low immunogenicity and ease of manufacturing [3,4,7]. However, such approaches have led to low levels of transgene expression. New approaches using synthetic polymers have been developed to optimize therapeutic efficacy for non-viral vectors. These strategies, each of which will be briefly discussed, include antisense oligonucleotides, siRNA, naked ►plasmid DNA, or plasmid DNA modified by ►liposomes or synthetic polymers, all of which have produced transient pain control lasting from days to as long as 4 weeks. Antisense oligonucleotide and siRNA are similar in that both are injected i.t. to inhibit the expression of proteins that are known to mediate neuropathic pain. However, the inhibitory effects are by different mechanisms. Antisense oligonucleotides are oligonucleotides that bind with specific, complementary messenger RNA sequences to the target gene. Gene activation is prevented once these complementary oligomers bind messenger RNA. However, oligonucleotides are quickly eliminated by degenerative nuclease enzymes, supporting the use of antisense oligonucleotides as diagnostic tools for the involvement of particular genes in neuropathic pain rather than as therapeutic treatments. Inhibition of gene expression by siRNA is achieved when this molecule is associated with a cytoplasmic multiprotein complex called, ribonucleic acid-induced silencing complex (RISC). In turn, RISC utilizes the siRNA antisense strand as a template to bind and selectively degrade messenger RNA after gene transcription has occurred [2]. Antisense oligonucleotides targeted against proteins implicated in spinal cord pain processing include cyclic AMP response element-binding (CREB), NaV1.8 (a tetrodotoxin resistant sodium channel), the N-methyl-D-aspartate (NMDA) receptor subunit R1, or the metabotropic glutamate receptor type 1, and lead to decreased allodynia and pain-related behavior in several experimental rodent pain models. Delivery of siRNA against the NMDA receptor subunit, 2B (NMDA-R2B), the transient receptor potential vanilloid receptor 1 (TRPV1), and against the ionotropic purinergic type 2X3 receptors decreased both allodynia and pain-related behaviors for up to 5 days [4,7].

Although plasmid DNA delivery to target cells is considered to be the least effective, strategies aimed at improving plasmid-based gene delivery are rapidly expanding [3] and show promise for future clinical applications. Plasmid DNA therapy relies on host transcription machinery for exogenous DNA expression. Several methods used to optimize gene delivery include engineering elements within the plasmid vector (exogenous DNA expression cassettes), electroporation (►In vivo electroporation), gene gun delivery or chemical modification by liposomes or synthetic polymers [4,7,9,10]. The plasmid-based gene delivery system is attractive because it tends to be less immunogenic, is easy to manufacture, and lacks the dangers associated with some viral vectors (i.e. insertional mutagenesis resulting in tumors). Successful attenuation or reversal of pathological pain was produced by i.t. plasmid DNA gene delivery that lasted up to 6 weeks [4,7,9,10]. In these studies, genes encoding either opioid peptides or anti-inflammatory cytokines were examined for neuropathic pain control. These studies are unique not only in applying plasmid-based vectors for intrathecal gene transfer, but also in some cases, the long duration of therapeutic efficacy for pain control [9,10], supporting a strong potential for clinical utility.

Spinal cord plasmid DNA gene transfer is typically limited to transient therapeutic expression either with naked or chemically modified plasmid DNA. A single i.t. IL-2 plasmid DNA injection reduced neuropathic pain for 3 days, prevented acute inflammatory-induced pain, and produced spinal cord mRNA and protein expression for 3 days. However, repeated-injection methods have produced improved plasmid DNA gene expression [9,10]. Indeed, repeated injections of plasmid DNA encoding the anti-inflammatory gene, IL-10, at inter-injection intervals of 2–3 days, leads to a reduction in hyperalgesia and allodynia lasting for up to 6 weeks [7]. One drawback using plasmid DNA vectors for i.t. gene delivery is the dose required to achieve prolonged pain control in rodent models because of inefficient uptake of plasmid DNA. The high dose may limit the potential clinical application of plasmid vectors because an estimated ~290 mg plasmid DNA may be required for a person of 81 kg (180 pounds) to control pathological pain. One possible solution has been the application of cationic agents such as ►polyethylenimine (PEI), liposomes, or synthetic polymers such as ►poly(lactic-co-glycolic) (PLGA) to sustain gene expression while decreasing the required dosages. Micro-encapsulation of plasmid DNA within PLGA does not significantly disrupt the functional integrity of plasmid DNA and produces a significant attenuation of allodynia at reduced doses (~100-fold decrease) in a rodent model of neuropathic pain [10].

Further development of methods to chemically modify plasmid DNA for improved gene delivery to control chronic pathological pain continues to rapidly expand. Overall, the number of clinical gene therapy trials to control chronic pain is expected to grow substantially.

## General Constrained Optimization

### Definition

A general constrained optimization problem is defined by an objective (cost) function, and the corresponding equality and inequality constraint functions. The distribution problem in biomechanics is typically expressed as a general constrained optimization system.

►Distribution Problem in Biomechanics

## General Fascia

### Definition

Collagen fiber reinforced connective tissue sheet that envelopes the whole body below the subcutaneous fat tissue.

►Intramuscular myofascial force transmission
►Epimuscular Myofascial Force Transmission and Intermuscular Interaction

## Generality Problem

### Definition

This problem arises for reliabilist accounts of knowledge:

There seems to be no "fact of the matter" about how general the description has to be that is given of the method employed in acquiring a specific belief.

Therefore, there seems to be no "fact of the matter" about knowledge either.

►Knowledge

## Generalization

### Definition

Animal trained to respond to a particular stimulus shows responding not only to that stimulus but also to stimuli that differ from the original stimulus along the stimulus dimension. This spread of the effect of discrimination training is called generalization. The rate of responding has a peak at the trained stimulus and a slope called the generalization gradient.

►Discrimination

## Generalization of Learning

### Definition

The improvement of detection or discrimination achieved through training transfers to similar (classes of) stimuli.

►Sensory Plasticity and Perceptual Learning

## Generalization of Motor Skills

### Definition

Some learned motor skills are not effector specific and can be easily transferred between different parts of the motor system. Such motor skills are generalized.

►Motor Learning

## Generalized Epilepsy with Febrile Seizures Plus (GEFS+)

### Definition

GEFS+ is an autosomal dominant disorder that displays generalized epilepsy symptoms that can persist beyond early childhood age (6 years). Known causative genes are a $GABA_A$ receptor γ subunit gene, GABRG2, α subunit genes of sodium channels, SCN1A and SCN2A and an associated β subunit of sodium channels, SCN1B.

## Genetic Basis of Behavior

### Definition

Behavior in general has two components: an inherited or innate component and a component acquired by the animal in its individual live. The inherited component may have a variable contribution to a given behavior. There has been a long debate about the influence of inheritance on human behavior (nature versus nurture), but it is now accepted by most scientists that human behavior as well as animal behavior are influenced by both components.

## Genetic Defect

### Definition

Genes represent a code or set of instructions for cells to make proteins. The correct protein is made if the code in the gene is correct. However, the code in a gene can be modified or mutated (e.g. made defective) for several reasons. When this occurs the protein may not be formed at all, or only a portion of the protein may be formed. The result is a loss or incomplete function of the protein.

## Genetic Imprinting

### Definition

Genetic imprinting is a genetic mechanism whereby gene expression depends on parental origin. Certain

imprinted genes are expressed only from the allele inherited from the mother, whereas others are expressed only from the allele inherited from the father.

Epigenetic mechanisms control imprinting, with the two major ones being DNA methylation and histone modifications. The imprinting process is reversible in the next generation. Imprinting occurs in the early embryo either in the eggs or sperm of the ovaries and testes, respectively.

## Genetic Linkage

### Definition

Occurs when specific alleles are inherited jointly, because they are found close to each other on the same chromosome.

## Genetic Mapping

### Definition

Genetic mapping is used to help identify a gene underlying a mutant phenotype in an animal model or a disease in humans. The relative position on the chromosome of a mutant phenotype associated with a mutation of an unknown gene is determined by identifying the frequency at which the phenotype follows various genetic markers whose position on the chromosome is known.

## Genetic Marker

### Definition

An identifiable portion of the DNA whose inheritance can be followed.

## Genetic Modifier Screen

### Definition

Genetic modifier screen – when changing the gene dosage of a component of a particular genetic pathway enhances or suppresses the existing phenotype of the mutated gene in question. A significant advantage of this method is the ability to identify genes without any prior knowledge of the genetic regulation of the phenotype.

## Genetic Screens (Use of Zebrafish Forward Genetic Screens to Uncover Novel Regulators of the Vertebrate Nervous System)

Curtis R. French, Andrew J. Waskiewicz
Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

### Definition

The forward genetic screen aims to identify mutations that produce a certain ►phenotype. A mutagen is used to cause random mutations in the germ line of the organism. Once mutants have been isolated, the mutated gene can be genetically mapped and molecularly identified.

### Characteristics

The ►forward genetic screen involves creating random mutations in the germ line of an organism, for example, the ►zebrafish, which can be passed on to future generations. In a typical F2 screen, mutations are induced in one copy of a particular gene, thereby creating a fish that carries mosaic germ line mutations (parental generation). A mutagenized fish is then bred to a phenotypically normal "wild type" fish, creating F1 heterozygous progeny. F1 fish are then bred with siblings, to create clutches of fish in which half are wild type, and half are heterozygous for an induced mutation (F2 generation). Fish from the F2 generation are then crossed to siblings to create the F3 generation. Clutches derived from two F2 fish that are heterozygous for an induced recessive mutation will contain homozygous mutant fish in one quarter of the progeny, and can thus be screened for resulting phenotypes. Other variations of this screen have been adapted, such as the haploid screen, which negates the need for an F2 generation. In this case, the F1 generation female eggs are fertilized with UV-irradiated sperm that contain no functional genetic material. The now haploid egg can develop and the desired phenotype should be readily visible as there is no wild type version of the gene to mask the

phenotype created by the mutated copy. Although Laploid screens are labor saving, morphological development is not entirely normal, so they are more useful in studying early embryo pattening events. Genetic screens that have uncovered genes that regulate the development of the zebrafish nervous system are described below.

In contrast to forward genetic screens, scientists have often used ►reverse genetics to implicate different genes in the development of the zebrafish nervous system, as well as other ►model organisms. This system involves manipulating a candidate gene and observing the resulting phenotype. In zebrafish, this entails the creation of ►morphants, where the function of one particular gene is inhibited. Creating a morphant involves injecting one-celled zebrafish embryos with ►morpholino(s) oligonucleotides directed against a specific messenger RNA sequence, which results in the inability of that messenger RNA molecule to be translated into a functional protein.

## Introduction

Humans have used genetic methods – unknowingly at first – to shape their surrounding world. Systematic agriculture, including the selection of crops with desirable traits, dates to 9500 B.C. Similarly, domestication of dogs, sheep, goats, and cattle dates to 9000–7000 B.C. In each of these cases, humans practiced selective breeding to encourage or fix traits that they wished to be present in later generations. With the rediscovery of the work of Gregor Mendel (1822–1884), the pea, which coincidentally was one of the first crops to be cultivated, revealed the major rules of heredity. The combination of gene-based heredity with the advent of easily manipulated model systems such as the fruitfly *Drosophila melanogaster*, the nematode *Caenorhabditis elegans*, and the zebrafish, *Danio rerio,* have facilitated a novel scientific approach: the forward genetic screen. In the twentieth century, scientists turned their attention to the mysteries of the nervous system, with a goal of understanding the mechanisms that govern neural connectivity, learning, and memory.

Zebrafish are small, tropical, fresh water fish. Adult zebrafish are approximately 2 inches long, reach sexual maturity at 3 months, and are prolific breeders, generating 100–200 embryos per week. The pioneering work of George Streisinger (1927–1984) established that these traits make zebrafish an ideal model for vertebrate neural function and development, and harnessed these traits to conduct some of the earliest vertebrate genetic screens [1].

## Regulators of Neural Patterning and Neurogenesis Uncovered by Morphology-based Screens

Early zebrafish ►saturation screens focused on alterations in morphology, and were successful in uncovering key molecules that pattern the nervous system. Defects in midbrain-hindbrain boundary, axial ►mesoderm, and somite formation have revealed conserved signaling cascades that influence neural differentiation and regional patterning.

The *cyclops* (*cyc*) mutation was originally discovered as a zygotic lethal mutant that blocks floorplate formation and causes cyclopia [2]. A spontaneous enhancer of *cyc*, *squint* (*sqt*) was identified, and *cyc; sqt* double mutants entirely lack ►endoderm and the majority of mesoderm. Three other mutants, *one-eyed-pinhead* (*oep*), *bonnie-and-clyde* (*bon*), and *schmalspur* (*sur*) have similar functions in regulating mesendodermal formation. Molecular cloning of the lesions in each of these mutants has demonstrated that these mutants define the Nodal signaling pathway in zebrafish. Sqt and Cyc are Nodal ligands; Oep is a Nodal co-receptor; and Bon and Sur are functionally overlapping Smad2 transcriptional cofactors. Nodal signaling is hypothesized to function largely in the ►embryonic shield, leading to the specification of endoderm and axial mesoderm. The anterior-most axial mesoderm is known as the prechordal plate and underlies the ventral forebrain neuroectoderm. Signals emanating from the prechordal plate are necessary to specify both ventral and midline identity, so it is logical that Nodal pathway mutants lack forebrain midline identity and therefore are cyclopic.

## Midbrain-Hindbrain Boundary Mutants

Mutants were identified that lack the midbrain-hindbrain boundary (MHB), a key tissue not just because it separates midbrain and hindbrain, but also because it acts as a regional signaling center. These mutants include *acerebellar* (*ace*), *no isthmus* (*noi*) and *spiel ohne grenzen* (*spg*). Researchers have identified the genetic lesion causing each of these mutants: *ace* is caused by a mutation in *fibroblast growth factor 8* (*fgf8*); *noi* is caused by a mutation in the paired domain transcription factor *pax2a*; and *spg* is caused by a mutation in the POU domain transcription factor *pou2/oct4/pou5f1*. Fgf8 and Pax2a, together with other key patterning genes, specify the identity of cells near the MHB and regulate the expression of the other MHB genes, while the *pou2/pou5f1* gene is required for proper initiation of *pax2a* expression. Neurons in each of the mutants are misspecified. For example, the posterior commissure neuron is not properly specified in *noi* mutants.

## Somite Mutants Reveal Neurogenesis Defects

Somites are bilaterally paired units of paraxial mesoderm that form building blocks for muscle, dermis, and skeleton. In the vertebrate embryo, somites form in an ordered, stepwise fashion starting in the anterior trunk, proceeding to the tail. Researchers found mutants that affected all somites, and three mutants, *deadly seven* (*des*), *after eight* (*aei*), and *white tail/mindbomb* (*wit/mib*), that affected only posterior somites. Analysis of neuronal populations in these posterior somite mutants demonstrated that each also has a defect in neuron

number. The first born neuron (and also the largest neuron) in the zebrafish primary nervous system is the Mauthner (Mth) neuron. Two Mth neuron cell bodies are located in hindbrain segment rhombomere 4 (r4). In *mib* and *des* mutants, 8–10 Mth neurons are observed indicating a profound defect in the regulation of neuronal specification. Molecular cloning of each of these somite mutants demonstrated that they encode members of the Notch-Delta signaling pathway: *mib/wit* is caused by mutation in an E3 ubiquitin ligase that targets Delta; *aei* is zebrafish *deltaD*; and *des* is *notch1a*. The discovery of these zebrafish mutations allowed researchers to determine that Notch-Delta signaling is important for both cyclic gene expression in somites and for regulating the correct number of neurons.

## Zebrafish Marker Screens Identify Regulators of Neural Patterning, Migration, and Differentiation

Morphology screens were successful in identifying important regulators of neural patterning and differentiation, but the zebrafish nervous system is largely transparent and unobservable. A series of screens have directly targeted neural development, taking advantage of region specific gene expression, antibodies which recognize developing neurons, and transgenic green fluorescent protein (GFP) lines that label specific neurons.

The nervous system is divided along the anterior-posterior axis into a series of regional domains, including forebrain, midbrain, hindbrain, and spinal cord. Each of these regions is further subdivided as evidenced by subdomains of tissue-specific gene expression. Within the hindbrain, for example, the zinc finger transcription factor *krox20/egr2b* is expressed in segments rhombomere 3 (r3) and r5. Using whole-mount ►*in situ* hybridization as an assay, researchers identified four zebrafish mutants that perturb hindbrain patterning. These mutants, *valentino* (*val*), *lazarus* (*lzr*), *vhnf1/tcf2*, and *spg*, express lower levels of *krox20/egr2b* than wild type embryos. The *val* locus encodes a basic-leucine zipper transcription factor known as Mafb. *in situ* hybridization for *mafb* and cell transplantation demonstrate that it specifies segment r5 and r6 identity. The *vhnf1/tcf2* mutant encodes *variant hepatic nuclear factor 1* (*vhnf1*), is expressed in the caudal hindbrain, and mutants fail to initiate *mafb* expression. Two MHB mutants, *spiel-ohne-grenzen* (*spg*) and *acerebellar* (*ace*) have also been instrumental in understanding hindbrain patterning. The *spg* and *ace* mutants have helped define that hindbrain segment r4 is the site of a fibroblast growth factor signaling center, expressing both *fgf8* and *fgf3*. The combined activities of these two signaling molecules together with *lazarus* (*lzr*), a Pbx transcription factor, initiates *egr2b*/*krox20* expression in r3 and r5. Research on these key zebrafish hindbrain patterning mutants has formed the cornerstone of our understanding of vertebrate hindbrain patterning [3].

## Left-Right Asymmetry

The human nervous system has intrinsic left-right laterality. Psychologists and early neurobiologists were the first to discern brain handedness. Although it was originally believed that L-R asymmetry was a uniquely primate characteristic, there is considerable evidence that the fish, chick, and dog brains possess intrinsic L-R distinctions. Within zebrafish, the organization of the pineal and habenular nuclei display consistent polarity. For example, the parapineal, an accessory of the pineal, is located on the left side of the pineal gland in embryonic zebrafish. The *cyclops* gene is similarly expressed on the left side of embryo and blocking Nodal signaling leads to randomization of parapineal orientation. Researchers have now developed an extensive catalog of left- or right-specific genes, and genetic screens are underway to identify additional regulators of embryonic laterality.

## Myelination Screens

In contrast to invertebrate nervous systems, vertebrate nervous systems are myelinated, facilitating rapid transmission of electrical impulses over large distances. Oligodendrocytes in the central nervous system (CNS) and Schwann cells in the peripheral nervous system (PNS) form a membrane sheathe that surrounds axons. In order to identify a genetic pathway for ►myelination, researchers conducted genetic screens to detect defects in expression of *myelin basic protein*. Researchers found five loci that affect PNS-specific myelination, with two of these encoding Erbb2 and Erbb3, the receptors for Neuregulin. Since it is known that Neuregulin's signaling to Erbb receptors is required for Schwann cell differentiation in mammals, the screen is certainly capable of identifying critical regulators of myelination. Three mutants were characterized that affected only CNS-specific myelination. One of these mutants is encoded by *monorail/foxa2*, a winged-helix transcription factor. Previous data has shown that *foxa2* is required for *sonic hedgehog* (*shh*) expression in the midline and *shh* is required for oligodendrocyte differentiation. Three additional mutants were identified that affected myelination in both CNS and PNS.

## Neural Migration Screens

During development, incredibly precise mechanisms control the exact positioning of each neuron. A small subpopulation of neurons differentiate in one position and subsequently migrate to their proper destination. These migrations, largely categorized as either radial or tangential, describing the direction of movement with respect to the axis of the tissue, are themselves carefully orchestrated events that are critical for neuronal function. In zebrafish, one of the most dramatic neuronal migrations, facial (nVII) branchiomotor neuron cell bodies moving from rhombomere 4 (r4) posteriorly to

r6 and r7, is easily observed in living embryos using the *isl1: GFP* (GFP driven under the control of the *isl1* promoter) transgenic zebrafish line. Genetic screens and analysis of existing mutants has demonstrated that two genetic pathways are essential for migration, Pbx-Hox to define neural identity and the non-canonical Wnt pathway to maintain integrity and polarity of neural tissues.

## Axon Pathfinding and Projection: Retinal Ganglion Cell Axons

The nervous system plays a highly specialized role in the development of vision. The neural retina must differentiate from surrounding tissue to include many different cell types that are required for functionality. In zebrafish, the neural retina begins to become distinct from surrounding tissues at the 14–15 h post fertilization (hpf), with the formation of the first neurons within the retina by 29–34 hpf. The earliest known postmitotic neurons, retinal ganglion cells (RGCs), are of great importance as they eventually extend their axons to connect with a visual processing center, which in zebrafish, is known as the optic tectum. This process is tightly regulated, as proper pathfinding toward the tectum, and mapping of axons onto the optic tectum is essential for normal vision. Genetic screens have revealed genes that are required for this precise mapping, as well as genes required for differentiation of these highly specialized neurons.

A highly informative screen conducted by the Friedrich Bonhoeffer lab in 1996 uncovered at least 114 mutations that affect the ability of retinal ganglion cells to properly project toward [4] and map onto optic tectum [5]. To visualize RGC axons, lipophilic fluorescent dyes, which dissolve and are transported along the length of axon membranes, were injected into the zebrafish retina. Nineteen distinct mutants displayed errors in axon projection toward the optic tectum. Another 44 distinct mutants displayed defects in the ordering of the topographic map on the tectum, or the formation of proper axon termination fields. Subsequent studies have identified genetic identities and molecular functions for many of these genes, greatly expanding our understanding of the molecular control of vision in vertebrate species.

In one such mutant, *belladonna* (*bel*), retinal ganglion cell axons project toward the ipsilateral tectal lobe as opposed to the normal contralateral tectal lobe. As a result, zebrafish homozygous for the *belladonna* mutation display a reverse optokinetic response (OKR) and oculomotor instabilities (spontaneous ocular movements) in the absence of stimulation. The *belladonna* mutation was mapped via positional cloning to a locus containing a Lim-homeodomain transcription factor (*lhx2*). Given that the RGC axons project toward the ipsilateral tectal lobe instead of crossing the midline of the forebrain and extending toward the contralateral tectal lobe, the authors hypothesize that Lhx2 is necessary for forebrain patterning to produce guidance cues directing axons across the midline, and toward the contralateral tectal lobe [6]. Consistent with this theory, diencephalic expression of the transcription factor *dlx2* is strongly reduced. Thus, Lhx2 is required for proper patterning of the forebrain and potentially the production of guidance cues that allow for RGC axons to cross the midline.

Recently, a transgenic line of zebrafish was created in the lab of Herwig Baier that expresses Green Fluorscent Protein (GFP) under the control of the *brn3c* promoter/enhancer. This drives expression of GFP in a subset of retinal ganglion cells that map to the tectum and allows for large scale screening of RGC axon guidance defects in embryos without having to fix and inject lipophyllic dyes into the retina. Thus, a GFP based screen would be less labor intensive, and allow the visualization of RGC axon defects multiple developmental stages as GFP can be viewed in live embryos. It is likely that more GFP transgenic zebrafish will be created in the years to come, with expression in different subsets of RGC axons, and greatly facilitate the identification of genes required for RGC ►axon pathfinding and mapping.

## Neural Retina Differentiation

Differentiation of the neural retina is tightly regulated throughout development of the embryo, and perturbations in this process can lead to profound vision defects. To uncover genes required for the differentiation of different eye cell types, Jarema Malicki and colleagues (1996) conducted a genetic screen, paying particular attention to mutants that showed defects in eye morphology in live embryos and laminar structure in cross section. The zebrafish eye is an excellent tool for the study of eye laminar structure and is well characterized, highly organized, and cell types can be readily determined by their position and shape. Furthermore, molecular markers have been established to identify different cell types in the event that mutants display altered eye cell shapes or positions.

The screen by Maliciki et al. uncovered 49 mutations that affect the morphology and/or laminar structure of the eye [7]. These included mutants that fail to specify specific cell types, retardation of eye growth, retinal degeneration, and abnormal development of the eye anlage often leading to cyclopia. Further research has identified genetic loci for many of these mutants, and revealed valuable information as to how the mutated gene is required for proper eye development.

## Behavioral Screens: Vision

Genetic screens for mutants in eye morphology, as well as retinal ganglion cell pathfinding and mapping, have given great insight to the genes that govern these processes. However further studies are often required

G

to determine the extent of visual functionality in these zebrafish. An alternative approach by means of screening zebrafish behavior can uncover mutants with generalized visual system defects. Brockerhoff and colleagues utilized this approach to study the optokinetic response in mutagenized zebrafish, and uncovered 18 optokinetic-defective mutants [8]. This assay is relatively simple, and involves detecting eye movement in response to a moving drum displaying alternating black and white vertical stripes.

The majority of mutants uncovered using this assay have obvious morphological eye defects, indicating that aberrant retinal differentiation or organization is likely responsible for the visual system defect and would thus be readily identified in morphological screens. However, two mutants were found to have no obvious morphological defect, but lacked the wild-type optokinetic response. One mutant, *no optokinetic response* (*noa*) are able to move their eyes (in response to physical stimuli), but do not move their eyes in the direction of drum rotation. Electroretinography (ERG) analysis indicated that the defect is likely the result of impaired synaptic transmission between photoreceptor and bipolar cells, or in the bipolar cells themselves.

The sensitivity and robustness of the optokinetic assay has made it a powerful tool for genetic screens in zebrafish. Mutants have been uncovered that have been later found to represent defects at various stages of visual system development, such as *melanin deficiency (sandy)*, *lack of ganglion cells (lakritz)*, and *optic-nerve disorganization (grumpy and sleepy)* [9]. This approach has the advantage of detecting mutants with defects in any of the processes that govern the development of the neural retina as well as RGC pathfinding and mapping.

## Behavioral Screens: Locomotion and Chemical Preference

Behavioral screens in zebrafish have been utilized in recent years for a variety of purposes extending beyond the study of vision. Screens for locomotion behavior that have uncovered mutants with neural and neural/muscular defects. To this end, mutants with reduced locomotion, mechanosensory defective mutants, "spastic" mutants, circling mutants and motor circuit defective mutants have been identified [10]. In the realm of medical science, behavioral screens have been utilized to identify mutants with increased/decreased sensitivity to cocaine. In this assay, mutagenized fish are placed in a tank that is separated into two halves, but allows movement between halves. Cocaine is administered to one side, with wild-type fish showing a preference, or ►chemotaxis for that side over the other, reflecting cocaine's rewarding effect. A preliminary screen uncovered three mutant families that do not display the normal preference for cocaine. Although these mutants have yet to be mapped, the genes are promising targets for pharmaceuticals that may alleviate chemical addiction.

## The Future of Zebrafish Screens

Recent advances in transgenic technology have greatly simplified the production of transgenic lines, providing a plethora of new screening lines. Unfortunately, new mutants are becoming rare. One concern is the existence of 30% duplicate genes in zebrafish. These have been retained since the evolutionarily ancient teleost genome duplication. These gene pairs are likely to have partially overlapping function making the isolation of genetic mutants challenging. To circumvent this problem, researchers have begun large-scale efforts to create gene knockouts encompassing the entire genome. Two promising technologies are currently at the forefront: ►Tilling and ►viral insertional mutagenesis. In the coming years, these two technologies will create 1,000's of new zebrafish strains that will advance our understanding of the developing vertebrate nervous system.

## Genetic Vaccination

►Neuroinflammation – DNA Vaccination Against Autoimmune Neuroinflammation

## Genetics

### Definition

Genetics is the study of the properties of single genes or groups of genes.

## Genetics and Molecular Biology of Protein Expression, Localization and Function

Sarah McFarlane
Department of Cell Biology and Anatomy, Hotchkiss Brain Institute, Faculty of Medicine, University of Calgary, NW, Calgary, AB, Canada

For a neuron to function properly, it must first acquire during ►development a particular morphology, but one that can be subsequently altered in a plastic way in response to changes in the environment of the organism and/or of the neuron itself. In addition, appropriate sets of molecules have to be expressed and targeted to their correct subcellular compartments. An obvious example is that for any given neuron the proper ►neurotransmitter release machinery needs to be present at the ►synaptic nerve terminal at the end of the axon, and the ►neurotransmitter receptors must be expressed on the dendrites. In fact, the very establishment of the ►polarity of the developing neuron depends on the appropriate targeting of proteins, for example the ►par proteins and ►RhoGTPases. Notably, the identity and location of the particular proteins that are required is dynamic and changes both during the development of the neuron, and as it carries out its function in the adult. Two examples are illustrative. First, during development some neurons respond to the neurotransmitter ►gamma amino butyric acid (GABA) by depolarizing. As they mature, these neurons begin to express a different ►chloride co-transporter protein that allows GABA to hyperpolarize the membrane. This change in ►chloride homeostasis is critical for the establishment of GABA as one of the main inhibitory neurotransmitters in the adult brain, and involves a new gene being turned on and another off as development proceeds. The second example takes place in the adult, where changes in protein expression occur in response to alterations in neuronal function. The underlying mechanism in this case involves neural activity inducing the different component parts (►exons) of a gene to be mixed and matched by a process called ►alternative splicing, which changes the sequence or localization of the encoded protein. Here, neural activity regulates the distribution of two different splice variants of the ►N-methyl D-aspartate (NMDA) ►glutamate receptor in the ►postsynaptic membrane of cortical neurons [1]. The exon encoding the C2 domain of the receptor, which restricts ►NMDA receptors to the ►endoplasmic reticulum (ER), is used when neurons are electrically active, whereas the C2′ exon, which targets receptors to the plasma membrane (►Cell membrane – components and functions), is employed when neurons are silent.

In summary, it is critical that a cell expresses the correct proteins at the right time and in the appropriate subcellular compartments, and there are multiple levels by which this requirement can be regulated. Here, I give an overview of the regulatory mechanisms in the nervous system that ensure that proteins are active in their correct time and place, providing illustrative examples. I also discuss some of the molecular and genetic tools available for their study in the embryonic, adult and diseased nervous systems.

### Regulation at the Level of Gene Transcription

The human ►genome has approximately 23,000 protein-coding genes (at last estimate, by sequence annotation; ensembl.org/Homo_sapiens/index.html). Only about 1.5% of the human genome, however, codes for proteins. The majority of the remaining sequence is in fact transcribed into ►non-coding RNA.

Notably, ►model organisms such as the fruitfly ►*Drosophila melanogaster* and worm ►*Caenorhabditis elegans*, have comparable numbers of genes in their genome as humans [2,3]. Thus, the complexity of humans, and, in particular, of their nervous system, cannot arise simply from a modest increase in the number of protein-coding genes present in their genome. Most of the differences between species in fact occur within non-protein coding regions, as is the case for the vast majority of the approximately 15 million changes at the DNA level between the genomes of humans and chimpanzees. Hence, it is not differences in the genes present in the two species that account for their differences. Rather the intricacy and size of the human nervous system likely comes about by the exquisite and careful turning on and off of protein-coding genes. ►Gene transcription is regulated by ►transcription or trans-acting factors, which either trans-activate or trans-repress the transcription of specific target genes. Ultimately, ►DNA transcription results in the production of a ►pre-mRNA that is processed into the final mature ►messenger RNA (►mRNA), which will be ►translated (►RNA translation) into protein by the cell.

Genes can be turned on and off as a result of signals extrinsic to the neuron. Indeed, a neuron's differentiation in the developing embryo, and its function in the adult, depends on it being able to respond to extrinsic signals that induce rapid, local changes and/or longer-term changes in gene expression. Thus, neuronal function depends on both the appropriate expression of molecules that are extrinsic to the cell (►cell non autonomous) (►cell autonomy), and ones that mediate the response to these molecules and are intrinsic to the cell (►cell autonomous, cell autonomy). Extrinsic signals come from both neighboring and distant cells. An example of the latter are secreted molecules called ►morphogens, which regulate the expression of sets of genes in a responding population of neuronal cells in a concentration-dependent manner.

Neurons require the appropriate receptors in order to respond to extrinsic signals. Much work has gone into identifying the signals and their receptors, as well as dissecting the regulatory pathways by which they impact gene transcription. Generally, extrinsic factors bind to receptors in the membrane, inducing ►signal transduction cascades that ultimately promote the activation of downstream transcriptional effectors, often via the translocation of these downstream effectors into the nucleus, where they can activate or repress gene transcription. Forward signaling involves a ►ligand binding to a receptor and activation of a signal transduction cascade in the receptor-expressing cell. In some instances, ►reverse signaling can occur whereby the molecule considered to be a "receptor" binds a "ligand" intimately associated with the plasma membrane and causes activation of a signal in the ligand-expressing cell. Interestingly, proteins do not actually have to contain an intracellular domain to participate in reverse signaling: ephrinAs lack a cytoplasmic domain entirely, but by their localization to ►lipid rafts they control the recruitment of intracellular signaling proteins to the rafts. Reverse signaling plays a role in various developmental events, and, where reported, occurs local to that part of the cell so that a signal does not get sent to the nucleus.

Because a neuron's axon and dendrites are distant from the nucleus, mechanisms have evolved to transport the signals long distances within the cell. These include rapid events such as $Ca^{2+}$ signals that arise either from $Ca^{2+}$ entry through ►ligand-gated channels or ►voltage-gated ►channels (►Calcium channels) in the plasma membrane, or from the endoplasmic reticulum. Alternatively, slower signaling from distal parts of the cell to the nucleus can occur by transport of either proteins that are internalized into ►endosomes, or activated soluble molecules. In the latter case, the signals are likely transported in an active fashion, potentially facilitated by ►importin-mediated transport [4]. ►Retrograde transport of signals is important during development, and for ►synaptic plasticity and ►regeneration in the adult. For example, ►bone morphogenetic protein-dependent growth of the ►presynaptic element of the *Drosophila* ►neuromuscular junction requires activation of the ►Smad pathway. In this case, local signaling results in long-term, stable molecular and structural changes to the presynaptic element via Smad-dependent regulation of gene transcription in the nucleus.

Ultimately, activation of a multi-component transduction pathway results in translocation of a downstream factor or complex into the nucleus [4], where it influences the binding of a complex of interacting transcription factors and proteins to DNA at specific sequences known as ►transcription factor binding sites that are present in a gene's ►regulatory region including in ►promoter and/or ►enhancer elements. Ultimately DNA transcription is altered. Interestingly, recent evidence suggests that transmembrane proteins (Cell membrane – components and functions) classically thought of as molecules that transduce signals across the plasma membrane, such as the ►Notch receptor, ►receptor tyrosine kinases [5] and ►$Ca^{2+}$ channels, can be proteolytically cleaved to produce protein fragments that translocate to the nucleus to directly impact gene transcription.

The mammalian genome encodes for approximately 1,500 proteins with known DNA binding motifs [6]. Researchers are trying to understand how they regulate DNA transcription. Transcription factors generally do not bind DNA in isolation, but rather do so as complexes with other transcription factors and proteins.

Changing the proteins with which an individual transcription factor interacts can potentially alter the genes upon which it acts and/or its effectiveness at modifying gene expression. The individual components of these complexes are being elucidated by the use of ►chromatin immunoprecipitation. To identify the distinct DNA sequences to which they bind, ►bioinformatic approaches are commonly used. A researcher will look either for already established DNA binding ►consensus sequences in regions upstream of the coding regions of genes, or take advantage of species conservation to search these regions for short domains of nucleotide conservation between species. While such approaches can identify binding sites, they cannot be used in isolation, as many binding sequences are short, appear frequently in the genome, and are often not functional. Recently, a large-scale version of the chromatin immunoprecipitation assay was used at a genome-wide level to identify the entire set of direct targets of transcription factors [7]. Once identified, the functionality of regulatory elements is confirmed by careful deletion and mutational analyses of the identified regions. Gene regulatory sequences can be found downstream of the gene, within ►intronic (►intron) sequences, and as far as 1 Mb from the start of transcription. Thus, it can be difficult sometimes to identify all the on/off switches for a particular gene. The use of ►bacterial artificial chromosomes, which allow researchers to play with large DNA sequences that hopefully contain all of the regulatory sequences for a gene of interest, has helped get around this issue.

A careful ►*in situ* hybridization analysis of most of the transcription factors expressed in the mouse nervous system indicate that many have spatially and/or temporally restricted expression patterns, but rarely are transcription factors expressed exclusively in a specific cell type [6]. Thus, it is likely, and has been shown experimentally, that transcription factors act in combination to control cell type specification and/or differentiation, contributing to the acquisition of particular features of a neuron. Indeed, many transcription factor binding sites are clustered into ►*cis*-regulatory modules that can bind specific combinations of 2–10 transcription factors. Further, the expression of a single gene within a cell may require multiple transcription factors, which bind to sites in different cis-regulatory modules. The interaction between transcription factors has been particularly well studied in the developing nervous system. For instance, the identity of specific neurons in the vertebrate spinal cord and ►*Drosophila* neuropeptidergic neurons are each determined by a ►combinatorial transcription factor code, whereby the subset of transcription factors expressed by the neural progenitor dictates the type of neuron it becomes. The particular repertoire of transcription factors a neuron expresses is critical for its differentiation during development, and is also likely to be important for its function in the adult [8,9], though considerably little is known of the function of transcription factors in the mature nervous system.

One way to generate complexity given a set number of genes is to diversify the mRNA transcripts that arise from DNA transcription. Diversification can arise by several means, both at the transcriptional and post-transcriptional levels (see below). One mechanism that may have widespread importance in the brain, given its prevalence, is the alternative usage of promoters, whereby different promoters are used to regulate transcription of a single gene. Indeed, over 50% of human genes may be subject to such regulation [10,11]. Usually different promoters are used in different tissues, and while the proteins generated from the alternate promoters are identical, their ►5′ untranslated regions (UTRs) differ. mRNA transcript diversification also results from stochastic regulation of gene expression, whereby a transcription factor complex randomly activates transcription of one of several related genes [12]. The choice of which ►olfactory receptor to express is illustrative. A mouse olfactory neuron chooses from a subset of over 1,000 olfactory receptors based on its location in the ►olfactory epithelium, followed by stochastic expression of a single receptor and repression of the other choices. The stochastic selection of expression of a single olfactory receptor in a neuron may involve a ►locus control region upstream of each olfactory receptor gene cluster. Amazingly, this region can recruit a transcriptional activation complex to control gene expression ►*in cis*, and/or interact with the promoters of olfactory receptor genes located on different ►chromosomes to control their transcription ►in *trans*. Interestingly, in humans, whose dependence on olfaction is minimal, many of the olfactory receptor genes are likely ►pseudogenes.

Importantly, gene expression can be altered in a stable, sometimes inheritable fashion, by a host of ►epigenetic processes that impact the state of the ►chromatin, but do not alter the underlying DNA sequence [13]. Because of space constraints, DNA is packed in the nucleus as chromatin, which consists of DNA wrapped around four core ►histones. For the transcription complex to get access to and transcribe DNA, the chromatin complex around a gene has to relax and open up. Epigenetic mechanisms serve to provide cell specific contexts that modulate the success of transactivating factors at controlling DNA transcription. Current research in epigenetics is focused on elucidating how covalent and non-covalent modifications to DNA and histone proteins can influence gene expression, though we know little about how these changes are sometimes inherited through cell division. Modifications of the histone proteins, including ►acetylation (►Histone acetylation), ►methylation,

►phosphorylation, ►ubiquitination,► citrullination and ►sumoylation alter DNA-histone interactions and hence transcription [14,15]. The nature of these distinct histone modifications on any given gene defines its histone code. A special case of epigenetic control that regulates neural development and brain function is ►genetic imprinting, whereby only one allele (maternal or paternal) of a gene is expressed while the other is silenced. Epigenetic control can impact disease progression, as appears to be the case for human brain ►gliomas that are sensitive to the proliferative effects of transforming ►growth factor β (TGFβ) signaling [16]: gliomas with an unmethylated promoter for the platelet-derived growth factor B (PDGF-B) (Growth factors) gene respond to TGFβ. In contrast, a PDGF-B promoter methylated on cytosine residues of ►CpG dinucleotides is not bound by the downstream TGFβ signaling transcriptional effectors, the regulatory Smads, and so the glioma fails to proliferate in response to TGFβ. Defects in epigenetic control can also themselves cause disease. For instance, the neurodevelopmental genetic disorder called ►Rett syndrome, characterized by mental retardation, is caused by mutations in the ►X-linked ►disease gene encoding for methyl-CpG binding protein 2, which binds methyl-CpG and attracts chromatin modification complexes [17].

Researchers use gene expression profiling technology such as ►SAGE and ►microarray analyses to assess the complement of genes that are expressed at any one time by either a tissue, a specific population of nervous system cells, or most incredibly at a single-cell level [18]. These types of analyses have to take into consideration several unique issues when applied to the nervous system (as discussed in [19]), but are being used successfully by researchers in an attempt to identify those genes that are important in a biological or disease process. Comparisons are made between at least two highly related samples that differ by some critical variable: time, treatment, cell type, disease, etc. From the list of genes that are differentially expressed between two samples, researchers can either identify specific genes they feel are worthwhile to study, or get an overview of the types of gene classes that are activated or inactivated in response to the variables discussed above.

## Regulation at the mRNA Level (Post-transcriptional Control)

Genes often have multiple exons, separated by ►introns. In many cases the mRNA transcript that is generated from DNA is ►alternatively spliced in the nucleus, so that certain exons are not present in the final mature mRNA [20]. Indeed, genome analyses estimate that 60–80% of human genes can undergo alternative splicing. This mixing and matching of exons generates different forms of the same protein from the same gene, but with distinct features: unique protein ►isoforms can differ subtly or dramatically in function, in their levels of expression and in their cellular and subcellular localization. An extreme example of alternative splicing occurs with the ►Down's Syndrome Cell Adhesion Molecule (►DSCAM) in *Drosophila*, where splicing can generate over 38,000 different forms of the protein. Several different forms of alternative splicing can occur, which are not restricted to the use of alternate exons, but can include alternative 5′ or 3′ splice sites, retention of intron sequences and alternative ►polyadenylation sites. Alternative splicing can mediate differential subcellular targeting, for instance of ►ion channel isoforms to axons or soma/dendritic compartments. In other cases, alternative splicing produces isoforms with distinct functional properties. At a tissue level, alternative splicing can generate specific expression patterns of splice variants by the differential expression and function of ►splicing factors and ►RNA binding proteins [21]. Recently, such regulation was shown to be important even at late stages of cell differentiation within the nervous system; the RNA binding protein How and the splicing factor Crooked neck protein mediate ►alternative splicing and glial maturation. When alternative splicing fails it results in the generation of proteins with altered function, and expression characteristics, and can result in disease. For example, ►frontotemporal dementia with ►parkinsonism results from the aberrant splicing of the tau mRNA, resulting in protein isoforms that tend to aggregate [22].

Once transcribed and processed, mRNAs leave the nucleus, with the help of ►exportins, and are translated within the cytoplasm to make proteins. It had been thought that ►mRNA translation occurred only in the cell body and that proteins were then shipped off to different parts of the cell. While this is clearly the main route by which proteins are made and get to where they need to be, there is evidence for ►local or subcellular mRNA translation both at the tip of the developing axon (e.g. β-►actin), called the ►growth cone, and in dendrites in response to changes in the activity of synapses (e.g. ►CAMKII) [23,24]. Thus, ►local mRNA translation seems to be a sensible solution to the requirement for speed when responding to changes in the environment in regions of a neuron that are distant from the cell body.

The mechanisms that control the subcellular targeting of mRNA are starting to be elucidated [23,24]. mRNA targeting is controlled by sequences within the mRNAs themselves. These are recognized, likely in the nucleus, in a specific fashion by a relatively large number of trans-acting factors which form complexes that are referred to as localizing ribonucleoprotein particles (RNPs). RNPs are unable to translate in the absence of an initiating signal, a mechanism which ensures that once exported from the nucleus, translation

only occurs once the RNPs become localized. Localization of RNPs is not random and is dependent on the ►cytoskeleton. The mechanisms involved are multiple and include interactions with ►myosin motors and ►microfilaments, and microtubule motors such as ►dynein and ►kinesin [23].

Cells can also regulate mRNA levels independently of gene transcription by RNA silencing mechanisms that involve the ►micro RNA (►miRNA) pathway. miRNAs are ~22 nucleotide double-stranded RNAs that are transcribed from ►non-coding stretches of DNA that show imperfect base pairing (pairing over 6–8 nucleotides) with the 3′ untranslated regions of specific transcripts. These interactions prevent the cell from translating mRNAs into protein either by inhibiting translation, or, in some cases, by destabilizing the mRNA [25]. There are hundreds of miRNAs in the nervous system, each of which can inhibit translation of multiple transcripts. In fact, it has been estimated that over a third of mRNAs are regulated by miRNAs. miRNAs are implicated in neural development and in synaptic plasticity in mature neurons. Interestingly, miRNAs may serve to control mRNA abundance and translation in distal regions of the cell, far from the global regulatory mechanisms of transcription available in the nucleus. In the case of localized mRNAs, it is not clear whether miRNA repression occurs during or after transport. miRNA can also control the other main mechanism of post-transcriptional regulation, alternative splicing [26]; knockdown of a key RNA binding protein causes a global switch in alternative splicing from a non-neuronal to a neuronal pattern.

## Regulation at the Protein Level

When mRNA translation occurs locally, protein products are available immediately at the site where they are needed. More often, however, proteins are synthesized within the soma and then have to be shipped off to the appropriate subcellular compartment. This is a particularly formidable task for neurons given their dendrites with complex morphologies and axons that extend for long distances from the cell body. Moreover, proteins often need to be there at the same time as essential interactors. To have some appreciation for the complexity of this last issue, recent ►proteomic experiments indicate that approximately 1,000 different proteins are present at the synapse [27]. In fact the glutamate neurotransmitter NMDA receptor complex and its associated signaling complex on its own has 185 different players: the NMDA receptor, scaffolding proteins and enzymes. Another example is the complex of proteins that is present at the migrating edge of cells and growth cones and interacts with the actin cytoskeleton, the ►integrin-dependent adhesion contacts. These structures are made up of 50 unique proteins that mediate cell adhesion to the extracellular matrix.

Many of the mechanisms involved in protein trafficking are fundamental to all eukaryotic cells and have been worked out in yeast, but neurons have also evolved unique mechanisms that serve their particular requirements as ►polarized structures [28]. A set of trafficking mechanisms exists for long-distance transport to the axon terminals and distal dendritic spines, whereupon local trafficking machinery takes over. These local mechanisms determine where and when proteins are inserted or removed from the membrane, and recycled or degraded. Further, they are often controlled by electrical activity (►Action potential). For instance, the local machinery makes alterations in the repertoire of proteins expressed in dendritic spines to accommodate changes in the inputs a cell receives.

Proteins first have to be sorted between the cytoplasm and the membrane. One mechanism involves a ►signal peptide at the N-terminus of proteins that are secreted or integrated in the membrane (transmembrane) that directs them into the endoplasmic reticulum (ER) after translation. The proteins are then transferred to the ►Golgi apparatus, eventually emerging on the cell surface through the trans-Golgi network. Targeting of proteins can be regulated by changes in the physiological state of the neuron. For instance, subcellular targeting of proteins can depend on neuronal activity. An example here involves RhoGTPases that are predominantly cytoplasmic when inactive, but in their active state are targeted to the membrane based on a C-terminal consensus sequence within the proteins themselves. Targeting can also depend, in proliferative neural precursors, on the stage of the cell cycle. For instance, ►prospero is a protein whose asymmetric localization in the dividing *Drosophila* neuroblast depends on the cell cycle.

Defects in the ability of proteins to move smoothly through the ER-Golgi network can result in neuronal disease. For instance, early familial onset ►Parkinson's disease can arise from mutations in ►alpha synuclein that interfere with normal ER-Golgi protein transport. A major job of the ER is to properly fold proteins. Defective folding often leads to proteins that aggregate, and aggregates accumulate and over the long term cause neuronal degeneration. The dire consequences of aggregation have meant that neurons protect against it through two distinct mechanisms. Protein ►chaperones assist protein folding, correct folding errors and hold back improperly folded proteins in the ER, whereas ubiquitination targets misfolded proteins for degradation by the ►proteasome.

Proteins next get sorted to somatic, axonal and/or dendritic compartments. The mechanisms that regulate this sorting share commonalities with those used in apical/basal targeting of proteins in epithelial cells. Here, and in neurons, different modes of targeting are possible and include directed targeting, transcytosis and selective retention [29]. In directed targeting,

post-Golgi carriers recognize sequences in proteins that they use to deliver proteins to specific subcellular domains. This appears to be especially true of targeting to axons. In transcytosis, proteins are integrated in a non-specific fashion into the plasma membrane and then translocated to the axonal nerve terminal by endocytic carriers. In selective retention, proteins are integrated in both axons and dendrites, and then removed selectively by endocytosis from one compartment and not the other [30]. Finally, a number of local targeting mechanisms exist to refine the localization of proteins within the complex organization of the ►postsynaptic density and the presynaptic element [28]. The issue of protein trafficking within the cell has been particularly well studied with respect to ►receptor trafficking at the postsynaptic element, which may underlie several forms of synaptic plasticity in the adult. What is particularly remarkable in neurons is their ability to maintain their unique polarity for the life time of the animal despite the continuous recycling of both membrane and proteins. At the same time, neurons retain the ability to rapidly modify shape in response to changes in neuronal activity, for example at the dendritic spine.

Protein function can be altered by a series of ►post-translational modifications. Some modifications occur in the endoplasmic reticulum (e.g. ►N-glycosylation, ►disulfide linkages) while others occur within the cytoplasm or at the lipid membrane (e.g. phosphorylation, dephosphorylation). Proteins can be activated or inactivated by phosphorylation of specific serine/threonine/tyrosine residues by ►protein ►kinases. The phosphorylation state of different residues imparts different properties to the protein and is often required to activate or silence protein function. For example, signaling often involves ligand-induced phosphorylation of the transmembrane receptor. Receptor activation then results in adaptor proteins being recruited to binding sites in the cytoplasmic tail, and activation of downstream signaling. A protein whose function is highly dependent on phosphorylation is CAMKII, where the kinase is activated by phosphorylation of one specific residue and inactivated by phosphorylation of another. Interestingly, CAMKII is turned on by phosphorylation in excitatory neurons when $Ca^{2+}$ spikes are sufficiently frequent, allowing CAMKII to serve as a decoder of the temporal patterns of neural activity. Alternatively, protein activation (or de-activation) may require dephosphorylation by a ►protein phosphatase. Phosphatases remove phosphate groups and counter the function of protein kinases. Protein function thus depends on the balance between these two competing enzyme groups. Also, the function of proteins can be altered by the addition of groups, such as heparan sulfate and chondroitin sulfate ►glycosaminoglycan sugar side chains, and removal of important domains by proteolytic cleavage. Proteolysis will either inactivate a protein by eliminating a domain critical for function, or activate a protein whose functional molecular sites are hidden when the protein, or a component of the complex it assembles with, is in a non-cleaved state. A group of enzymes that undertake such cleavage events in the developing, adult and diseased nervous systems are ►metalloproteinases. Ubiquitination can also be important in controlling normal biological processes within neurons, as it results in the regulated removal of key signaling elements. For instance, positive control of growth at nerve-muscle contacts by ►BMP signaling is negatively regulated by ubiquitination of a downstream Smad effector.

The end result of all of these levels of regulation is that proteins end up expressed at the right time and place, and in the right state, to carry out their assigned function. Figuring out which proteins are required in tissue- and cell-specific events has been helped by the use of proteomics where comparisons are made between the levels and presence of proteins in two or more related samples that differ in some key variable. Directly looking at protein levels gets around the problem that mRNA levels are not always representative of the protein levels expressed by a cell.

## Genetics and Molecular Biology as Tools to Study Neuronal Development and Function

As mentioned earlier, the human genome contains approximately 23,000 protein-coding genes. The task now is to figure out what all the individual genes are doing, and what medical conditions arise when their function is either lost or altered. The strongest approaches available to elucidate protein function *in vivo* involve generating animals mutant for a particular gene, and investigating the consequences either on the development of the nervous system or on its function in the adult. Mutant animals can be produced by two means. In a ►forward genetics approach, a ►genetic screen is designed where model organisms such as *Drosophila*, ►*C. elegans* and ►zebrafish are treated with a chemical DNA mutagen that produces random mutations in their germ lines. The kin of the mutagenized animals are then screened for an identifiable ►phenotype in a researcher-defined biological process. The gene that is mutated can then be ►genetically mapped and identified. In mouse, an alternative commonly used approach involves ►reverse genetics, whereby a molecule of interest is removed from (►knocked-out) or added to (►knocked-in) the genome, creating a ►transgenic animal.

One of the issues often encountered in mice with the production of ►germ-line transgenics is that many gene products function in the early development of both neural and non-neural tissues, often resulting in embryonic or early postnatal lethality, which precludes their investigation in later developmental events and in

functions in the adult nervous system. To get around this issue, researchers often use a ►conditional transgenic, where a gene is knocked out in a specific tissue or cell type, and at a specific time. In mice the ►Cre/LoxP system, a site-specific recombination based approach, has proven useful in this regard. Meanwhile the ►GAL4/UAS system, which is based on the use of tissue-specific promoters, is used in zebrafish and *Drosophila*. In *Drosophila*, conditional transgenesis has also been taken to the single cell level with the use of ►Mosaic Analysis with a Repressible Cell Marker (MARCM), which has the added advantage of labeling those cells that are mutant.

A number of additional model organisms including chick, zebrafish and *Xenopus,* have proven extremely useful for understanding the molecular and cellular mechanisms underlying nervous system development. They develop rapidly, the embryos are readily accessible through most of their development, and one can have tight temporal and spatial control over gene manipulations without having to employ laborious germline transgenic approaches. In these organisms, as well as mouse, gain-of-function can be achieved by misexpression of the wildtype gene with tissue-specific, temporally regulated or ubiquitous promoters. Loss-of-function can be achieved by the use of an antisense ►morpholino oligonucleotide or ►siRNA (small interfering RNA) against an mRNA of interest to block translation, or a ►dominant negative mutant protein that interferes with the function of the endogenous wildtype protein.

As described above, a number of tools have been generated to identify genes and proteins important in normal or disease processes. In their simplest form, they involve looking for changes in the levels of expression of genes or proteins on a global scale within a tissue by the use of experimental approaches that include microarrays and SAGE for mRNA expression, and proteomics for proteins. Sophisticated bioinformatic tools have had to evolve to allow researchers to keep up with the large amount of data arising from high throughput DNA and protein sequencing, genome projects, and functional genomics and proteomics. Various computational tools are available that can be used to find and process this information.

## Genetics and Molecular Biology of Nervous System Disease

Of course, if any of processes described earlier go wrong, it ultimately results in the production of a non-functional protein, a protein that is mistargeted, or a protein whose levels and location are inappropriate. The functional consequences to the nervous system depend on the properties of the protein, the defect that occurs, and the extent of the redundancy of the molecules that control the biological events in which it takes part. In some cases, a single gene mutation (monogenic) can underlie a nervous system disorder. Mutations can take many forms, which include duplications, single nucleotide substitutions, deletions, inversions, splicing mutations and chromosome translocations. Even ►single nucleotide polymorphisms (SNPs) that are non-pathogenic can cause weak effects on the protein that when combined with other SNPs can result in a ►haplotype that increases disease susceptibility. With the sequencing of the human genome, the identification of mutations and their association with disease states will be facilitated. Importantly, defects do not have to be in the protein-coding region of the gene. For instance, in ►triple repeat diseases, a tri-nucleotide gene sequence, commonly CAG (encodes for glutamine), is tandemly repeated multiple times either in the protein-coding or non-coding (►non-coding DNA) regions of a gene.

In humans, a gene underlying a monogenic disease can be identified by ►positional cloning [32]. Briefly, this involves collecting DNA from affected individuals and a control group, mapping the gene to a region of the chromosome and sequencing genes in that region to identify changes in their DNA sequence. The process is greatly facilitated if a family with the disease/disorder can be identified. Unfortunately, the etiology of human nervous system disorders is often complex, with multiple genes (possibly dozens) contributing to a disorder with a single set of characteristics [27]. Moreover, factors such as age, gender and environmental inputs can influence the onset and progression of the disease. In the future, the ability to access and process large volumes of data will facilitate the identification of the molecular and genetic mechanisms underlying human nervous system disorders.

Of course, while a disease arises as a result of a mutation in one or several genes, the functional consequences occur at the level of the proteins. Systematic global approaches are now being used to try and understand the molecular basis of nervous system disease. A top-down approach takes a disease and uses global genome screening tools such as SNP, cDNA and oligonucleotide based microarrays to identify proteins with altered expression levels. This has been used to effect with ►multiple sclerosis, a chronic neuroinflammatory disease [31]. Alternatively, a ►proteomics approach can identify the proteins involved in a biological event or in a functional protein complex, and then automated searching of web-based data bases (data and text mining) can be used to identify human genetic diseases associated with mutations in proteins of the complexes [27]. Such an approach has been taken with the NMDA receptor complex and its involvement in disorders relating to synaptic function (e.g. ►autism, ►schizophrenia, ►bipolar disorder).

Transfer of the information we obtain about the molecular and genetic basis of disease to the clinic will depend on the development of strategies to fix disabled

molecular pathways. These include pharmacological interventions and the reintroduction of missing or broken proteins back into the affected nervous tissues with ►gene therapy. Knowing something about how protein expression, targeting and activity is controlled will be key in ensuring that nervous system function can be restored.

## Geniculo-cortical Pathway

►Geniculo-Striate Pathway

## Geniculohypothalamic Tract (GHT)

### Definition

One of the three major projections afferent to the suprachiasmatic nucleus. The cells of origin are located in the intergeniculate leaflet (IGL) of the lateral geniculate complex.

►Intergeniculate Leaflet
►Suprachiasmatic Nucleus (SCN)

## Geniculo-Striate Pathway

Daniel L. Rathbun, W. Martin Usrey
Center for Neuroscience, University of California, Davis, CA, USA

### Synonyms

Geniculo-cortical pathway; Visual thalamo-cortical pathway

### Definition

The geniculo-striate pathway is the set of axonal connections that project from the ►lateral geniculate nucleus (LGN) of the ►thalamus to the ►primary visual cortex. It is the single-greatest source of thalamic input to visual cortex and serves to relay visual information from retina to cortex.

### Characteristics

With the exception of ►olfaction, all sensory information destined for the cerebral cortex is communicated by neurons in the thalamus. In the visual system, neurons in the lateral geniculate nucleus (LGN) of the thalamus are the major relay of retinal input to the primary visual cortex (also called V1, striate cortex and area 17). The pathway between the LGN and visual cortex, called the geniculo-striate pathway, was initially characterized by the Russian physician Constantin von Monakow well over 100 years ago [1]. Since that time, the geniculo-striate pathway has been the focus of intense research and serves as a model for understanding the relationship between thalamus and cortex.

#### Retinal Inputs Establish LGN Responses

The majority of synapses made onto LGN neurons come not from the retina, but from non-retinal sources. Non-retinal sources of input include the brainstem (►parabrachial nucleus and the ►dorsal raphe nucleus), ►thalamic reticular nucleus, and visual cortex [2]. While non-retinal inputs adjust the responsiveness of LGN neurons, it is the retinal input that establishes the visual properties of LGN neurons. Indeed, the ►receptive fields and response properties of LGN neurons are remarkably similar to those of their retinal afferents in terms of size, sign (*on* vs. *off* ), contrast sensitivity, and color specificity. This similarity is largely due to the specificity of retinogeniculate projections and the low levels of ►synaptic convergence between the retina and LGN [3]. Neurons in the LGN respond to visual stimuli located in the ►contralateral visual field. Although individual LGN neurons receive input from just one eye, separate populations of neurons receive input from the contralateral eye and ipsilateral eye.

Most neurons in the LGN (and retina) have receptive fields with a concentric and antagonistic, ►center/surround organization. Approximately one half of LGN neurons are excited by bright spots of light that are surrounded by dark annuli (*on*-center/*off*-surround receptive field). The remaining neurons have the inverse relationship (*off*-center/*on*-surround receptive field). For both types of neurons, responses are diminished if the stimulus sign that excites the center of the receptive field extends into the surround. In addition to the *on* versus *off* distinction of LGN neurons, LGN neurons can be further distinguished on the basis of anatomical and

physiological criteria. In so doing, it is clear that the pathway from retina to cortex is comprised of multiple, parallel pathways [4].

## The Geniculo-Striate Pathway: An Overview

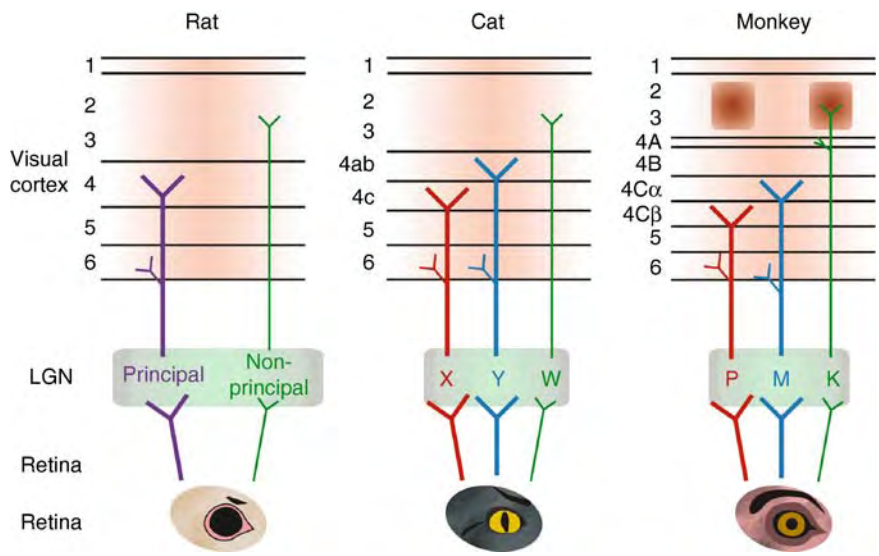
The geniculo-striate pathway establishes a functional architecture in primary visual cortex. The most notable feature of this architecture is ►retinotopy, whereby visual space (and the surface of the retina) is mapped across the surface of the cortex. In most species, the functional architecture established by geniculo-striate inputs also includes ►ocular dominance columns and ►orientation columns (described below).

The geniculo-striate pathway is not homogeneous, but comprised of parallel pathways that convey distinct visual information to the cortex. Although the specific details of these parallel pathways differ between species, many aspects of the geniculo-striate pathway are shared (Fig. 1).

Most notable of the shared attributes is the division of projections that terminate in either the ►granular layer of cortex (layer 4; note: many axons targeting layer 4 also send a sparse collateral projection into layer 6) or the supragranular layers (layers 1–3) [2]. In all species, the pathway terminating in cortical layer 4 arises from neurons located in the principal layers of the LGN, whereas the pathway terminating in layers 1–3 arises from neurons located in the non-principal layers (sometimes called the W-cell layers, intercalated layers, and/or koniocellular layers, depending on the species; described below). Compared to neurons in the non-principal layers, neurons in the principal layers generally have small receptive fields and produce short-latency, robust responses to visual stimulation. Furthermore, the axons of principal layer neurons and their synapses are significantly larger than those of neurons in the non-principal layers. Based on these properties, the pathway from the principal layers of the LGN to cortical layer 4 has been argued to function as a high-fidelity transmission line between the LGN and cortex, while the pathway from the non-principal layers to cortical layers 1–3 has been suggested to serve a more modulatory role (with the exception of primates, see below).

## The Geniculo-Striate Pathway: Rodents

In rodents, the geniculo-striate pathway follows the general plan (outlined above) with axons that terminate in either layer 4 or layers 1–3 (Fig. 1). Although the receptive fields of LGN neurons in the rodent are significantly larger than those of most other mammals, the distinction holds that neurons with projections to layer 4 have relatively smaller receptive fields and shorter response latencies than those with projections to layers 1–3. The geniculo-striate pathway in the ground squirrel appears to contain three classes of LGN neurons (described below for carnivores), however, more work is needed to be certain of this distinction in rats, mice and other rodents.



**Geniculo-Striate Pathway. Figure 1** Organization of the geniculo-striate pathway in three representative animals: rat, cat and monkey. In all mammals, including these examples, the majority of geniculo-striate axons terminate in cortical layer 4, a minority of axons terminate in cortical layers 1–3. In the cat, there are three parallel pathways to striate cortex – the X-cell pathway terminates in layer 4c, the Y-cell pathway terminates in layer 4ab, and the W-cell pathway terminates in layers 1–3. There are also three parallel pathways in the monkey – the parvocellular pathway (P) terminates in layer 4Cβ, the magnocellular pathway (M) terminates in layer 4Cα, and the koniocellular pathway (K) terminates in the layer 1–3 blobs.

Compared to carnivores and primates, the eyes of rodents are displaced further to the sides of the head. Consequently, the ►binocular visual field, is reduced in the rodent. The LGN therefore contains many more neurons with input from the contralateral eye than from the ipsilateral eye. The geniculo-striate pathway reflects this unequal distribution of retinal inputs, as the entire primary visual cortex responds to contralateral eye stimulation with a small portion also responding to ipsilateral eye stimulation. Restated, the geniculo-striate pathway in the rodent does not establish alternating ocular dominance columns similar to those in carnivores and primates (described below), but rather, establishes a single binocular field/column surrounded by a much larger monocular field/column.

## The Geniculo-Striate Pathway: Carnivores

The geniculo-striate pathway of the cat serves as a model for the carnivore pathway, as it has received the most attention and is arguably the best understood thalamo-cortical pathway in any species (Fig. 1). The cat LGN has two principal layers, A and A1, which receive input from the contralateral eye and ipsilateral eye, respectively, and project to cortical layer 4. Beneath the A layers are the C layers that contain cells with projections to cortical layers 1–3. Within the A layers, *on*- and *off*-center LGN cells are intermixed, as are X and Y cells. X and Y cells are members of two distinct parallel pathways that project to cortical layer 4. To summarize the major differences between X- and Y-cell pathways: (i) X cells receive input from ►beta ganglion cells in the retina, whereas Y cells receive input from ►alpha ganglion cells, (ii) X cells have smaller receptive fields than Y cells, (iii) X cells prefer stimuli that change or move at lower temporal frequencies (i.e., slower) than those preferred by Y cells, (iv) X cells display linear spatial summation, whereas Y cells display non-linear spatial summation, and (v) X cells have axons that are thinner and conduct action potentials somewhat more slowly than those of Y cells [reviewed in 4]. Although not emphasized here, the pathway from the C layers of the LGN to cortical layers 1–3 is largely comprised of the axons of W cells. LGN W cells have substantially larger receptive fields than those of X or Y cells and sluggish visual responses.

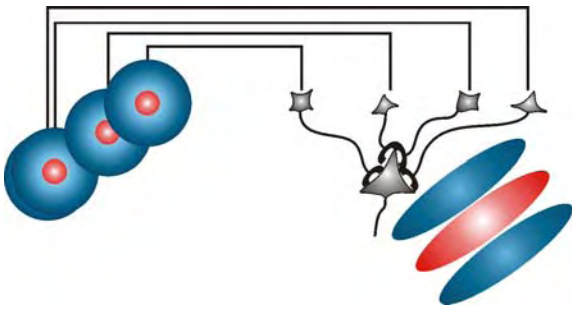
The projection patterns of X-, Y- and W-cells are distinct in the cat. Both X and Y cells project to layer 4; however, the axons of Y cells terminate in layer 4ab, while those of X cells terminate in layer 4c. The axons of W cells pass directly through layer 4 as they ascend to provide input to layers 1–3. In addition to showing laminar specificity in their projection patterns, LGN axons also display eye-specific projections. These eye-specific projections cluster to create alternating ocular dominance columns. Studies of the development of ocular dominance columns have provided crucial insight into our understanding of the role of neuronal activity during development.

A remarkable transformation of receptive field structure occurs at the geniculo-striate synapse. In contrast to the concentric, center/surround receptive fields of LGN neurons, neurons in cortical layer 4 (immediately postsynaptic to LGN axons) have receptive fields with elongated and alternating on and off subregions. ►Hubel and Wiesel called these layer 4 neurons "►simple cells" and presented the first model for the construction of their receptive fields (Fig. 2) [5].

In their model, a row of LGN cells with receptive fields of the same sign (on or off center) provides convergent synaptic input to a common cortical cell (the simple cell). As a consequence of this arrangement of inputs, the simple cell has a receptive field with elongated on and off subregions. In addition, the simple cell is selective to the orientation of a bar or edge of light. Subsequent work has largely supported this model for the generation of simple cell receptive fields and ►orientation selectivity [6]. The geniculo-striate pathway establishes columns of cells that share a similar orientation preference. Across the surface of the cortex, these orientation columns display systematic shifts in preferred orientation.

## The Geniculo-Striate Pathway: Primates

The distinction of parallel pathways within the geniculo-striate projection is remarkably clear in primates (Fig. 1) [7,8]. The primate LGN contains ►parvocellular, ►magnocellular and ►koniocellular neurons that are segregated into distinct LGN laminae. As neurons that receive input from the contralateral or ipsilateral eye are also segregated, the primate LGN generally contains at least two parvocellular layers, two magnocellular layers and two koniocellular layers. For



**Geniculo-Striate Pathway. Figure 2** The Hubel and Wiesel model for the emergence of the simple cell receptive field. In this model, multiple LGN neurons with collinear, same-sign (*on* vs.*off*) receptive fields provide convergent input onto a target cortical neuron. As a result of this organization of inputs, the target cell has a simple cell receptive field with elongated and adjacent *on* and *off* subregions. Adapted from [5].

example, the LGN of the macaque monkey has four dorsal parvocellular layers and two ventral magnocellular layers with koniocellular layers (also called intercalated layers) under and between each of the six layers.

Like the X, Y and W cells in the carnivore LGN, the parvocellular, magnocellular and koniocellular neurons in the primate LGN receive input from separate classes of retinal ganglion cells, give rise to axons that terminate in different divisions of visual cortex, and display distinct visual physiology. Parvocellular and magnocellular LGN neurons receive retinal input from ►midget and ►parasol ganglion cells, respectively. Less is known about the retinal input to koniocellular neurons; however, some are known to receive input from ganglion cells that convey ►S-cone (frequently called blue cone) information. The visual response properties of parvocellular and magnocellular neurons are well characterized. Compared to parvocellular neurons, magnocellular neurons have larger receptive fields, respond better to low contrast stimuli, are somewhat more sensitive to stimuli that are quickly moving or modulated at high temporal frequency, and respond with a shorter latency following the presentation of a visual stimulus. In addition, magnocellular neurons have little selectivity for color, while most parvocellular neurons are color-selective – particularly ►red/green opponent.

The axons of parvocellular and magnocellular neurons terminate in distinct subdivisions of cortical layer 4 – parvocellular axons terminate in layer 4Cβ and magnocellular axons terminate in layer 4Cα (Fig. 1). Koniocellular neurons have axons that terminate in cortical layers 1–3, however, only in patches of layers 1–3 called "blobs" that are rich in ►cytochrome oxidase. Accordingly, neurons in these recipient layers have visual responses in line with those of their LGN inputs. Finally, LGN axons carrying information from the contralateral and ipsilateral eye are remarkably segregated in their terminal fields in visual cortex. Consequently, alternating ocular dominance columns are robust in most primate species and individual blobs are eye specific.

### Spike Timing and Information Transmission in the Geniculo-Striate Pathway

With the advent of multielectrode recording techniques, it is now possible to examine the transfer of spikes between the LGN and visual cortex in vivo by recording from monosynaptically connected pairs of neurons. Results from such experiments show that the interaction time for geniculate spikes in driving a cortical response is quite brief – approximately 7 ms for spikes arriving from multiple presynaptic neurons and 15 ms for spikes arriving from the same presynaptic neuron [9]. These results are consistent with the view that, while geniculo-striate synapses experience synaptic depression, depression is saturated under normal visual conditions, thereby allowing brief, temporal summation to occur in the generation of postsynaptic responses [10]. Accordingly, geniculo-striate synapses are particularly well suited to transmit information carried in LGN bursts, high firing rates and correlated activity.

# Genome

## Definition

Genome is the complete DNA sequence, both protein coding and non-coding, contained in one set of chromosomes of an organism.

# Genomics

## Definition

Genomics is the study of the global properties of the DNA sequences, genomes, of related organisms.

## Genotype

### Definition

Genotype usually describes for an individual the exact DNA sequence for a specific allele.

## GENSAT Project

### Definition

The GENSAT (Gene Expression Nervous System Atlas) project is funded by the National Institute of Neurological Disorders and Stroke (NINDS) and aims to map the expression of all genes expressed in the mouse brain at various stages of development. This project is providing transgenic mice lines containing a BAC construct that expresses a marker gene under the promoters of the native genes and the information of expression patterns of the various genes in the brain.

## Geomagnetic Field

Michael Winklhofer
Department für Geo- und Umweltwissenschaften – Sektion Geophysik, Ludwig-Maximilians-Universität Munich, Munich, Germany

### Synonyms

Earth's magnetic field; terrestrial magnetic field

### Characteristics

#### Origin

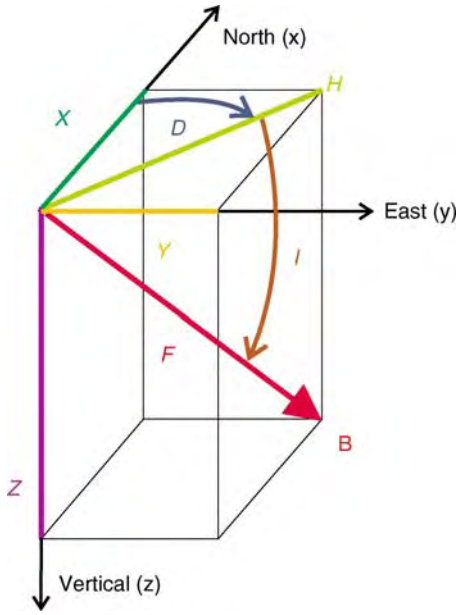
The magnetic field of the Earth, B, is a superposition of several magnetic fields generated by various internal and external sources. The primary and preponderant sources are convection currents in the metallic fluid outer core, called the geodynamo. The magnetic field due to the core, also referred to as the main field, varies slowly in time and smoothly over the Earth's surface, and therefore can be described by mathematical models such as the International Geomagnetic Reference field (►IGRF). The main field is spatially perturbed by the inhomogeneous magnetization of the crust and temporally perturbed by electric current systems in the ►ionosphere and ►magnetosphere, which in turn are affected by solar activity. The time-varying ionospheric currents, on the other hand, induce telluric currents in the Earth, which in turn generate the so-called magnetotelluric fields. Another example of secondary magnetic fields are those produced by oceanic current systems flowing through the Earth's magnetic field. Just recently, due to ocean tidal flow, the secondary magnetic field has been identified in magnetic-field data measured aboard the CHAMP satellite [1].

#### Magnetic Elements

The Earth's magnetic field is a (time-dependent) three-dimensional vector field. There are several triples of orthogonal components to completely describe the local magnetic field, B, at any given time and location in a geographically based coordinate system (Fig. 1).

These triples are, of course, equivalent to each other, and it is for practical and historical reasons that different sets are used interchangeably.

1) $B = (X, Y, Z) - X$ (north), $Y$ (east), and $Z$ (downward). These are the Cartesian components of B as projected on the geographical coordinates. The magnetic



**Geomagnetic Field. Figure 1** The seven elements of the geomagnetic field B, declination *D*, inclination *I*, total intensity *F*, horizontal intensity *H*, vertical intensity *Z*, north component *X*, and east component *Y*. Only three independent elements such as (*F*, *I*, *D*) or (*H*, *Z*, *D*) are needed to give a complete vector specification of the local geomagnetic field.

elements *X*, *Y*, and *Z* are quoted in units of intensity (magnetic induction, see below).

2) B = (*H*, *Z*, *D*) − *H* (horizontal), *Z* (downward), and *D* (declination). The horizontal intensity *H* is the projection of B on the local horizontal plane and points to magnetic north, which is the direction indicated by a magnetic compass. The declination is the horizontal angle between true north (along meridian) and magnetic north, reckoned positive eastward.
3) B = (*F*, *I*, *D*), with *F* (total field intensity), *I* (inclination), *D* (declination). The magnetic inclination is the dip angle of the total field vector B with respect to the local horizontal plane. Positive (negative) values of *I* indicate that field lines are directed downward (upward). The point at which *I* = + 90° (*I* = − 90°) is termed the north (south) magnetic, or dip, pole. It is this triple that is normally used in magnetobiology and ►palaeomagnetism. It is also the most intuitive representation of a vector, which is characterized by a magnitude and direction in space.

## Units

In SI units, the magnitude of the geomagnetic field vector, *F*, and that of its components *X*, *Y*, *Z*, *H*, is expressed in tesla (1 T), the unit of magnetic induction. In the Gaussian, or cgs, system, the unit of magnetic induction is the gauss, designated by G (Γ), with $10^4$ G = 1 T. Usually, *F* is quoted in units of nT ($10^{-9}$ T) or, in the cgs system, in gamma (γ), with 1 γ = $10^{-5}$ Γ = 1 nT.

## Magnetic Charts

### Global Field Maps

Due to the complex nature of the geomagnetic field (see section "Origin"), it is impossible to produce an accurate geomagnetic map. The global maps presented here refer to the latest IGRF model (IGRF 9), and basically show the long-wavelength variations due to the main field. With the main field dominating the geomagnetic field, the IGRF model is a good approximation of the real field on a global scale: For the reference year 2000, it is accurate to within 0.5° for *D* and *I* and about 200 nT for the intensity elements, although some areas exist with local anomalies exceeding the error margin of the IGRF.

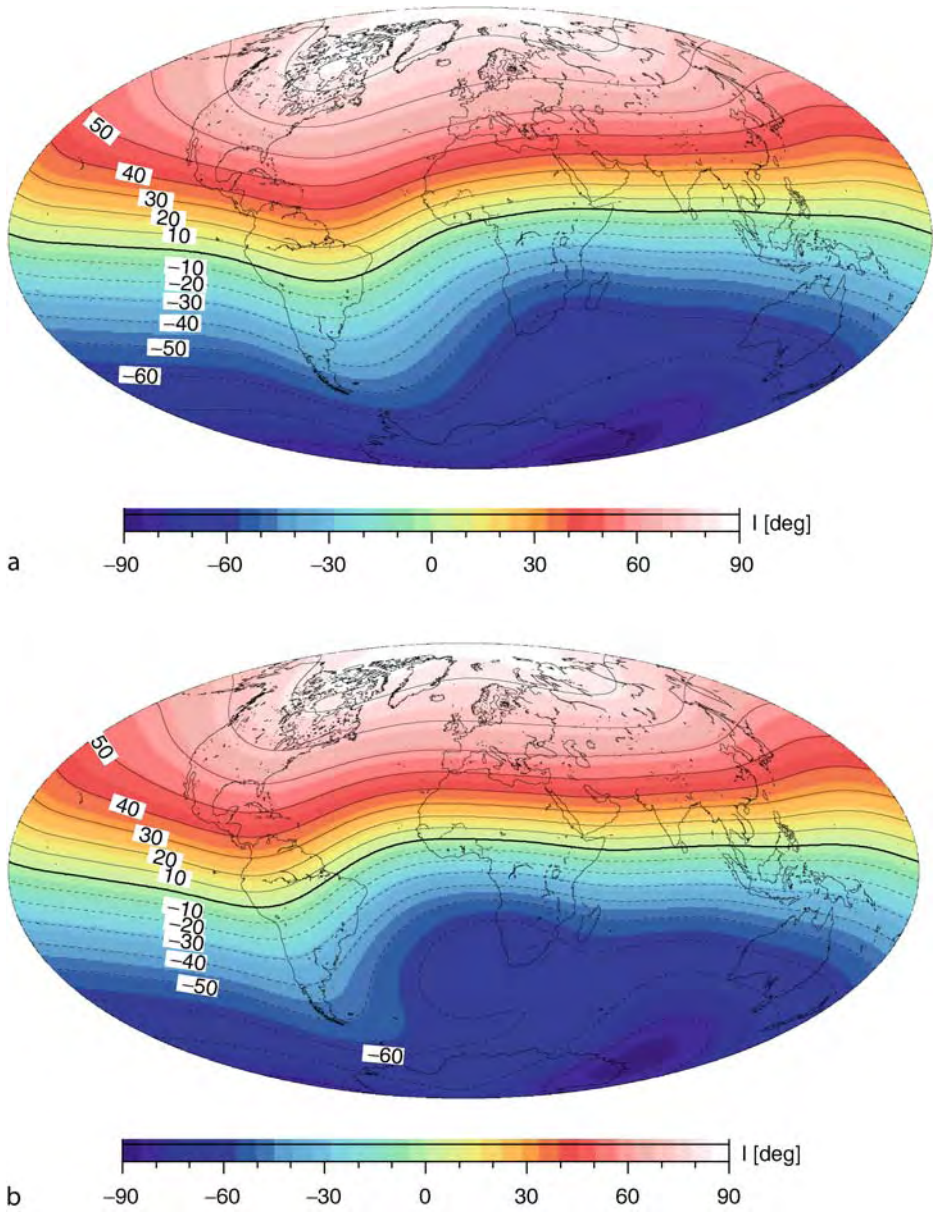
The most common display format for the distribution of magnetic elements over the Earth's surface are isomagnetic charts. These charts are contour maps of equal values of a given magnetic element and are called isogonic, or isoclinic for declination, or inclination, respectively. Charts showing isolines of intensity of a field component (*X, Y, Z, H, F*) are termed isodynamic. The lines of equal inclination (isoclinics) are also referred to as magnetic latitudes. The isoclinic defined by *I*= 0° is called magnetic (dip) equator, and winds about the globe at low geographic latitudes (Fig. 2). The inclination is downward (upward) throughout most of the Northern (Southern) hemisphere. In 2004, the IGRF north magnetic pole (*I* = 90°) was located at 82°N latitude and 113°W longitude, the IGRF south magnetic pole (*I* = −90°) was situated at 64°S, 138°E.

There are agonic (*D* = 0°) lines among the isolines for declination (Fig. 3). From Figs. 2 and 3 it can be seen that inclinations vary in a more regular manner over the globe than declination does. Especially at low latitudes, the isoclines form nearly parallel bands.

Here, changes in inclination can be used to determine relative changes in geographic latitude. The distribution of *F* is asymmetric (Fig. 4), with two pronounced large-scale magnetic anomalies, a deep global minimum over South Brazil (22,770 nT at 26°S, 55°W) and an intense maximum over Siberia (61,413 nT at 61° N, 105° E), which even exceeds the maximum (59,720 nT at 60° N, 100° W) associated with the magnetic north pole. The global maximum is located in the southern hemisphere (66,752 nT at 60°S, 138°E) near the south magnetic dip pole. Note that while the maxima in *F* are spatially associated with the dip poles, they do not coincide with them. The reason for this discrepancy is that the main field does not have a purely dipolar shape, or non-dipolar components. Nevertheless, the simplest model of a geocentric dipole, with its dipole axis inclined about 10.7° to the Earth's spin axis, can account for some 90% of the spatial variations of the main field on the Earth's surface. The theoretical poles of the geocentric inclined dipole are called geomagnetic poles. The north geomagnetic pole is near 79°N, 70° W, the south geomagnetic pole at the antipode, near 79°S, 110° E.

### Local Field Maps

While the main field varies relatively smoothly on a global scale (wavelengths greater than 3,000 km), the real geomagnetic field may change in a much more irregular fashion on a regional or local scale. Magnetic anomalies are due to magnetised rocks within the ►Earth's crust. The small-scale magnetic anomalies depicted in Fig. 5 are related to the local geology. The content of magnetic minerals in rocks varies from one rock type to the next, and so gives rise to variations in the natural magnetization across different rock units. Volcanic rocks contain a relatively large proportion of magnetic minerals, and therefore volcanic edifices such as cinder cones stick out on a magnetic anomaly map like a mountain in a topographic map. Many regions have their distinct magnetic fingerprint and so can provide animals with navigational information. A detailed map of the global crustal magnetic field (MF3) has recently been derived from data collected aboard the CHAMP satellite over three years [2].

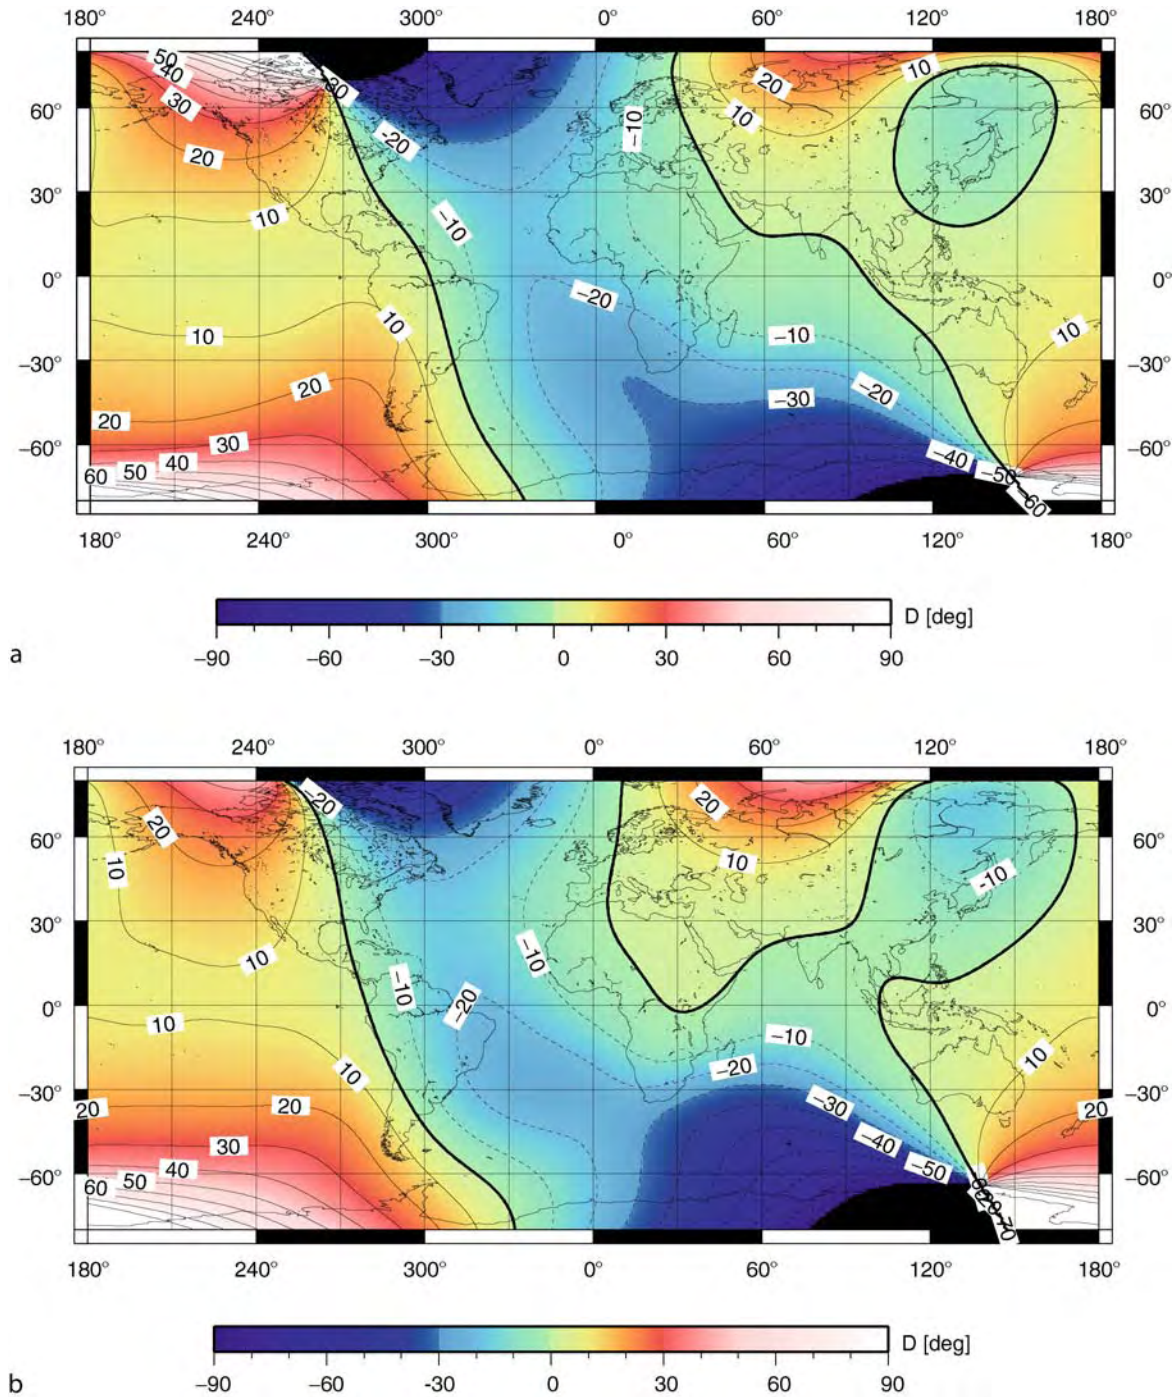


**Geomagnetic Field. Figure 2** Inclination according to International Geomagnetic Reference Field (IGRF 9) for the years 1900 (a) and 2004 (b) in isoclinic format, that is, contours are lines of equal inclination (magnetic dip latitudes). The thick black line demarcates the magnetic dip equator ($I = 0°$), where field lines are horizontal. Isoclinics for $I > 0$ ($I < 0$) are represented by *solid (dashed) lines*. Spacing between contours is 10°. The map is a cylindrical equidistant projection. All global charts are produced with GMT software, version 3.4.2 (http://gmt.soest.hawaii.edu/).

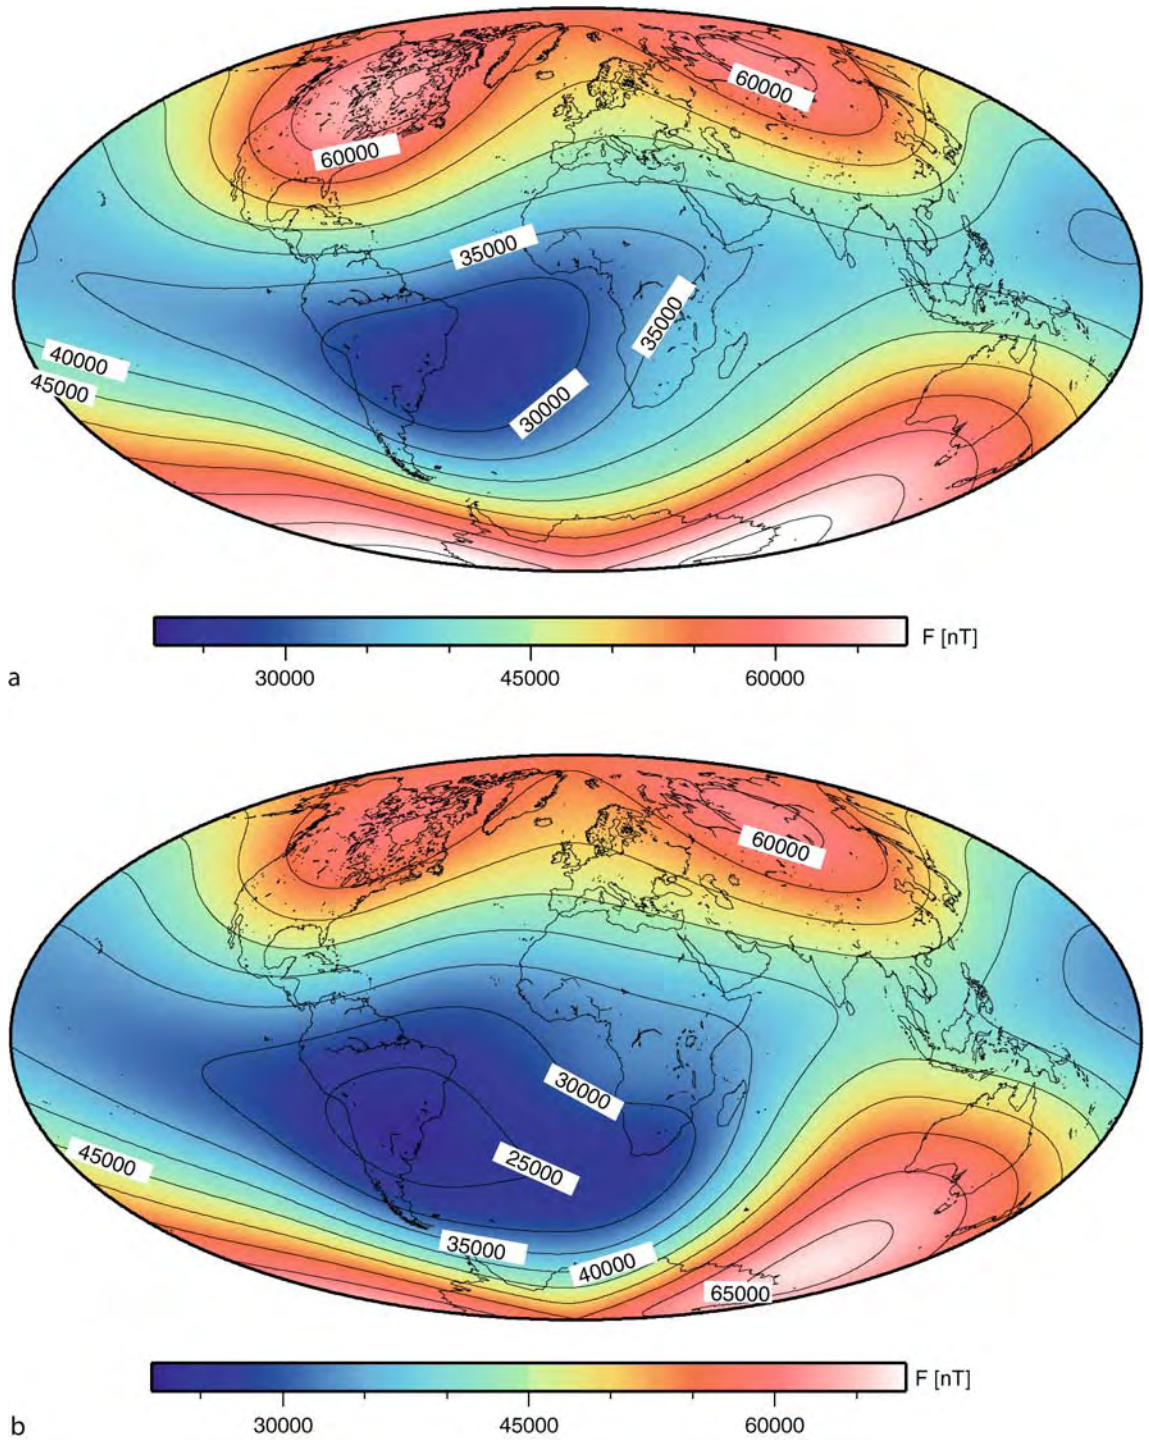
## Secular Variation

The magnetic elements change with time (compare charts for 1900 and 2004 in Figs. 2–4).

The largest changes are associated with the non-dipole part of the main field. In Fig. 3, one can see that the agonic line has moved westward across Eastern Europe and South America since 1900. There are also pronounced changes in the inclination over the South Atlantic (Fig. 2). Bullard et al. [3] calculated a secular change in $D$ of 0.32°/yr, and a westward drift of the non-dipole components of 0.18°/yr for the period 1907–1945. The observed westward drift may be explained as a consequence of the dynamo theory of the origin of the Earth's field, requiring the outer part of the core to rotate less rapidly than the inner part. Therefore, the core travels westward



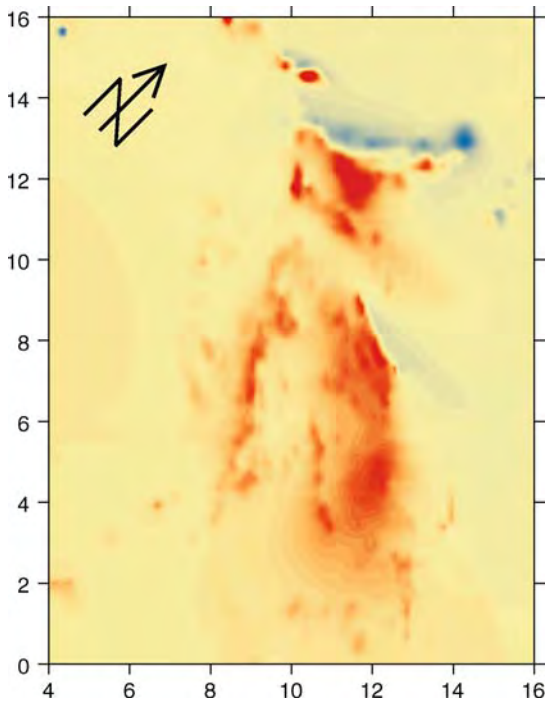
**Geomagnetic Field. Figure 3** Declination, *D* for the years 1900 (a) and 2004 (b) according to IGRF 9, in isogonic format. The thick contour wriggling around the globe is the agonic line ($D = 0°$). Isogonics for $D > 0$ ($D < 0$) are represented by *solid (dashed) lines*. Spacing between contours is 10°. Map projection: cylindrical equidistant with geographical grid underlain to emphasize local deviations of magnetic north from true north. Movies showing the evolution of the magnetic elements over the last four centuries are available under http://geomag.usgs.gov/movies.html.



**Geomagnetic Field. Figure 4** Total field intensity, *F* for the years 1900 (a) and 2004 (b) according to IGRF 9, in isodynamic format and equal area projection.

relative to the mantle, carrying minor features of the field with it.

Magnetic charts showing lines of equal change are referred to as isoporic. Figure 6 shows the current rate of change in *F*. At present, *F* is decreasing at the fastest rate in the North Atlantic offshore from South Carolina/USA, while it is increasing particularly rapidly over the Central Indian Ocean.



**Geomagnetic Field. Figure 5** Magnetic anomaly map, showing the deviation of the locally measured value of *F* from the value according to the IGRF for a 12 × 16 km$^2$ area around the site of the German continental deep-drilling programme in north-east Bavaria/ Germany. The anomaly ranges from + 100 nT (red) to –100 nT (blue). The map was obtained from an aeromagnetic survey flown at an altitude of 50 m. (Courtesy of Dr. J. Pohl).

## Polarity Reversals

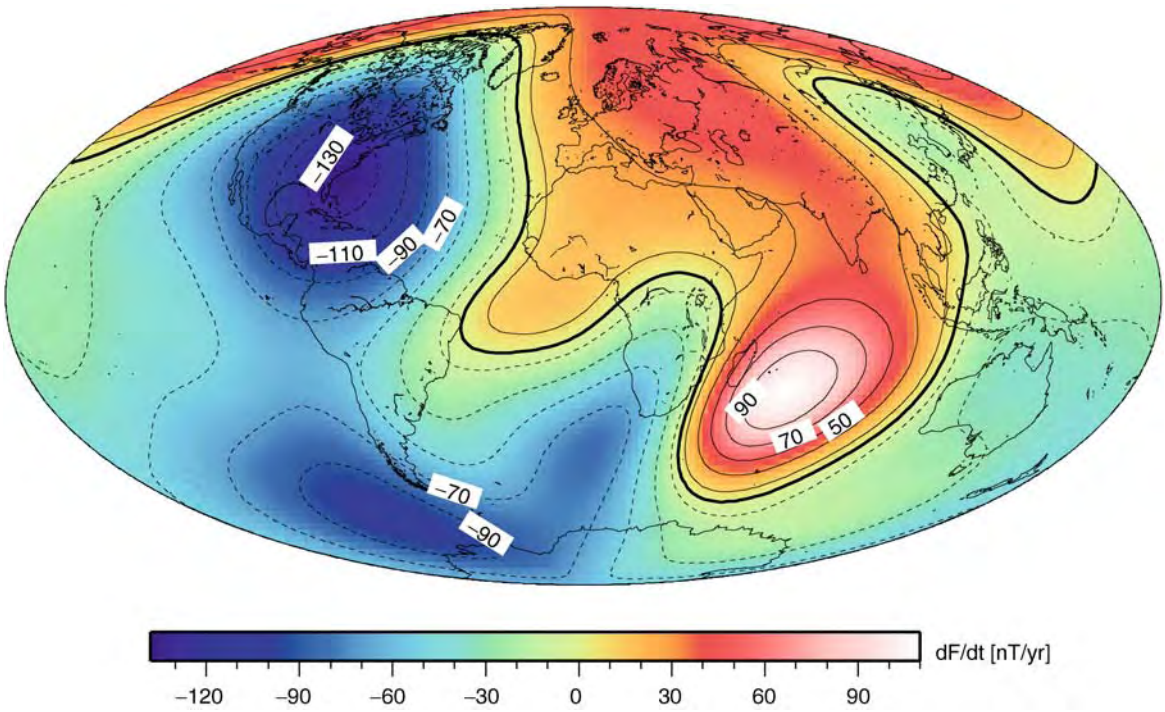
The dipolar component of the magnetic field has been dwindling by 5% per century since the first analyses by Gauss in 1835, and if it were to continue diminishing at the same rate, it would disappear in about 2000 years' time [4]. Even though it is not possible to predict the behaviour of the main field for the distant future, the temporary disappearance of the dipole field would be no extraordinary event in the Earth's history. In the palaeomagnetic record obtained from sediment cores or lava sequences, periods of low magnetic field strengths have frequently been observed, often in relation to geomagnetic polarity reversals.

Polarity reversals are the most spectacular temporal variations in the geomagnetic field. However, while the polarity of the solar magnetic field changes regularly, at a frequency of 11 years, polarity reversals of the geomagnetic field are distributed randomly over geological time (Fig. 7).

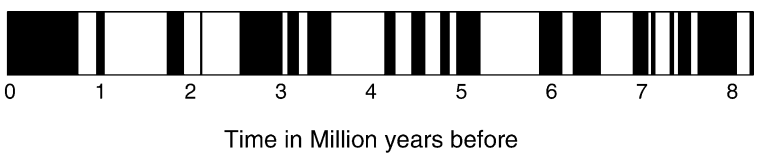
Several hundreds of reversals are documented in the palaeomagnetic record. Over the last five million years, some twenty reversals have occurred, the last one 780 kiloyears ago. Despite some recent progress in this field, it is still not clear how a polarity transition occurs in detail. Rather than simply being an instantaneous switch in polarity, a polarity transition appears to be a complicated process lasting at least a thousand years. From what has been observed in palaeomagnetic records and corroborated by numerical modelling [5], the onset of a polarity transition is marked by plummeting field intensities and erratic directional behaviour, which is interpreted in terms of an abating dipolar field. When the dipole builds up in the reverse direction and recovers its pre-transitional strength, the reversal is accomplished. Since the last reversal 780 kyrs ago, there seem to have been several reversal attempts, which obviously did not succeed. Such an aborted reversal attempt is often referred to as geomagnetic excursion, although geomagnetic excursions may also present periods of extraordinarily large secular variation. More high-resolution palaeomagnetic records worldwide are needed to resolve this question.

## Periodic and Transient Field Fluctuations of External Origin

In addition to the long-term ("secular") variation, there are also short-term fluctuations in the geomagnetic field from sources external to the Earth, transient or quasi-periodic in nature. Fig. 8 shows a magnetogram recorded on a "geomagnetically quiet" day compared to one recorded during a magnetic storm. Field variations on a "quiet" day have typical amplitudes of 20–30 nT. The quiet-day variation comprises a major diurnal variation (Sq – solar quiet) depending on solar time and a minor semidiurnal variation (L – lunar) depending on lunar time. Solar insolation is a function of daytime, latitude, and season, and therefore there are seasonal and latitudinal cycles superimposed to the diurnal variation. Nevertheless, because of their regular diurnal variations, the Sq variations may act as a zeitgeber to those animals whose magnetic sense is sensitive enough to detect changes of less than one per mille of the normal field intensity. The source of Sq variations are electric currents in the E-region of the dayside ionosphere, generated by moving charges in the main field like in a dynamo. The L variations represent tidal forces on the ionosphere also inducing dynamo currents. A magnetic storm, on the other hand, is a consequence of a solar burst, through which billions of tons of solar plasma are ejected into space and eventually hit the Earth's magnetosphere, causing large field disturbances that may last over several days. The magnetic field changes due to a magnetic storm that produces a different local field situation, and will therefore hamper navigation in animals that use local magnetic field anomalies as a map factor. Metaphorically speaking, these animals would be deceived by a magnetic fata morgana.



**Geomagnetic Field. Figure 6** Isoporic chart for 2004 showing the rate of change in *F* in nT/yr, according to IGRF 9. Contours are lines of equal decay rate *(dashed)* or equal growth rate (solid). Spacing between contours is 20 nT/yr, the thick black line represents 0 nT/yr. Equal area projection.



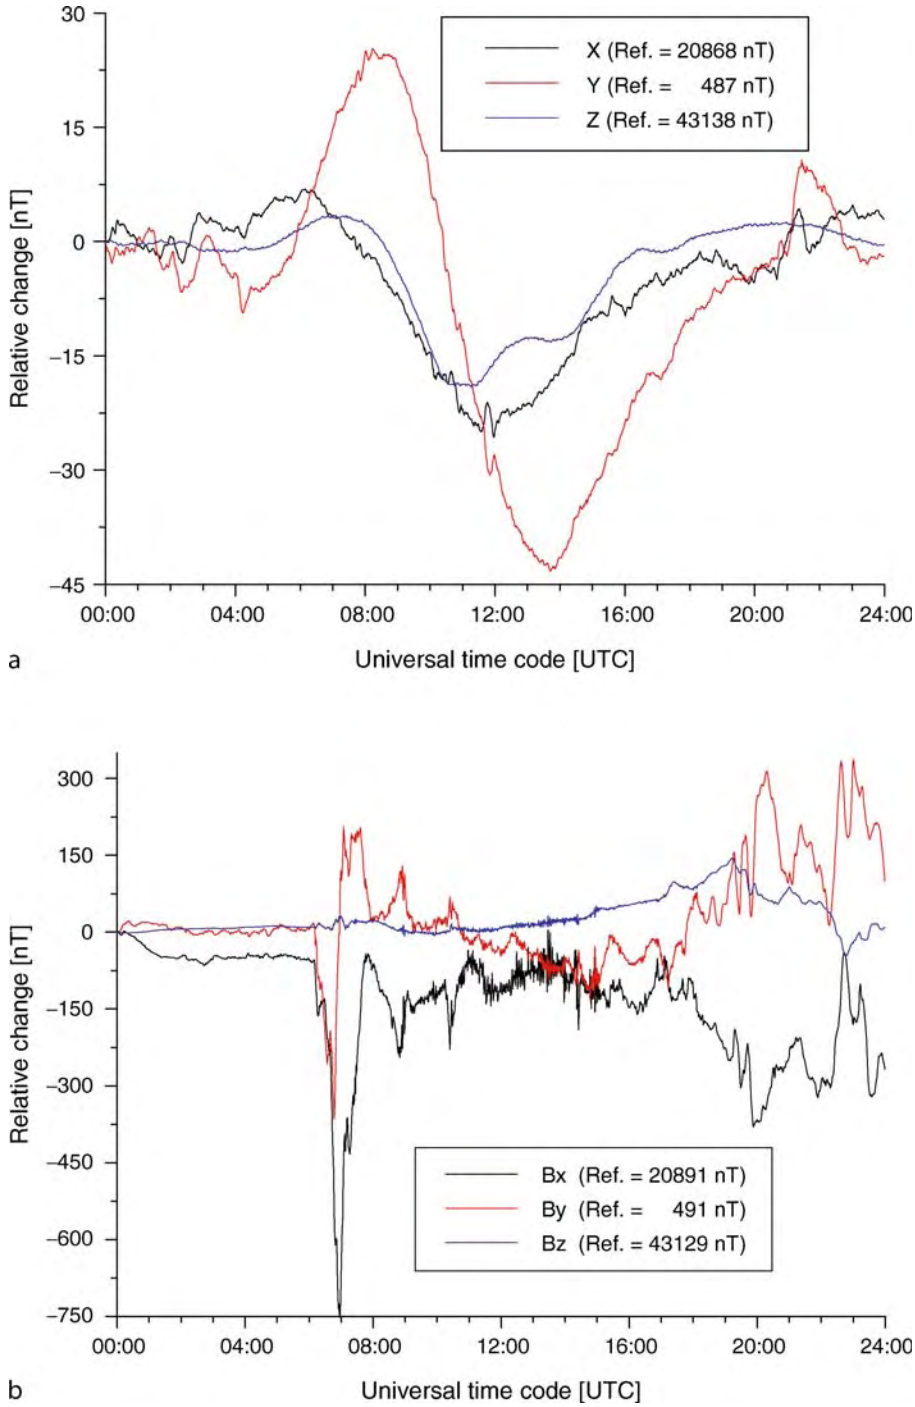
**Geomagnetic Field. Figure 7** Geomagnetic polarity time scale for the last seven million years. Normal (reversed) polarity intervals are black (white). Field reversals (transitions between two adjacent polarity intervals) have occurred irregularly in geological time.

## Theory

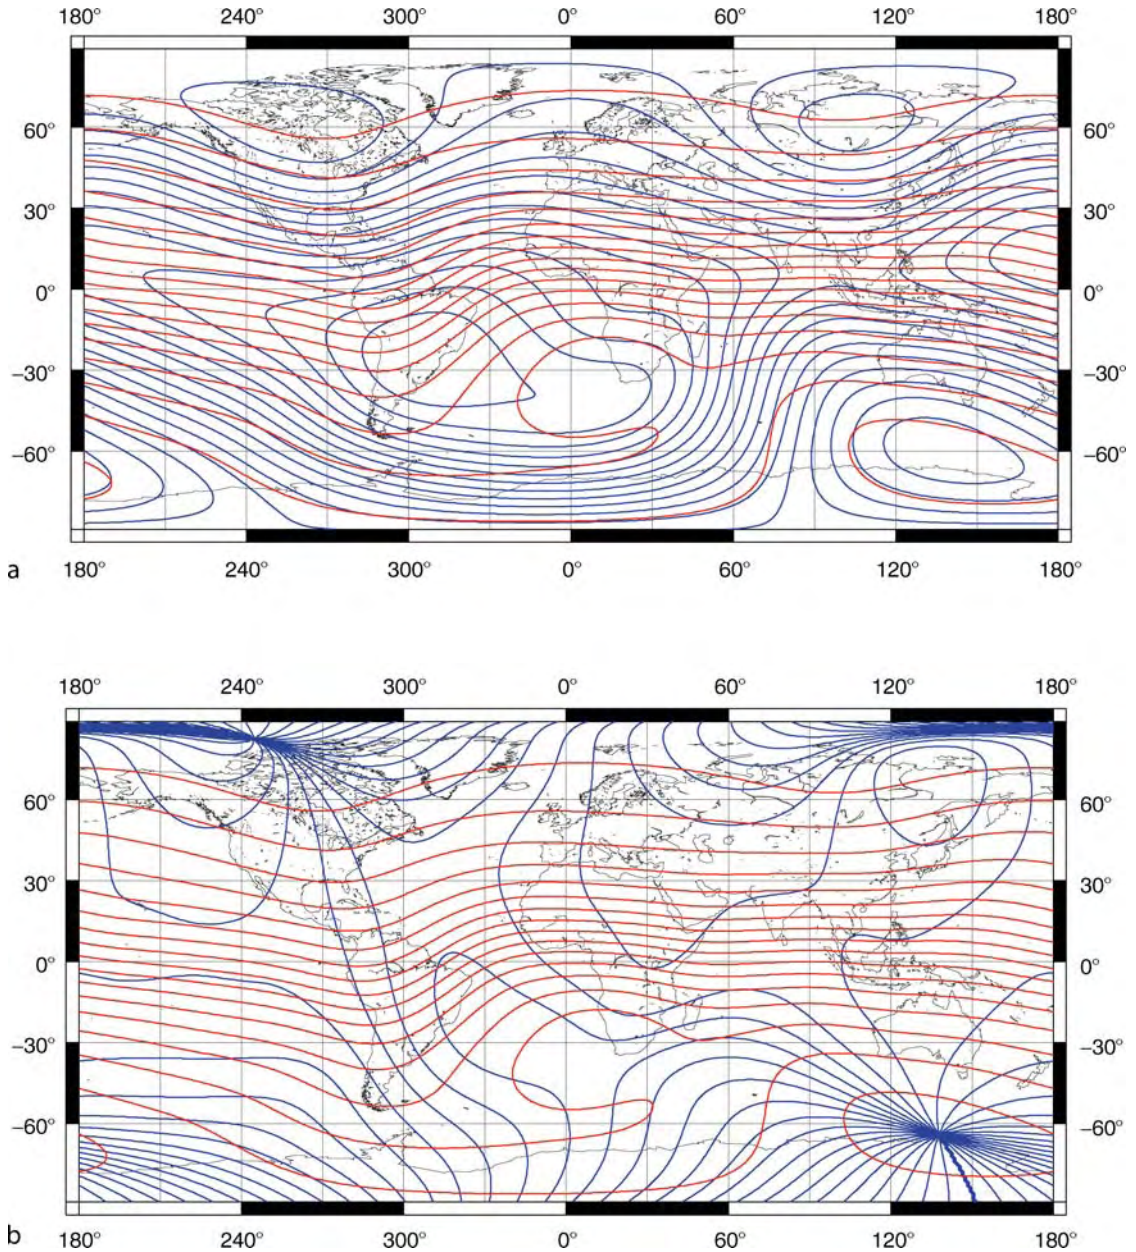
### *Geomagnetic Bi-Coordinate System*

The Earth's magnetic field contains considerable navigational information. The systematic variation of inclination with latitude over a global scale (Fig. 2) may provide an animal in its long travels with a reliable reference frame [6]. For precise navigation on the two-dimensional surface of the Earth, however, a *pair of* coordinates is required. The geographical coordinate system, with its regular grid of longitudes and latitudes, is unique in any point on the surface but cannot serve animals as a natural coordinate system because of its artificial nature. It has been postulated that two magnetic elements such as inclination and intensity [7,8] might form the basis of a natural bi-coordinate system; the pair inclination and declination may serve the same purpose, but celestial cues are needed to determine geographic North. In any case, the isolines of the respective elements would represent the natural latitudes and longitudes in that model.

Figure 9 shows that such grids are far from regular on a global scale, and more importantly, are not unique: There are several locations with identical magnetic coordinate values. Likewise, magnetic latitudes and longitudes nearly coincide over large regions (parallel isomagnetics), which means that either coordinate is useless. Examples are the North Atlantic region (*I-Fmap*) or the Equatorial Pacific (*I-D* map). These limitations are aggravated by local magnetic anomalies, rendering the real magnetic bi-coordinate grid even more irregular, yielding umpteen ambiguities. Navigation based on a magnetic bi-coordinate system alone, therefore, does not appear to be viable. This has also been concluded from the analysis of satellite telemetry



**Geomagnetic Field. Figure 8** Variations of the magnetic field elements *X, Y, Z* recorded over 24 h at the geophysical observatory near Munich, beginning at 0h UT on Sept 29, 2003 (*top*) and Oct 29, 2003 (*bottom*). To allow for a better comparison, the variations are plotted relative to the respective values at 0h UT. The upper magnetogram shows a diurnal field variation typical of a "magnetically quiet" day, while the lower one shows a stronger-than-average magnetic storm. Roughly one storm per year is larger than 250 nT at mid-latitudes of the Earth. Note that the scaling is largely different for the two magnetograms. Data available under http://obsfur.geophysik.uni-muenchen.de/.



**Geomagnetic Field. Figure 9** Two possible bi-coordinate systems based on the isolines of two magnetic elements. (a) Isoclinics of I (red) and Isodynamics of *F* (blue), (b) Isoclinics of I (red) and Isogonics of *D* (blue). Contour spacing is 10° for *D, I* and 2,500 nT for *F*. Reference year 2004, field model IGRF 9. Either natural bi-coordinate system is irregular as well as ambiguous and changes with time because of secular variation.

data on navigation behaviour in wandering albatrosses [9]. It is more likely that animals use distinct local and regional magnetic anomalies as magnetic map factors.

### *Possible Role of Magnetic Field on Evolution*

The Earth's magnetic field guards the biosphere by shielding the Earth from highly energetic solar and cosmic radiation. The ►solar wind is both protective and detrimental: On the one hand, it helps shield the planetary system from cosmic radiation. In times of high solar activity, the flux of cosmic protons with kinetic energy between 0.1 and 10 GeV is reduced by one order of magnitude [10]. High solar activity, on the other hand, results in more solar proton events, showers of highly energetic solar particles that cause partial destruction of the ozone layer, making the stratosphere temporarily more permeable to harmful UV radiation. Taken together, organisms may well be exposed to higher levels of UV

radiation during periods of low geomagnetic field intensity and high solar activity. In any case, organisms that use the geomagnetic field for orientation will be directly affected and have to retune their magnetic sense. During times of low geomagnetic-field intensity, the spatial field distribution on the Earth's surface may change completely from a dipole-dominated to a non-dipole dominated field geometry. Similarly, local magnetic anomalies, due to induced and remanent crustal magnetization, also become less pronounced or may change their fingerprint. Whether or not those changes turn out to be critical depends on the rate of change. The secular rate of decrease in dipole strength is roughly 50 nT/yr, obviously slow enough for organisms to adapt. In any case, an Earth with a weak magnetic field is more prone to suffer from perturbations by magnetic storms.

## Gestalt Psychology

Walter H. Ehrenstein
Leibniz Research Center for Working Environment and Human Factors, University of Dortmund, Dortmund, Germany

### Synonyms

Gestalt theory

### Definition

*Gestalt psychology* emerged as an alternative to elementalistic assumptions within the first two decades of the twentieth century. A then widely held view was that complex percepts were simply additive combinations of sensory elements tied together to larger complexes by mechanisms of associative learning. To Gestalt psychologists, notably Max Wertheimer (1880–1943), Kurt Koffka (1886–1941), and Wolfgang Köhler (1887–1967), structured entities, rather than "atomistic" elements, were the units of perception. According to them perception resulted from interactive processes within a "field" of dynamic "forces," based on correspondingly configured (isomorphic) brain processes.

### Characteristics

#### Antecedents

*Gestalt*, a German word variously translated as figure, form, configuration, or shape has played an important role in discussions of perception ever since it was used by Ernst Mach, professor of physics at Prague, in his Analysis of Sensations (1886) [1]. Mach showed that two black-white figures can be recognized at first glance to share the same Gestalt in spite of the difference in each of their constituent elements (due to a reversal of contrast polarity). Conversely, he demonstrated the difficulty in recognizing the commonality between two physically identical forms: a square resting on one side is rather different in shape from the same square rotated by 45°, so that it stands on one corner and hence becomes a diamond (see also Fig. 2). Mach's observation inspired Christian von Ehrenfels, an Austrian philosopher, who in 1890 coined the term *Gestalt quality* to denote the difference between the perceptual whole and the mere sum of its constituent parts or elements (*superadditivity*). Ehrenfels further noted that a configuration may retain the same overall quality even if each of its parts is changed (*transposition*). A melody, played in several different keys so that each note is changed while the relations among them are retained, still appears as the same *tonal Gestalt* [2,3].

#### Experimental Grounding

Such general statements and qualitative observations by themselves would not have made a powerful scientific trend. "Far from being armchair philosophers, the early Gestaltists were as active in the laboratory as any student of human behavior" [1]. As an academic discipline, *Gestalt psychology* is usually traced to 1912 with the publication of Wertheimer's experimental studies on apparent visual motion [2,3]. Two orthogonal lines presented briefly in the proper sequence will show *phi motion* (pure motion without object displacement) or, at a slightly longer interval, appear as a single bar moving through a right angle (optimal motion). In both

G

cases, the observed motion is an emergent phenomenon that cannot be reduced to the piecemeal features of the two static line stimuli. Wertheimer carried out his work in the laboratory of Friedrich Schumann at the University of Frankfurt am Main, where his colleagues, Kurt Koffka and Wolfgang Köhler, participated as subjects. In sharing the striking observations they were also attracted by the new *Gestalt theory* [2] that originated with these experiments.

## The Berlin School

The Gestalt school was established in Berlin, where Köhler had been appointed to the chair of psychology in 1922, largely on the strength of his monograph on *physical Gestalten* (1920) that linked Gestalt phenomena more firmly to electromagnetic field processes. The neural correlates of perception were postulated to resemble structural properties of perceived Gestalten (*isomorphism*) at a stage, at which brain processes assume the quality of conscious experience (*psychophysical level*) [3,4]. This was an early and systematic program to infer brain processes from percepts. It had been, again, anticipated by Mach who considered "illusory" percepts, such as brightness contrast, to rely on a fairly autonomous behavior of the sense organs, on the "dependence of retinal points on one another" (1868), rather than on errors in judgment.

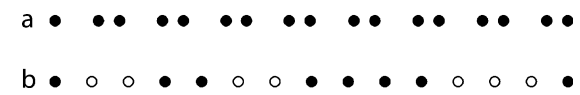
The Berlin school was transplanted to the US with the rise of Nazism in Germany in 1933, when Wertheimer emigrated to join the New School for Social Research in New York City, followed by Köhler who left for Swarthmore College in 1935, whereas Koffka had already taken a position at Smith College in 1927. Of the Gestalt trio, Köhler adapted most successfully to life in the US; he was president of the American Psychological Association in 1959 [2].

## Principles of Perceptual Organization

The principles that determine why "things look as the do" (Koffka, 1935) and why, out of a multitude of possible solutions, only one percept typically materializes, have become known as the *laws of seeing* [5]. Using simple dot and line figures, Wertheimer (1923) first formulated a set of ►*Gestalt laws* with proximity, similarity, closure, and common fate as principal factors.

*Proximity.* Other factors being equal, the nearer stimuli are to one another, the more likely they are to be organized into unified percepts. An example is shown in Fig. 1, where the dots are easily organized into pairs of dots. Note that it is almost impossible to see the spaced dots as belonging together, i.e., to break up the units based on proximity.

*Similarity.* Objects that share common features (such as brightness, color, size, form, or orientation) tend to be grouped together. For example, filled and outline dots



**Gestalt Psychology. Figure 1** Demonstration of proximity (a) and similarity (b) as Gestalt factors.

**Gestalt Psychology. Figure 2** Closure as Gestalt factor. The dots are seen to enclose a square or diamond rather than representing crosses: (×) or (+).

are readily grouped together, even if they are evenly spaced (Fig. 1b).

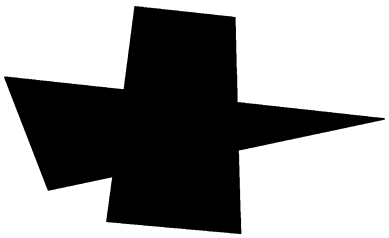
*Closure.* Components that constitute a closed entity rather than an open one are more readily organized into a single percept. For example, the two arrangements of four dots in Fig. 2 appear as rectangle or diamond rather than as crosses (×) or (+), because the former are closed.

Closure also accounts for the tendency to complete otherwise incomplete, e.g., partly occluded, objects (modal and amodal completion). The configuration shown in Fig. 3 appears as a triangle behind a trapezoid (Petter's rule). This perceptual option is favored over a complicated, 11-sided figure.

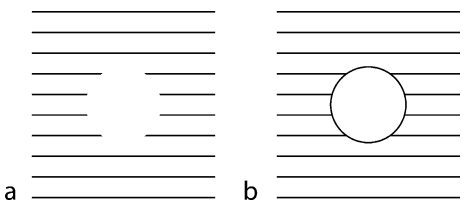
*Common Fate.* Stimuli moving simultaneously at the same rate and in the same direction are readily seen as a group, share a "common fate." This factor can tie together objects that are quite distant and different and is essential in dynamic figure-ground segregation. Where grouping otherwise fails to occur in a stationary display, it is readily seen as soon as parts of the display move. A well-camouflaged animal will remain hidden only as long as it is standing still; it becomes visible (pops out) as soon as it moves.

These and other Gestalt factors were essentially considered as bottom-up mechanisms built into the visual system through evolution of the organism as it interacted with stimuli in a natural setting. As such they are not unique to humans, but are also effective in a variety of species (insects, fish, birds, mammals) [3]. Camouflage and concealment counteract the very Gestalt principles that establish figure-ground segregation and perceptual grouping. Particularly effective are blobs and textures that interrupt existing boundaries or create new contours and offset surfaces, by suggesting "wrong" perceptual entities [5].

*Prägnanz principle.* A key assumption of Gestalt psychology under which particular organizing factors



**Gestalt Psychology. Figure 3** A trapezoid overlapping a triangle is seen rather than a complex shape (with 11 sides).



**Gestalt Psychology. Figure 4** The gap between the lines appears like a lemon-shaped surface (a), although the spacing allows for a perfect circle (b).

can be subsumed is the principle of *figural goodness* or *Prägnanz*. It denotes the tendency of the percept to become structured in the simplest, most regular and homogeneous way possible under the given stimulus conditions. This tendency was understood by Köhler (1920, 1940) as a self-organizing process, resulting from dynamic field forces inherent in the visual system and depending on global conditions of the system's equilibrium [3]. Thus, at a critically balanced energy distribution within brain fields, even a minor change of the stimulus or in the observer's state can precipitate a reorganization of the entire percept, causing a reversal of figure-ground segregation. Although the *Prägnanz* principle is supported by numerous examples [5], there are telling counterexamples. One (by Pinna, 1991), shown in Fig. 4, served Gaetano Kanizsa (1994) to illustrate "some real conceptual difficulties" of Gestalt theory [4]; it proves that a percept can indeed be *less* regular than afforded by its stimulus conditions (Fig. 4).

Even in cases that obey the Prägnanz principle, the question remains why we should see a stimulus pattern better than it is at the expense of veridicality. A possible answer is optimization in the interest of robust transmission of information. Straight lines, regular shapes are ubiquitous properties of objects in our daily environment. They are, however, rarely presented in their entirety. To make up for any stimulus occlusions or distortions, neural mechanisms may have evolved that strive to rectify crooked lines, fill in gaps, and complete surfaces, thereby restoring the stimulus to its original state [3,4].

## Gestalt Theory and Modern Neuroscience

It seems as if brain research has come to a stage comparable to that of the Gestaltists when they encountered the limitations of the elementalistic approach of psychophysics more than 80 years ago. Neural function is no longer understood as a mere addition of single-cell activities. Rather, neuronal responses have been shown to not only depend on the local stimulus that reaches the center of their ►receptive fields, but also on the presence of other stimuli in the surrounding parts of the ►visual field and the current state of the system. Gestalt terms that originally served to describe qualitative properties of figural grouping and segregation have meanwhile become essential concepts in grasping the significance of the spatiotemporal processing characteristics of the visual system [6–8]. The Gestaltists themselves tried to link perceptual organization to brain processes, notably Wolfgang Köhler who, inspired by the laws of thermodynamics, considered the brain as a homogeneous conductor of bioelectric forces [3]. However, the brain fields proposed as correlates of pattern perception and figural aftereffects (e.g., Köhler and Held, 1949), did more to hasten the demise of Gestalt theory than to promote it. Neurophysiologists in failing to establish firm evidence for such fields tended to dismiss Gestalt theory in general rather than Köhler's premature proposal in particular. The robust visual phenomena, however, continue to challenge neuroscientific accounts. Especially receptive (and corresponding perceptive) field organization [3,6–8] and synchronized coupling of neuronal activity within and across cortical areas [9,10] are increasingly favored as correlates of genuine Gestalt phenomena.

*Receptive field organization: A micro-Gestalt.* A basic notion made by Gestalt psychology (e.g., in studies of a homogeneous Ganzfeld by Metzger, 1930, and of figure-ground segregation by Ehrenstein, 1930) is the distinction between mere light sensation and structured perception. Without (suprathreshold) luminance differences Gestalt factors are ineffective. A figure will only emerge with an inhomogeneity that allows for segregation. The mechanism that encodes physical contrast is the *receptive field*. Receptive fields of retinal neurons are subdivided into a circular center and a concentric surround, either activated or inhibited by light falling into the center (*on-/off*-center neurons). Similar receptive fields are known to also code spectral or chromatic stimuli. A considerable degree of functional specialization exists at subsequent layers of visual processing with elongated receptive fields in ►area V1 that respond to line orientation and direction of motion. Color and motion are further processed by specialized cells in ►area V4 and ►area V5, respectively. There is also evidence of multi-purpose cells (Schiller, 1996), allowing for flexible, context-sensitive

interaction within distributed neural networks [4]. Thus, receptive fields – with their psychophysically established counterparts: ►*perceptive fields* – provide an organizing principle that allows for nonadditive, Gestalt-like integration of the initial stimulus input. Considering its various forms of center-surround antagonism and selective spatio-temporal sampling characteristics, receptive field organization has been proposed as a general neural correlate of Gestalt formation, regarded as a functional *micro-Gestalt* [3,4].

*Temporal binding.* Besides the striking correlations between the activity of highly specialized single neurons and Gestalt phenomena, temporal binding has been favored as a neural correlate of perceptual integration [9]. It consists of stimulus-dependent synchronized oscillations (within the range of 35–80 Hz) of even far-distant neurons. Especially the above mentioned Gestalt factor of *common fate* might be based on synchronized coupling of neuronal activity "tagged" by coherently moving stimuli. By this, objects can be tied together that may be widely distributed and rather different in form, size, or color. Temporal binding allows for flexible coupling of the spike activity of ever-new subsets of neurons within and even across cortical areas in response to global changes of the stimulus configuration; it has been found to be context-dependent and to reflect figural organization [9,10].

Gestalt phenomena, such as ►motion integration within and across apertures, ►velocity transposition, ►kinetic depth, ►figure-ground segregation, ►subjective contours, ►hidden forms and camouflage, or ►ambiguous figures, have become a major issue of current neuroscience [6–8,10]. They challenge neurophysiologists and computational modelers alike, especially in that they afford mechanisms that are not to be inferred from the physical stimulus alone.

### Definition

Chronic granulomatous vasculitis involving large vessels (e.g., arteriitis temporalis), mainly affects elderly people and presents with a variety of symptoms, including polymyalgia rheumatica, fever, weight loss, and anorexia. The involvement of cranial arteries (e.g., arteriitis temporalis) is often associated with severe ►headache and scalp tenderness, may lead to ischemic optic neuropathy and blindness in 50% of the cases unless expediently treated with glucocorticoids. The etiology is still unknown, but evidence suggests a cellular ►autoimmunologic reaction against a local antigen present in the arterial wall.

The glia (Greek for glue) or neuroglia are the non-neuronal supporting cells in the central nervous system, comprising the oligogodendrocytes, astrocytes and microglia.

►Transplantation of Olfactory Ensheathing Cells

## Glia Cells

### Definition

The term "glia" literally means "nerve glue" was assigned by Rudolph Virchow in 1859 referring to the "connective tissue" holding the neurons of the central nervous system together. Since its inception, the term glia has remained in use in its original form, though the functional attributes of glia cells have extended from mere structural and metabolic supporters of neurons to those of active participants in synaptic transmission.

## Glia Limitans

### Definition

At the surface of the brain and spinal cord are the layers of the meninges. The innermost layer is made up of three components, the layer of meningeal or leptomeningeal cells under which there is a layer of extracellular matrix, under which there is a layer of specialized astrocytic processes lying parallel to the meningeal surface. This inner layer of astrocytic process is the glia limitans. These three inner layers of the meninges have various functions, including the formation of a diffusion barrier between the cerebrospinal fluid and central nervous system (CNS) tissue (essential for the fine control of the composition of the extracellular fluid), the exclusion of inflammatory cells and probably mechanical protection. During development the processes of radial glia form a glia limitans; the structure plays an important part in cell migration.

# Glial and Neuronal Reactivity to Unconjugated Bilirubin

D. Brites, A. Fernandes, A. S. Falcão, M. A. Brito, R F. M. Silva
Centro de Patogénese Molecular - UBMBE iMed.UL, Faculdade de Farmácia, University of Lisbon, Lisbon, Portugal

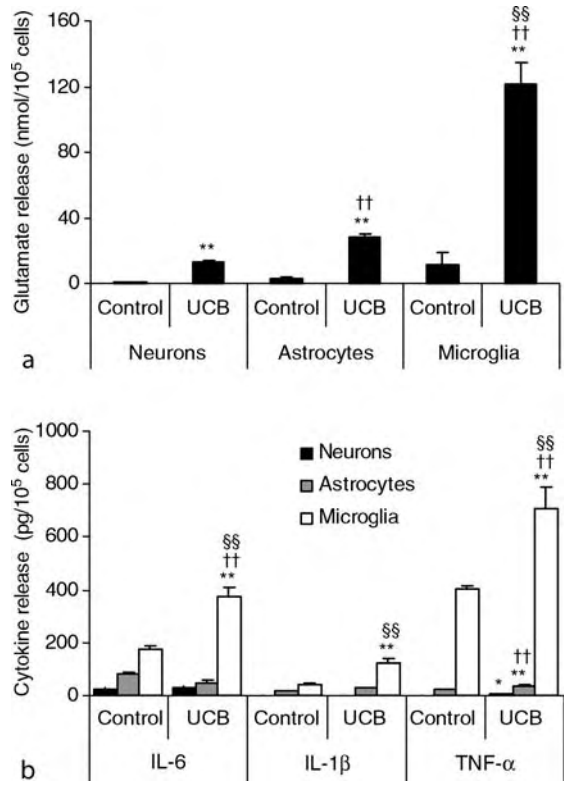
## Definition

In neonatal life there is an increased production of unconjugated ►bilirubin (UCB), due to a shorter life span of the erythrocytes, and a reduced hepatic clearance of UCB leading to its serum retention. In these conditions, elevated levels of UCB may become toxic to the central nervous system (CNS), thus causing ►kernicterus and other neurologic effects that are more severe in preterm than in term infants, even though the molecular mechanisms that trigger UCB neurotoxicity are still not completely clarified. Interestingly, UCB was shown to enhance the release of ►glutamate from nerve cells, an effect that may engender ►excitotoxicity. Recent studies also demonstrate that UCB stimulates ►microglia, ►astrocytes, and even ►neurons to produce ►tumor necrosis factor (TNF)-α, ►interleukin (IL)-1β and IL-6. However, while microglia and astrocytes are the most active cells, neurons are much less responsive. Immunostimulation appears to be mediated through ►TNF-α receptor 1 (TNFR1), the ►mitogen-activated protein kinase (MAPK) signalling pathways and the activation of the ►nuclear factor kappa B (NF-κB). Identification of the potential points of therapeutic modulation are an important prelude for the development of new therapeutic strategies to prevent or reduce the emergence of neurodevelopmental disabilities following unconjugated hyperbilirubinemia.

## Characteristics

### Nerve Cell Response to Bilirubin

A great body of evidence suggests that accumulation of extracellular glutamate is toxic to neurons and that astrocytes protect neurons by removing glutamate from the extracellular space. Several studies point out that brain damage by UCB requires the participation of glutamate toxicity. Incubation of astrocytes, neurons and microglia with 100 μM UCB in the presence of 100 μM human serum albumin (HSA) for 4 h at 37°C, to mimic a severe neonatal hyperbilirubinemia, leads to the release of glutamate to the extracellular space. Comparing the results obtained in neurons, astrocytes and microglia, the glial cells were most reactive to UCB. Levels of glutamate release by astrocytes were ~2-fold higher than those observed in neurons (Fig. 1A)



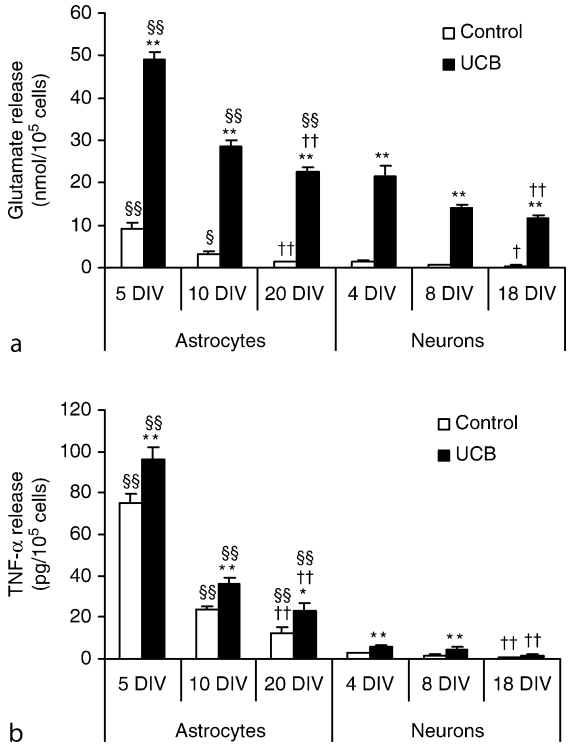
**Glial and Neuronal Reactivity to Unconjugated Bilirubin. Figure 1** Microglia is the most reactive neural cell to unconjugated bilirubin (UCB). Rat cortical neurons, astrocytes and microglia were cultured for 8, 10 and 20 days *in vitro*, respectively, and incubated with either no addition (control) or 100 μM purified UCB, in the presence of 100 μM human serum albumin, at pH 7.4, for 4 h, at 37°C. The release of glutamate (a) and cytokines (b) to the incubation media was assessed by an enzymatic assay and ELISA, respectively. The highest release of glutamate and cytokines is observed in microglial cells, followed by astrocytes and finally by neurons, indicating that the first cell type is the most responsive to UCB stimulus. Values are means ± SEM of at least three independent experiments. $^{*}P < 0.05$ and $^{**}P < 0.01$ Versus respective control; $^{\dagger\dagger}P < 0.01$ Versus neurons; $^{\S\S}P < 0.01$ Versus astrocytes. Derived from data of Falcão et al. [1] and of Gordo et al. [2].

[1]. The release of glutamate by microglia was ~8- and ~4-fold over the values obtained for neurons and astrocytes, respectively [2]. Thus, microglia is the most susceptible neural cell to UCB-induced release of glutamate. It is worthwhile to point out that microglia have also shown an increased vulnerability to UCB-induced ►cell death by both ►necrosis and ►apoptosis (8% and 11%, respectively), as compared to neurons and astrocytes (5% and 4%, respectively, either for necrosis or apoptosis) [1,2].

The ►inflammation in the CNS, termed ►neuroinflammation, is a key component of host defence

responses to peripheral inflammation and CNS injury. Although this physiological response is considered necessary for the resolution of the injury, if present for long time periods it may contribute to the severity of the clinical picture and to secondary damage owing to an augmented inflammatory reaction, which will exacerbate the already altered homeostasis of the injured brain parenchyma [3]. Release of inflammatory mediators, as a consequence of neuroglial activation, initiate multiple signalling pathways that, although independent, may interact with each other and influence the magnitude and duration of the inflammatory response. ►Cytokines are multifunctional pleiotropic proteins that play crucial roles in cell-to-cell communication and cellular activation, being considered the major effectors of neuroinflammation. Although the number of cytokines released following a brain insult and the diversity of their actions may be overwhelming, there is a temporal pattern of cytokine induction that is usually reproduced in the development of neuroinflammation. First, injury induces a rapid mRNA upregulation of the proinflammatory mediators TNF-α and IL-1β which establishes a cytokine network. Both cytokines are known to trigger the secretion of IL-6 that is responsible for the reduction of TNF-α production.

Although the molecular pathogenesis of UCB-induced brain damage is not completely understood, several studies indicate that UCB-induced nerve cell injury is initiated at the level of membranes leading to neuronal excitotoxicity, mitochondrial energy failure or increased intracellular calcium concentration triggering apoptotic pathways and necrosis. Interestingly, we have also shown, for the first time, that UCB enhances the release of proinflammatory cytokines. In astrocytes incubated with UCB in the presence of HSA for 4 h at 37°C we have observed the release of TNF-α and IL-1β (Fig. 1B). In contrast, there was a depression in the secretion of IL-6 [4,5]. Comparative secretion of TNF-α by the three nerve cell types indicate that astrocytes produce ~4-fold more than 8 neurons and that microglia release ~24-fold more than astrocytes. Release of IL-1β was not detectable in neurons and again microglia was the main producer of this pro-inflammatory cytokine. Interestingly, the secretion of IL-6 that was suppressed by UCB in astocytes was slightly increased in neurons and markedly enhanced in microglia [1,2]. Collectively, our data support the conclusion that microglia is the most responsive neural cell to UCB-induced release of cytokines. To note that for prolonged astroglial exposure to UCB there was an increase in the secretion of TNF-α and IL-1β with a maximum at 12 h and a sustained elevation at 24 h after UCB addition, as well as of IL-6 that showed the greatest production at 18 h. This later IL-6 secretion is probably due to the action of released TNF-α and IL-1β rather then to a direct effect of UCB. Since both TNF-α and IL-1β have shown to induce the loss in astrocyte viability demonstrated either by LDH release or apoptosis [6] we may speculate that UCB-induced cytokine production, by mediating cell injury, can further contribute to exacerbate neurototoxicity.



**Glial and Neuronal Reactivity to Unconjugated Bilirubin. Figure 2** Reactivity of astrocytes and neurons to unconjugated bilirubin (UCB) is increased in undifferentiated cells. Rat cortical astrocytes and neurons, cultured for 5, 10 and 20 days *in vitro* (DIV) or 4, 8 and 18 DIV, respectively, were incubated with either no addition (control) or 100 μM purified UCB, in the presence of 100 μM human serum albumin, at pH 7.4, for 4 h, at 37°C. Release of glutamate (a) and TNF-α (b) to the incubation media was assessed by an enzymatic assay and ELISA, respectively. The highest release of glutamate and the pro-inflammatory cytokine TNF-α is observed in less differentiated cells, decreasing with the maturation state, indicating that immature nerve cells are more vulnerable to the effects of neonatal jaundice. In addition, responsiveness of astrocytes is higher than that of neurons, regardless the differentiation state. Values are means ± SEM of at least three independent experiments. $^{*}P < 0.05$ and $^{**}P < 0.01$ Versus respective control; $^{\dagger}P < 0.05$ and $^{\dagger\dagger}P < 0.01$ Versus 4 DIV neurons or 5 DIV astrocytes in the same experimental conditions; $^{\S}P < 0.05$ and $^{\S\S}P < 0.01$ Versus neurons in equivalent developmental stage and experimental condition. Derived from data of Falcão et al. [1].

### Less Differentiated Astrocytes and Neurons are More Reactive to Bilirubin than More Mature Cells

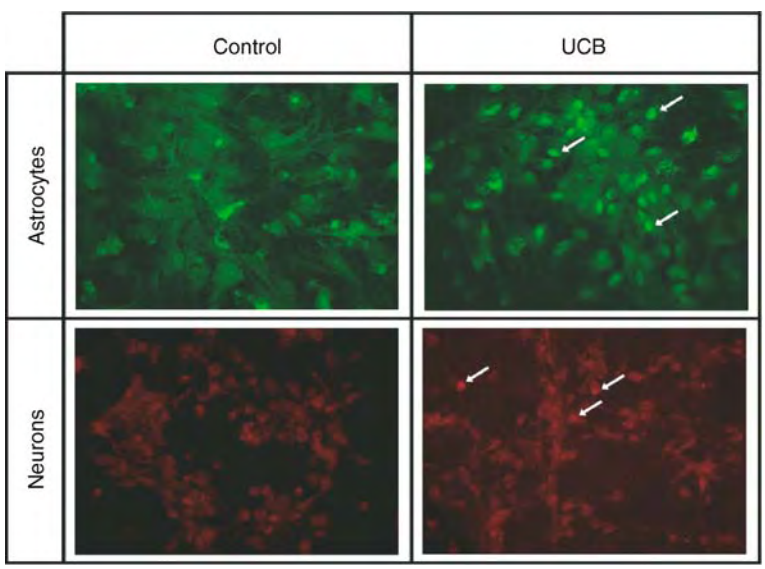
Prematurity has been considered to be a significant aggravating factor for UCB neurotoxicity, since preterm newborns have an increased susceptibility to UCB brain injury during moderate to severe neonatal jaundice. Thus, in one of our most recent studies we evaluated UCB-induced glutamate release in astrocytes and neurons cultured for different days, in order to relate the differentiation state with cell reactivity to UCB. Neurons and astrocytes at different stages of differentiation were incubated with UCB in the presence of HSA, for 4 h at 37°C. As shown in Fig. 2A, UCB markedly increased glutamate release, particularly in the immature cells. Comparing the results obtained in both cell types, glial cells were much more reactive to UCB, as demonstrated by the increased levels of glutamate release (~2-fold higher values than those observed in neurons, $P < 0.01$) [1]. Cell-age dependent pattern of inflammatory response was also evaluated in the same conditions. Our studies showed that the release of TNF-α was greater in younger than in older cells, with astrocytes producing higher amounts than neurons (Fig. 2B) [1,2]. Interestingly, while the astroglial secretion of IL-1β reproduced that of TNF-α, neurons were unable to develop a similar response. In contrast, IL-6 secretion was inhibited by UCB in astrocytes at all cell-ages, while the pattern of IL-6 release did not significantly change in neuronal cells exposed to UCB.

Having verified that UCB-induced production of TNF-α was enhanced in immature cells, particularly in astrocytes, we evaluated whether this higher responsiveness could be due to a developmentally regulated pattern of NF-κB activation. This transcription factor appears to modulate cell fate depending on the nature of the stimuli and the cell type involved [7]. NF-κB activation was investigated by following its translocation to the nucleus by immunocytochemistry (Fig. 3). When compared to neurons, astrocytes presented a much higher number of NF-κB positive nuclei, namely in the immature stage. In fact, after incubation with 50 μM UCB in the presence of HSA, for 4 h at 37°C there was an increment of 2.4% NF-κB positive nuclei in neurons ($P < 0.05$) and of 6.5% in astrocytes ($P < 0.01$), which raised to 4.0% and 9.0%, respectively, when cells were incubated with 100 μM UCB [1]. However, as cells grow old, this difference becomes less noticeable.

Altogether, these results provide a basis for the proneness of premature babies to UCB neurotoxicity.

### Inflammatory Signalling Pathways Involved in Astroglial Activation by Bilirubin

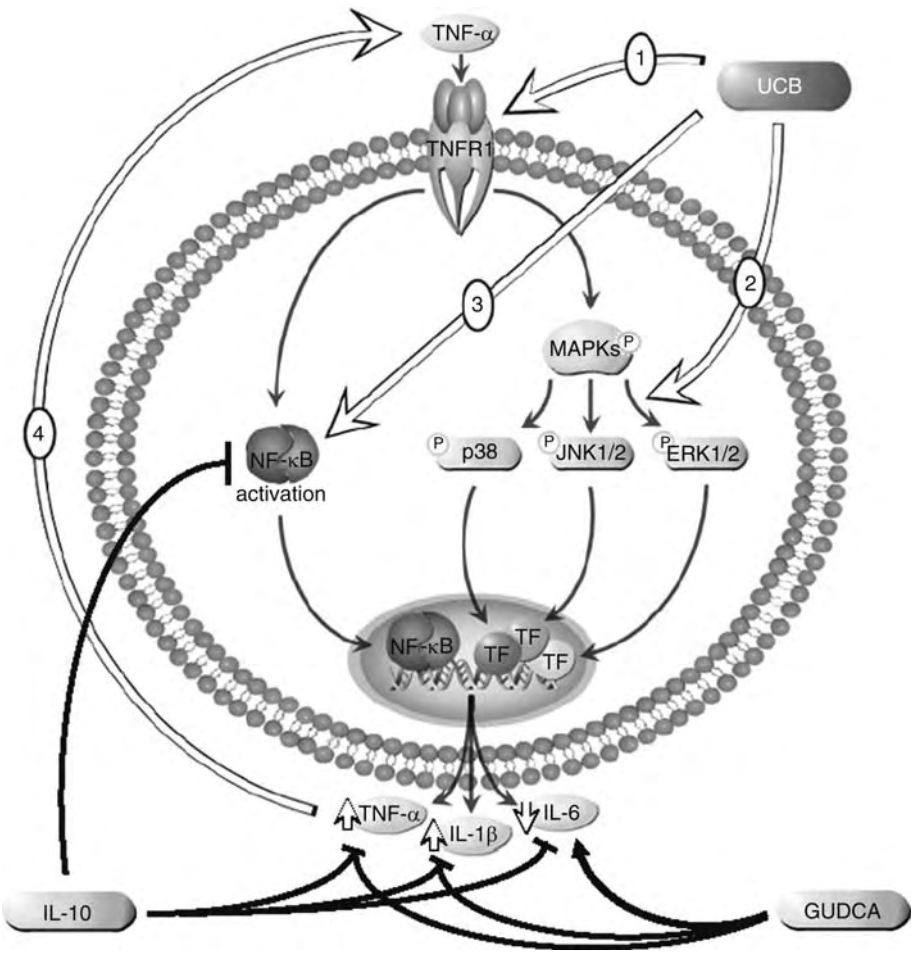
Production and release of cytokines depend on inducible gene expression mediated by activation of cell signaling.



**Glial and Neuronal Reactivity to Unconjugated Bilirubin. Figure 3** NF-κB activation in neurons and astrocytes is induced by unconjugated bilirubin (UCB). Neurons and astrocytes were cultured for 8 and 10 days *in vitro*, respectively, and incubated with 50 μM purified UCB, or no addition (control) in the presence of 100 μM human serum albumin, at pH 7.4, for 4 h, at 37°C. Cells were immunostained with an antibody against p65 NF-κB subunit, followed by a species-specific fluorescent secondary antibody labeled with TRITC in neurons (red) or with FITC in astrocytes (green). Translocation of NF-κB is visualized by intense coloration of the nucleus, contrasting to cytoplasm localization. When compared to neurons, astrocytes presented a much higher number of NF-κB positive nuclei. Representative NF-κB positive nuclei are indicated by arrows. Original magnification: 516x.

Primary inflammatory stimulus may act through membrane receptors like TNFR1, which cause the activation of four major intracellular signaling pathways that are cascades of protein kinases, namely the three distinct MAPK pathways, p38, c-Jun-*N*-terminal kinases 1 and 2 (JNK1/2) and extracellular signal-regulated kinases 1 and 2 (ERK1/2), and the one leading to activation of NF-κB [8].

Incubation of astrocytes with UCB and HSA resulted in a rapid biphasic activation of TNFR1 during the 24 h observation period [6]. The early phase was detected as early as 15 min ($P < 0.01$), peaking at 1 h (>5-fold, $P < 0.01$), followed by a sustained increment and a slight elevation at 12 h (>3.5, $P < 0.01$). While the early-phase activation may result from a direct interaction of UCB with the TNFR1, the secondary activation may be due to the action of IL-1β and IL-6 produced during astrocyte exposure to UCB. Downstream to UCB-induced expression of TNFR1 it was observed a rapid and transient activation of p38 at 30 min (∼3-fold, $P < 0.01$) with a peak between 1 and 2 h (>4.5-fold, $P < 0.01$), a later but more sustained activation of



**Glial and Neuronal Reactivity to Unconjugated Bilirubin. Figure 4** Schematic representation of the signaling pathways involved in astrocyte reactivity to unconjugated bilirubin (UCB). UCB interaction with astrocytes for 4 h causes a rapid increase of the cell surface receptor TNFR1 protein levels (*arrow 1*), leading to phosphorylation of MAPKs and activation of transcription factors (TF) resulting in the secretion of cytokines TNF-α and IL-1β. TNFR1 signaling may also involve NF-κB activation and its consequent translocation into the nucleus where it promotes the up-regulation of cytokines. In addition, UCB may rapidly diffuse through the cell membrane directly inducing the activation of MAPKs (*arrow 2*) and NF-κB (*arrow 3*). The overall signal transduction pathway further occurs by the engagement of TNF-α with its specific receptor TNFR1 (*arrow 4*). Both IL-10 and glycoursodeoxycholic acid (GUDCA) reduce UCB-induced release of TNF-α and IL-1β to control values, while suppression of IL-6 release was only counteracted by GUDCA. Contrasting with GUDCA, IL-10 was also able to inhibit NF-κB nuclear translocation. Derived from data of Fernandes et al. [6].

JNK1/2 from 1 to 4 h (~3.5-fold, $P < 0.01$) and a less pronounced ERK1/2 activation, with a peak at 2 h (~2.4-fold, $P < 0.01$). Nuclear translocation of NF-κB occurred from 1 h onwards with a maximal localization in the nuclei of astrocytes of ~12% at 4 h [6]. As far as we know, only the report of Lin et al. [9] addressed this topic. These Authors have shown that UCB, in the absence of HSA, significantly induced the p38 MAPK phosphorylation at 1 h without involving JNK activation in rat cerebellar granule neurons. However, our data indicated that exposure of neurons to UCB leads to a slight production of cytokines, i.e. only 3.1 pg/$10^5$ cells of TNF-α, in contrast with 12.5 pg/$10^5$ cells produced by astrocytes in the same conditions [1], probably accounting to the activation of the three MAPKs in our astrocyte model (Fig. 4). Our demonstration that activation of MAPKs and NF-κB occurs between 1 and 4 h after UCB treatment and precedes marked up-regulation of cytokines reinforces the concept that UCB-induced astroglial cytokine production involves these pathways. Interestingly, only the inhibition of JNK1/2 and ERK1/2 pathways, but not of p38 cascade, abrogates UCB-stimulated NF-κB nuclear translocation, which indicates that activation of this transcription factor occurs downstream of JNK1/2 and ERK1/2 [10]. The dissection of the molecular mechanisms involved in UCB neurotoxicity may yield new targets upon which to focus drug discovery efforts aimed at reducing brain injury and disabilities.

### Promising Therapeutic Strategies Directed to Prevent Neuronal and Glial Reactivity to Unconjugated Bilirubin

Inflammation of the brain and its contribution to CNS injury is a relatively new area of research and clinical interest, but is now the focus of extensive investigation. Hence, therapeutic strategies have been designed to regulate cytokine bioactivity in the CNS diseases. We have done some studies with the anti-inflammatory cytokine IL-10 and the bile acid glycoursodeoxycholic acid (GUDCA). Experiments were performed in rat cortical astrocytes treated with UCB, GUDCA, IL-10, UCB plus GUDCA, UCB plus IL-10 or no addition, for 4 h at 37°C. Both IL-10 and GUDCA were able to reduce UCB-induced release of TNF-α and IL-1β to control values, while suppression of IL-6 release was only counteracted by GUDCA. Intriguingly, UCB-induced NF-κB nuclear translocation was inhibited in the presence of IL-10 but not of GUDCA (Fig. 4). In addition, neither GUDCA nor IL-10 has any effect on glutamate release, suggesting that this phenomenon occurs by a distinct mechanism independent of cytokine production (unpublished observations).

Collectively, our data suggest that IL-10 and GUDCA may prove to be interesting drugs for the prevention of neurotoxicity associated with moderate to severe unconjugated hyperbilirubinemia.

### Synonyms

Reactive Gliosis; Gliosis; Astrocytosis; Glial Reaction to Injury

### Definition

The term glial scar describes the structure that develops at regions of CNS injury. Macroscopically, a region of pale tissue that looks similar to scar tissue in the skin or elsewhere in the body comes to surround the area of damage. However, the cellular and molecular composition of glial scar tissue is very different from that of scar tissue outside the CNS.

### Characteristics

In its mature form, the glial scar is predominantly an astrocytic structure [1]. Electron microscopic studies reveal many hypertrophic interweaving astrocytic processes, containing abundant intermediate filaments and joined frequently by junctional complexes, mediated by ►connexins that are upregulated after injury. There may be abundant ►extracellular matrix. The scar tissue develops over a period of weeks. The first event after mechanical or ischemic injury is an invasion from the blood stream of polymorphs. These cells usually remain close to damaged blood vessels, and disappear within 1–2 days unless there is continuing infection. Within 24 h monocytes enter from the blood stream, and are initially seen as large round cells with typical monocyte morphology. Over a period of approximately a week after injury these cells will usually disappear, many of them assuming the appearance and morphology of CNS ►microglia. CNS microglia become activated following injury, responding with proliferation, hypertrophy and upregulation of markers such as the complement receptor CD11b and secretion of numerous growth factors and ►cytokines. Also rapidly responsive to injury are the cells expressing the ►chondroitin sulfate proteoglycan NG2 that have been variously called ►oligodendrocyte precursor cells (OPCs), polydendrocytes and synantocytes. In the absence of an agreed name they will be called ►NG2 + ve cells in this article. Within 24 h of injury these cells upregulate NG2, hypertrophy and then start to proliferate so that by 3 days there are large numbers of these cells surrounding the injury [2]. Their numbers then start to decline, and by 1 month few are seen. Their fate is not determined, although it seems probable that many die, while others may participate in ►remyelination by

becoming ►oligodendrocytes. The reaction of ►astrocytes to damage is the particularly distinctive feature of the glial scar. These cells hypertrophy their processes, upregulate intermediate the filament molecules GFAP, nestin and vimentin, and may also start to express MHC class II receptors. There is also an upregulation of extracellular matrix molecules, including ►tenascin and several chondroitin sulfate proteoglycan molecules (►neurocan, NG2, ►versican, brevican, ►phosphacan, aggregcan) [3]. The sulfation pattern of the glycosaminoglycan chains of these molecules changes after injury. The astrocytes upregulate CD44, a cell surface receptor that binds hyaluronan, a key component of the CNS extracellular matrix. Where there is physical injury to the ►meningeal layer of the CNS the fibroblast-like cells of the meningeal layer proliferate and migrate into the injury to cover the exposed CNS surface, leading to a re-formation of the ►glia limitans. This is the structure that surrounds the normal CNS consisting of a layer of ►meningeal cells, a thick layer of extracellular matrix to which are applied hypertrophic ►astrocyte processes [4]. At the interface between meningeal cells and astrocytes a collagen IV containing layer of matrix develops. Also in this lesion core region there are proliferating vascular ►endothelial cells and fibroblasts. Eventually the lesion core frequently also fills with ►Schwann cells. As the glial scar ages, the numbers of NG2 + ve cells and microglia decline, leading eventually to the predominantly astrocytic scar, usually bounded on one surface by a re-formed glia limitans. This is a stable structure that can persist for many months after the initial insult. However, if embryonic tissue is inserted into an injured region of the CNS it usually prevents the formation of a glia limitans around itself, and suppresses scar formation.

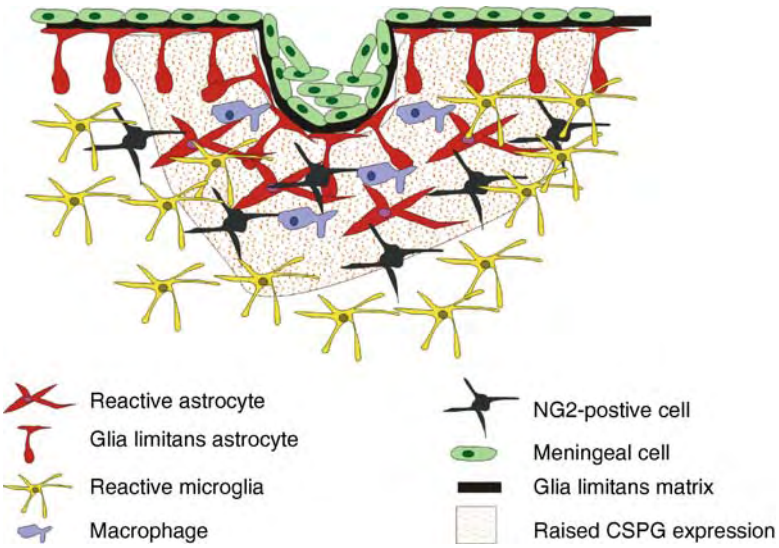
## Where Do Glial Scars Develop?

The process of reactive gliosis is initiated by many forms of CNS pathology. The picture described above is seen where there is mechanical or ischemic damage. However, initiation of gliosis does not require destruction of cells. A much-studied model is where gliosis is initiated by a ►peripheral nerve injury, causing activation of microglia and astrocytes around the motor neurons. A glial scar-like tissue is also found in the inflammatory demyelinating lesions of ►multiple sclerosis. Here, the inflammatory process causes invasion of blood-borne inflammatory cells with a large number of macrophages and lymphocytes. There is activation and proliferation of microglia and NG2 + ve cells, together with hypertrophy and proliferation of astrocytes. The appearance of this tissue varies as the lesion develops, the early inflammatory lesions generally having large numbers of activated microglia, macrophages, NG2 + ve cells and a loose astrocytosis [5]. In chronically demyelinated lesions there is little sign of inflammation, and there is a dense astrocytosis with astrocytic processes closely surrounding axons. Some NG2 + ve cells persist, but in chronic lesions that do not successfully myelinate many of the remaining axons show signs of damage with deposition of transported proteins such as APP, and most of these axons will eventually die.

A reactive gliosis is seen around the plaques and tangles of ►Alzheimer's disease, which takes the form of ►reactive astrocytes strongly expressing GFAP, usually with hypertrophied and activated microglia. A gliosis is also associated with some other neurodegenerative diseases such as Huntington's disease, but not usually with Parkinson's disease.

## Function of the Glial Scar

The function of the glial scarring process has not been fully established. It is probable that, as in the rest of the body, the glial scar acts to seal off the CNS from infection. In addition the correct functioning of the CNS depends on very precise control of the extracellular ionic and biochemical environment, to a much greater degree of stability than is found in the rest of the body. Re-sealing the CNS from the general body environment by means of the glial scar will achieve this. Astrocytes in scar tissue play a key role in the formation of the ►blood-brain barrier through their interaction with endothelial cells. All forms of CNS damage lead to the death of cells, the debris from which has to be removed, which is achieved mainly by the cells of the macrophage lineage in glial scars. Much has recently been learned about the function of scar tissue through experiments in which reactive astrocytes are deleted in a transgenic mouse expressing the HSV-TK gene under a GFAP promoter. Following CNS damage and gangcyclovir treatment to kill reactive astrocytes, there is a failure to re-seal the blood brain barrier, increased and more widespread invasion of inflammatory cells and increased neuronal death [6]. The glial scar plays an important part in modulating repair processes in the CNS, discussed later in this article. The function of the glial scar reaction in neurodegeneration and in inflammatory lesions such as multiple sclerosis is less clear. In ►demyelination, activation of the NG2 + ve cells is probably an important precursor to remyelination, and inflammation has been shown to be essential for successful remyelination. The extensive cross-talk between the various glial cell types is probably part of this process. In Alzheimer's disease, the microglia in the glial scar tissue may be involved in converting amyloid into the fibrillar form, and may also be involved in ingestion of amyloid material as part of the continuing turnover of plaque protein. The ability of reactive astrocytes to express MHC class II molecules together with co-stimulatory molecules such as B7 and CD40 means that they may present antigen and be involved in T cell activation, and therefore be involved in promoting Th2 responses relevant to inflammatory diseases affecting the CNS (Fig. 1).



**Glial Scar. Figure 1** The diagram shows a glial scar as it would appear approximately 10 days after injury. The penetrating wound cavity has been lined with meningeal cells, re-creating the glia limitans. There is proliferation of NG2 + ve cells and microglia, with some invasion of macrophages from the bloodstream. The astrocytes become hypertrophic, with upregulation of GFAP. Chondroitin sulfate proteoglycans are upregulated around the injured region.

## Factors Involved in the Formation of the Glial Scar

The processes that initiate and control the glial scarring reaction are extremely complex and not fully understood. Any process that leads to inflammation within the CNS will initiate the reaction, and opening of the blood-brain barrier may also be an initiating event. Much of the investigative work on the control of the process has been carried out in the comparatively simple model in which the glial reaction around motor neurons is activated by a peripheral nerve lesion, and much of this work has focused on the facial nerve nucleus after facial nerve lesions. The glial reaction here must be initiated by the motor neurons whose axons have been damaged, but from that point on there is complex dialogue of cytokines and growth factors between neurons, microglia and astrocytes. One of the first cytokines to be upregulated within the damaged neurons is ►Interleukin 6 (►IL-6), and IL-6 knockout animals show a very diminished glial response to axotomy. However, from the moment when microglia, neurons and astrocytes become activated a dialogue is initiated that involves multiple molecules, including ►TGF alpha and beta, ►TNF alpha, ►CNTF, IL-1, ►Interferon Gamma (►IFN gamma) and many other molecules. Different aspects of the glial reaction are under different forms of control. Thus peripheral nerve section activates astrocytes and microglia but not NG2 + ve cells [7]. Formation of the glial scar may be modulated by the presence of embryonic CNS tissue. Embryonic transplants provoke little glial reaction, less upregulation of tenascin and ►chondroitin sulfate proteoglycans (CSPGs), and my partially dissolve an existing scar.

## Effects of the Glial scar on Repair Processes

Much of the interest in the glial scar centers on its effects on repair processes within the CNS. In particular ►axon regeneration fails in the CNS, and the axons tips often appear to have stopped growing within glial scar tissue. Remyelination occurs within an environment of reactive gliosis which can affect the process in various ways.

### *Axon Regeneration*

There are many experiments that demonstrate that glial scar tissue is particularly inhibitory to axon regeneration. Thus axons from transplanted sensory neurons regenerate their axons readily in undamaged CNS white matter, but stop when they encounter a glial scar surrounding an injury, and inhibition of scarring with antimitotic treatment permits some axon regeneration after injury. There are many molecules within the damaged CNS that inhibit axon regeneration. On oligodendrocytes, and therefore on the myelin debris found in scar tissue, are ►NogoA, ►MAG and ►OMgp which inhibit axon regeneration via the Nogo receptor and other mechanisms [8]. The major inhibitory molecules within glial scar tissue, however are proteoglycans and particularly chondroitin sulfate proteoglycans (CSPGs) [9]. There is a general upregulation of CSPGs within reactive glial tissue, the molecules being produced by both astrocytes and

NG2 + ve cells. Neurocan, phosphacan, brevican are produced by astrocytes, NG2, phosphacan, neurocan, versican are produced by NG2 + ve cells, and aggrecan is produced by neurons and other cell types. All these CSPG molecules have been shown to be inhibitory to axon growth, although some axon types, particularly embryonic axons, can grow in their presence. The mechanism of inhibition is complex. However the glycosaminoglycan (GAG) chains of the CSPGs are a major source of the inhibition, and digestion of these by the bacterial enzyme ►chondroitinase can remove inhibition to axon growth in tissue culture assays but more importantly treatment with the enzyme promotes axon regeneration in vivo. However the CSPG core proteins, particularly NG2 and neurocan, also have direct effects on axon growth independently of GAGs. Because removal of GAGs with chondroitinase reduces the inhibitory effects of CSPGs on axon growth, it has been injected into brain and spinal cord injuries, leading to increased axon regeneration and recovery of function [10]. A DNA enzyme which inhibits GAG synthesis has also been effective. An increase in intermediate filaments in astrocytes is always seen in the glial scar. Animals with a knockout of both GFAP and vimentin show less hypertrophy of astrocyte processes after injury and more extracellular space. There is increased regeneration of some axons after injury in these animals, and the mechanism may again involve a change in the extracellular matrix with increased expression of the growth-promoting molecules laminin and fibronectin. In the lesion cavity of the damaged CNS there is an accumulation of fibroblast-like cells which come from the ►meninges or from meningeal-like cells which surround large blood vessels. This lesion core is usually an absolute barrier to axon regeneration [9,11]. Meningeal cells are highly inhibitory to axon growth through expression of the CSPGs NG2 and versican and the growth-inhibitory ►class 3 semaphorins, which bind to the CSPG GAG chains. At the interface between these cells and astrocytes a collagenous membrane is deposited. Disruption of the formation of this collagenous structure using an iron chelating agent, which removes the iron required by the collagen synthesis pathway, also promotes regeneration past CNS injuries. Finally, glial scar tissue usually contains myelin debris containing the inhibitory molecule NogoA. Blocking antibodies to NogoA produces robust axon regeneration with recovery of function.

### *Remyelination*

The role of gliosis in remyelination has been debated for many years and it is still not possible to provide a definitive description of its role. Where the CNS is demyelinated there is generally an astrocytosis. However the part played by astrocytes in remyelination is complex. Remyelination after CNS damage can be by Schwann cells or by oligodendrocytes. It is clear that astrocytes exclude Schwann cells from the CNS, and Schwann cell myelination is therefore only seen in regions that contain a low density of astrocytes. Whether an astrocytosis inhibits or promotes oligodendrocyte remyelination is controversial [12]. Regions of persistent demyelination devoid of astrocytes can be created by injection of ethidium bromide followed by irradiation. Oligodendrodyte precursors transplanted into these lesions will form new myelin, and this can be enhanced if the cells are accompanied immature astrocytes. However co-transplantation of astrocytes aged in culture inhibits remyelination, so it is possible that the type of astrocytes found in chronic demyelinated lesions may be inhibitory. Highly upregulated on reactive astrocytes in demylinated regions and other forms of glial scar is the hyaluronan receptor CD44. Overexpression of this molecule in rodents leads to accumulation of extracellular matrix and inhibition of remyelination. In order for remyelination to occur the NG2 + ve cells must proliferate, engage with axons and differentiate into oligodendrocytes. It appears that the presence of inflammation is essential to this process, with a reduction in remyelination after macrophage depletion. Oligodendrocyte precursors injected into the taiep mutant mouse, which loses its myelin after birth to be replaced by an astrocytosis, do not remyelinate unless inflammation is induced.

## Synonyms

Glial development

## Definition

"Gliogenesis" means the generation of glial cells from progenitor cells that generate neural cells (neural stem cells). It occurs during development of the central nervous system when neural progenitor cells switch to generating glial cells following the generation of neurons (neurogenesis).

## Characteristics

Glial cells in the central nervous system are composed of astrocytes, oligodendrocytes and microglia. The former two combined are called macroglia and are generated from neural progenitor cells lining the surface of ventricle during development. These immature pluripotent progenitor cells give rise to both neurons and macroglial cells. In the developing central nervous system, mature neurons appear first, followed by the appearance of mature astrocytes and then mature oligodendrocytes. Thus neurogenesis occurs earlier than gliogenesis.

### Neurogenesis and Gliogenesis

It is still under serious debate whether the cell that has generated neurons earlier generates glial cells later, or whether there are two populations of the neural progenitor cells from an early time point in development that generate the two lineages.

In the mammalian central nervous system during early development, cells that compose the neuroepithelium send out processes extending across the entire thickness of the nervous system, which attach to both ventricular and pial surfaces. They are actively dividing and begin to produce neuroblasts, which migrate towards the pial surface along the processes. The original dividing cells (which are often called neuroepithelial cells) begin to express glial fibrillary acidic protein (GFAP), a marker for astrocytes in primates, thus they are named "radial glial cells." Migration of newly generated neuroblasts is guided by the processes of radial glial cells.

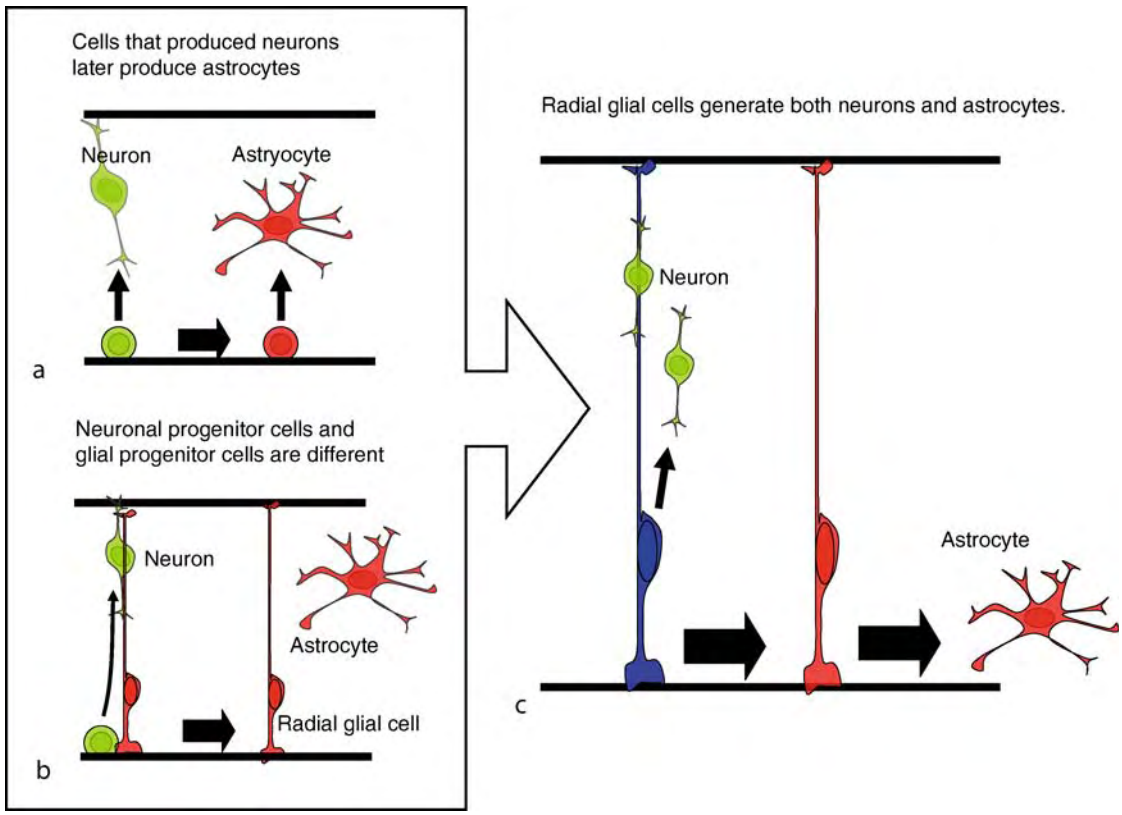
There have been many models to explain this sequential generation of neurons and macroglias in the nervous system. To make the story simple all the models can be categorized into two groups, (i) cells that produced neurons earlier produce astrocytes later (Fig. 1a) [1] and (ii) neuronal progenitor cells and glial progenitor cells are different from an early time point in development (Fig. 1b) [2].

Both models agree that at a late stage of development radial glial cells generate or transform into astrocytes [3]. Therefore, the question is "Who produces the neuron?" Tritiated thymidine incorporation studies indicated that newly generated neurons undergo final cell division before migrating to the pial surface along the processes of radial glial cell. However, the cells undergoing mitosis in the ventricular zone did not seem to bear processes characteristic of radial glial cells. This would support the model in which neurons and glial cells are generated from two separate progenitor cell populations (neurons from the mitotic cells in the ventricular zone and glial cells, especially astrocytes, from the radial glial cells).

Recently, several studies demonstrated that radial glial cells do generate neurons (Fig. 1) [4,5]. Thus at least in some cases, radial glial cells serve as neural stem cells and produce both neurons and glias. However, further studies are needed to demonstrate whether this is a general phenomenon or not. Especially in the primate brain where radial glial cell processes extend long distances, it is very difficult for processes to extend or retract in preparing for the mitosis.

### Generation of Astrocytes and Oligodendrocytes

So far, generation of neurons and astrocytes has been discussed. How about oligodendrocytes? It had been believed that oligodendrocytes are generated after the generation of astrocytes in any region of the central nervous system. However, the study of Warf et al. (1991) [6] demonstrated that only the ventral half of the rat spinal cord could produce oligodendrocytes at embryonic day 14, suggesting that oligodendrocytes are generated in a restricted region of the spinal cord. This has proved to be true in all regions of the central nervous system. The generation of oligodendrocytes has been shown to require expression of the *olig2* gene, which is induced by sonic hedgehog. Since sonic hedgehog is produced



**Gliogenesis. Figure 1** Two models to explain sequential generation of neurons and astrocytes. A model is Fig. 1a illustrates that cells that produced neurons later produce astrocytes, whereas a model in Fig. 1b illustrates that cells that produced neurons and those producing astrocytes are different. More specifically it was suggested that radial glial cells are destined to produce astrocytes only 1(b). However, as shown in Fig. 1c, at least in some regions of the rodent central nervous system radial glial cells have been shown to produce neurons. It is not clear yet whether this is a general phenomenon or not.

in the most ventral portion of the spinal cord (floor plate), olig2 expression is restricted to one of the ventral domains called the pMN domain. This domain is characterized by the production of motoneurons. The generation of oligodendrocytes is thus restricted to the pMN domain from where they migrate to the entire spinal cord.

However, recent studies demonstrated that at least a minor population of oligodendrocytes is generated from more dorsal regions of the spinal cord [7,8,9]. Although these regions do not express the olig2 gene, cells migrated out from these oligodendrogenic regions begin to express olig2 soon after they leave the ventricular zone. Moreover, lineage-tracing experiments revealed that olig2-expressing cells in the ventricular zone of the pMN domain become not only oligodendrocytes but also astrocytes [10]. Therefore, at present there is no evidence to indicate the presence of a glial progenitor that only gives rise to either astrocytes or oligodendrocytes. However, there are some regions in the central nervous system that generate oligodendrocytes more abundantly than do other regions.

# Gliomas

Maciej M. Mrugala
Departments of Neurology and Neurosurgery, University of Washington Medical School, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

## Synonyms

Brain cancer; Glial neoplasm; Glioma; brain tumor

## Definition

Gliomas are a group of primary brain tumors that arise from cells of neuroectodermal origin. In early embryonal development the neural plate and neural groove arise from neuroectoderm, a specialized portion of ectoderm. Mature elements of the central nervous system (CNS): neurons, astrocytes, oligodendrocytes, etc. arise from pluripotent primitive cells of neuroectoderm. Gliomas are neuroectodermal tumors that are named based on their cell type of origin; for example, ►astrocytomas show features of astrocytes.

## Characteristics

### Classification

Primary brain tumors form a large and diverse group with at least 19 basic categories and many sub-categories. Astrocytomas account for approximately 80% of all malignant brain tumors. All gliomas, including astrocytomas, oligodendrogliomas, mixed oligoastrocytomas, and ►ependymomas are classified based on their histological and immunohistological features. Histologic pattern of recognition by light microscopic examination remains the standard tool used for classification of gliomas and other brain tumors. Molecular genetic alterations that play an important role in the biology of glial neoplasms are being increasingly used for more precise diagnosis and subclassification [1]. There are several classification and grading systems for gliomas, specifically for astrocytomas. First historical attempts to classify this diverse group of neoplasms were undertaken in mid 1800s by a German pathologist Rudolf Virchow, who actually coined the name "glioma" and introduced it into the pathological literature. Older classification systems include the Kernohan grading system (1949), the Ringertz grading system (1950), St. Anne/Mayo system (1988), and the most commonly used today World Health Organization (WHO) grading system introduced in 1993. In contrast to most tumors of systemic organs (lung, breast, colon) brain tumors are not staged and the standard TNM (Tumor size, Node involvement, Metastases) system is not applicable. WHO classification divides gliomas into grades based on histopathologic features of anaplasia, such as nuclear pleomorphism, mitotic activity, microvascular proliferation and necrosis. WHO classification recognizes four distinct grades of astrocytoma (Table 1). Grades I and II represent slow growing tumors, while grades III and IV are aggressive, fast growing neoplasms. Each WHO grade is associated with different prognosis and dictetes treatment choice [2]. Astrocytomas can additionally be divided into two distinct categories: diffuse or circumscribed (Table 2). The diffuse astrocytomas infiltrate brain parenchyma, making it very difficult for a surgeon to achieve gross total resection (Fig. 1). These tumors can undergo anaplastic progression over time. Circumscribed astrocytomas carry a better prognosis, since they can frequently be nearly totally resected.

Oligodendrogliomas differ from astrocytomas by their distinct histopathological appearance. Due to the tissue fixation artifact tumor cells have a distinct perinuclear halo giving the tissue so called "fried egg" appearance (Fig. 2). Oligodendrogliomas also frequently infiltrate

brain parenchyma. Specific molecular genetic alterations are associated with this tumor type and its progression to the anaplastic form. Loss of heterozygosity (LOH) for chromosome 1p and 19q frequently found in oligodendrogliomas is associated with better prognosis and response to alkylating chemotherapeutic agents.

Several primary brain and spinal cord tumors can exhibit ependymal differentiation. Ependyma is a layer of cells lining cerebro-spinal fluid (CSF) spaces (ventricles and their connections) within the CNS. While a large percentage of supratentorial (located above the *tentorium cerebelli*) ependymomas arise intraparenchymally without contact with CSF spaces, the majority of posterior fossa tumors are intraventricular. The histologic hallmark of ependymoma is a perivascular pseudorosette (Fig. 3). Seven different subtypes of ependymoma have been described, ranging from benign subependymoma to highly malignant ependymoblastoma (Table 3).

| Ependymoblastoma |

Other less commonly encountered types of glial neoplasms include brain stem glioma and *Gliomatoisis Cerebri*. Brain stem gliomas are histologically similar to astrocytomas but, as indicated by the name they are

located within the brainstem structures. *Gliomatosis cerbri* is a malignant glial neoplasm diffusely infiltrating large areas of the brain without forming an identifiable mass.

Tumors that exhibit neuronal differentiation are rare. Since mature neurons are incapable of division, it was postulated that these tumors may arise from neural stem cells. Of the six major types of the tumors with exclusive neuronal differentiation the majority are low grade (Table 4). Mixed glioneuronal tumors also occur. One example is ganglioglioma that is composed of a mixture of mature neuronal tumor cells and neoplastic astrocytes [2,3].

## Cell of Origin and Signaling Pathways

Gliomas have been previously thought to arise from de-differentiated mature brain cells in response to exogenous signals or genetic alterations. In the 1990s, when neurogenesis in the adult brain was recognized, the hypothesis that tumors may arise from neural stem cells (NSCs) was proposed. NSCs express nestin and glial fibrillary acidic protein (GFAP), two proteins that are also found in subpopulations of tumorigenic cells isolated from human gliomas. Nestin positive NSCs and isolated glioma cells also express the cell surface marker CD133. CD133 positive stem cells were found to have increased ability to self-renew, form tumor spheres in cultures and generate cellular phenotypes expressing both neuronal and glial markers. Both CD133 immunoreactive NSCs and their progenitors may be the targets for transformation, eventually leading to development of gliomas [3].

Several cellular signaling pathways have been identified in gliomas. Primary glioblastomas (WHO grade IV) frequently overexpress oncogenes such as epidermal growth factor receptor (EGFR) and platelet derived growth factor receptor (PDGFR). Mutations that frequently occur in glioma impact *p53, RB1*, and phosphatidylinositol 3-kinase (PI3-K) signaling pathways. In addition *PTEN* mutations and methylation are common in high grade astrocytomas and are responsible for abnormally high levels of activity in the PI3-K pathway. mTOR (mammalian target of rapamycin) is a signal transduction mediator also linked with the PI3-K pathway. It regulates protein synthesis and cell growth and its inhibition may be beneficial in therapy of glioma. Alteration (epigenetic silencing through methylation) of the activity of certain DNA repair enzymes, such as $O^6$-methylguanine-DNA methyltransferase (MGMT) was shown to be beneficial in patients with malignant gliomas (glioblastoma) treated with alkalyting agents [3,4].

Figure 4 depicts critical molecular pathways important in gliomas and lists targeted molecular therapeutics being tested in clinical trials.

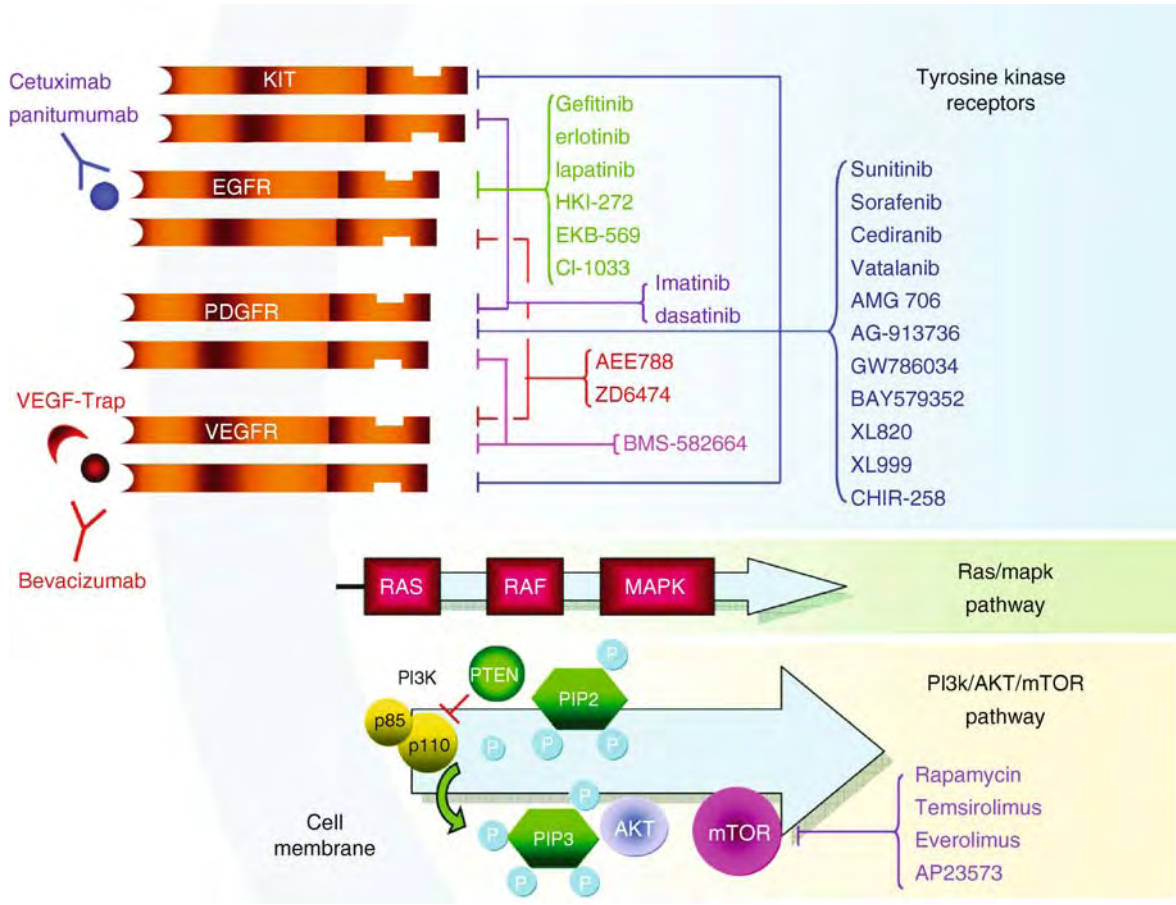
## Etiology

The etiology of brain tumors remains largely unknown. Carcinogenic risk factors for human gliomas have been studied extensively. Conclusive evidence exists only for a few known exposures. Therapeutic ionizing radiation is a strong risk factor for intracranial tumors, particularly meningiomas and gliomas. Even at very small doses, used in the past for treatment of ringworm infections of the scalp (*Tinea capitis*), the relative risk for developing brain tumor was shown to be high. Therapeutic radiation for acute lymphoblastic leukemia in children is also associated with high risk of developing glioma, and particularly glioblastoma WHO grade IV. The number of brain tumors among patients who received cranial radiation was reported to be 27 times greater than in the general population [5,6]. Survivors of Hiroshima and Nagasaki atomic bombings have been found to have an increased incidence of CNS tumors [7]. There was a dose-dependent relationship in this population that was particularly pronounced for schwannomas (tumors arising from Schwann cells). Exposure to low doses of diagnostic radiation [(dental X-rays, computer tomography scans (CT)] does not seem to play a significant role in glioma [5,8]. Occupational exposures (atomic energy, airline pilots and staff exposed to cosmic radiation) may have slightly increased risk for brain tumors, although more definite studies are needed. Electromagnetic field exposure has been suspected of influencing risk and progress of brain tumors, but no causal connection has been established. Cell phones that produce non-ionizing radiation of the same type as microwave ovens have not been conclusively shown to increase risk for glioma. One Swedish study found a significant risk of ▶acoustic neurinoma (odds ratio [OR] = 3.5) among analogue cellular telephone users. Anecdotal reports linking brain tumors to head trauma date back to the early 1900s when Dr. Harvey Cushing described several cases of presumed trauma related mengiomas. The evidence for gliomas is much less convincing. Experimental studies have suggested that physical trauma may be a co-carcinogen.



**Gliomas. Figure 4** Schematic representation of the molecular pathways important in glioma with associated targeted molecular therapeutics. From Omuro et al. (2007) Mol Cancer Ther 6(7):1909–1919 [4], with permission.

Several occupations (e.g. carpenters) that carry a risk for head trauma may have excess of brain tumors. Repetitive injuries are particularly risky. As many as three case-control studies showed increased risk for developing meningiomas in individuals with repetitive head injuries.

Studies examining dietary, habitual (smoking), and occupational risk factors have not provided solid evidence supporting increased risk for glioma [5,6].

A few rare genes and chromosomal abnormalities can greatly increase ones risk of developing brain tumor. For example CNS tumors are associated with Down syndrome and Neurofibromatosis among other disorders (Table 5).

**Gliomas. Table 5** Hereditary syndromes associated with brain tumors

| Tumor type | Genetic syndrome |
|---|---|
| Glioma | NF-1[a], NF-2[b], Turcot syndrome, Tuberous sclerosis, Gardner syndrome, familial polyposis Li-Fraumeni syndrome |

| Meningioma | NF-2 |
| Schwannoma | NF-2 |
| Ependymoma | NF-2 |

[a]NF-1 – neurofibromatosis type 1
[b]NF-2 – neurofibromatosis type 2

## Epidemiology

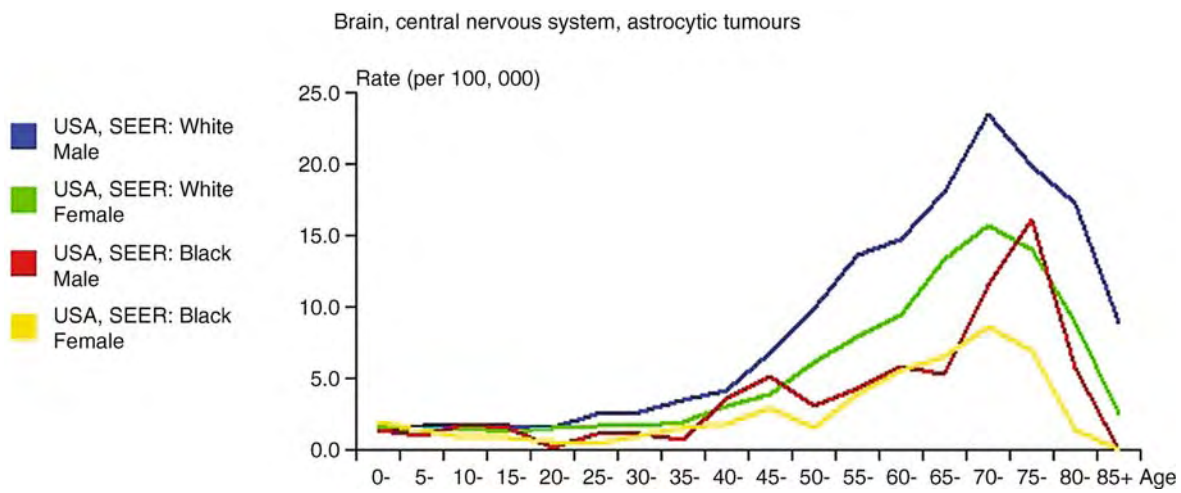
There are two different sources of data regarding the incidence of brain tumors in the US population. Surveillance, Epidemiology and End Results (SEER; http://seer.cancer.gov/) program, subsidized by the National Cancer Institute collects data on malignant brain tumors only [9]. Data from SEER include 13 state registries and represent about 26% of the US population. A second source of data comes from the Central Brain Tumor Registry of the United States (CBTRUS; http://www.cbtrus.org/) [10]. This database includes both benign and malignant brain tumors corresponding

to grades I–IV on the WHO scale. Based on SEER data it is estimated that 20,500 men and women (11,170 men and 9,330 women) will be diagnosed with and 12,740 men and women will die of cancer of brain and other nervous system tumors in 2007. From 2000–2004, the median age at death for cancer of the brain and other nervous system tumors was 64 years of age. The annual incidence of malignant brain tumors for both genders and all races between 1992 and 2002 was estimated at 6.8 per 100,000 person-years. The incidence for primary benign tumors in the same time period was 4.2 per 100,000 person-years. Based on SEER database (1988–1992), the incidence rate of developing an astrocytic tumor is about 5.0 per 100,000 for white females and 8.0 for white males. Incidence rates for the same type of tumor for black population were 2.5 for females and 4.0 for males (Fig. 5).

Brain tumors account for only about 2% of cancers but the survival rates are very low. In fact, the 5-year survival rates for brain tumors are the sixth lowest among all types of cancer following pancreas, liver, esophagus, lung and stomach. Considering the two most malignant grades (WHO III and IV), the 5-year survival rates are 28.2% for grade III and only 2.9% for grade IV. Age-specific mortality rates, when analyzed for all races and both genders seem to show gradual increase with each decade of life until the age 55, after which there is a dramatic increase in the mortality rate from brain tumors. Despite the grim prognosis for survival, it has been shown recently that 5-year survival rates for all primary brain tumors have increased over the past 30 years from 22% to 32%.

Many studies have documented a rising incidence rate for brain tumors, especially in the industrialized countries. When we look at the trend from 1970s to 1990s, there was an estimated 18% increase in the incidence rate. Looking back into the 1950s and comparing the rates with the 1990s, an 80% increase can be seen (data available for white population only).

Since 1992 until now, the incidence rates seem to have stabilized, with only small yearly fluctuations. It is not completely clear what factors are predominantly responsible for the trends we observe, however, it is believed by some researchers that the increasing incidence rates observed before 1992 may have, at least in part, resulted from better ascertainment. This includes more complete ascertainment with improved diagnostic imaging technology computer tomography (CT) and magnetic resonance imaging (MRI), better access to health care and greater number of specialists in the field of neurology and neuro-oncology. Incidence rates for brain tumors were on the rise not only in the United States but also in other parts of the world. Similar factors are postulated to be responsible for this observation throughout the globe. The highest rates are noted in the well developed, industrialized countries like the United States, Canada, Australia and United Kingdom. Greater incidence rates are correlated with the availability of better detection systems in these countries. Intra-country variations in the incidence rates are also observed. For the United States, the highest rates were documented for Maine (8.5 per 100,000 person-years) while the lowest were for Hawaii (3.9 per 100,000 person-years). These variations, in contrast to international trends, do not seem to correlate with socioeconomic status. What is interesting, however, is the fact that most migrants adopt the brain cancer incidence rates of their host country. This suggests that environmental factors, at least to some degree are responsible for the development of brain tumors.



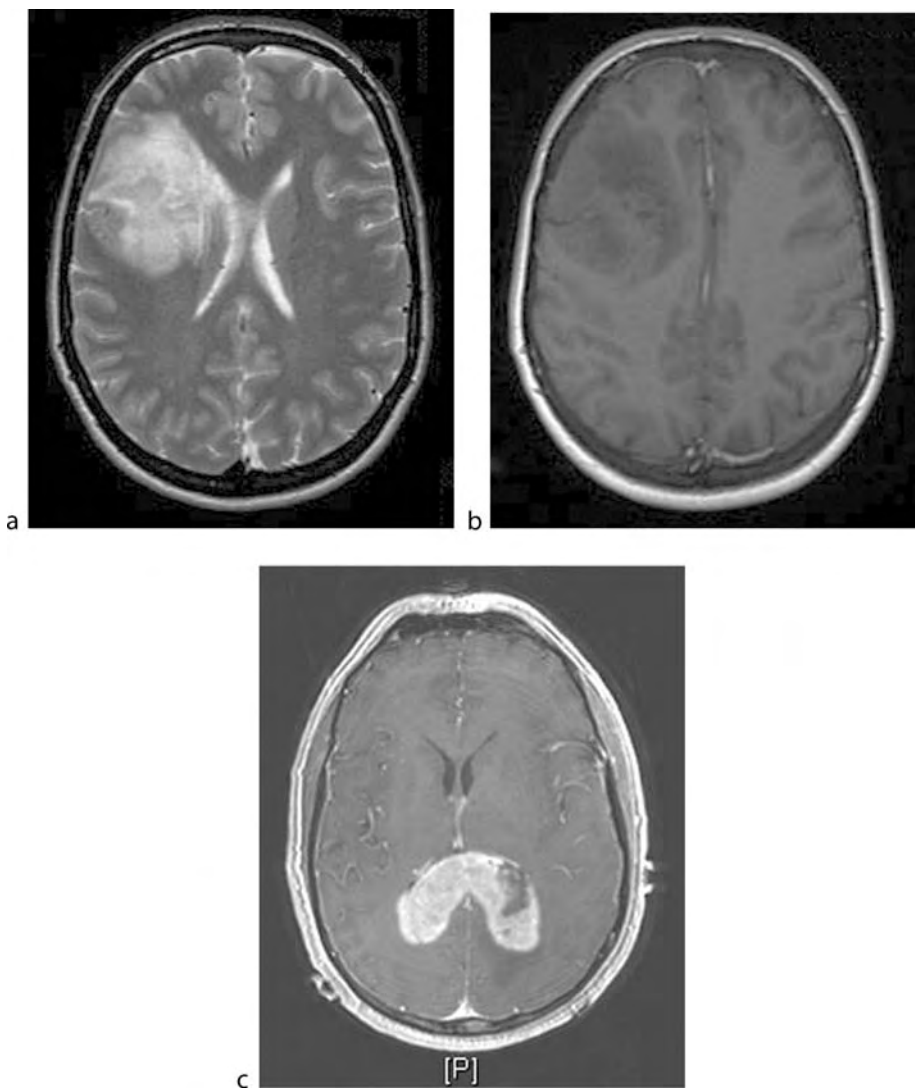
**Gliomas. Figure 5** Incidence of astrocytic brain tumors in the United States from SEER database (1988–1992) plotted by gender and ethnicity. Note the highest incidence in white males and the lowest in black females.

## Clinical Features and Diagnostic Approach

Gliomas may be found throughout the CNS. Depending on the size and location they may produce different symptoms. Patients can experience headaches, seizures, motor or sensory symptoms, visual deficits or coordination problems. Imaging studies such as CT and MRI are the primary diagnostic modalities used in the detection and characterization of gliomas (Fig. 6) – [see brain imaging section of the encyclopedia]. Final diagnosis is achieved by obtaining a tissue sample for histopathological testing through either biopsy or gross total resection of the lesion when possible. Molecular testing of the tissue samples is already being done and can provide prognosis and guide treatment choices for selected patients.

## Treatment

Surgical intervention is needed when a glioma is suspected for two reasons: to provide precise histopathological diagnosis and to achieve gross total resection when possible, since this may influence ultimate prognosis. Due to the heterogeneity of gliomas, successful future treatments will include multimodal therapies. Currently for low grade gliomas surgery and/or radiation are usually utilized, while for high grade tumors addition of chemotherapy is necessary. Only a few chemotherapeutic agents cross blood-brain barrier (BBB) – [see blood brain barrier section of the encyclopedia] which makes therapy of this disease challenging. Various delivery techniques



**Gliomas. Figure 6** Magnetic resonance imaging (MRI) of glial neoplasms. (a) Low grade glioma (oligodendroglioma) in the right frontal lobe – T2 MRI sequence; (b) T1 image from the same patient with administration of contrast, note lack of contrast enhancement frequently seen in low grade tumors. (c) High grade glioma (glioblastoma), T1 MRI sequence with administration of contrast, note contrast enhancement in the lesion spanning the *Corpus callosum*.

are being used including delivery of chemotherapy directly into the resection cavity (BCNU polymer wafers), intracranial catheters (convection enhanced delivery) and techniques focusing on disruption of the integrity of the BBB to allow for better penetration of chemotherapeutics into the tumor. Even with recent progress and identification of a subgroup of patients with high grade glioma (glioblastoma) who have better chances for response to therapy with the alkalyting agent temozolomide, the prognosis remains poor with median survival around 14 months from the time of diagnosis. Further improvements in the drug delivery technologies are necessary. Recognition of the role of different molecular pathways in the biology and progression of gliomas already guides development and use of targeted molecular therapeutics.

## Gliosis

►Glial Scar

## Global Amnesia

### Definition

An early term used to refer to memory loss. This term is generally not used as much today as a result of a better understanding that there are several types of memory loss that can occur depending on which brain structures are affected. See transient global amnesia.

►Amnesia

## Global Aphasia

### Definition

Inability to comprehend language and to speak as well as read, write, repeat words or name objects. It results from large lesions of ►Broca's area, ►Wernicke's area and the ►arcuate fasciculus, thereby being associated also with right ►hemiplegia, right ►hemisensory defects and mostly, right ►homonymous hemianopsia.

►Broca's Area
►Wernicke's Area

## Global Attention

### Definition

Global attention often refers to the alertness or wakefulness of an organism. Global attention is controlled by neurons in the reticular formation of the midbrain. Neurons in this region affect cortical activity by projecting to thalamic neurons, thereby gating neural activity that passes through the thalamus and regulating oscillatory activity in which the thalamus is involved.

Activity of the reticular formation is also accompanied with desynchronization of the cortical activity, such as recorded by the electroencephalogram. Noradrenaline is the most important neurotransmitter involved in global attention.

►Attention

## Global Image Motion

### Definition

Motion of the whole visual field, as for example caused by head or body motion.

►Rertinal Direction Selectivity and Starburst Amacrine Cells
►Visual Field

## Global Linearization

### Definition

An approach to the design of nonlinear control systems, where the controlled system is first transformed into an equivalent linear system using variable transformations.

Also referred to as feedback linearization.

►Nonlinear Control Systems

## Global Minimum

### Definition

The global minimum defines the unique minimal solution of an optimization problem that is defined by the minimization of the objective (cost) function. It defines the minimal cost solution of many possible minima that can occur in a general constrained problem.

Minima that are not global are referred to as local minima, and they typically do not define the desired solution of an optimization problem.

►Distribution Problem in Biomechanics

## Globus Pallidus

### Definition

Part of the basal ganglia and a deep telencephalic nucleus that is a main recipient of massive outputs from the caudate nucleus and putamen.

Occupying the medial pointing apex of the lentiform nucleus, the globus pallidus is split by a thin layer of myelinated fibers (internal medullary lamina) into an external (lateral) segment that projects principally to the subthalamic nucleus and substantia nigra and an internal (medial) segment that projects to the brainstem reticular formation and via a relay in the thalamus, to motor staging areas of the cortex.

►Basal Ganglia

## Glomerular Contrast Enhancement

### Definition

The systematic spatial clustering of glomeruli responding to chemically related odorant stimuli may facilitate olfactory contrast enhancement by allowing local networks of inhibitory interneurons to narrow the range of mitral cell projection neurons responding to each of the similar odorants, which typically stimulate a large number of overlapping odorant receptors and sensory neurons.

►Contrast Enhancement
►Glomerular Map
►Olfactory Bulb

## Glomerular Filtration Rate (GFR)

### Definition

GFR is a renal parameter to estimate a clearance, which is the volume of fluid filtrated into the Bowman capsule per unit time.

►Blood Volume Regulation

## Glomerular Layer of the Olfactory Bulb

### Definition

The glomerular layer is the lamina of the olfactory bulb just internal to the olfactory nerve. It is comprised of

olfactory glomeruli and juxtaglomerular neurons, which include periglomerular cells, so-called short axon cells, and external tufted cells.

►Glomerular Map
►Olfactory Bulb

# Glomerular Map

Brett A. Johnson, Michael Leon
Department of Neurobiology and Behavior, University of California, Irvine, CA, USA

## Synonyms

Odotopic Representation; Chemotopic Representation; Glomerulus Map

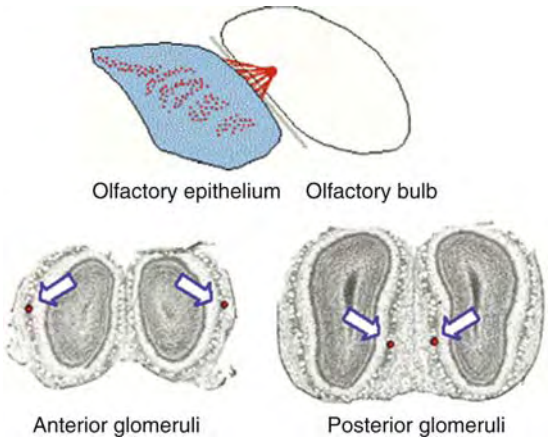
## Definition

The orderly and species-stereotypical projection of ►olfactory sensory neurons from the ►olfactory epithelium into glomeruli of the main ►olfactory bulb produces a glomerular map wherein individual consistently located glomeruli can be related to individual ►odorant receptor genes. Because odorant receptors are differentially activated by a characteristic set of odorant ligands, different odorants activate characteristic spatial patterns of activity in the ►glomerular layer of the olfactory bulb (►odotopic representation). Because odorants that share particular aspects of chemical structure and/or overall molecular properties overlap in their stimulation of receptors and glomeruli, and because glomeruli responding to similar odorant chemicals tend to be located near one another in the bulb, the glomerular map can be described in terms of odorant chemistry (►chemotopic representation). Similarities in the spatial patterns of activation of glomeruli can be related to similarities in perceived ►odor.

## Characteristics

### Olfactory Sensory Neuron Projections

Individual olfactory sensory neurons in the olfactory epithelium of the rodent nose appear to express only a single allele of a single odorant receptor gene, the protein product of which largely determines which odorant stimuli effectively activate each sensory neuron. Sensory neurons expressing the same odorant receptor generally are widely scattered within zones constrained in the dorsal-ventral axis but spanning the entire anterior-posterior axis of the nose (Fig. 1).



**Glomerular Map. Figure 1** Olfactory sensory neurons expressing the same odorant receptor gene are widely distributed across the anterior-posterior axis of the main olfactory epithelium in the nose (*red dots in top panel*), but converge in their projections to only a few (usually two) glomeruli in the main olfactory bulb. The projection is symmetrical between the left and the right bulbs and involves a more rostrally and dorsally located lateral glomerulus as well as a more caudally and ventrally located medial glomerulus.

However, the axons of sensory neurons expressing the same receptor converge tightly in their projection along the ►olfactory nerve through the cribiform plate of the skull and into the olfactory bulb, where they synapse with the dendrites of ►mitral cells and both inhibitory and excitatory ►interneurons in ball-shaped compartments of neuropil called ►olfactory glomeruli, located in a lamina of the bulb called the glomerular layer [1].

A typical rodent ►olfactory glomerulus receives projections only from sensory neurons expressing the same single receptor gene, and most receptor genes are associated with projections to only a few glomeruli. The most characteristic projection involves as few as two glomeruli for each odorant receptor, one of which is located on the lateral aspect and the other on the medial aspect of the bulb [2]. The sensory neurons projecting to glomeruli in the lateral bulbar aspect tend to be located in the lateral parts of the nose, whereas the sensory neurons projecting to medial glomeruli are located either medially along the nasal septum or in ventral nasal recesses. Dorsal and internal parts of the nose (also known as the central channel), which contain sensory neurons expressing class I receptors, project to dorsal parts of the olfactory bulb, whereas peripheral and ventral parts of the nose expressing class II receptors project ventrally [3]. The lateral member of a pair of homologous glomeruli is located more dorsal and anterior in the bulb than is the medial member of the pair (Fig. 1).

Glomeruli receiving projections from sensory neurons expressing a particular odorant receptor are located in similar positions in different individuals of a given species [2], although there is some variation (several glomerular diameters) even between the left and right bulbs of the same animal [3]. The positioning of glomeruli during development can be affected by genetically engineered deletions or substitutions of the odorant receptor gene/protein in the olfactory sensory neurons [3].

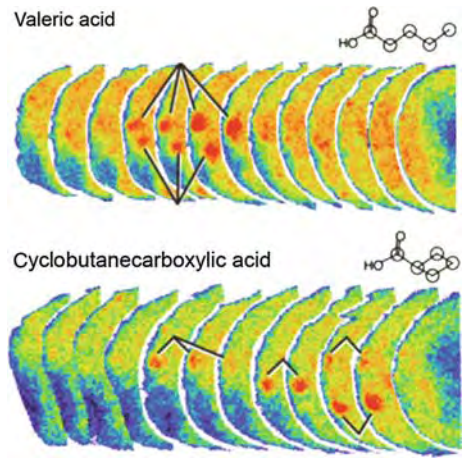
Principles of the projection pattern in the ►accessory olfactory bulb differ from that for the main bulb, because homologous sensory neurons in the ►vomeronasal organ project to multiple, less well-compartmentalized glomeruli in the accessory bulb. There also appear to be somewhat different patterns of organization in the olfactory systems of different animal species, although the principles of odotopic and, to some extent, chemotopic organization to be discussed below also have been described in fish and insects such as honeybees and *Drosophila* [4].

## Odotopic Representation

As is predicted from the anatomy of the epithelium-to-bulb projection, and from the fact that odorant stimuli are detected by the expressed odorant receptors, the inhalation of an odorant generates a pattern of differentially activated glomeruli in the rodent olfactory bulb. This pattern can be monitored by several methods, including uptake of metabolic labels such as $^{14}$C-labeled 2-deoxyglucose, electrophysiological recording, optical imaging, detection of activity-regulated ►immediate early gene products, and ►functional magnetic resonance imaging [4,5]. The pattern of activity is very similar between different individual animals of the same species and can be very different for different odorants (Fig. 2). The difference in patterns between odorants evoking the perception of distinct odors suggested the possibility that the spatial pattern might determine, or at least be related to, odor perception and discrimination (spatial coding of olfactory stimuli).

## Chemotopic Representation

Receptors anywhere in the body rarely are completely specific for a single ►ligand molecule. Rather, parts of an effective ligand typically can be modified without a complete loss of receptor activation, although changes in affinity and/or efficacy generally attend almost any modification. In contrast, other aspects of the same ligand molecule can be more critical for activation of the receptor, and modifications of these elements can cause complete loss of activation. Critical molecular features of a ligand typically either are involved in binding to chemical groups on the receptor molecule or are important for proper access of the ligand to the receptor's binding site. Receptors can be thought of as



**Glomerular Map. Figure 2** The activation of distinct sets of glomeruli by different, but related, odorants is illustrated here using stacks of pseudocolor-enhanced images of 2-deoxyglucose uptake in coronal sections from one rat exposed to valeric acid and another rat exposed to cyclobutanecarboxylic acid. The posterior half of the lateral aspect of the olfactory bulb is shown, with warmer colors denoting greater uptake. There is partial overlap in the activation of certain clusters of glomeruli (*left*), but other activated clusters of glomeruli are spatially distinct.

detectors of these critical molecular features, and given the large number of distinct odorant chemicals that are emitted by objects and exposed to each receptor by airflow across the epithelium during inhalation, it is reasonable to think of olfactory receptors as detectors of these features rather than as detectors of specific odorant molecules.

By studying pure odorant chemicals that differ incrementally in structure, it has been possible to characterize some of the molecular features responsible for the activation of particular olfactory glomeruli, because related odorant chemicals often are found to overlap in their stimulation of glomeruli in particular regions of the bulb [4,6]. The overlap is typically only partial, with each related odorant optimally stimulating distinct glomeruli in the same general neighborhood. These clusters of similarly specific glomeruli, alternatively called "domains" or "modules," also are evidenced by the increasing number of nearby glomeruli that tend to be activated upon increasing the concentration of flexible odorant ligands capable of assuming a variety of conformations.

The description of the locations of glomerular activity in terms of odorant chemistry has led to the concept of chemotopic organization in the olfactory system. Most ►olfactory glomerular modules can be characterized with respect to their responsiveness to odorant functional groups (e.g., carboxylate or hydroxyl groups), or elements of hydrocarbon structure (e.g., aromatic rings

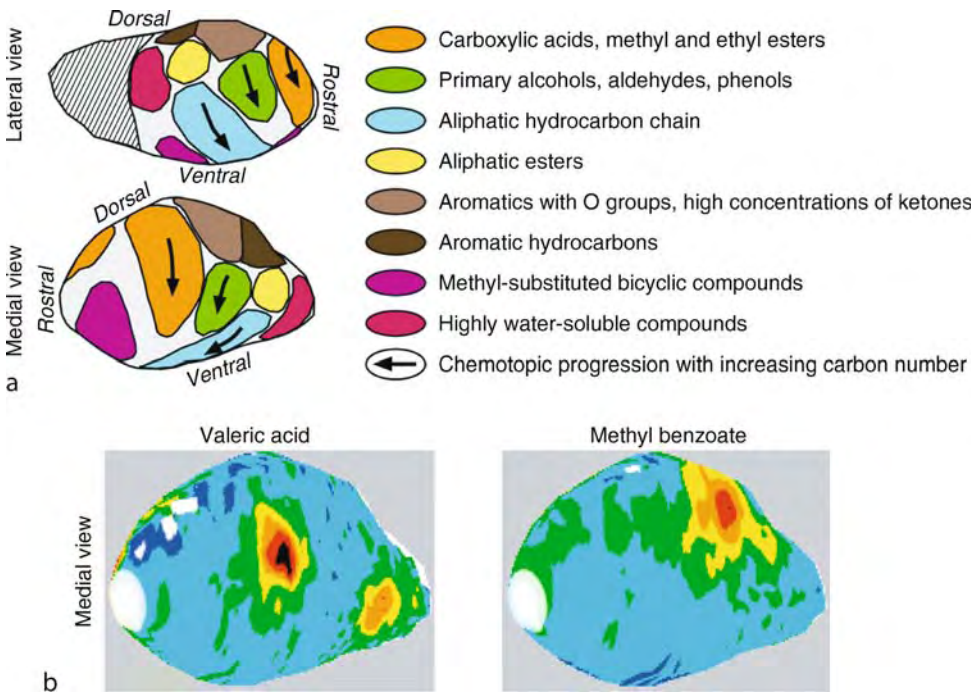
or bicyclic structures), although at least one posterior module is responsive to highly water-soluble molecules independent of the particular functional groups or hydrocarbon structure of the odorants (Fig. 3) [4]. Response modules identified with respect to odorant chemistry are typically present as pairs in the lateral and medial aspects of the olfactory bulb, reflecting the paired medial and lateral projection of sensory neurons expressing homologous odorant receptor genes.

In several glomerular modules, the location of activity shifts progressively with increasing carbon number or molecular length along various homologous series of aliphatic odorant ligands (Fig. 3) [7]. Increasing carbon number tends to be associated with the activation of more ventral glomeruli in rats. This progression may be related to the tendency of more hydrophilic odorants (shorter chemicals in a homologous series) to be more strongly adsorbed in the nasal mucosa of the olfactory epithelium, and thereby more constrained to interact with receptors in the dorsal-projecting central channel through which odorized air first passes during inhalation [3]. More hydrophobic, longer odorants may not adsorb as strongly and therefore may be freer to interact with receptors in more peripheral and ventral parts of the nose projecting more ventrally in the bulb.

Systematic chemotopic progressions of activity indicate that glomeruli with the most similar odorant specificity tend to be located nearer to one another within these modules. This type of anatomical organization may represent ►glomerular contrast enhancement, using local interneurons arrayed in a center-surround, ►lateral inhibition network to allow odorants that generally stimulate strongly overlapping sets of receptors to be represented by a smaller, more distinct, set of mitral cell projection neurons in the bulb [8]. In general, the spatial clustering of glomeruli with similar response profiles also would tend to facilitate contrast enhancement, and this may have been the selective pressure underlying chemotopic organization involving glomerular modules.

## Relationship to Olfactory Perception

When activity across the glomerular layer is normalized, it becomes easier to visualize similarities and



**Glomerular Map. Figure 3** Glomeruli that respond to odorants with similar structural features or overall molecular properties tend to be spatially clustered to form functional glomerular modules in the olfactory bulb. (a) Both the lateral and the medial views of a 3-dimensional model of the map of responses (2-deoxyglucose uptake) to identified molecular features across the entire glomerular layer of the rat bulb (http://leonserver.bio.uci.edu). In several modules, there is a systematic relationship between the location of the response and the molecular length within homologous series of aliphatic odorants possessing the same functional group(s). Arrows indicate the direction of these chemotopic progressions with respect to increasing odorant length. (b) Average 2-deoxyglucose uptake on the medial aspect of the glomerular layer in response to valeric acid (a carboxylic acid with an aliphatic hydrocarbon chain) and methyl benzoate (an aromatic odorant with an oxygenic functional group). Greater uptake is indicated by warmer colors.

differences in patterns of activity evoked by different odorants. Matrices containing z score-normalized values also can be compared quantitatively by correlation analysis to determine the degree of similarity between maps involving meaningful pairs of odorants. These calculations show both that more closely related odorant chemicals evoke more similar overall activity patterns and that the degree of pattern similarity is predictive of the degree of similarity in perceived odor [5,9]. Rodents are inherently accurate at discriminating the odors of even closely related odorants, especially with prior experience. Therefore, these analyses require the use of behavioral assays capable of showing odor generalization spontaneously, such as odorant cross-►habituation in naïve animals, or odorant confusion tasks [5,9].

Normalization of representations by z scores also results in more similar activity patterns for different concentrations of the same odorant, which tend to be perceived as having similar odors. Computational modeling of the network of so-called short axon cells in the glomerular layer suggests the possibility that the bulb itself may normalize input to mitral cells in a manner similar to z scores, thus explaining the superior power of normalized activity patterns to predict perceived odor similarities [10].

# Glomerular Oscillations

## Definition

Glomerular oscillations are slow oscillations, coupled with breathing, which are evoked by olfactory stimulation and which represent the receptor neuron input to the olfactory bulb (OB).

►Temporal Coding

# Glomerulus

## Definition

Glomeruli are spherical conglomerate of neuropil (diameter of 50–100 μ) that consists of the incoming axons of the olfactory sensory neurons and the dendrites of the main projection cells (mitral cells) in the olbactory bulb.

►Odorant Receptor

# Glomerulus Map

►Glomerular Map

# Glossopharyngeal Nerve

## Definition

The glossopharyngeal nerve is the IXth cranial nerve.

The nerve root emerges from the lateral aspect of the medulla, just rostrally to rootlets of the vagus (Xth) nerve, with which the glossopharyngeal is closely related, both anatomically and functionally.

The glossopharyngeal nerve has two peripheral ganglia. The superior ganglion lies in the jugular foramen and contains the cell bodies of neurons that convey somatosensory information from retroauricular regions, terminating centrally in the spinal trigeminal

nucleus. The inferior or petrosal ganglion, which is extracranial, contains the soma of visceral afferent fibers that terminate centrally in the nucleus of the solitary tract. General visceral afferent fibres convey tactile, thermal and painful sensations from the mucosa of the posterior tongue, tonsils, pharynx and eustachian tube, while special visceral afferent fibers convey taste sensation from the posterior third of the tongue. The carotid sinus nerve, a branch of the glossopharyngeal, carries information from a baroreceptor in the bifurcation of the common carotid artery, the carotid sinus, relevant for the regulation of blood pressure.

The glossopharyngeal also carries efferent fibres.

Parasympathetic preganglionic fibers from the inferior salivatory nucleus will pass via the lesser petrosal nerve and synapse in the otic ganglion, which in turn innervates the parotid gland. Other efferent fibers, originating from the nucleus ambiguus, innervate parts of the pharyngeal musculature.

## Glucagon

### Definition

Glucagon is the hormone secreted by alpha cells of the islets of Langerhans in the pancreas. It responds to high blood glucose and acts to decrease blood glucose concentration.

## Glucocorticoid (GR) Receptor

### Definition

Nuclear receptor involved in steroid action and in mediating the stress response. The GR has a low affinity for glucocorticoids and is widely distributed in the body and brain.

►Hypothalamo-Pituitary-Adrenal Axis, Stress and Depression

## Glucocorticoids (GCs)

### Definition

Class of steroid hormones (including cortisol in primates and corticosterone in rodents) that are secreted from the adrenal upon stress exposure. GCs exert a wide range of genomic and non-genomic actions throughout the brain and body with potent effects on e.g. energy metabolism, the immune system and cognition.

►Hypothalamo-Pituitary-Adrenal Axis, Stress and Depression

## Glutamate

### Definition

Glutamate (also referred to as glutamic acid) is one of the 20 amino acids which build up proteins. Glutamate is a key molecule in cellular metabolism and the main excitatory neurotransmitter of the central nervous system. Glutamate does not cross the blood-brain barrier and is synthesized from glucose via the Kreb's cycle or by transamination of α- ketoglutarate. Inactivation of glutamate is accomplished by reuptake into glial and neuronal cells. In glial cells glutamate is converted to glutamine. Glial cells release glutamine, which is then transported into neurons where it is converted back to glutamate by glutaminase. Glutamate activates ionotropic receptors and metabotropic receptors, which are thought to participate in cognitive functions like learning and memory. In excess, glutamate triggers excitotoxicity, causing neuronal and glial cell death.

## Glutamate Excitotoxicity

### Definition

Glutamate is the most common excitatory neurotransmitter in the central nervous system that activates postsynaptic neurons by change in membrane potential-depolarization.

Under conditions in which glutamate is released in excessive quantities or is not taken up by the glial cells, glutamate builds up at the junctions between neurons, the synapses. This excessive glutamate "overexcites" the postsynaptic neurons – glutamate excitatoxicity.

# Glutamate Receptor Channels

## Definition

Glutamate receptor channels are ligand gated channels that open in response to binding of the neurotransmitter glutamate. There are three types of glutamate receptors, which are distinguished by their sensitivity to glutamate analogs: N-methyl-D-aspartatic acid (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate. Glutamate is the major excitatory neurotransmitter in the brain and mediates normal brain development and excitotoxic responses in disease. GluR subunits appear to be derived from an inverted KIR channel to which sequential bacterial gene modules have been appended to the amino terminus including a modulatory, periplasmic binding protein domain and a ligandbinding domain from G protein-coupled metabotropic receptors.

# Glutamate Receptors

## Definition

Receptors for the excitatory neurotransmitter glutamate. Glutamate receptors consist of ionotropic and metabotropic glutamate receptors.

## Definition

►Glutamate excitotoxicity is caused by sustained activation of glutamate ►receptors. In recent years, it has been shown that glutamate can also be toxic to white matter ►oligodendrocytes and to myelin by this mechanism. In particular, glutamate receptor-mediated injury to these cells is mediated by alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainate and N-methyl-D-aspartate (NMDA) glutamate ►receptor types.

Alterations of glutamate homeostasis in white matter can determine glutamate injury to oligodendrocytes and myelin. Astrocytes are responsible for most glutamate uptake in synaptic and non-synaptic areas and consequently, are the major regulators of glutamate homeostasis. Activated microglia in turn may secrete cytokines and generate radical oxygen species, which impair glutamate uptake and reduce the expression of glutamate ►transporters. Finally, oligodendrocytes also contribute to glutamate homeostasis.

As a consequence, ionotropic glutamate receptors, the intermediaries of the signal cascades they activate, and glutamate transporters are potential targets for drug development to treat white matter damage in acute and chronic diseases.

## Characteristics

### Function

Glutamate signaling is carried out by glutamate receptors and glutamate transporters [1,2]. Glial cells express most of these receptors and transporters [3,4]. In particular, cells of the oligodendrocyte lineage express functional AMPA, kainate, and NMDA receptors throughout a wide range of developmental stages and species, including humans. Moreover, oligodendrocytes also express receptors of all three groups of metabotropic glutamate receptors but their levels are developmentally regulated and are very low in mature cells of this lineage.

Glutamate uptake from the extracellular space by specific glutamate transporters is essential for the shaping of excitatory postsynaptic currents and for the prevention of excitotoxic death due to overstimulation of glutamate receptors. Glutamate transporter 1 (GLT-1; excitatory amino acid transporter 2 [EAAT2] in the modern nomenclature) exhibits the highest level of expression among all the glutamate transporters characterized so far and is responsible for most glutamate transport [2]. Glutamate transporters are expressed by astrocytes and oligodendrocytes. The main transporter expressed by oligodendrocytes is glutamate aspartate transporter (GLAST; EAAT1 in the modern nomenclature), but glutamate transporters EAAT2 and EAAT3 are also expressed by cells of the oligodendroglial lineage.

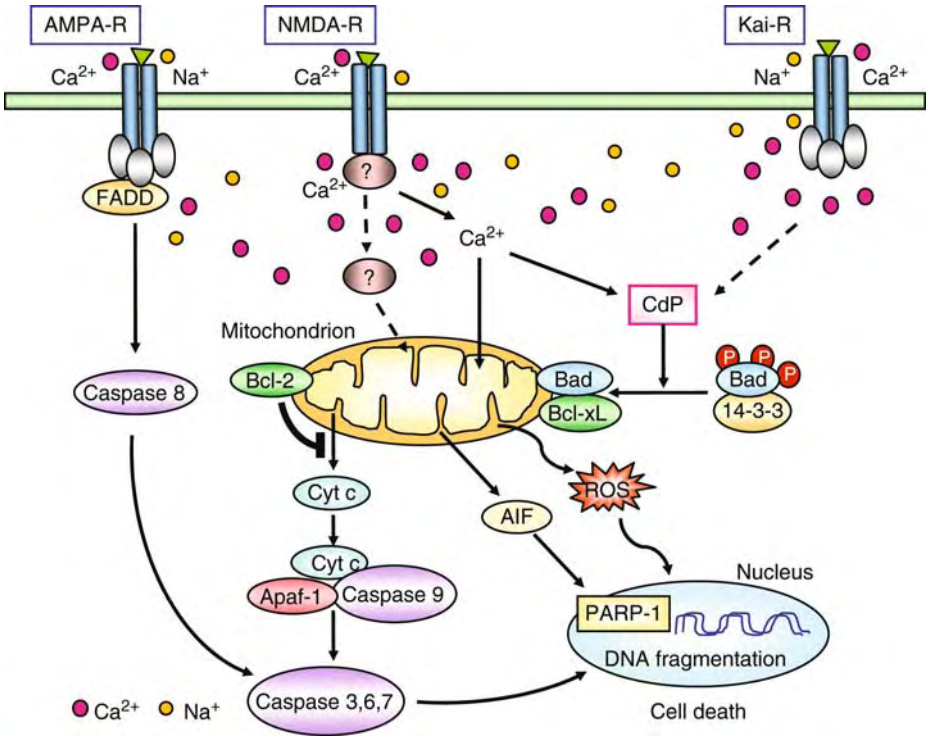
### Description of the Process

Numerous studies carried out over the last few years have shown that, in addition to neurons, glial cells can die by excitotoxicity. Oligodendroglia is the glial cell type most vulnerable to excitotoxicity. The first

evidence that oligodendrocytes are highly vulnerable to glutamate was obtained in primary cell cultures over ten years ago from today [5]. After a 24 h exposure to glutamate, oligodendroglial death was comparable to that described in neurons. However, oligodendroglial toxicity was not mediated by glutamate receptors, as in neurons, but rather by a transporter-related mechanism involving the inhibition of cysteine uptake, which results in glutathione (GSH) depletion and cellular vulnerability to toxic free radicals [5]. More recently, it was shown that prolonged activation of glutamate receptors is toxic to oligodendrocytes *in vitro* and *in vivo* (reviewed in [3]). This toxicity is directly related to $Ca^{2+}$ influx subsequent to receptor activation, and it is greatly attenuated in the absence of $Ca^{2+}$ in the culture medium.

Glutamate can also cause glial demise indirectly by inducing the release of toxic agents. In microglia, activation of AMPA and kainate receptors results in the release of tumor necrosis factor-α (TNF-α), which can potentiate glutamate neurotoxicity and kill oligodendrocytes, destroy myelin and damage axons [6]. Moreover, inflammatory cytokines including TNF-α and interleukin (IL)-1β, which are commonly released by reactive microglia can impair glutamate uptake and trigger excitotoxic oligodendrocyte death. Indeed, inhibition of the expression and functioning of glutamate transporters in axonal tracts is sufficient to induce oligodendroglial loss and demyelination, which demonstrates that the integrity of oligodendrocytes and white matter depends on proper glutamate transporter function [3].

Activation of AMPA, kainate or NMDA receptors in oligodendrocytes leads to $Ca^{2+}$ influx, an effect which is totally abolished by selective receptor antagonists or by removing this cation from the culture medium. The mechanisms triggered by NMDA receptor-mediated insults to oligodendrocytes have not been clarified yet [4]. However, the types of excitotoxic oligodendrocyte death induced by activation of AMPA and kainate receptors are known to depend on the intensity and duration of glutamate exposure. A central event to this process is the accumulation of $Ca^{2+}$ within mitochondria, which leads to depolarization, increased production of oxygen free radicals (ROS), and release of proapoptotic factors that activate caspases (Fig. 1).



**Glutamate-Mediated Injury to White Matter: Mechanisms and Clinical Relevance. Figure 1** ▶Glutamate receptor-mediated oligodendrocyte toxicity. Activation of receptors leads to $Ca^{2+}$ overload, generates ROS, Cyt c and apoptotic protease activating factor 1 (Apaf-1) activates caspases and PARP-1 respectively. In addition, $Ca^{2+}$ influx triggered by Kai-R stimulation but not by AMPA-R activates calcineurin (CdP) which dephosphorylates Bad and facilitates apoptosis. Finally, activation of NMDA receptors (NMDA-R) also initiates oligodendrocyte death which is entirely dependent on $Ca^{2+}$ influx, however the molecular mechanisms activated by these receptors are not known yet. Modified from [3].

Glutamate at non-toxic concentrations (within the micromolar range) can also induce oligodendrocyte death by sensitizing these cells to complement attack [7]. Intriguingly, complement toxicity is induced by activation of kainate, but not of AMPA, NMDA or metabotropic glutamate receptors, and abolished by removing $Ca^{2+}$ from the medium during glutamate priming. Oligodendrocyte death by complement required the formation of the membrane attack complex, which in turn increased membrane conductance, induced $Ca^{2+}$ overload and mitochondrial depolarization as well as a rise in the level of ROS. Treatment with antioxidants and inhibition of poly (ADP-ribose) polymerase-1 (PARP), but not of caspases, protects oligodendrocytes against damage induced by complement. This novel mechanism of glutamate-induced toxicity to oligodendrocytes is also shared by neurons and may be relevant to glutamate injury in acute and chronic neurological disease with primary or secondary inflammation.

## Clinical Relevance

In humans, white matter constitutes about 50% of brain volume and consequently glutamate-induced oligodendrocyte death is highly relevant to the pathophysiology of CNS diseases. In addition, primary and/or secondary glutamate damage to oligodendroglia in grey matter may also contribute to the onset and progression of acute and chronic brain and spinal cord disorders. Thus, loss of oligodendrocytes and/or damage to white matter occurs in stroke, traumatic injury, neurodegenerative diseases, ►multiple sclerosis (MS) [3], as well as in psychiatric diseases [8]. The cases of stroke, periventricular leukomalacia (PVL) and MS are succinctly described below.

In humans, most cases of focal ischemia and occlusion of major cerebral arteries damage both grey and white matter. Energy deprivation causes neuronal death, axonal dysfunction and loss of oligodendrocytes, which are very sensitive to transient oxygen and glucose deprivation [9]. After 1h under these conditions, the viability of oligodendrocytes in mixed glial cultures is severely impaired, an effect which is attenuated by AMPA/kainate antagonists. In turn, immature oligodendrocytes are even more sensitive to ischemic injury than their mature counterparts. *In vivo* models of stroke and cardiac arrest such as permanent middle cerebral artery occlusion and brief transient global ischemia also induce rapid oligodendroglial death.

Periventricular leukomalacia (PVL), the main substrate for cerebral palsy, is characterized by diffuse injury of deep cerebral white matter, accompanied in its most severe form by focal necrosis. Injury to oligodendrocyte progenitors, caused in part by glutamate and the subsequent derailment of $Ca^{2+}$ homeostasis, contributes to the pathogenesis of myelination disturbances in this illness. In addition to this mechanism, glutamate induced depletion of glutathione and the subsequent oxidative stress in PVL also contributes to damage to oligodendrocytes, which are sensitive to oxidative stress in part because of their high lipid and iron content.

In MS, the immune system attacks the white matter of the brain and spinal cord, leading to disability and/or paralysis. Myelin and oligodendrocytes are lost due to the release of cytotoxic cytokines by immune cells, autoantibodies and toxic amounts of glutamate [3,10]. In turn, experimental autoimmune encephalomyelitis (EAE), an animal model which exhibits the clinical and pathological features of MS, is alleviated by AMPA and kainate receptor antagonists. Moreover, blockade of these receptors in combination with anti-inflammatory agents is effective even at an advanced stage of unremitting EAE, as assessed by increased oligodendrocyte survival and remyelination, and corresponding decreased paralysis, inflammation, CNS apoptosis and axonal damage.

Furthermore, glutamate levels are increased in acute MS lesions and in normal-appearing white matter in MS patients [10]. Potential cellular sources contributing to enhanced glutamate levels in CSF include activated microglia, which can release glutamate via the reversal of glutamate transporter function, a process which is potentiated under pathological conditions. In addition, oxidative stress may also contribute to the increase in glutamate concentrations in the extracellular space, since free radicals reduce the efficiency of glutamate transporters. Other factors which may contribute to perturbing glutamate homeostasis include altered activity of the glutamate producing enzyme glutaminase in activated macrophages/microglia in close proximity to dystrophic axons, and altered expression of the glutamate transporters EAAT-1 and EAAT-2 in oligodendrocytes as a consequence of enhanced exposure to the proinflammatory cytokine TNFα [3]. Overall, these alterations likely lead to high extracellular glutamate levels and an increased risk of oligodendrocyte excitotoxicity in MS.

## Regulation of the Process

Oligodendrocytes display great vulnerability to overactivation of AMPA, kainate and NMDA receptors. The proper functioning of glutamate uptake is critical to prevent glutamate-induced damage to oligodendrocytes and drugs that regulate the function and expression of glutamate transporters have the potential to attenuate glutamate insults to glial cells. Likewise, positive regulators of the expression of glutamate transporters also have a protective potential. These include transforming growth factor (TGF)-α and epidermal growth factor (EGF), which by signaling through EGF receptors and activation of phosphoinositol-3-kinase (PI3K) and nuclear factor-κB (NF-κB), a transcription factor, strongly enhance EAAT2 expression. In addition, clinically used β-lactam antibiotics are also potent activators of glutamate expression and thus hold great therapeutical potential.

Another set of molecular targets to prevent glutamate insults to oligodendrocytes lie downstream of glutamate receptors activation. For instance, tetracyclines, which attenuate mitochondrial damage subsequent to insults including excitotoxicity, protect oligodendrocytes and white matter, making these antibiotics promising candidates for the treatment of acute and chronic diseases with oligodendrocyte loss. On the other hand, drugs supporting the management of $Ca^{2+}$ overload subsequent to glutamate receptors activation may improve oligodendrocyte viability.

In summary, knowledge about the mechanisms leading to glutamate receptor-mediated oligodendrocyte injury will facilitate new pharmacological strategies for the treatment of CNS disorders which cause white matter damage.

## Glutamatergic Receptors

### Definition

Glutamic acid acts on two general classes of receptors (thus, glutamatergic receptors): metabotropic, which are G-protein coupled, and ionotropic, which are ion channels. *N*-methyl-D-aspartate (NMDA) and non-NMDA (alpha-amino-3-hydroxy-5-methylisoxazole-4-proprionic acid, AMPA) receptors are two of the most important ionotropic glutamatergic receptors.

## Glutamic Acid

### Definition

Glutamic acid is an amino acid that elicits neuronal excitatory effects. Glutamic acid is the major excitatory transmitter in the mammalian central nervous system.

## Glutaminergic Neurons

### Definition

Neurons that release glutamate as a neurotransmitter.

## Glycemia

### Definition

Glycemia refers to the concentration of glucose in blood.

## Glycine

### Definition

Glycine is an inhibitory transmitter in the adult brain and is also a modulator of N-methyl-D-aspartate (NMDA) receptors. Glycine is recognized as being part of the amino acid family of classical neurotransmitters.

Glycine appears to have an inhibitory effect in only certain areas of the brain, such as the spinal cord, medulla, and retina. Glycine activates GLY receptors leading to the influx of chloride into the postsynaptic cell leading to inhibition. More recently, glycine has been shown to bind to a site on NMDA channels, which increases the conductance of this channel.

## Glycogen

### Definition

A polysaccharide of glucose which serves as an energy store in liver, muscles, brain and other tissues.

Glycogen is formed from glucose to be stored in tissues under the influence of insulin and broken down to glucose to be used as fuel under the influence of glucagon, secreted respectively by the beta and alpha cells of the pancreas in response to different levels of glucose in the blood. In the liver, glycogen serves as a major store of readily available glucose for the whole body as well as the liver, where it can represent 8% of tissue weight. In muscle, it represents a smaller percentage of the tissue (~2%) but serves nonetheless as a critical, immediate reserve of glucose for the muscle cells themselves. In brain, glycogen represents a similarly small proportion of the tissue and is stored only in glial and not in neuronal cells. Brain glycogen levels change over the sleep-wake cycle. Just as fatigue in muscles occurs with depletion of glycogen, central fatigue also occurs following prolonged activity associated with decreases in glycogen during waking.

Just as rest allows replenishment of the glycogen stores in muscles, sleep allows replenishment of depleted glycogen stores in brain.

## Glycogen Synthase Kinase 3b (GSK-3b)

### Definition

A serine/threonine protein kinase, one of many kinases that phosphorylate glycogen synthase. GSK-3β phosphorylates adenomatous polyposis coli (APC), preventing microtubule plus-end capping, thereby reducing stability and decreasing motility. In response to growth factor stimulation (TrkA activation) the activity of GSK-3β is inhibited by Akt phosphorylation, thus allowing microtubule plus-end capping by APC.

►Growth Factors
►Microtubule

## Glycogenolysis

### Definition

The breakdown of glycogen into glucose-1-phosphate by the action of the enzyme glycogen phosphorylase.

## Glycolic Acid, Lactic and ε-Caprolactone (ε-Caproic Acids)

### Definition

These are naturally occurring hydroxyl acids. These are utilized for synthesizing biodegradable polymers: polyglycolic acid, polylactic acid and poly-ε-caprolactone in medicine. The degradation speed of poly ε- caprolactone under physiologic conditions is slower than that of polyglycolic or polylacitc acid.

►Transplantation o Artificial Materials for Nerve Regeneration

## Glycolipid

### Definition

A membrane lipid molecule with a short carbohydrate chain attached to a hydrophobic tail.

►Membrane Components

## Glycolysis

### Definition

The sequence of reactions that converts glucose to pyruvate.

## Glycoprotein

### Definition
A protein molecule with one or more oligosaccharide Chains.

►Membrane Components

## Glycosaminoglycans

### Definition
Glycosaminoglycans are long unbranched sugar side chains that are attached to the protein core of proteoglycans. The sugars are polysaccharides made up of a repeating disaccharide unit.

## Glycosylation

### Definition
Glycosylation is a post-translational modification by which sugars are added to proteins or lipids. Sugars can either be N-linked (to the amide nitrogen of asparagines side chains) or O-linked (to the hydroxy oxygen of serine and threonine side chains).

## Glycosylphosphatidyl Inositol (GPI)

### Definition
Glycosylphosphatidyl inositol (GPI) is a glycolipid that can be attached to the C-terminus of a protein, thus anchoring it to the plasma membrane. The phospholipid is attached in the endoplasmic reticulum as a posttranslational modification.

## GlyR

### Definition
Glycine receptor.

►Glycine

## Gnathostomata

### Definition
Craniates with jaws and paired fins.

►The Phylogeny and Evolution of Amniotes

## Gnathostomes

### Definition
Vertebrates with true jaws (chondrichthyans, actinopterygians, sarcopterygians).

►Evolution of the Brain: In Fishes
►Evolution of the Telencephalon: In Anamniotes

## GnRH Neurons

### Definition
(Synonym: LHRH neurons) A small subset of neurons in the anterior hypothalamus which secrete gonadotropin releasing hormone (GnRH). GnRH neurons form the final common pathway for central control of reproduction in vertebrates. GnRH triggers the release of gonadotropins (luteinizing hormone and follicle stimulating hormone) from gonadotrope cells in the anterior pituitary, which regulate puberty onset, gametogenesis, and estrus cycling.

►Gonadotropin Releasing Hormone (GnRH)

## Goal-Oriented Behavior

### Definition
Synonym of motivated behavior. Complex behavior elaborated by an animal to reach a specific goal which could be motivated by natural (food, sex, fear) or artificial (drug) stimuli.

## Goldman-Hodgkin-Katz Equation

### Definition

Goldman-Hodgkin-Katz equation is also called constant field equation.

►Membrane Potential: Basics
►Intracellular Recording

## Golgi Apparatus

### Definition

The Golgi apparatus is an endo-membranous organelle that is responsible for modifying and packaging proteins that are synthesized by the rough endoplasmic reticulum. The Golgi apparatus furthermore sorts proteins destined for lysosomes, the constitutive and regulated secretory pathway.

## Golgi Epithelial Cells

### Definition

Another name for Bergmann glia in the cerebellum (see above).

## Golgi Stain

### Definition

The Golgi stain is a method using silver nitrate to densely stain an entire single neuron including its dendrite and axon branches. Only a small subset of neurons are stained with the Golgi method, so the entire structure of those few neurons that are stained is visible for study. There is currently no explanation for why the Golgi method stains only a selected subset of neurons or of why those particular cells are stained. Camillo Golgi shared the Nobel Prize in Medicine with Santiago Ramón y Cajal in 1906.

## Golgi Tendon Organ

### Definition

A mechanoreceptor (with group Ib afferent fibers) located at the junction between the muscle fibers and tendon, which responds preferentially to the force and rate of change of force of the muscle fibers that attach to it directly.

## Golgi Type-I Neuron/Cell

### Definition

A type of pyramidal neuron identified with a long process that leaves the gray matter to travel in the white matter. It can be thought of as a projection neuron.

## Golgi Type-II Neuron/Cell

### Definition

The Golgi type-II neuron is a type of stellate neuron whose short axonal process remains in the gray matter. It can be thought of as an interneuron.

## Gonadotropin

### Definition

A protein hormone secreted by the pituitary gland that acts to stimulate the gonads.

►Hypothalamo-neurohypophysial System

## Gonadotropin Releasing Hormone (GnRH)

### Definition

Also known as luteinizing hormone-releasing hormone (LHRH) is a neuroendocrine decapeptide. There can be

up to three (GnRH1, GnRH2, GnRH3) distinct forms (at the amino acids level) found in vertebrates. The form found in the hypothalamus regulates reproductive function in vertebrates, the other forms are thought to neuromodulatory in function.

## Gourmand Syndrome

### Definition

Newly (1997) discovered rare eating disorder associated with lesions of the right frontal lobe. Patients develop a preference for fine eating.

►Neural Coding of Taste

## gp 41

### Definition

It is a viral (HIV) envelope protein found in association with gp120 protein, and is involved in the fusion of virus with the host cell. It is also said to activate host inflammatory responses including activation of the complement system.

►Central Nervous System Disease – Natural Neuroprotective Agents as Therapeutics

## gp130

### Definition

Cytokine signaling is mediated by a group of receptors that form signaling receptor complexes. gp130 is a highly promiscuous cytokine signaling receptor essential for various mammalian cell growth and homeostasis pathways. The receptors for the neurotrophic molecules LIF, IL-6 and CNTF all form receptor signaling complexes with gp130.

## G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages

Joël Bockaert
Université de Montpellier, CNRS UMR5203, Montpellier, France; Inserm U661, Montpellier, France

### Synonyms

Seven transmembrane receptors; 7TM receptors; Heptahelical receptors

### Definition

The evolution and survival of complex multicellular organisms greatly depend upon the capacity of their cells to communicate with each other and with their environment. After the cloning of many genes and the availability of complete genome sequence data from human and many species, one of the surprises was to find that detections of sensory messages (such as light, odours, ►pheromones, gustative molecules) as well as cell-cell communication messages (such as hormones, neurotransmitters, growth and developmental factors) are assured by a few families of proteins. The most common one is the G-protein coupled receptor (►GPCR) family [1–4]. GPCRs are receptors that are made up of seven transmembrane integral proteins. They have two functions: one is to recognize sensory or cell-cell communication messages, the other is to transduce these messages into activation of other proteins associated, via lipids, to the internal surface of the cell: the G proteins. G proteins are heterotrimeric proteins. G proteins are heterotrimeric proteins composed of Gα, Gβ, Gγ subunits. Gβ and Gγ are always associated. In their inactive form, Gα binds GDP and forms a complex with Gβγ. When a GPCR is activated by a sensory or a cell-cell communication message (also called first messengers) they catalyze the GDP/GTP exchange on the Gα. Gα-GTP is released from Gβγ and both Gα-GTP and Gβγ interact with specific effectors. Effectors can be enzymes such as the adenylyl cyclases and phospholipase C which produce intracellular messages (also called second messengers) such as adenosine 3′-5′ cyclic-monophosphate (►cAMP) and inositol 1,4,5-trisphosphate (IP3), respectively. These second messengers modify cellular functions (division, secretion, movement, differentiation, etc.) via cascades of biochemical reactions. The cellular biochemical events following GPCR activation are called ►signal transduction. Effectors can also be ionic channels that modify the cellular potential, leading to the modulation

of action potentials in neurons, contraction in cardiac muscles, secretion, etc. There are 17 genes coding for Gα, 5 for Gβ and 14 for Gγ, that are found in many, but by no means all possible combinations. Each GPCR can activate several G proteins and thus can induce a whole array of different cellular signaling events. In addition to interacting with G proteins, GPCRs also interact with many GPCR interacting proteins (GIPs) which modulate their targeting to a specific cell area, their trafficking to and from the membrane, the fine-tuning of their signaling, as well as their desensitization [2,4].

## Characteristics

Indeed, GPCRs constitute the most abundant family of genes in most animal genomes. In human, there are between 500 and 800 odorant GPCRs (ORs) and about 360 GPCRs for intercellular messages such as hormones, neurotransmitters, (these GPCRs are called endo-GPCRs). This represents about 3.3% of the total number of genes in the human [1,3].

These numbers and the main roles played by GPCRs in physiology explain why GPCRs are of interest for all domains of research, especially physiology, pharmacology and medical research. Another reason is the fact that among the 360 endo-GPCRs, more than 100 are still "orphan" GPCRs. "Orphan GPCRs" are GPCRs for which no endogenous ►ligands (hormone, neurotransmitter) are known. Although every year, few new endogenous ligands are discovered, many remain to be found. Many pharmaceutical and academic laboratories are interested because this is a way to discovering new physiological regulators and new drugs. Indeed, GPCRs represent the targets of more than 50% of the drugs currently on the market. To provide a few examples, morphine, anti-psychotics, some anti-hypertensive drugs, anti-histaminic, inhibitors of prolactin secretion, drugs for asthma, anti-migraine drugs and new anti-HIV drugs (anti-CCR5) all act on specific GPCRs.

The occurrence of GPCRs and G-protein signaling dates back to 1.2 billion years ago, which is well before plants, fungi and animals emerged from a common ancestor. The first glutamate-like GPCRs are found in the sponge (*Geodia cydonium*) and in slime mould (*Dictyostelium discoideum*). Fungi (*Saccharomyces cerevisiae*) express pheromone GPCRs. However, GPCRs had no evolutionary success in plants. In contrast, a remarkable expansion of GPCRs appeared in Bilateria species such as insects, nematodes, trematodes (500–800 million years ago) and of course in vertebrates (500 million years ago) [3].

## The Three-Dimensional Structure and the Different GPCR Classes

All GPCRs share a central core domain made up of seven transmembrane domains (TM-I to TM-VII) called heptahelical domains (HD) connected by three extracellular (E-I to E-III) and three cytoplasmic (C-I to C-III) loops (Fig. 1).

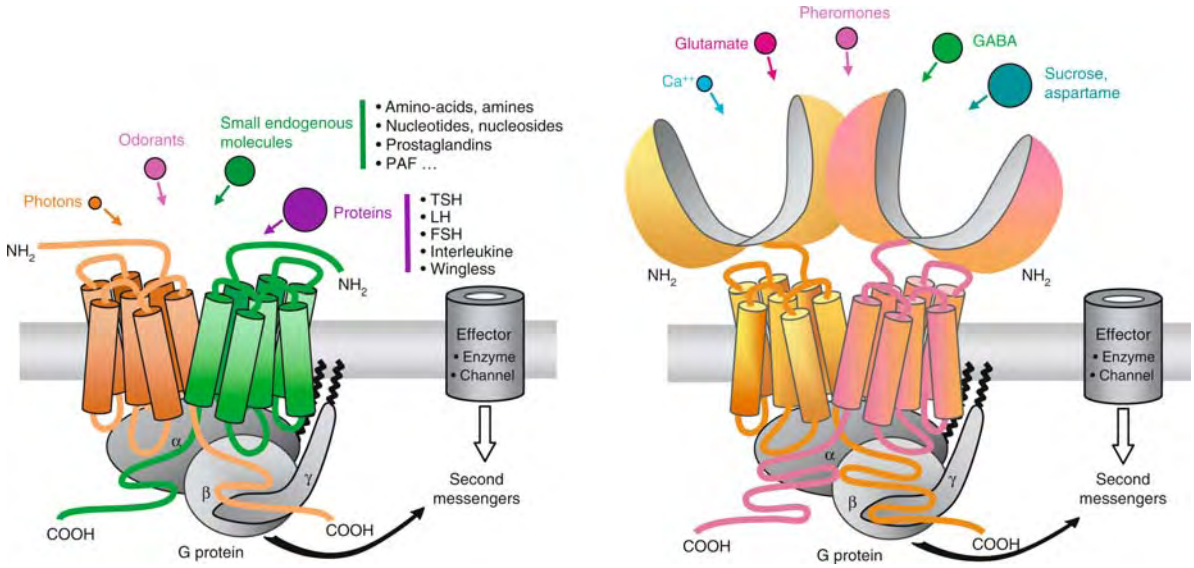
The N-terminal domain is extracellular and the C-terminal domain is intracellular. The only crystal structure obtained is the crystal of inactivated rhodopsin (receptor of photons). GPCRs are dimeric structures (Fig. 1) most of them are homodimeric (two identical monomers), whereas some of them are heterodimeric (two different monomers). Among the latter, we can find a receptor for the major inhibitory receptor GABA (gamma aminobutyric acid), the $GABA_B$ receptors are formed from associating GB1 and GB2, the receptor for sweet molecules (sucrose, aspartame) composed of T1R2 and T1R3, the receptor for the Umani taste (glutamate taste typical of Asian food) composed of T1R1 and T1R3 (Fig. 2).

Based on the nature of their HD protein sequences, several GPCR classes can be defined (Fig. 2).

- **class 1**: contains the majority of GPCRs including those for odours in vertebrates (olfactory receptors: ORs), rhodopsin, receptors for small neurotransmitters (adrenaline, serotonin, dopamine, endocannabinoids, enkephalins, etc.) or large hormones (TSH = thyroid stimulating hormone, LH = luteinizing hormones, etc.).
- **class 2**: contains receptors for large hormones such as glucagon, secretin, calcitonin, etc.
- **class 3**: this is a particularly original class because of its structure (Fig. 1), the binding site for the ligand is in the extracellular domain within the two lobes of a Venus-fly trap like domain. It contains the receptors of glutamate (mGluRs), $GABA_B$, sweet molecules (T1R2-T1R3), for Umami taste (T1R1-T1R3), some pheromone receptors (V2Rs) and a calcium receptor ($Ca^{2+}$) [5].
- **class 4**: contains a family of pheromone receptors (VIR).
- **class 5**: contains receptors such as the frizzled receptors for regulators of embryonic development such as the **Wnt.**
- **class 6**: contains GPCRs for cAMP only found in the slime mould *Dictyostelium discoideum*.
- **class 7**: contains receptors for bitter taste (►T2Rs).
- **class 8**: contains receptors for odorants in Drosophila.

## Activation of GPCRs

Until recently, pharmacologists working on GPCRs used the traditional "receptor occupation theory." The receptor was under an inactive conformation (R) and in the presence of an ►agonist ligand (A), the AR* complex was formed which was active ($R + A \leftrightarrow RA^*$). GPCRs are now considered, similarly to receptor channels (for example nicotinic receptors), as ►allosteric proteins. They are in equilibrium between several conformations, some being inactive and some being



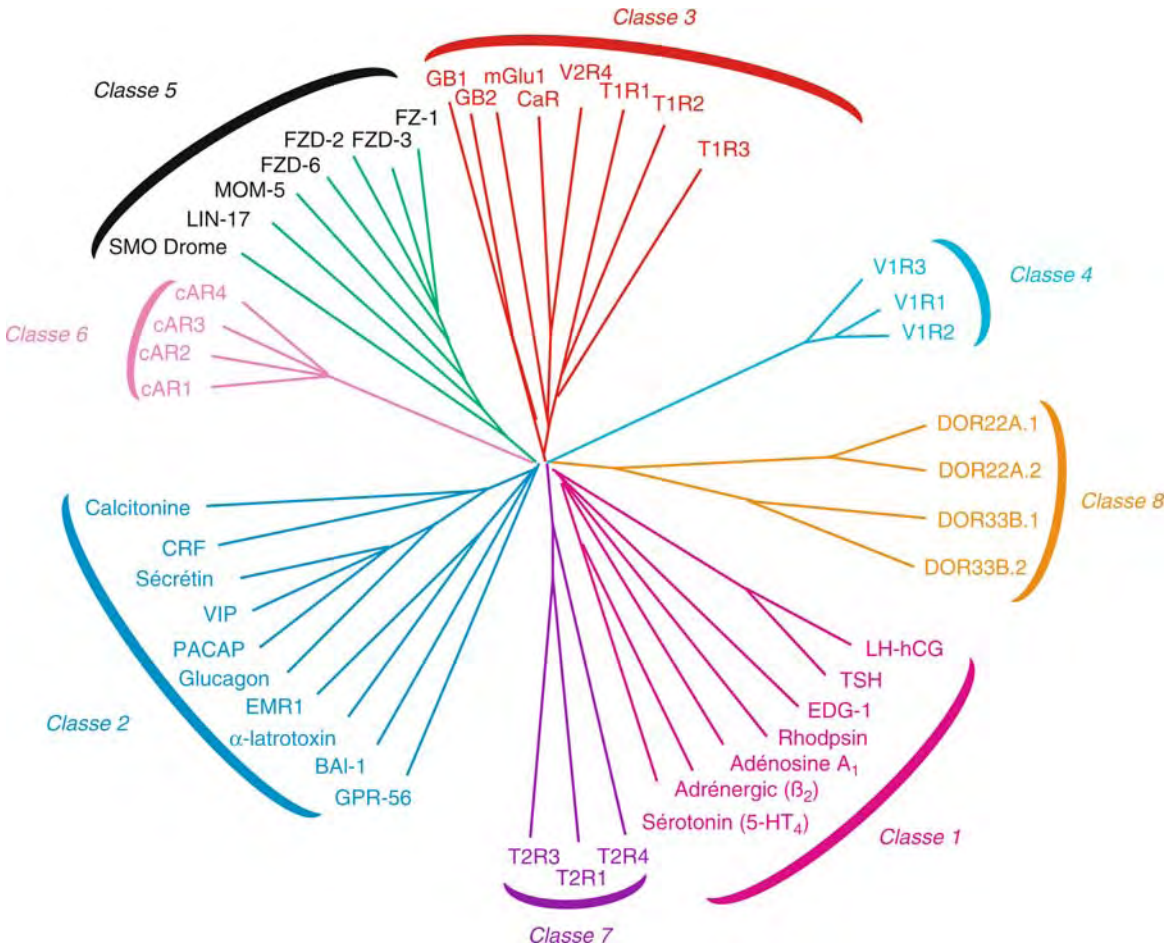
**G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages. Figure 1** GPCRs are dimers that stimulate heterotrimeric G proteins(a) Class 1 GPCRs recognize a wide variety of ligands of different chemical nature, photons, odorants, small endogenous molecules (such as amino-acids), serotonin, adrenaline, prostaglandins, adenosine, ATP and hormonal or regulatory proteins (such as TSH, LH, interleukin). Depending on the size of the ligand, the binding site is within the transmembrane domain or more at the external surface of the receptor.(b) Class 3 GPCRs have a particular structure. The binding site of ligands is localized within the external N-terminal domain. It is formed of two lobes which enter the ligand. This two-lobe domain is called the Venus flytrap module (VFTM) because it resembles the two leaves from the *Dionea muscipula* which trap insects.

active. The different agonist ligands for a given GPCR (endogenous message molecules, natural active compounds, such as morphine or synthetic active drugs, such as medicinal drugs) select particular active conformations [6]. Some GPCRs may be under an active conformation without a ligand: the receptor is "constitutively" active. In these cases, it is possible to find ligands which reverse this activity: they are called ►"inverse agonists". There are two categories of "constitutive" GPCRs. The first one includes mutated GPCRs resulting often in pathologies (see GPCRs and human pathologies). The second one includes GPCRs which are physiologically "constitutive." This is the case for the MC4R, a receptor for the anorectic hormone α-MSH (melanocortin). α–MSH further stimulates the receptor, resulting in reduced feeding, whereas the other physiological hormone, called agouti-related peptide which is an inverse agonist, is a potent anorectic regulator [7].

## An Example of GPCRs as Key Players in Physiology: GPCRs for Odours and Pheromones

Humans and animals have an extraordinary capacity of discriminating thousands of odorants [8]. This is assured by specific neurons from the nasal cavity, called the main olfactory epithelium (MOE). Each olfactory neuron expresses only one of the 1000 ORs. However, each given OR can recognize different ORs, but with different affinities. Odorant recognition is a combinatorial coding strategy whereby a given odorant activates a particular constellation of receptors. When an odorant binds to an OR, a G protein called Gs, is activated which stimulates the adenylyl-cyclase of the olfactory neurons. Adenylyl cyclase synthesizes cAMP by interacting directly with a $Ca^{2+}/Na^{+}$ channel (called the OCNC1 = olfactory-specific cyclic nucleotide gated channel), which depolarizes the neuron and generates the sensory signal.

Animals need specific strategies to recognize and attract mates and to identify the social status of conspecifics [9]. In many species, this involves the emission and recognition of message molecules, called pheromones. Pheromones control behaviors largely reproducible and genetically determined. In rodents, neurons expressing pheromone receptors are localized in a specific nasal cavity area called the vomeronasal organ (VNO) [9]. In the human and higher primates, the vomeronasal system is probably not functional. In rodent VNO, two types of GPCRs are expressed. The apical part expresses the V1R family, which constitutes the entire class 4 of GPCRs (Fig. 2), whereas the basal part expresses the V2R family of GPCRs. The V2Rs belong to



**G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages. Figure 2** Phylogenic-tree classifying the different GPCRs Protein sequences (excluding the N-terminal and the C-terminal domains) were multi-aligned and a tree was calculated using Clustal W. A bootstrap analysis was performed on the tree construction. The tree was drawn using Tree View. Eight classes of GPCRs were recognized (see text and 2).

class 3 GPCRs that are closely related to metabotropic glutamate receptors (Fig. 2). In order to be functional, V2Rs must be associated with the M10 and M1 families of the non-classical major histocompatibility complex (MHC) molecules and β2-microglobulin. The mouse V1R and V2R gene families include about 150 functional genes each. V1R and V2R signaling involves activation of a G protein called Gq which stimulates a phospholipase C resulting in IP3 and diacylglycerol (DAG), followed by the production of arachidonic acid. This second messenger activates a cation channel, called TRPC2 (transient receptor potential channel) and thus depolarizes the neurons [9].

The recent unexpected finding was that both receptors for olfaction (ORs) and receptors for recognition of pheromones are important for rodent sexual behavior and gender specific aggression [9]. ORs are essential to trigger mating behavior, whereas GPCRs from the vomeronasal system (V1Rs, V2Rs) are essential to control the sex-specificity of reproductive behavior and male-male aggression. The possible implication of ORs of MOE, in addition to GPCRs of VNO, in pheromone-conditioned behavior may explain why, in human, some pheromonal types of responses have s been observed in spite of a non-functional VNO system. This includes the synchronization of menstrual cycles in women living together, the effect of male androstadienone contained in sweat, in the alteration of women's mood and salivary cortisol levels [9].

## GPCRs and Human Pathologies

The first pathology associated with GPCR dysfunction was *Retinitis pigmentosa* (RP) [10]. Indeed, one of the hereditary forms of RP was associated with the

3q21-qter locus which is the locus of rhodopsin. Two types of GPCR mutations may be responsible for pathologies [10]. The gain-of-function mutations, in which the receptor becomes constitutively active (see Activation of GPCRs), and the loss-of-function mutations. The loss-of-function mutations are largely hereditary. More than 150 mutant alleles have been identified in RP but also in nephrogenic diabetes insipidus (NDI) in which mutations affected the vasopressin V2 receptors. Among other pathologies associated with GPCR loss-of-function, one can quote: the Hirschsprung syndrome (mutation of the endothelin B receptor), ovarian dysplasia (mutation of the follitropin receptor) and many others. Among the most studied gain-of-function mutations are sporadic and hereditary toxic thyroid hyperplasia observed in the absence of auto-immunity Graves' disease, which is largely due to constitutively active TSH receptors. One can also quote the congenital night blindness (constitutively active rhodopsin) or the familial male precocious puberty (constitutively active LH receptors).

# G-Protein Coupled Receptors in Sensory Neuron Function and Pain

Derek C. Molliver
Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

## Synonyms

Metabotropic receptors; Pain and ligand-gated channels/receptors; GPCRs

## Definition

The function of membrane-bound receptors coupled to intracellular signaling pathways (GPCRs) in pain-sensing neurons.

## Characteristics

Quantitative information:

G protein-coupled receptors (GPCRs) have a canonical seven transmembrane domain structure and may act as homo-dimers or may bind with other GPCR family members to act as heterodimers. They couple to heterotrimeric G proteins through specialized intracellular domains.

Approximate molecular weights of G proteins:

Gα: ~ 40,000

Gβ: ~ 35,000

Gγ: ~ 8,000

Sensory neurons of the trigeminal and dorsal root ganglia (DRG) transduce mechanical, chemical and thermal stimuli to inform the organism of changes in bodily tissues and the external environment. Particularly important to the survival of the organism is the detection of potentially damaging (nociceptive) stimuli that lead to the sensation of pain. Pain-sensing neurons (nociceptors) innervate the entire body and interact intimately with their target tissues and with the immune system, responding to stimuli that threaten the well-being of the organism. Furthermore, nociceptors can increase their sensitivity to environmental stimuli in response to factors released by peripheral tissues or immune cells after injury. This nociceptor hypersensitivity leads to enhanced pain (►hyperalgesia) (see ►Hyperalgesia and Allodynia), which may elicit survival-promoting responses such as escape behavior and protective guarding of the injured area. Activated nociceptors also play a role in maintaining the integrity of peripheral tissues by releasing neuropeptides that promote vasodilation, immune cell infiltration and wound healing. However, persistence of nociceptor hypersensitivity after the injury has healed may lead to the development of chronic pain. Therefore, the mechanisms underlying the functional plasticity of

nociceptors have received much attention as possible contributors to the development of pathological pain states caused by injury or disease.

A major mechanism regulating nociceptor sensitivity is the action of cell-surface receptors that interact with guanine nucleotide-binding proteins (►G proteins) to control intracellular signaling systems in nociceptors. These G protein-coupled receptors (GPCRs) act through ►second messenger pathways to (i) acutely modulate the function of other receptors, ion channels and enzymes, and (ii) induce lasting changes in neuronal functional properties by activating transcription. Many different GPCRs are co-expressed in nociceptive neurons, and the mechanisms that regulate both signaling specificity and signal integration within individual neurons represent areas of active investigation. While this essay focuses on the role of GPCRs in pain signaling, it should be noted that GPCRs are expressed by most or all somatosensory neurons, and their roles in the transmission of other sensory modalities, such as fine touch and proprioception, are poorly understood.

## Functional Organization of GPCRs

GPCRs make up the largest superfamily of proteins in eukaryotic cells, with more than 1,200 identified genes. At least 150 are orphan receptors (receptors with no known ligands). Roughly a third of drugs in clinical use target GPCRs, focusing on about 30 well-characterized receptors [1]. All GPCRs share a canonical structure similar to rhodopsin, the first GPCR whose structure was identified, with seven transmembrane domains linked by three intracellular and three extracellular loops.

G proteins are ►heterotrimers: they include a Gα subunit that binds and hydrolyzes guanosine triphosphate (GTP) and a Gβ and Gγ dimer that are tightly bound and do not dissociate under physiological conditions. In the inactive state, G protein heterotrimers are bound together and Gα is bound to GDP. Activation of a GPCR by its ligand causes the receptor to bind inactive G protein trimers and promote the binding of GTP to the Gα subunits. This causes Gα to dissociate from the GPCR and from the βγ dimer. The traditional model of GPCR function is that active Gα monomers then bind and activate a target effector molecule such as adenylate cyclase to initiate intracellular signaling. However, in many cases both Gα and Gβγ are capable of regulating downstream effectors. G protein activation is terminated by hydrolysis of the GTP to GDP, which allows Gα to bind the βγ subunits and return to the inactive state.

Multiple genes exist for each of the G protein subunits that give rise to proteins with different functional properties [2]. At least 17 α subunits, 5 β subunits and 13 γ subunits have been identified. Selectivity of GPCR signaling is determined by the association of G proteins with specific receptors, but the structural basis of this relationship has not been well characterized. Gα subunits are grouped into four families: ►Gs (including Gs and Golf), ►Gq (Gq, G11, G14, G15 and G16), ►Gi/o ($Gi_1$, $Gi_2$ and $Gi_3$, Go and Gz) and ►G12 (G12 and G13) families.

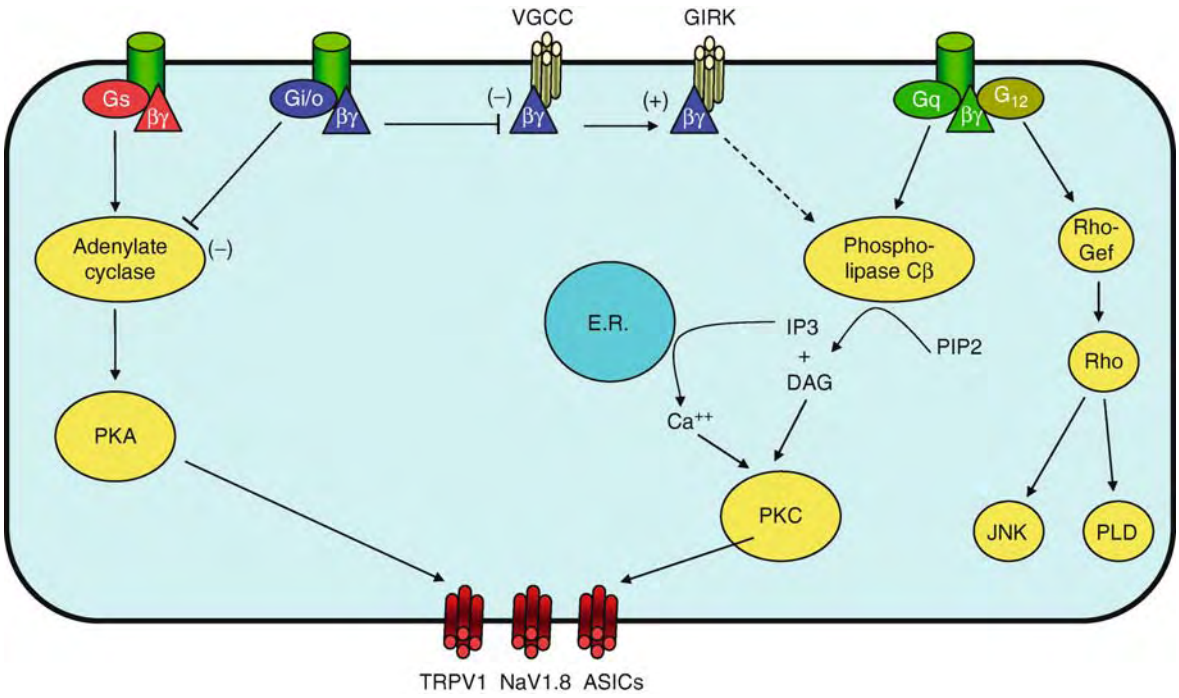
The web of signaling pathways that can be activated by specific G proteins have been described in detail elsewhere [3]. Below are the principal effectors of each of the families of G proteins (Fig. 1).

Selectivity of these signaling pathways for neurons of specific functional modalities is restricted by the selective expression of the GPCRs, the G protein isoforms and their downstream effector molecules. For instance, Gq and G11 are ubiquitously expressed in DRG sensory neurons, whereas G14 is expressed in a restricted subset of neurons, and G15 and G16 are not expressed [4]. Gi/o proteins are the most widely expressed family of Gα subunits. Go is highly expressed in neurons as well as some non-neuronal tissues, whereas Gz is expressed in DRG primarily during development. Likewise, phospholipase C (PLC) isoforms PLCβ1, 3 and 4, which are activated by Gq/11, show restricted expression in subsets of DRG neurons, whereas PLCβ2 is not expressed in these cells. Protein kinase C (PKC) and calcium-calmodulin dependent protein kinase isoforms, which can be activated downstream of PLC, also show restricted patterns of expression.

## Mechanisms for Modulation of Nociceptor Function

Activation of GPCRs in primary sensory neurons in response to inflammation or traumatic injury results in a cascade of intracellular signaling events. These signals are integrated to modulate the function of other receptors and ion channels that determine nociceptor sensitivity to noxious stimuli. Activation of Gq-coupled receptors can be excitatory or inhibitory, but most examples of endogenously-expressed Gq-coupled receptors indicate that these receptors are pro-nociceptive. Well-characterized examples include receptors for inflammatory mediators released by peripheral tissues and immune cells in response to injury, such as bradykinin (B2), serotonin receptors, ATP (P2Y2), and *p*rotease-*a*ctivated *r*eceptors (PAR2). Gq-evoked phospholipase C (PLC) activation and subsequent release of calcium from intracellular stores may promote neurotransmitter release at the presynaptic terminal, and can activate protein kinase C (PKC) in combination with diacylglycerol synthesized by PLC. Increased intracellular calcium may also lead to activation of gene expression, resulting in lasting changes in neuronal excitability.

GPCRs acutely alter neuronal excitability by modulating the function of both voltage-gated ion channels and channels that are specialized to gate currents in response to specific pro-nociceptive stimuli, such as extreme temperatures, acid and ATP. This represents a key



**G-Protein Coupled Receptors in Sensory Neuron Function and Pain. Figure 1** Diagram of the best-characterized intracellular signaling pathways activated by the different G protein family members in primary sensory neurons. G protein-coupled receptors regulate neuronal excitability by indirectly modulating the function of voltage-gated channels, such as voltage-gated calcium channels (VGCC) and G protein-gated inwardly-rectifying potassium channels (GIRK), and sodium channels like NaV1.8, as well as ligand-gated ion channels, such as the acid-sensing ion channels (ASICs) and TRPV1, a heat and proton sensor. Gq and G11 have highly similar pharmacological profiles and are thus often referred to as Gq/11. All three Gi gene products inhibit adenylate cyclase, whereas Go appears to act primarily through its βγ subunits. The dotted line represents the possible activation of phospholipase C by βγ subunits that has not been verified in sensory neurons. Abbreviations: *E.R.*, endoplasmic reticulum; *JNK*, c-jun N-terminal kinase; *PKA*, protein kinase A; *PKC*, protein kinase C. See text for references.

mechanism for the development of painful hypersensitivity in response to inflammation. For example, members of the *t*ransient *r*eceptor *p*otential (TRP) family of ion channels are expressed in subsets of nociceptors and likely contribute to the detection of thermal stimuli of varying intensities [5]. Both Gq- and Gs-coupled receptors modulate nociceptor responsiveness by enhancing the function of TRPV1, a TRP family member that senses heat and acid (see Fig. 1). GPCRs implicated in this process to date include the prostaglandin and β-adrenergic Gs-coupled receptors, as well as the Gq-coupled bradykinin receptors, PAR-2, serotonin receptors, muscarinic acetylcholine receptors and P2Y2. Activation of Gq-coupled receptors results in a decrease in the temperature threshold of TRPV1 so that it may gate current at body temperature, potentially causing nociceptors to be activated under conditions that normally would not be painful. TRPV1 appears to be a critical integrator of signals produced by GPCRs in response to inflammatory injury, because mice lacking TRPV1 do not develop the painful heat hypersensitivity that normally accompanies inflammation [5]. Modulation of TRPV1 occurs through phosphorylation-dependent mechanisms that have not been fully characterized, but require the activation of PKC epsilon (by Gq-dependent signaling) or PKA (by Gs signaling). Another TRP family member implicated in the response to noxious irritants, TRPA1, is similarly regulated by GPCRs. Other pro-nociceptive ligand-gated channels also show enhanced function in response to inflammation, including the ATP-gated ion channel P2X3 and the *a*cid-*s*ensing *i*on *c*hannel ASIC3.

Both Gs- and Gq-coupled receptors also increase nociceptor excitability by enhancing the function of voltage-gated channels, particularly ►voltage-gated calcium channels (VGCCs) and the ►tetrodotoxin-resistant sodium channels NaV1.8 and NaV1.9 (see Fig. 1) (see ►Voltage-gated ion channels and pain). PKC and PKA are key effectors for modulation of voltage-gated channels. In contrast, Gi/o-coupled receptors are generally antinociceptive, and mice lacking Go are hypersensitive to noxious stimuli [6]. Gi/o effects are mediated through the inhibition of

adenylate cyclase and thus PKA by the Gα subunit, as well as both the inhibition of VGCCs and the activation of ►G protein-activated potassium channels (GIRKs) by βγ subunits. These are the primary mechanisms of action of the opioid receptors (mu, delta, kappa, and the opioid receptor-like (ORL1) receptor), which are the most widely-studied family of Gi-coupled GPCRs and the targets of opioid analgesics like morphine. Unfortunately, potentially severe side effects of these analgesics are mediated by opioid receptors expressed outside of the pain neuraxis, including suppression of respiration and peristalsis. Other Gi-coupled receptors acting in nociceptors include adrenergic receptors, adenosine A1 and A3 receptors, Group II metabotropic glutamate (mGluR) receptors, cannabinoid receptors and somatostatin receptors. In many cases, Gi receptors are expressed in the same neurons with Gq- and Gs-coupled receptors, suggesting the idea that opposing receptor subtypes act as a sort of "push-pull" mechanism to determine nociceptor sensitivity.

Attempts to link the expression of specific GPCRs to functionally-distinct subsets of sensory neurons have been only partly successful, in part because sensory neuron neurochemistry appears to be linked at least as closely to the type of target tissue as to the sensory modality conveyed by the neuron. However, a broad distinction has been observed between nociceptors that are labeled by the plant lectin IB4 and express the trophic factor receptor Ret and the ATP-gated ion channel P2X3, and a largely separate population of nociceptors that express pro-inflammatory neuropeptides and the trophic factor receptor TrkA. This distinction provides a framework for the analysis of signaling molecules with restricted expression in sensory neurons. Recently, the orphan GPCR MRGD was identified in IB4-positive neurons and was found to be exclusively expressed in neurons with unmyelinated axons innervating the epidermis, supporting earlier reports that most epidermal afferents are of the IB4-binding variety. Other GPCRs are also preferentially expressed in this population of neurons, including the histamine receptor H1, which is critical for the sensation of itch mediated by histamine (see ►Nociceptors and characteristics), the bradykinin receptor B1and the nucleotide receptor P2Y1. Conversely, many GPCRs have been identified that are expressed preferentially in the TrkA- and neuropeptide-expressing population, including PAR2, the PGE2 receptor, the bradykinin receptor B2 and P2Y2. Opioid receptors are also more highly expressed in TrkA-positive neurons, providing an anatomical basis for the effectiveness of peripheral opioid analgesics in inflammatory pain.

## Regulation of GPCR Function

GPCR function is modulated by accessory proteins called regulators or activators of G protein signaling (RGS or AGS, respectively), and GPCR kinases (GRKs), which terminate GPCR signaling by phosphorylating the receptor, targeting it for internalization and either destruction or recycling. Other regulatory proteins include the integrin family of cell adhesion receptors and scaffolding proteins, such as β-arrestins, *A kinase anchoring proteins* (AKAPs) and Homer, that bind together GPCRs with their downstream effectors [1]. RGS proteins regulate GPCR function by binding activated Gα subunits (primarily Gi and Gq family members) and increasing the rate of GTP hydrolysis, thereby decreasing signal duration, amplitude, or both [10]. They may also act as scaffolding molecules. At least 10 different RGS mRNAs are expressed in DRG. In particular, RGS3 and RGS4 are highly expressed in sensory neurons with unmyelinated axons likely to be nociceptors (i.e., C fibers), and their expression is down-regulated in response to nerve injury, resulting in enhanced GPCR signaling that could contribute to neuropathic pain [7]. Whereas RGS3 is ubiquitously expressed in nociceptors, RGS4 is selectively expressed in the IB4-binding subpopulation that provides the majority of cutaneous innervation.

GPCR-associated proteins are involved in targeting receptors to pre- or postsynaptic sites, to specific membrane domains, and in the assembly of signaling complexes. In addition, they may assist in membrane insertion and internalization of receptors. The best-characterized examples have been identified for the β-adrenergic and mGluR receptors, both of which are expressed in nociceptive neurons. In the extreme case, interacting proteins may be capable of activating receptors in the absence of ligand. Such is the case with the scaffolding protein Homer, which couples Gq-linked mGluRs to intracellular calcium release sites. Neuronal activity upregulates expression of a short isoform of Homer, Homer1a, that uncouples mGluRs and reduces glutamate-evoked calcium release from intracellular stores [8].

Another important form of GPCR regulation is receptor ►heterodimerization, which can alter receptor pharmacology and downstream signaling [9]. GPCRs that may heteromultimerize in sensory neurons include opioid and adrenergic receptors (between members of the same family and also between opioid and adrenergic receptors) and the Gq-coupled ATP/UTP receptor P2Y2 with Gi-coupled adenosine receptor A1. P2Y2 has been implicated in excitatory signaling in nociceptors. Coadministration of agonists to cells expressing both P2Y2 and A1 resulted in an inhibition of Gi signaling and enhanced Gq signaling. Dimerization between A1 and the Gq-coupled P2Y1, resulting in a unique pharmacological profile, has also been reported to occur in neurons.

In summary, GPCRs provide a powerful regulatory system that modulates nociceptor sensitivity in

response to changes in the state of peripheral tissues. Although receptors of different types are extensively co-expressed, their function is tightly regulated and is altered in injury and disease states. As a result, GPCRs are being aggressively targeted in the search for novel analgesics and techniques for therapeutic intervention in pathological pain syndromes.

## Gracile Fasciculus

### Definition

The gracile fasciculus is a large bundle of axons running just medial to the cuneate fasciculus. Together the cuneate and gracile fasciculi form the dorsal columns in the dorsal medial part of the spinal cord. The dorsal columns are formed by the axons of neurons in the dorsal root ganglia just outside the spinal cord and carry somatosensory information from the body to the caudal medulla. The gracile fasciculus carries information from the legs and the lower trunk.

## Gracile Nucleus

### Definition

The gracile (Latin for slender) nucleus is a slender nucleus located next to the midline in the caudal medulla. It receives tactile, proprioceptive and vibratory input from the leg and lower trunk by way of the gracile fasciculus. The cuneate nucleus is lateral to it (see above).

## Graded

### Definition

Continuous, not in a discrete manner. Graded responses mean that responses are analogue, but not digital, and increase or decrease without a gap.

## Graded Potential

### Definition

A local, non-regenerative, non-propagating change in membrane potential that varies in magnitude, in proportion to the intensity of a stimulus and resultant change of membrane current. The graded potential decreases exponentially with distance from its source, and therefore serves as a short distance signal in excitable tissue.

►Action Potential Propagation

## Gradient Descent

### Definition

Gradient descent is an optimization algorithm. For a system whose task is to approximate a given function,

its performance error is given in terms of the system's parameters. Gradient descent attempts to minimize this error by adjusting the parameter values incrementally.

The direction of adjustments (i.e., whether to increase or decrease a certain parameter's value) is determined by the gradient of the error function with respect to each parameter in turn. This can easily be visualized in the two-dimensional case (i.e., for a system with two parameters). The error can then be described as an error surface, and valleys in that surface represent local error minima. Any given parameter setting corresponds to one point on that surface. The gradient of the error indicates the direction of steepest descent, i.e., in which direction of each dimension the parameter setting has to be adjusted so as to reach a point closer to the nearest minimum. A problem with gradient descent is that they may get stuck in a local minimum and fail to reach the global minimum.

►Connectionism

## Grand Mal Seizures

### Definition

►Tonic-clonic Seizures

## Grandmother Neuron

### Definition

A concept for the description of the way of coding information in the nervous system. A grandmother neuron is a neuron that codes for very specific information (your grandmother only). Some evidence for specific coding comes from the finding of face neurons and hand neurons. The opposite, competitive concept is distributed or ensemble coding.

## Granular Cells

### Definition

Via the mossy fibers they receive afferent impulses from the pontine nuclei, spinal cord and myelencephalon.

►Cerebellum

## Granule Cell System

### Definition

Group of neurons that include the excitatory granule cells and the inhibitory Golgi, stellate and cartwheel neurons in the molecular layer of the dorsal cochlear nucleus.

►Cochlear Nucleus

## Grapheme

### Definition

The minimal contrastive unit in the writing system of a language (e.g., t vs. n).

►Lexical-Gustatory Synesthesia

## Grasping

### Definition

The act of closing the digits around and object so as to take hold of it.

## Graviception

### Definition

Graviception refers to the sensory processes that contribute to the generation of neural signals encoding the orientation of the gravity vector with respect to the organism. There are both kinematic and kinetic aspects to graviception. The kinematic aspect relates to the fact that access to an accurate neural representation of the direction of gravity provides information about the orientation and motion of the body with respect to earth vertical. The kinetic aspect is that gravity exerts a force on the body or parts of the body that would produce an acceleration if unopposed. Therefore, sensory systems that signal the presence of forces that oppose the acceleration due to gravity contribute to graviception.

Vestibular sensory signals are considered to be the primary contributor to graviception. However, the sensory signals from the two types of vestibular sensors (semicircular canals and otoliths) do not provide a direct measure of the orientation of the gravity vector. Rather, the signals from these two types of sensors must be appropriately combined by a sensory integration process to yield a reasonably accurate, although still imperfect, measure. From a more global perspective, information from virtually all sensory systems that encode signals that are correlated with changes in body orientation with respect to gravity can be considered to be contributors to graviception. But typically, sensory signals from systems such as vision and proprioception are not thought of as contributors to graviception. The integration of information from vision and proprioception with graviceptive information is considered to be another stage in the process of forming an overall sense of orientation.

## Graviceptors

### Definition

Graviceptors refer to the sensory receptors and sensory systems that contribute to providing a neural representation of the direction of gravity with respect to an organism and of motion of the organism with respect to the gravity vector. The vestibular system is a major contributor to graviception.

►Peripheral Vestibular Apparatus
►Posture – Sensory Integration

## Gravitational Potential Energy

### Definition

The energy associated with the vertical displacement of an object in a gravitational field (g). Related to its height (h) and mass (m) by

►m.h.g.
►Energy/Energetics

## Gravito-inertial Acceleration (GIA)

### Definition

The vector sum of all linear accelerations and the equivalent acceleration of gravity.

## Gravity

### Definition

All masses generate an attractive force on other masses.

The pull of the Earth's mass on other masses is called gravity.

## Gravity Perception

►Verticality Perception

## Green Fluorescent Protein (GFP)

### Definition

A gene isolated from jellyfish that causes green fluorescence GFP, which has been engineered to attach to a gene or promoter of interest to show the expression pattern of that protein within a model organism or cell.

## Greigite

### Definition

Ferrimagnetic thiospinel, chemically Fe3S4.

►Magnetic Bacteria

## Grey Matter

### Definition
The part of the brain consisting of nerve cell bodies, dendrites and synapses, together with glial cells. This region is responsible for processing information that is then transmitted to the neuronal axons.

## Grid Cells

### Definition
Neurons discharging selectively at multiple locations distributed in a regularly spaced hexagonal lattice (i.e., each node is surrounded by a hexagon of adjacent nodes).

►Neural Bases of Spatial Learning and Memory

## Grief

### Definition
Grief constant emotional pain. The term is usually used in the context of mourning for a loved person. During grief there is less interest in the environment, decreased ability to love and decreased activity.

►Personality Disorder

## Grip – Power Grip

### Definition
A grasp in which an object is held tightly against the palm using the four fingers on one side and the thumb on the opposite side, enabling the subject to wield the object with considerable power, as in grasping a hammer.

►Motor Cortex – Hand Movements and Plasticity

## Grip – Precision Grip

### Definition
A grasp in which a typically delicate object is held between the tip if the thumb and the tip of the index finger, usually for purposes of fine manipulation.

►Motor Cortex – Hand Movements and Plasticity

## Ground Reaction Forces

### Definition
Forces arising at the area of contact between the body and environment. This usually involves the foot and ground; however, analogous reaction forces can occur at the hand if it is in contact with a stable object or surface.

►Postural Strategies

## Group Fascicular Repair

### Definition
Adaptation of individual fascicular nerve bundles, using microsurgical techniques. The group fascicular repair technique requires an internal dissection of the nerve.

Individual large fascicles may be sutured individually.

## Growth Cones

Kevin C. Flynn, James R. Bamburg
Molecular, Cellular and Integrative Neurosciences Program, Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, USA

### Synonyms
Leading process; Axonal tip

## Definition

Growth cones are the specialized motile structure at the growing tips of developing and regenerating axons and dendrites. They are responsible for directed axon extension, dendritic growth and arborization, and consolidation of the motile tip into the cylindrical axon or dendrite. They were discovered over 100 years ago by Ramon y Cajal who wrote that the "cono de crecimiento" (growth cone) "may be regarded as a sort of battering ram, endowed with exquisite chemical sensitivity, with rapid amoeboid movements, and with certain impulsive force, thanks to which it is able to proceed forward and overcome obstacles met in its way, forcing cellular interstices until it arrives at its destination" [1].

Although they can assume diverse morphologies, growth cones of neurons cultured on flat substrata are generally hand shaped structures, with membranous ►lamellipodia (veils) in-between long finger-like extensions called ►filopodia (Fig. 1).

As extremely motile structures that can sense and respond to various types of ►guidance cues, growth cones can alter their shape and dynamics in response to their environment leading to directed growth (axon guidance). In addition, growth cones are sites where new material is incorporated into the plasma membrane. In fact, the majority of the cargo shipped during ►axonal transport is destined for the growth cone, providing the material necessary for the growing axon.

Growth cone motility and directional migration depend on the reorganization of the underlying ►actin and ►microtubule cytoskeleton and localized protein synthesis, which are spatially regulated in response to membrane receptors interacting with extracellular guidance cues [9,13]. Targeting therapies to growth cones may thus be an approach to nerve regeneration (see below). In addition, other recent studies suggest that certain developmental disorders and genetic diseases may result from problems directly affecting the growth cone [11].

## Characteristics

### Quantitative Description

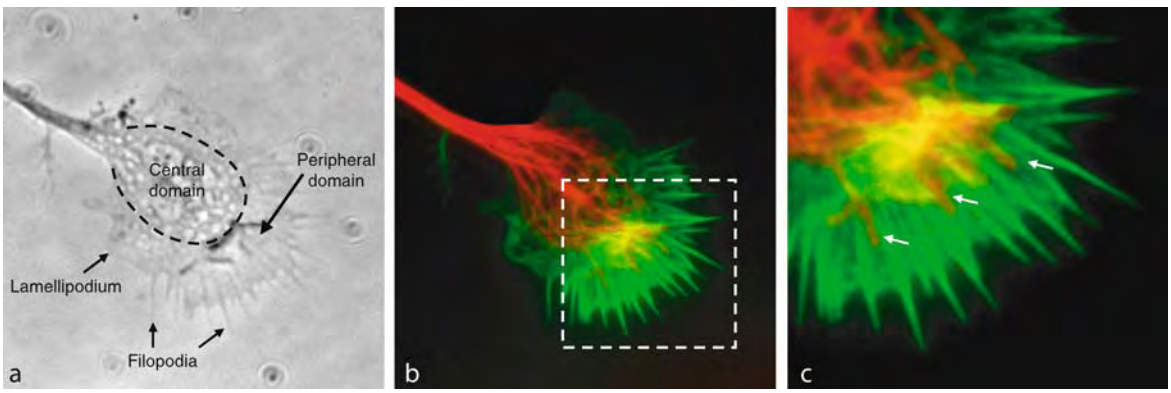
#### *Size and Morphology*

Most data on the morphological characteristics of growth cones are derived from studies performed on neurons cultured on glass. These *in vitro* studies have relevance *in vivo*, with many of the same structures identified in developing tissue. Among neurons commonly used in research, rat and chick dorsal root ganglion and spinal cord neurons, retinal ganglion neurons, and rat and mouse hippocampal neurons have smaller growth cones with average areas of about 50–200 μm², whereas growth cones of bag cells of the sea slug *Aplysia* can reach sizes of 2,000 μm² in surface area. *In vivo*, *Xenopus* retinal ganglion neurons have growth cone areas averaging about 75 μm².

The growth cone has two easily discernible domains, defined by the cytoskeleton and organelles contained therein [2,6]. The peripheral domain (P), which mainly consists of actin networks and filament bundles, is generally very thin, often 1 μm or less. The central domain (C), on the other hand, is rich in ►microtubules and membranous organelles and can be up to several microns thick. The zone between these two domains is referred to as the transition zone (T).

#### *Cytomechanics of Growth Cones*

As a pulling engine, the growth cone elongates the axon via tension generated through adhesion to the substratum.



**Growth Cones. Figure 1** The neuronal growth cone. (a) Phase image of the axonal growth cone of a hippocampal neuron in culture. (b) Fluorescent image showing microtubules (immunostaining with Texas-Red secondary antibody) and actin filaments (stained in green with fluorescein-phalloidin). Microtubules are largely confined to the central domain of the growth cone, whereas actin filaments are localized to the peripheral domain. (c) Magnified view of *highlighted region* in (b). A few microtubules penetrate into the peripheral domain of the growth cone (*arrows*) where they associate with actin filament bundles.

There is a direct correlation between growth cone advance and neurite tension. In accordance with Newton's third law, growth cones also exert a rearward force, or traction, on the substrate in order to advance. A single filopodia of a chick sensory neurite can generate an estimated 50–90 μdynes of force whereas the entire advancing growth cone can exert a force of 100–500 μdynes. When this same force is applied exogenously, it is sufficient to induce neurite elongation. Conversely, the growth cones of CNS neurons, such as those from the chick forebrain and rat hippocampus, have a lower threshold, with 20–40 μdynes of tension sufficient to initiate elongation. Once the threshold is reached, however, the growth cone advance for both forebrain and sensory neurons is directly proportional to applied tension; growth rates increase 1–3 μm/h for each μdyne of applied tension [7].

The tension generated in the growth cone is presumably due to the contractile actions of myosin motor proteins on actin filaments. As mechanical force is applied to growth cones, the axon fills with polymerizing microtubules, which are necessary for axon elongation, suggesting that tension itself can signal to stimulate microtubule polymerization. In the absence of actin filaments in the P domain, neurites can still elongate due to microtubule assembly, but the advancing tips are unable to respond to guidance cues [2,14].

### *Rates of Growth*

Growth rates *in vitro* and *in vivo* are highly variable, depending on the nature of the neuron, and the substratum and local environment. *In vitro*, hippocampal neuronal axons have been reported to have an average growth rate of about 6 μm/h with maximal growth rates averaging 20 μm/h [12]. Chick sensory neurons have axonal growth rates that are highly dependent on the culture conditions and range from 6 to 100 μm/h [13]. *In vivo*, growth cone advance at a maximal rate of 40 μm/h has been reported in the transparent tail fin of frog tadpoles. Retinal ganglion cell axons in *Xenopus* embryos grow 60 μm/h in the optic tract, but reduce to 16 μm/h when they approach the target area in the optic tectum [6].

### *Lower Level Components*

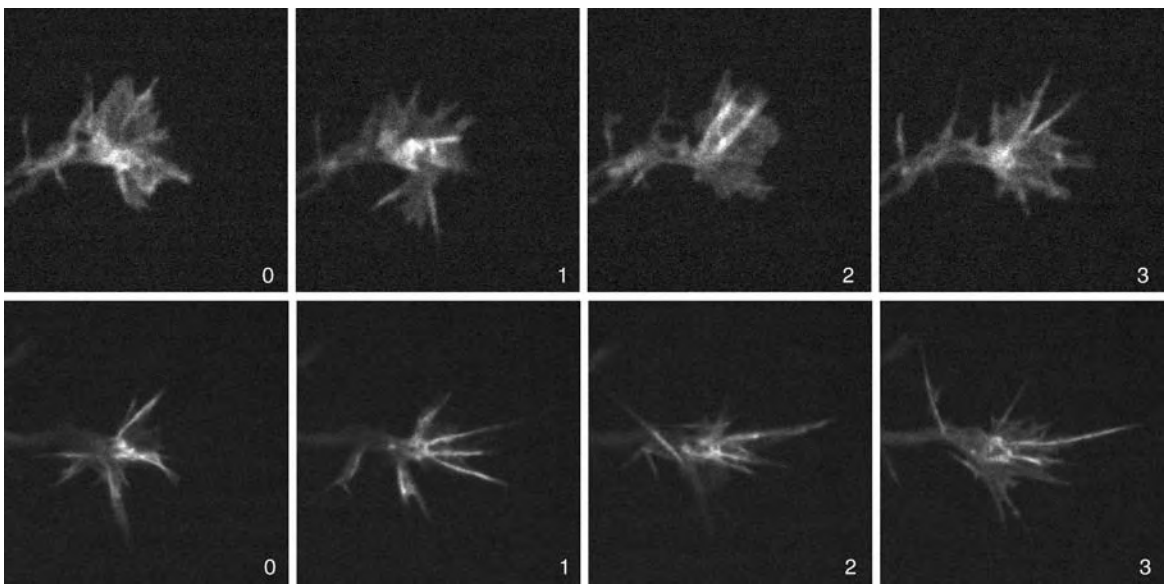
Filopodia probe the local environment and sense molecular cues that can lead to various growth cone responses such as turning (Figs. 1 and 2).

Lamellipodia veils make up much of the growth cone surface area, can provide mechanical tension and contribute to growth cone motility (Figs. 1 and 2).

►Focal contacts are localized throughout the surface of lamellipodia and filopodia in growth cones where they play an important role in axon growth and guidance.

## Structural Regulation

The actin filament network of the peripheral domain of the growth cone largely determines the structure and dynamics of filopodia and lamellipodia (Fig. 2). Drugs that disrupt actin polymerization, such as cytochalasin and latrunculin A, disrupt growth cone



**Growth Cones. Figure 2** Actin dynamics in neuronal growth cones. Fluorescence micrographs of two growth cones of cultured embryonic day 18 rat hippocampal neurons expressing a β-actin-red fluorescent protein chimera. Images in each row are taken at 1-min intervals (numbers at *bottom right*). Growth cone in *top row* shows prominent lamellipodia, whereas the one in the *bottom row* shows more prominent filopodia.

structure, including the loss of filopodia and collapse of lamellipodia. Most actin filaments are oriented with their faster growing (barbed) ends pointing towards the outside of the growth cone. Filopodial growth occurs by polymerization of actin filaments with subunits adding at the tip of the ►filopodium, which pushes the membrane out. Lamellipodial protrusion occurs as the underlying meshwork of actin filaments are polymerized at the leading edge. When lamellipodia lose their attachment to the substratum, they form "ruffles" (loose lamellipodial membranes) which collapse backwards into the growth cone. Actin that assembles at the leading edge of the growth cone is under tension from myosin motors, resulting in a continuous retrograde flow of newly assembled filaments away from the leading edge to the transition zone where they disassemble. The amount of retrograde flow decreases with increasing rates of forward motility as the cytoskeleton is coupled to the substratum [2,14].

Microtubules are the main skeletal component of the central domain of the growth cone. They extend from the cell body in a discontinuous but overlapping manner down the length of the neurite into the growth cone and are oriented with their growing plus ends towards the P-domain. Microtubules also serve as the main transport for cellular material that gets incorporated at the growth cone, including vesicles needed for the expanding membrane and cytoskeletal proteins (see axonal transport). As dendrites mature, microtubules undergo a mixing of polarity, whereas in axons microtubules continually maintain a distal orientation of their plus ends. Microtubules in the proximal regions of the growing neurite become stabilized with associated proteins, however, those in the distal neurite and growth cone continue to undergo cycles of extension and retraction (dynamic instability). After entering growth cones, these dynamic microtubules splay out and occasionally penetrate into the actin-rich lamellipodia and filopodia of the P-domain where they play an important role in axon pathfinding (Fig. 1c arrows). The retrograde flow of actin often captures some of the microtubules that extend into the P-domain, causing them to buckle and break [2,14].

Focal contacts in the growth cone have to rapidly form and disassemble in order for migration to occur. In migrating cells, the speed of cell migration is the highest at intermediate levels of adhesiveness. This level of adhesiveness is determined by various parameters including ligand concentration, receptor density, ligand-receptor affinity, and the presence of intracellular signals. These factors ultimately affect the substrate-cell adhesion molecule (CAM)-actin interface. For example, CAM clustering and ligand binding increases the level of CAM-actin interactions. In addition, intracellular signaling mediated by tyrosine phosphorylation may enhance or weaken CAM-cytoskeletal coupling [14]. Guidance cues can also affect assembly and disassembly of focal contacts in filopodia altering lamellipodial advance, which can determine growth cone guidance.

## Higher Level Processes

During embryonic development, growth cones navigate axons and dendrites to their appropriate targets and are involved in the formation of synapses necessary for correctly wiring the nervous system (see below under Functions). After injury to the nervous system, a nerve's capacity for regeneration depends on its ability to reform a functional growth cone (see below under Pathology).

### *Lower Level Processes*

Filopodial dynamics are critical to growth cone pathfinding. In addition, filopodia are important for neurite branching and determining the ultimate arborization and connectivity of the nervous system [16].

Lamellipodial veil expansion and shrinkage is also important in growth cone pathfinding. The lamellipodial cross-linked actin meshwork provides a framework for growth cone adhesion to the substrate and mechanical tension to aid subsequent growth cone movement. On a uniform substrate, growth cone turning may be correlated with lamellipodial size [16].

Membrane addition and the incorporation of cytoskeletal subunits also occur at growth cones and support the elongation of the growing process. Anterograde transport of membrane bound vesicles and cytoskeletal polymers, occurs along microtubules via kinesin motors [6].

Protein synthesis within the growth cone, particularly of actin and actin regulatory proteins, is critical to growth cone function. Decreased localized translation of β-actin mRNA in growth cones may contribute to smaller growth cones and decreased axon extension [4]. Several growth stimulatory factors enhance the transport of locally translated mRNAs from the cell body to the growth cone. Some guidance cues also require local protein synthesis to cause structural changes in growth cones [2].

## Process Regulation

The ►Rho family of small guanosine triphosphatases (Rho ►GTPases) are pivotal intracellular switches that transduce signals from many of the ►guidance cue receptors on the growth cone membrane to the actin and microtubule cytoskeleton [3]. The Rho GTPases Rac1 and Cdc42 regulate both filopodia and lamellipodia in growth cones through downstream actin effectors and are involved in axon growth and guidance [2,6,13].

Signal transduction pathways from extracellular guidance cues to cytoskeletal binding proteins are responsible for the regulation of filopodial and lamellipodial

extension and retraction. The "clutch" model proposes that filopodial protrusion occurs by actin assembly when actin filaments are fixed with respect to the substrate (the "clutch" is "engaged") [14]. Retraction, conversely, occurs when myosin II exerts a contractile activity on actin filaments that have not anchored to the substratum via focal contacts (the "clutch" is "disengaged"), leading to retrograde flow of the actin. Filopodial dynamics are regulated by changes in actin assembly and myosin contractility mediated by the Rho family GTPases [4,6].

The initiation of filopodial and lamellipodial protrusions depends on actin polymerization and occurs through the actions of membrane bound proteins in the family of enabled/vasodilator stimulated phosphoprotein (Ena/VASP), which inhibit the capping of actin filament barbed ends and also their branching by the Arp2/3 complex [2]. In non-neuronal cells the Arp2/3 complex plays an important role in filament branching at the leading edge of expanding lamellipodia, but in neurons, the Arp2/3 complex plays important roles in the initiation of neurite outgrowth and in both lamellipodial and filopodial formation and dynamics. Proteins that enhance barbed end formation, actin recycling and polymerization, such as cofilin, actin depolymerizing factor (ADF), and profilin, contribute to filopodial and lamellipodial expansion. ADF/cofilin proteins play essential roles in filopodial extension and growth cone turning in response to guidance cues [4,16].

The growth-associated protein ►GAP-43 plays an essential role in growth cone motility during development. GAP-43 interacts with second messengers, particularly phosphtidylionositol(4,5)bis phosphate, and its ability to increase transient calcium concentrations suggests it functions to regulate actin dynamics affecting growth cone structure and motility [2].

## Function

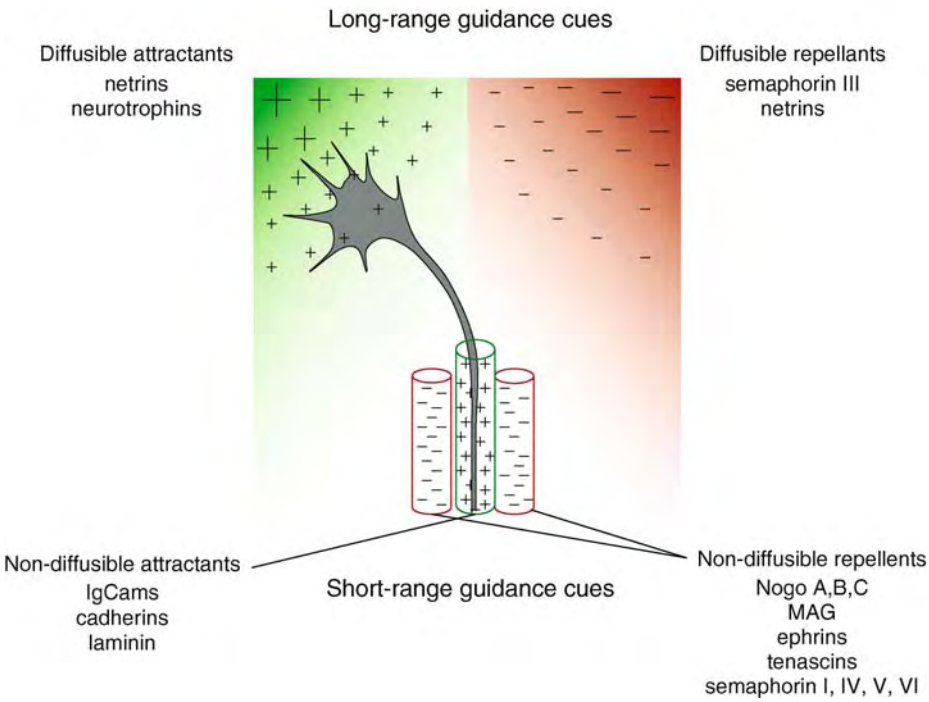
Neuronal growth cones are responsible for the proper navigation of nerve fibers through the embryonic environment to their proper synaptic partners. This is a daunting task. In adult humans, there are trillions of neurons, each connecting with thousands of synaptic partners in an intricate network of neural circuits. Correctly wiring all this depends on the proper functioning of growth cones, which extend the axon along the correct pathway, choose the target region within which to terminate, and recognize specific cells on which to synapse. Growth cones must act as both guidance cue sensors and sites of signal transduction, leading to a range of dynamic behaviors such as increased growth rates, retraction, turning, stalling, branching and fasciculation.

Guidance cues fall into four main categories: diffusible attractants and repellents, and non-diffusible (or substrate-bound) attractants and repellents [15]. General examples of cues in each category are presented in Fig. 3, but some molecules can be both attractive and repulsive cues, depending on when during development the neurons are exposed and on other conditions, particularly the intracellular concentration of second messengers such as cAMP, cGMP or calcium [13].

Guidance cues regulate the cytoskeleton leading to dynamic changes in growth cone structure and motility. ►Neurotrophins, such as BDNF, enhance formation and length of growth cone filopodia [6,14], which facilitates turning towards a gradient of BDNF [13]. Conversely, when a growth cone encounters a repellant cue, such as Semaphorin III, turning away from the cue results from localized F-actin depolymerization [6].

Growth cones navigate through complex environments to distances often more than a thousand times the diameter of the cell body. In some cases the navigation pathway is broken into segments by intermediate targets ("choice points" or "guidepost cells"), which present guidance information allowing growth cones to change course [15]. Growth cones *in vivo* generally assume one of two possible morphologies; a broad veil-like structure with multiple filopodia, or a bullet-shaped appearance with few filopodia. Generally, "►pioneer axons" that initially grow into an uncharted region of the embryo have the former appearance; this is consistent with the idea that the growth cones must make guidance decisions based on cues in the novel environment. Later axons will often fasciculate, using earlier pioneering axons as a track to grow along, and these growth cones have less filopodia [12]. Fasciculation may help simplify the development of complex nervous systems in which axons grow in successive waves [15].

Some guidance molecules appear to have unique gradients with a particular "address" that is recognized by specific axonal growth cones with a complementary gradient of receptors [12,15]. Growth cone pathfinding and target selection often result in topographic maps that are neural representations of the world. As growth cones approach their target and the target is selected, they undergo morphological changes and mature into presynaptic specializations known as ►terminal boutons. In the target region, growth cones slow and may arborize if multiple targets are to be innervated, as in the optic tectum, or may maintain a single dynamic growth cone, as during the innervation of muscle fibers [12]. When the growth cone contacts its target, its filopodia retract, and the membrane becomes closely associated with the target cell through adhesive contacts. Although some of the presynaptic neurotransmission machinery is present in growth cones before ►synaptogenesis, after target selection there is an accumulation of presynaptic vesicles. During muscle fiber innervation, the motor neuron growth cone induces the aggregation of acetylcholine receptors on the post-synaptic muscle cell. A rise in



**Growth Cones. Figure 3** Schematic of growth cone guidance cues. There are four main types of guidance cues: diffusible (long-range) attractants and repellents, and substrate bound (short-range) attractants and repellents. Displayed are examples of each type. Diffusible guidance cues are secreted by cells in the embryo to either attract or repel growing axons, and thereby influence the particular trajectory the axon navigates. Netrin, a typical diffusible cue, attracts commissural axons to the ventral spinal cord, but netrin can also be a potent repellent. Semaphorins typically serve as repulsive guidance cues and can be secreted (Sema III) or substrate bound (Sema I, IV, V, VI). Other short-range guidance cues include components of the extracellular matrix, such as growth promoting laminin, and proteins expressed on the surface of cells, such as growth inhibiting Nogo, expressed on the myelin surface. The different guidance cues may be present simultaneously to influence pathfinding of developing axons and growth cones must be able to integrate the signals into one final behavioral outcome.

intracellular calcium and cAMP following target formation may be important to converting the growth cone into the specialized presynaptic terminals. Maturation of synapses often requires days to weeks, during which synapse-specific proteins are synthesized and incorporated into presynaptic and postsynaptic regions [12].

## Pathology

Problems in growth function have important implications for nervous system damage. Transecting nerve axons in the adult central nervous system (CNS) results in permanent impairment. Conversely, severing nerves of the peripheral nervous system (PNS) can be followed by regeneration and nearly full functional recovery. The difference is due to down-regulation of myelin components that are growth inhibitors in the PNS, thus allowing axon regeneration. Oligodendrocytes, which provide CNS myelin, express molecules such as Nogo and myelin associated glycoprotein (MAG), which inhibit axon re-growth following injury [20].

Following a lesion, transected axons can reform growth cones that appear functionally equivalent to those observed in development. Severed nerve fibers attempt re-growth, but are unable to penetrate the injury site. It is known that neurons from the adult CNS can extend axons *in vitro*. When severed CNS axons are given a PNS sheath, the axons are able to grow several centimeters [12]. Thus, it appears that the inhibitory molecules of CNS myelin are mainly responsible for the inability of a reformed CNS growth cone to regenerate a neurite. Targeting therapies to growth cones may facilitate CNS regeneration.

Abnormalities in growth cone pathfinding and target selection during development can lead to defects in nervous system function. There is little work directly linking developmental diseases with growth cone-specific defects, but some recent data implicates growth cone malfunction in certain pathologies. For example, growth cone irregularities may contribute to the pathology of spinal muscular atrophy (SMA), an autosomal recessive disease caused by deletion mutation in the

telomeric copy of the spinal neuron survival gene (SMN1). SMA is characterized by progressive muscular weakness due to specific degeneration of α motor neurons. SMN may facilitate the transport and/or local synthesis of proteins, such as β-actin, that are critical in growth cone function. Motor neurons from the SMA mouse model have decreased axon elongation and smaller growth cones, presumably due to decreased β-actin levels [11]. Though not conclusive, this suggests that abnormal growth cone function should be considered in investigating developmental disorders.

## Therapy

Potential nerve regeneration therapies have targeted myelin-associated receptors or signal transduction pathways localized to growth cones. The Nogo antibody, IN-1, can be used to block the function of Nogo, which normally signals to prevent growth cone advance. Infusion of the IN-1 antibody into the CNS of a rat with spinal cord damage results in the long distance regeneration of only a few corticospinal axons, but these impart a significant functional recovery [5,8]. These studies demonstrate that adult mammalian CNS nerve regeneration is possible, if the inhibitory effects of myelin are blocked.

An alternative approach to regeneration has targeted intracellular signaling pathways in neurons. Modulating the neuronal signaling responses has shown success at overcoming the inhibitory properties of myelin. For example, it has been shown that manipulation of Rho GTPase signaling promotes regeneration *in vivo*. Other studies have demonstrated that elevation of cAMP levels allows growth cones to overcome the inhibitory effect of MAG and myelin [5]. Increasing neurotrophins with pumps or gene therapy techniques does not increase long-distance regeneration, but does promote local sprouting, re-innervation and remodeling in the CNS [8].

►Axonal Regeneration

# Growth Factors – Overview

Hidefumi Fukumitsu, Shoei Furukawa
Laboratory of Molecular Biology, Gifu Pharmaceutical University, Gifu, Japan

## Definition

A group of proteins regulate the survival, differentiation and growth of various cell types, including neurons.

The precisely regulated generation and positioning of neuronal cells and the correct establishment of neuronal connections during development are essential for the proper function of the nervous system. Such a sophisticated nervous system is generated by a developmental program that involves early patterning, determination of the neural cell fate, axon–dendrite specification, target innervation, cell death, synaptogenesis and synaptic refinement and myelination. Many growth factors are crucial for this developmental program. There are essays specializing in each step of the developmental program in this Encyclopedia; in this essay about "growth factor" we have discussed the biochemical characteristics of each growth factor.

## Characteristics

### Description of the Structure/Process/Condition

#### *Epidermal Growth Factor (EGF) Family*

EGF is a 53 amino acid peptide, containing six spatially conserved cysteine residues (CX7 CX4–5 CX10–13 CXCX8 C) that form three intermolecular disulfide bonds. This consensus sequence is known as the EGF-like motif. The EGF family includes ►transforming growth factor-α (TGF-α), amphiregulin (AR), heparin-binding EGF-like growth factor (HB-EGF), β-cellulin (BTC), epiregulin (EPR), epigen (EPI), neuregulin (Nrg)-1, neuregulin-2 (NTAK, DON-1), Nrg-3, Nrg-4, Nrg-5 and Nrg-6. All of the EGF-family proteins exist in a proform as type I transmembrane proteins consisting of an EGF motif flanked by an N-terminal extension and a C-terminal membrane-anchoring domain. Soluble ligands are produced through extracellular cleavage of the integral membrane precursor proteins, although there is no obvious homology in the predicted cleavage sites. Many studies have shown that metalloprotease activity is required for their release [1].

#### *Fibroblast Growth Factor (FGF)-Family*

FGF1–FGF23 have been identified in humans and mice. However, FGF19 is the human ortholog of mouse FGF15. In total, the human–mouse FGF family consists of 22 members (see essay on fibroblast growth factor in this Encyclopedia).

#### *Hedgehog (Hh)-Family*

The Hh-family includes Sonic hedgehog (Shh), Indian hedgehog (Ihh) and Desert hedgehog (Dhh) (see essay on Sonic hedgehog in this Encyclopedia). The Wnt and Hh families are found to be differentiation factors; therefore they are not classified as growth factors. However, we include these families in this essay, because they are very important for cell growth and differentiation of the developing nervous system.

#### *Hepatocyte Growth Factor/Scatter Factor (HGF/SF)*

HGF/SF is a multifunctional polypeptide, originally discovered in the late 1980s as a unique protein that promotes hepatocyte proliferation and liver regeneration. The amino acid sequence is highly homologous with plasminogen, a pro-enzyme of serine protease, involved in dissolving fibrin clots. Like plasminogen, inactive pro-HGF is synthesized and secreted as a single chain, then pro-HGF is cleaved between Arg and Val by serine proteases to convert it to the mature, physiologically active form. Thus, mature HGF consists of a light chain of 30 kD and a heavy chain of 60 kD linked by a disulphide bond. The heavy chain contains four kringle domains and a hairpin loop, which is almost the same as the heparin-binding domain. Therefore, pro-HGF secreted from cells binds to extracellular matrix molecules until its conversion to mature HGF as described below.

A novel serine protease, HGF activator (HGFA), which has potent activity for cleavage of pro-HGF, has been purified from human sera. Other serum serine proteases such as blood coagulation factor XIIa, tissue type plasminogen activator and urokinase are also known to be capable of cleaving pro-HGF to form mature HGF. Compared with these serine proteases however, the proteolytic activity of HGFA for HGF is more powerful. HGFA is also synthesized and secreted as an inactive pro-form. The cleavage of pro-HGFA by a serine protease such as thrombin is essential for its activation [2].

#### *Insulin-Like Growth Factor (IGF)*

IGF I and II are growth-promoting peptides, members of a superfamily of related insulin-like hormones that includes insulin and relaxin in the vertebrates and bombyxin, locust insulin-related peptide and molluscan insulin-like peptide in invertebrates. However, insulin and IGFs are the most closely related in terms of primary sequence and biological activity. The IGFs are major growth factors whereas insulin predominantly regulates glucose uptake and cellular metabolism. They consist of A, B, C and D domains. Large parts of the sequences within the A and B domains are homologous to the α- and β-chain of human proinsulin. This sequence homology is 43% for IGF-I and 41% for IGF-II. No sequence homology exists between the C domains of IGFs and the C peptide region of human proinsulin. The C domain of the IGFs is not removed during prohormone processing; thus the mature IGF peptides are single chain polypeptides. The gene encoding IGF-I is highly conserved, such that 57 of the 70 residues of the mature protein are identical among mammals, birds and amphibians [3].

#### *Platelet-Derived Growth Factor (PDGF)*

PDGF was purified to homogeneity in the late 1970s as a factor from platelets that promotes the proliferation of mesenchymal cells. Over the next 10–15 years, additional studies revealed that there are two PDGF genes (A and B) and three biologically active forms of the PDGF protein, AA, BB and AB. In the last five years two additional members of the PDGF family PDGF-CC and PDGF-DD were discovered. The PDGF C and D chains have a unique two-domain structure with an $NH_2$-terminal CUB (compliment subcomponents C1r/C1s, Uegf and Bmp1) domain and a COOH-terminal PDGF/vascular endothelial growth factor domain. Whereas secreted PDGF AA, BB and AB can readily activate their cell surface receptors, it has been suggested that extracellular proteolytic removal of the CUB domain is required for the growth factor

domain of PDGF CC and DD dimers to preferentially activate αα-PDGFR and ββ-PDGFR respectively [4].

### Neurotrophin (NT)-Family

The NT-family includes nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT-3, NT-4/5, NT-6 and NT-7. NT-6 and -7 only exist in fish (see essay on neurotrophin in this Encyclopedia).

### Stem Cell Factor/Mast Cell Growth Factor/Kit-Ligand/ Steel Factor (SCF/MGF/KL/SF)

Stem cell factor (SCF) is produced in soluble and membrane bound forms, resulting from alternative splicing around the exon 6 of the gene. They differ in sequences amino-terminal of the transmembrane segment. Soluble form SCF is processed rapidly and efficiently by proteolytic cleavage to produce a secreted protein of 164 amino acids. In contrast, the membrane bound form lacks the major proteolytic cleavage site that is responsible for the generation of secreted protein and thus represents a more stable membrane form of the protein. Ultimately, in some cells membrane bond form-SCF is also processed to produce secreted protein, using a secondary cleavage site encoded by exon 7 sequences. This cleavage occurs at a slower rate [5].

### Transforming Growth Factor (TGF)-β Superfamily

The ►transforming growth factor-β (TGF-β) superfamily consists of a large family of structurally related polypeptide growth factors. These can be phylogenetically divided into two main groups, the TGF-β/activin and bone morphogenetic protein (BMP)/growth and differentiation factor (GDF) branches. These can be subdivided into several related sub-groups based on their sequence similarity and relationship to evolutionarily conserved molecules in primitive organisms (see essay on transforming growth factor in this Encyclopedia). Glial cell line-derived neurotrophic factor (GDNF) is classified in this family because of its structural similarity, but functions via tyrosine-kinase receptor c-Ret with GPI-linked alpha receptor (GFR-α 1–4) or via GFR-α alone [6].

### Vascular Endothelial Growth Factor (VEGF) Family

The VEGF family of molecules currently consists of six growth factors, including VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E and placental growth factor. VEGF-A is currently the most well characterized member of the VEGF family and is composed of at least five isoforms due to alternative gene splicing. These vary in length from 121 to 206 amino acids (121, 145, 165, 189 and 206) and differ by the presence or absence of sequences located in exons 6 and 7. Exon 8 is common to all isoforms. Exons 6 and 7 have been shown to encode the ECM-binding domain of the protein. This domain is able to bind heparin sulfate proteoglycans and other matrix proteins and is thought to be responsible for the sequestration of VEGF within the matrix. Thus the matrix constitutes a reservoir for the growth factor, which becomes liberated by matrix breakdown via extracellular enzymes such as heparinases and plasmin. Matrix metalloproteinases (MMPs) have also been implicated in the regulation of VEGF bioavailability from extracellular stores [7].

### Wnt-Family

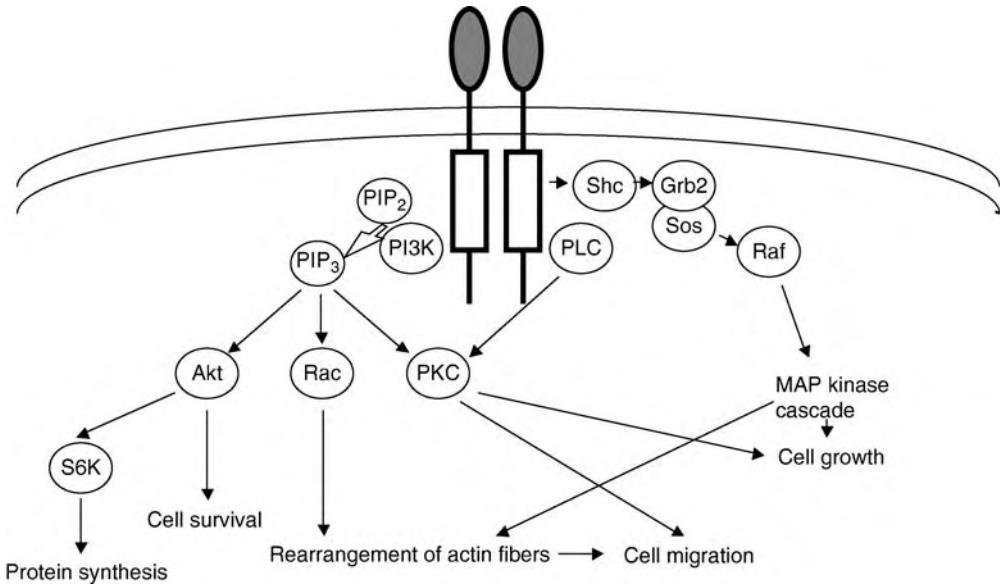
The Wnt-family includes wnt-1 to wnt-16. Wnt proteins have only recently been characterized. To some extent, early difficulties in isolating active Wnts are now explained by the finding that Wnt molecules are palmitoylated and therefore much more hydrophobic than predicted from the primary amino acid sequence. The palmitoylation on a cysteine residue was found by mutant analysis to be essential for function. Treating Wnt with the enzyme acyl protein thioesterase results in a form that is not hydrophobic and not active, strengthening the evidence that the palmitate is important for signaling. Because this cysteine is conserved in all known Wnt proteins, it is likely that all Wnts are palmitoylated. It remains an intriguing question as to how palmitoylated Wnt molecules are transported [8].

## Higher-Level Structure/Processes/Conditions

### Receptors and Signal Cascade

#### Receptor-Type Tyrosine Kinase Superfamily

Receptors of many growth factors belong to receptor-type tyrosine kinases (RTKs), which are composed of an amino-terminal extracellular domain (ECD) that binds ligands, a single transmembrane domain (TMD) and an intercellular domain containing a tyrosine kinase catalytic unit. The superfamily of receptor-type tyrosine kinases includes c-kit (receptor of SCF), trk (high affinity receptor for the neurotrophin family) and the receptor for EGF, FGF, HGF, IGF, PDGF and VEGF. Signaling begins with ligand binding, which stabilizes receptor dimerization, thereby juxtaposing the tyrosine-kinase domains of the RTKs on the cytosolic face of the membrane. These kinase domains cross-activate each other by phosphorylation of critical residues within the catalytic domains and then further phosphorylate critical tyrosines outside the catalytic domain, which in turn function as docking sites for proteins containing SH2 or PTB domains. These latter proteins recognize primary sequence around the phosphorylation sites of receptors and act either as adaptors to recruit other proteins to the signaling complex or harbor catalytic domains capable of propagating the initial signal further. For example, the SH2-adaptor Grb2 recruits a component of the Ras signaling cascade (Fig. 1).



**Growth Factors – Overview. Figure 1** Signaling cascade activated by receptor-type tyrosine kinase. After growth factors bind to their specific receptors, the two receptors form a homodimer (dimerization) and tyrosine residues inside their receptors are phosphorylated (auto-phosphorylation). The phosphorylated tyrosine residues interact with and phosphorylate signaling molecules. The phosphorylated molecules sequentially activate down-stream signaling molecules. These pathways finally promote special sets of gene expression. To avoid excess signaling, the growth factor-receptor binding complex is then immediately taken into the cell body and degraded.

Another example is the SH2 domain-containing enzyme phospholipase Cγ, which is recruited to the phosphorylated receptor to provide access to its phospholipid substrate in the plasma membrane. One of the hydrolysis products of phospholipase Cγ activates protein kinase C. Eventually, a complex network of positive and negative regulators participates in the down-stream signaling, which precisely manipulates the transcription of a specific set of genes [9].

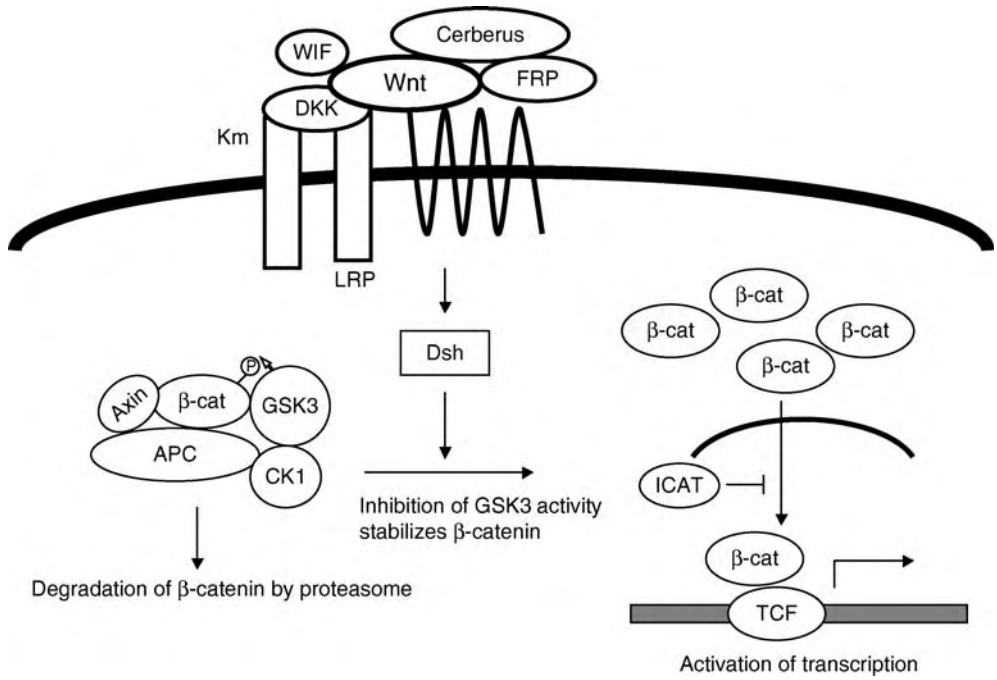
### *Receptor-Type Serine/Threonine Kinase Family*

TGF-β and BMP family members interact through extracellular domains of heteromeric complexes composed of type I and type II serine threonine kinase receptors (►Transforming growth factor-β receptor). In general type II receptors are constitutive kinases responsible for ligand binding and for transphosphorylation of the type I receptor on a glycine–serine rich domain (GS domain). The phosphorylation of this domain activates the type I kinase which then phosphorylates downstream components of the ►Smad signaling pathway (members of the Smad family) (see essay on transforming growth factor in this Encyclopedia).

### *Wnt Receptor*

Wnts receptors, Frizzleds (Fz)s, are serpentine receptors with seven transmembrane-spanning domains and a long N-terminal extension called a cysteine-rich domain (CRD), closely related to G protein-coupled receptors. Wnt proteins bind directly to the Fz CRD. In *Drosophila* and in cultured cells, over-expression protein of the DFz2 receptor fails to activate Wnt signaling unless its cognate ligand, Wingless, is present, suggesting that Fz activates a down-stream signaling cascade in a ligand dependent manner (Fig. 2).

In addition to Wnt/Fz interactions, Wnt signaling also requires the presence of a single-pass transmembrane molecule of the LRP family, identified as the gene Arrow in *Drosophila* and as LRP5 or 6 in vertebrates. LRP5 consists of five conserved motifs that are characteristic of the LDL-receptor family: (i) LDL-receptor repeats required for ligand binding, (ii) four EGF-receptor-like cysteine-rich repeats with associated YWTD (Tyr-Trp-Thr-Asp) spacer domains, (iii) a putative signal peptide for protein export, (iv) a single membrane-spanning segment and (v) a cytoplasmic tail with NPXY (Asn-Pro-X-Tyr) motifs for receptor internalization. Extrapolating from LRP6, it is probable that the first and second EGF repeats and the associated YWTD domains participate in interactions with the Fz–Wnt complex, whereas the third and fourth EGF-YWTD domains bind to secreted antagonists, such as the Dickkopf (Dkk) family. The transport of LRP from the ER to the cell surface requires a specific accessory molecule called Boca in *Drosophila* and Mesd in mice; mutation of these genes produce phenotypes similar to



**Growth Factors – Overview. Figure 2** The canonical Wnt signaling pathway in cells not exposed to a Wnt signal (*left panel*), β-catenin is degraded through interactions with axin, APC and the protein kinase GSK-3. Wnt proteins bind to the Frizzled/LRP receptor complex at the cell surface (*right*). These receptors transduce a signal to Disheveled (*Dsh*) and to axin, which may directly interact. As a consequence, the degradation of β-catenin is inhibited, and the protein accumulates in the cytoplasm and nucleus. β-catenin then interacts with TCF to control transcription.

loss of Arrow/LRP themselves. It has been proposed that Wnt molecules bind to LRP and Fz to form a receptor trimeric complex.

Receptor activation in turn somehow activates Disheveled (Dsh), the most proximal cytosolic component known. The precise role of Dsh in pathway activation is still not clear, but it may be intricate because the pathway branches downstream of Dsh. In canonical Wnt signaling, Dsh is involved in turning off a protein complex dedicated to the degradation of β-catenin (β-cat, called Armadillo in *Drosophila*). Inactivation of the destruction complex allows β-cat to accumulate within responding cells and to enter the nucleus where it binds to Tcf, the transcriptional effector of the Wnt pathway. This complex recruits other proteins to drive transcriptional activation of Wnt target genes.

A hallmark of Wnt pathway activation is the elevation of cytoplasmic β-cat protein levels. In the absence of Wnt signaling, β-cat is phosphorylated by the serine/threonine kinase, casein kinase Iα (CKIα) and GSK-3. The interaction between these kinases and β-catenin is facilitated by the scaffolding proteins, axin and APC. Together, these proteins form α-catenin "degradation complex," which allows phosphorylated β-cat to be recognized by β-TrCP, targeted for ubiquitination and degraded by the proteosome. Activation of Wnt signaling inhibits β-cat phosphorylation and hence its degradation. The elevation of β-cat levels leads to its nuclear accumulation and complex formation with LEF/TCF transcription factors. β-cat mutant forms that lack the phosphorylation sites required for its degradation are Wnt unresponsive and can activate Wnt target genes constitutively [10].

## Function

In the higher multi-cellular organisms, the cells respond to environmental stimuli like growth factors. Signaling through the receptors of the growth factors described above regulates a wide range of biological phenomena during the development of the nervous system. In most cases, the neural cells express certain sets of receptors for growth factors and the dynamic cross-talks of upstream and/or down stream signaling cascades, initiated by interaction between ligands and receptors, manipulate expression of special sets of genes or directly modify the cell structures and functions of neural cells. We have essays on each developmental step of the nervous system in this Encyclopedia.

# Growth Factors – Survival/Plasticity

Deborah Young
Department of Molecular Medicine & Pathology, Department of Pharmacology & Clinical Pharmacology Faculty of Medical & Health Sciences, University of Auckland, Auckland, New Zealand

## Synonyms

Neurotrophic factors

## Definition

Growth factors are proteins that support the proliferation, migration, differentiation and survival of cells (neurons, glia) within the nervous system during early development and throughout adult life.

## Characteristics

Growth factors constitute a broad range of structurally diverse proteins that mediate a wide array of biological functions in the brain including neurogenesis, neuronal survival/►apoptosis, neurite outgrowth and synaptic plasticity. These functions are mediated by binding of the growth factor to its cell surface receptor(s), which are in many cases, receptor tyrosine kinases, leading to the activation of intracellular cell signaling cascades.

Growth factors are classified into families either on the basis of the specific receptor classes by which they mediate their effects or on the basis of conserved structural motifs that are shared amongst family members (Table 1).

Neurons are supported throughout life by the actions of a repertoire of growth factors and specific neuronal populations rely on specific growth factors for their maintenance and survival. For example, glial cell-line derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF) are major growth and survival factors for dopaminergic neurons in the substantia nigra, the neuronal population affected in Parkinson's disease. The growth factor families that have a major influence in the brain include:

*Neurotrophins*: The neurotrophins are the most well studied growth factor family [1]. Nerve growth factor (NGF) was the founding member in this family that also includes brain-derived neurotrophic factor (BDNF) and neurotrophins 3 and 4 (NT3, NT4). All neurotro-

phins are synthesized as larger ~30–35 kDa precursors or proneurotrophins before the N-terminal prodomain, a peptide sequence that promotes folding of the protein and trafficking to secretory vesicles, is proteolytically cleaved prior to yield the secreted mature ~11–15 kDa neurotrophin. The mature neurotrophins mediate their biological effects by binding to two structurally distinct classes of receptors – the Trk family of receptor tyrosine kinases, to which NGF preferentially binds to the TrkA receptor, BDNF and NT3 to the TrkB receptor, NT3 to the TrkC receptor, – and the p75 neurotrophin receptor ($p75^{NTR}$) to which all mature neurotrophins bind with equal affinity. More recent evidence has shown that both precursor forms of NGF and BDNF (proNGF and proBDNF) can also be secreted from cells and have functional activity [2].

Insulin-like growth factors (IGFs): The three members of this family, insulin, IGF-1 and IGF-II exert their effects by binding to two cell surface receptors, the IGF-1 (or type I) and IGF-II (or type 2) receptors [3]. The IGF-1 and IGF-II receptors bind IGF1 and IGF-II respectively with the highest affinities but also allow binding by other family members with lower affinity. However, the IGF-II receptor does not bind insulin. All IGFs can also interact with the insulin receptor but with much lower affinity. The IGF-1 receptor is a heteromeric protein harboring two identical α-subunits containing a cysteine rich IGF-binding site and two transmembrane β-subunits that have tyrosine kinase activity. Activation of this receptor tyrosine kinase leads to phosphorylation of multiple cytoplasmic substrates such as the adaptor molecule insulin receptor substrate (IRS-1/4) proteins and the Shc proteins which bind to Grb2 and stimulate the activity of the Ras and mitogen activated protein (MAP) kinase pathway which involves Raf-1 and extracellular signal-related kinase (ERK)-1/2. Alternatively, IRS proteins can also activate the phosphatidylinositol-3 kinase (PI-3K) pathway via the adaptor protein p85.

Epidermal growth factor (EGF) family: members of this family share at least one common structural motif, the EGF domain that consists of six conserved cysteine residues that form three disulfide bonds. Like the neurotrophins, most members are synthesized as precursors before the mature peptide is released by proteolytic cleavage. The activity of EGF family members is mediated by the EGF receptor/ErbB receptor tyrosine kinases. The binding of the ligand to the EGF receptor leads to formation of heterodimers with one of three related proteins, ErbB2, ErbB3 and ErbB4 leading to downstream activation of MAP kinase and PI-3K pathways [4].

Fibroblast growth factor (FGF) family: The FGF family currently consists of 22 ligands and five cell surface receptor tyrosine kinases that are also expressed as several splice variants in humans [5]. All FGF ligands share a conserved 120 amino acid central heparin-binding domain that is involved in the formation of stable FGF ligand-receptor interactions. FGF ligand binding induces dimerisation of the receptors and cross-phosphorylation of tyrosine residues leading to recruitment of intracellular second messengers including phospholipase Cγ and subsequent protein kinase C activation or Ras/Raf signaling and activation of the MAP kinase cascade. FGF1 (acidic fibroblast growth factor) and FGF2 (basic fibroblast growth factor) are the two prototypical members of this family. FGF1 is expressed predominantly in neurons and is primarily involved in promoting neuronal maturation and differentiation, whereas FGF2 is expressed in neurons and glial cells and is a potent mitogen that promotes proliferation of neural stem cells to either a neuronal or glial cell fate.

Transforming growth factor beta (TGF-β) family: this large superfamily comprises as many as 30 proteins in mammals and those with relevance to the central nervous system include the three TGF-β isoforms (TGF-β1–3), activins and inhibins, nodal, bone morphogenetic proteins (BMP), growth/differentiation factors (GDFs) [6]. The most well-studied are the TGF-β isoforms which act in a highly contextual manner depending on the cell type and environment. Thus these proteins may stimulate proliferation or induce differentiation, promote cell survival or induce apoptosis, initiate and or reduce inflammation. The three isoforms are synthesized as large precursors that are cleaved intracellularly by furin to release a C-terminal prodomain called the latency associated peptide (LAP) and the N-terminal active peptide. Each peptide forms homodimers and LAP non-covalently binds to the homodimer to keep it inactive before the complex is secreted and activated by a still poorly understood process. The actions of all three TGF-β isoforms are mediated by a high-affinity receptor complex comprised of the TGF-β type 1(ALK5) and type 2 serine/threonine kinase (TβRII) subunits. A third receptor called betaglycan, has no apparent intracellular signaling activity and regulates ligand availability to ALK5 and TβRII. Binding of the ligand to the ALK5/TβRII complex leads to phosphorylation of ALK5 and recruitment of receptor-regulated Smad (R-Smad) proteins, which translocate to the nucleus and, together with other transcription factors, regulate gene transcription. R-Smads 2 and 3 transmit signal for the TGF-β and activin pathways while Smad 1, Smad 5 and Smad 8 do the same for the BMP pathway. TGFβ1, 2 and 3 and their receptor are expressed are at low levels within neurons, astrocytes, microglia in the normal CNS.

Glial-derived neurotrophic factor (GDNF) and related ligands neurturin, artemin and persephin are distant relatives of the TGF-β family [7]. GDNF has attracted substantial attention as it is a potent survival factor for midbrain dopamine-containing neurons,

which degenerate in Parkinson's disease as well as spinal motoneurons which degenerate in amyotropic lateral sclerosis. Members of the GDNF family signal through the RET receptor tyrosine kinase by binding to glycosyl phosphatidylinositol-anchored receptors termed GFRα1 to 4, in collaboration with signaling receptor subunits such as the RET tyrosine kinase or the $p140^{NCAM}$ isoform of the neural cell adhesion molecule NCAM.

## Effects on Cell Survival/Apoptosis

Neuronal cell survival and death decisions need to be tightly regulated in order to maintain functional neuronal circuits. Neurons depend on the presence of optimal amounts of growth factors for their survival and their importance is highlighted in neurodegenerative diseases, where reduced growth factor signaling appears to be a major contributor to the degeneration of specific neuronal populations that depend on that growth factor for survival. Thus for example, impaired cortical production and supply of BDNF to the medium spiny neurons in the striatum is believed to contribute to the susceptibility of these cells to insult by toxic huntingtin protein fragments and excitotoxic and oxidative stressors in Huntington's disease. Similarly, age-related decreases in IGF1 and BDNF signaling in the hippocampus have been reported which might contribute to age-related cognitive impairment and BDNF signaling may be compromised early in the course of Alzheimer's disease [8]. As a consequence of these findings, a major therapeutic focus for many neurodegenerative diseases has centered on elevating growth factor levels or growth factor signaling to counter the degenerative effects of the disease. Numerous studies have shown that exogenous administration of recombinant growth factor protein or application of ►gene therapy technology rescues or promotes neuronal survival in animal models of epilepsy, stroke, Parkinson's, Alzheimers's or Huntington's disease as well as neuronal loss that accompanies aging (see Chapter on Gene Therapy). Similarly, behavioral interventions such as calorie restriction, environmental enrichment or voluntary exercise which induce growth factor expression also increase the resistance of the brain to traumatic or chemical insults. Growth factor expression (e.g. FGF, BDNF) can also be induced in response to brain injury or ischemia and may be a cellular defense mechanism in an attempt to rescue dying neurons.

One of the most recent findings is that members of the neurotrophin family can mediate cell survival or death decisions. The mature neurotrophins promote neuronal survival and differentiation through Trk receptor activation, whereas proneurotrophin-mediated interaction with the $p75^{NTR}$ and various binding partners including sortilin and NOGO initiates biological responses including apoptosis, myelination and neurite outgrowth. These observations coupled with findings that secreted proneurotrophins can also be cleaved extracellularly by proteinases such as matrix metalloproteinase-7 and plasmin predict that neurotrophin action is tightly regulated by several mechanisms; the expression of distinct neurotrophin receptors that determine the responsiveness of the cell, the secretion and ratio of pro- versus mature neurotrophins and the expression of extracellular proteases that mediate conversion of proneurotrophins to mature forms [2].

Although growth factors may act on distinct receptors, the neuroprotective signal transduction pathways are often similar and involve the (PI3K)/Akt pathway which inhibits the apoptotic action of Forkhead and B-cell leukemia/lymphoma 2 (BCL-2)-associated death protein (BAD), the MAP kinase signaling pathway that promotes the activity or expression of anti-apoptotic BCL-2, and the transcription factor cyclic AMP responsive element binding (CREB).

## Effects on Brain Plasticity

The survival-promoting effects of many growth factors are also coupled to their effects on neural plasticity. At the synaptic level, growth factors can affect synaptic plasticity by promoting ►long-term potentiation (LTP) or ►long-term depression (LTD), cellular correlates of learning and memory. Of the neurotrophins, BDNF is the most well-studied for its role in regulating hippocampal LTP and more recently, proBDNF has been shown to facilitate LTD [1]. The impact of the strengthening or weakening of these synaptic connections can contribute to synaptic remodeling including stimulating axonal branching, dendritic growth and activity-dependent refinement of synapses. Therefore, neuroprotective strategies involving growth factors can have a dual effect by not only promoting neuronal survival but also recovery of function. For example, GDNF is neuroprotective of surviving dopamine neurons in animal models of Parkinson's disease but also promotes recovery from motor deficits by stimulating axonal sprouting and increasing dopamine production in the remaining surviving neurons. Similarly, bFGF is also effective in promoting neurite regeneration from injured axons by promoting sprouting at the proximal part of the injured axon that may lead to formation of new synapses and recovery of neural circuits.

Growth factors can also modulate brain plasticity at the cellular level, most notably by stimulating ►neurogenesis in the adult brain. Neurogenesis that occurs in the hippocampal brain region in adult life is an important mechanism that influences learning and memory and may enable organisms to adapt to environmental changes [9]. Voluntary exercise, exposure to enriched environments and calorie restriction all stimulate hippocampal neurogenesis and this process is thought to be mediated by the coordinated interaction between BDNF, VEGF, IGF1, FGF2 and EGF which induce the proliferation of neural precursors and support the differentiation and survival of

newborn neurons [10]. Hippocampal neurogenesis declines precipitously with ageing, primarily due to a reduction in neuronal precursor proliferation that consequently impacts on the number of mature neurons generated and this may be due to the reduced supply or composition of the growth factor cues (e.g. FGF2, IGF1 and VEGF) that drive hippocampal neurogenesis.

# Growth Factors and Pain

Kathryn M. Albers
Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

## Synonyms

Pain and growth factors; Nociception and growth factors

## Definition

Primary sensory neurons that transmit painful mechanical, thermal or chemical stimuli are highly dependent on growth factors for their embryonic survival and postnatal maturation. In adult systems, the role of growth factors changes and although they continue to provide ►trophic support, they also modulate afferent (sensory) properties. This is particularly true following tissue injury where changes in growth factor tissue content can have profound effects on sensory neuron gene expression and functional properties. This is best illustrated by the changes associated with inflammatory pain conditions where increased production of growth factors leads to sensitization of ►primary sensory afferents.

## Characteristics

### Growth Factors Affect Different Subpopulations of Sensory Afferents Through Receptor Tyrosine Kinase Signaling

Although several types of growth factors have survival and growth-promoting effects on sensory neurons, most studies of neurotrophic factors in relation to pain signaling have focused on members of two major families. The first of these is the neurotrophin family, which in mammals includes the founding member nerve growth factor (NGF), neurotrophin-3 (NT3), neurotrophin-4 (NT4) and brain-derived growth factor (BDNF). Neurotrophins are small (120 amino acids, 13 kDa) basic proteins that share approximately 50% amino acid homology between family members. They bind as homodimers to the external domain of transmembrane ►receptor tyrosine kinase proteins known as trks (tropomyosin related kinases). Binding of growth factor ligand stabilizes Trk receptor dimerization and allows subsequent auto- and trans- phosphorylation of tyrosine residues. Phosphotyrosines serve as binding sites for adaptor proteins, many of which contain src homology 2 (SH2) domains. Trk kinases signal through several cellular pathways that include PI3K, PLC and ras/MAPKs. Neurotrophins bind trk receptors in a preferential manner: NGF binds the receptor trkA, NT3 binds trkC and BDNF and NT4 bind trkB. How specificity of growth factor signaling through each receptor is attained is an area of significant interest. Some specificity may develop through interaction of trk receptors with the single pass transmembrane receptor p75, which can bind all neurotrophins.

Another growth factor family with importance in pain signaling is the glial cell line-derived neurotrophic factor (GDNF) family. The small (~13 kDa) proteins GDNF, neurturin, artemin and persephin comprise this family. These GDNF family ligand (GFL) proteins are classified as a subfamily of the transforming growth factor beta (TGF-β) superfamily of growth factors. GFLs bind as homodimers to activate the rearranged during transfection (Ret) receptor tyrosine kinase through binding of GPI-anchored co-receptor proteins known as growth factor receptor (GFR) alpha proteins. Preferential binding of GDNF ligands is found for each GFR, with GDNF binding GFRα1, neurturin

binding GFRα2, artemin binding GFRα3 and persephin binding GFRα4.

## Growth Factors are Essential for Nociceptor Neuron Survival

Sensory afferents that transmit noxious heat, chemical, or mechanical stimuli can be divided into two major subtypes based on their growth factor requirements during embryonic development and postnatal maturation. This subdivision generally relates to whether the sensory neurons express trkA or Ret kinases and whether they are ►neuropeptide rich or neuropeptide poor. Peptide rich ►nociceptors express trkA, calcitonin gene related peptide (CGRP) or substance P (SP) and many require NGF for survival during development and have a relatively small cell body. The axons of these afferents are either thinly myelinated Aδ fibers or unmyelinated C fibers. TrkA expressing, NGF-dependent neurons primarily terminate in the superficial lamina (I and II) of the spinal cord dorsal horn. Mice genetically engineered to lack a functional NGF or trkA gene lose ~70% of DRG neurons, lack CGRP-positive (peptidergic) neurons and have impaired response to sensory stimulation. Most exhibit postnatal lethality due to deficits in sensory and sympathetic systems. In humans, genetic analysis of subjects diagnosed with ►congenital insensitivity to pain with anhidrosis (CIPA) syndrome have an assortment of mutations that inhibit normal function of the trkA gene [1].

In addition to trkA neurons, the dorsal root ganglion (DRG) contains a subpopulation of sensory neurons responsive to BDNF that express trkB. Mice that lack functional trkB or BDNF genes exhibit loss of ~30% of DRG neurons and sensory deficits related to detection of mechanical stimuli. TrkB neurons are of both large and small diameter and in the wildtype ganglia comprise 10–30% of the DRG population. The DRG also contains NT3-responsive trkC expressing neurons (~20%). Many of these neurons have large-diameters, thickly myelinated axons and serve proprioceptive function. Mice lacking NT3 have up to 78% loss of DRG neurons. Although some trkB and trkC DRG neurons are likely to contribute to nociception, the major transmitters of pain stimuli are trkA neurons.

The peptide poor nociceptor neurons can be defined by their binding of the isolectin B4 (IB4) and lack of CGRP or SP. These neurons are primarily dependent on GDNF family members, most notably GDNF and neurturin. They tend to be small to medium in diameter and have central projections that primarily terminate in inner lamina 2 of the spinal cord dorsal horn. An interesting exception to this peptide-rich/IB4-positive dichotomy is that most (80%) of the sensory neurons responsive to artemin that express the GFRα3 receptor also express CGRP peptide and trkA, and are therefore responsive to both NGF and the artemin GFL.

## Postnatal Role in Nociceptor Differentiation

NGF is required for the developmental survival of sensory neurons and for their postnatal differentiation [see ►Fitzgerald essay]. Modulation of NGF tissue content during the immediate postnatal period can have profound affects on primary afferent subtypes in the adult [2]. In studies of rats treated with an antiserum to NGF during a critical postnatal period (day 4–day11), electrophysiologic analysis of Aδ afferent subtypes showed a complete depletion of the nociceptive Aδ high threshold mechanoreceptor (HTMR) population. This depletion was accompanied by an increase in the proportion of the non-nociceptive low threshold mechanoreceptive (LTMRs) Aδ population (D hairs). Anti-NGF treatment did not change the total number of DRG neurons, leading to the conclusion that NGF is required for postnatal development of HTMRs and that in its absence, HTMRs differentiae into LTMRs. In support of this possibility, overexpression of NGF in the skin of developing transgenic mice caused a sevenfold increase in the number of HTMRs and depletion of LTMRs. This result may, however, reflect both the survival and differentiation actions of NGF [2].

## Neurotrophin Growth Factors Sensitize Adult Nociceptors

Growth factor-induced sensitization of nociceptors is particularly associated with inflammatory pain conditions. Sensitization reflects increased neuron excitability, which alters normal sensory processing and elicits pain. Many chronic pain conditions in humans (e.g. arthritis, bladder cystitis, pancreatitis, etc.) are inflammatory in nature and can be linked to increased growth factor expression or trk receptor signaling. Studies have focused on the effect of NGF and trkA signaling in peripheral sensory afferents. NGF modulation of afferent sensitization and pain transmission occurs using indirect and direct mechanisms. Indirectly, growth factor and cytokine (e.g. TGFβ, PDGF, IL1β) content increases in cells (mast cells, macrophages, immune cells) within inflamed tissues that in turn increase NGF expression. NGF binds and activates trkA receptors expressed on mast cells, keratinocytes, immune cells and sympathetic nerve terminals. This leads to synthesis of additional inflammatory mediators (e.g. TNF-α and interleukin-6). Preventing the increase in NGF during experimental inflammation using anti-NGF or trkA-IgG decoy proteins diminishes ►hyperalgesia associated with inflammation.

NGF directly modulates afferent activity via binding of trkA on sensory nerve terminals. TrkA activation stimulates SP and CGRP expression on transcriptional and translation levels. Peptide release following sensory afferent depolarization results in ►neurogenic inflammation [►see Vasko essay]. NGF signaling is also important for increased activity of ion channel

G

proteins involved in neural transmission in inflammatory conditions. Increased NGF enhances expression and activity of the transient receptor potential vanilloid 1 (TRPV1) receptor. Through trkA binding, NGF can potentiate TRPV1 activity by regulating phosphorylation of TRPV1 using mechanisms that include the serine/threonine kinases PKC and PKA, calcium/calmodulin-dependent kinase II and the tyrosine kinase c-src. TRPV1 activation is required for the development of thermal hyperalgesia associated with inflammation. NGF also increases activity of other channel proteins that affect afferent sensitivity that include acid sensing ion channel 3 (ASIC3), voltage-gated sodium channels and a receptor for bradykinin, an inflammatory mediator peptide that increases in inflamed tissue. Thus, NGF enhances the activity of neurons by sensitizing receptors (e.g. TRPV1, BK receptors), increasing their responses to thermal and chemical (capsaicin) stimuli, protons (ASIC3, TRPV1) and neuromodulator peptides (CGRP, SP and bradykinin).

NGF-mediated changes in channel, receptor and peptide expression are likely to contribute to the thermal and mechanical hyperalgesia that is induced in rodent and human subjects following NGF injection. In healthy humans, subcutaneous injection of recombinant NGF produces thermal hypersensitivity within 30 min and mechanical sensitivity within hours. Intravenous injection of NGF produces a mild to moderate muscle pain in a dose-dependent manner. Local injection of NGF had a greater effect, producing hyperalgesia at the injection site that at high doses persisted for several weeks. Thus, long-term changes in sensory processing occur in response to changes in growth factor signaling. These effects were more pronounced in women and may underlie, at least in part, sex-related differences in pain sensitivity [see ►Shinal and Fillingim essay].

Experimental manipulations in which anti-NGF strategies are used to reduce or prevent pain have been successful. Blockade of NGF/trkA signaling has been found effective, particularly in models of inflammation. In current human clinical trials, an anti-NGF compound is being tested on subjects as a means to prevent chronic osteoarthritis pain. NGF has also been used in clinical trials in attempt to reverse diabetic associated peripheral neuropathies that include numbness, loss of thermal sensation and abnormal tingling sensation [3]. Injection of NGF caused localized sensitivity, but no overall beneficial effect in sensory perception was recorded. However, topical NGF has successfully been used for treatment of degenerative corneal disease resulting from changes in trigeminal nerve innervation [4].

## Neurotrophins and Central Sensitization

The inflammation-associated sensitization of primary afferents by NGF can also impact spinal transmission and lead to ►central sensitization [see ►Sandkühler essay]. In response to peripheral inflammation and increased NGF expression, nearly all trkA-expressing sensory neurons increase expression of the neurotrophin BDNF. Subsequent anterograde transport and activity-dependent release of BDNF from dense-core vesicles in terminals that project to the superficial dorsal horn leads to sensitization of spinal neurons (and generally to ascending pain pathways). Centrally released BDNF binds trkB receptors expressed on spinal interneuron and projection neuron populations. Binding activates trkB receptors, leading to subsequent phosphorylation and activation of several signaling pathways. Importantly, trkB activation stimulates activity of excitatory NMDA glutamate receptors. In this manner BDNF/trkB signaling acts to potentiate central glutaminergic transmission and increase nociceptive transmission. BDNF can also modulate central pain pathways by increasing descending pain facilitation at the level of the rostroventral medulla.

## GDNF-Family Ligands and Nociceptor Function

In addition to neurotrophin growth factors, members of the GDNF family may also have roles in sensory neuron pain signaling. Similar to neurotrophins, GFLs are important for development and postnatal differentiation of various sensory neuron subpopulations. GDNF and neurturin support development of Ret-expressing DRG neurons that are peptide poor and bind IB4. Artemin supports a subpopulation of Ret-positive neurons that express CGRP and SP peptides and the TRPV1 and TRPA1 channels. Artemin responsive neurons, although expressing Ret and its GFRα3 co-receptor, also express trkA and are therefore responsive to NGF.

In comparison to NGF, the role of the GDNF-family ligands in afferent sensitization and pain signaling in the adult nervous system is much less understood at this time. In neuropathic pain, intrathecal application of GDNF reduced thermal and mechanical sensitivity associated with peripheral nerve injury [5]. Artemin injections also reduced behavioral hyperalgesia associated with nerve injury [6], although in another study, no effect on pain behavior was reported [7]. These different outcomes may relate to the animal model, dosage and/or delivery approaches used.

GDNF-family members appear to have a role in inflammatory pain signaling. In a rodent inflammatory pain model (Complete Fruend's Adjuvant, CFA), anti-GDNF proteins decreased hyperalgesia associated with inflammation [8]. In humans, artemin and its receptor GFRα3 were significantly over-expressed in chronic pancreatitis [9]. Expression was related to the degree of neural hypertrophy, pain severity and inflammatory infiltrate. In animal studies, footpad skin injected with the inflammatory compound CFA caused a tenfold rise in artemin mRNA [10]. In addition, injection of artemin (or

GDNF or neurturin) in footpad skin caused a transient (<24 h) increase in behavioral thermal sensitivity. Co-injection of artemin and NGF, which both increase in CFA inflammed tissue, led to prolonged heat hyperalgesia lasting up to 7 days. Thus, traumatic or chronic insults resulting in a combined increase in NGF and artemin may produce long-term effects on noxious thermal sensitivity.

In summary, growth factors in the neurotrophin and GDNF families have profound effects on the development, differentiation and functional properties of sensory afferents that transmit painful stimuli. Although their principal effect appears to be at the primary afferent level, accumulating evidence supports an important role at the spinal cord level as well.

# Growth Inhibitory Molecules in Nervous System Development and Regeneration

Gerlinde A. Metz, Jamshid Faraji
Canadian Centre for Behavioural Neuroscience, Department of Neuroscience, University of Lethbridge, Lethbridge, AB, Canada

## Definition

Growth inhibitory and repulsive guidance molecules are major regulators of neural pattern formation and nervous system stability. Repulsive guidance molecules are expressed to direct growing axons or dendrites to appropriate targets during development. Neurite growth inhibitors are mainly found in central nervous system (CNS) myelin, where they are thought to support connective stability. After injury, however, neurite growth inhibitors may restrict regeneration and plasticity, thus impeding functional recovery.

## Characteristics

### Mechanisms of Axo-Dendritic Guidance

During development of the nervous system, multiple molecular signals participate in the formation of neuronal networks. Once a cell has migrated from the site of origin to its final location, the goal is to establish connections with one or more appropriate target structures, including other neurons. These connections are established by sending out axons and dendrites, the neuron's processes for transmitting and receiving information, respectively. Axons and dendrites have the task to select correct targets, which can be far away from their location in the brain. Both, cell migration and the formation of complex connection patterns among a large number of neurons are accomplished by finely tuned interactions of a variety of guidance molecules. Among these molecules, repulsive guidance cues and growth inhibitors have raised particular interest because of their clinical relevance.

The Spanish histologist Santiago Ramón y Cajal was one of the first to hypothesize that chemical signals in the cell environment play a fundamental role in guidance of axons and dendrites to the appropriate target cells. It is now clear that it is the coordinated

action of chemoattractive and chemorepulsive signals that supply the directional information to pathfinding axons and dendrites. The final decision whether a signal has attractive or repulsive effects is made by the growth cone, the dynamic actin-supported apparatus at the tip of the extending neurite [1]. The growth cone interprets guidance signals that are present in the surrounding by translating the message into changes in intracellular levels of second messengers, such as cyclic nucleotides. A reduction in cyclic nucleotide levels in the growth cone, for instance, can switch an attractive response to a repulsive one [1,2]. In addition to the roles of repulsive signals, their receptors, and their intracellular signal transduction have recently been redefined as more complex than previously thought.

The responses to repulsive cues range from deviation in growth direction to the collapse and retraction of the growth cone. Cell repulsion requires rapid changes in actin filaments and microtubules while downregulating adhesion to other cells and to the extracellular matrix that surrounds these neurons. The repulsive molecules can be bound to the surface of cell membranes or to the extracellular matrix, operating by contact at short distances, or they can be soluble, thereby acting as long-distance cues via a ►chemical gradient. The directed growth of neurites to their targets over long distances suggests that the correct targets produce chemotactic signals that diffuse towards receptive neurons, thus generating gradients along which growth cones orient their direction of growth.

## Repulsive Molecules Guide Axons to Their Targets During Development

A number of molecules with repulsive action have been implicated in axo-dendritic guidance. The four most prominent candidates are the conserved families of ►semaphorins, ►netrins, ►slits and ►ephrins. Interestingly, many repulsive molecules, including semaphorins and netrins, can exert bifunctional effects depending on age and type of neuron. Thus, growth cones can respond differently to a specific guidance molecule at different stages during nervous system development. For example, semaphorins, a family of secreted and transmembranal proteins, can either promote or reduce neurite outgrowth. Semaphorins were originally identified as repulsive guidance signals [3], however, they can also function as chemoattractants with important roles in developmental and pathological processes. The attractive activity stimulates growth and orients neurites toward an increasing semaphorin concentration, while the repulsive activity orients neurites toward a decreasing semaphorin concentration. In the latter case, interaction with the two components of semaphorin receptors, plexin and neuropillin, regulates cytoskeletal changes that lead to detachment from the substratum and subsequent growth cone deflection or even repulsion. Thus, semaphorins are able to antagonize axonal regeneration after injury, particularly in the CNS. Interestingly, in the peripheral nervous system (PNS) semaphorin mRNA levels become downregulated upon injury, which then provides a permissive environment for regeneration. In addition to limiting regenerative axon growth, semaphorins have been suggested to mediate ►apoptosis, a form of ►programmed cell death.

During development of the nervous system, apoptosis serves to optimize connections and pattern formation by elimination of surplus neurons. It is estimated that about half of the original cell population in the nervous system is eliminated by apoptosis. The classic view is that erroneous axons die as a result of a limited supply of neurotrophic substances, which are provided by the target cells upon formation of synaptic contacts. Thus, only neurons with synaptic connections to appropriate target cells survive. Recent findings, however, indicate that apoptosis not only occurs as a consequence of an unsuccessful competition for neurotrophic factors, but also in response to local high concentrations of repulsive guidance molecules. Excessive levels of molecules such as semaphorin3A might relay a cell death signal to neighboring neurons and determine their survival. Even in adulthood, the presence of high levels of repulsive molecules can expose susceptible neuron populations to unfavorable conditions and eventually cause cell death.

The observation that repulsive guidance molecules may act as neuronal death factors has also been made for proteins of the netrin family, which historically were the first chemotropic guidance molecules identified. Netrins determine neuronal survival by inducing cell death in regions of insufficient netrin-1 concentration. Netrins carry out their attractive and repulsive functions by interacting with two receptors, the deleted in colorectal cancer (DCC) and the uncoordinated-5 (UNC-5) receptors, respectively. Recently, DCC and UNC5H have been named dependence receptors because they promote neuronal survival, differentiation or migration in the presence of a ligand, and initiate or amplify apoptosis in the absence of ligand availability [4]. Indeed, DCC appears to directly interact with specific caspases, the key enzymes in the cascade of apoptosis. The conditional induction of apoptosis may represent a mechanism to determine neuronal fate during pathfinding and the elimination of neurons during development.

Aside from inducing apoptosis, the classic role of netrins during development is to act as bifunctional signals with attractive and repulsive consequences, depending on the type of neuron. Based on these functions, netrins play a vital role in embryonic midline development at various CNS levels in animals with bilateral symmetry. For example, netrin-1 is expressed in the floor plate, a structure of the neural tube

separating the left and right components of the basal plate to organize midline symmetry. The floor plate stimulates and directs outgrowth of commissural axons along a long-range gradient toward the ventral midline. At the same time, netrin-1 acts as a repellant to provide a barrier for specific axons that must not cross the midline. For fine-tuning the projection patterns of specific axon populations, netrin-1 cooperates with other guidance molecules, including slit proteins. Slit proteins are expressed by the floor plate at the brainstem level, where they delimit motoneuron trajectories, while their receptor roundabout (Robo) is expressed by dorsally projecting motoneurons. Thus, the slit-Robo system selectively prevents dorsally, but not ventrally projecting motoneurons from crossing the midline of the hindbrain. The graded presence of guidance molecules that directs growth cones might be driven by graded expression patterns of transcription factors, such as observed in the optic system.

In the optic system of lower vertebrates, axons of retinal ganglion cells encounter several choice points in their pathway. In one of them, the midline chiasm, retinal ganglion cell axons either cross or avoid the midline and project to the optic tectum in topographic order. The key molecule in directing these axons to form a topographic array is ephrin-B, a member of the membrane-bound ephrin family. B-type ephrins participate in patterning of retinal ganglion cells through attractive actions along a nasal-temporal gradient, which is complemented by repulsive actions of A-type ephrins for anterior-posterior topographic mapping. The effect of guidance molecules such as ephrins on a specific population of neurons, such as retinal ganglion cells, depends on the presence of the respective receptors. For example, B-type ephrins in the mouse chiasm exert repulsive actions on those retinal ganglion cells that express the receptor EphB1 but not on others. Thus, many guidance molecules of restricted expression patterns in the nervous system, including netrin-1 and ephrin-B, can assume multiple and changing functions in neurite guidance [5].

Some of the guidance cues described above are diffusible to form chemical gradients that may influence the trajectories of extending neurites far away from the source of secretion. It is estimated that growth cones can detect gradients that differ by as little as 1–2% across their diameter. In other cases, guidance cues are substrate- or membrane-bound and act on nearby axons. Repulsive substrate-bound molecules, such as extracellular matrix proteins and myelin-associated glycoproteins, can also lead to collapse of the growth cone upon contact. When they cause retraction of the growth cone, they are referred to as neurite growth inhibitors. Many of the growth inhibitory proteins appear as the CNS matures, hence their presence bears considerable clinical importance.

## Neurite Growth Inhibitors Limit Axonal Regeneration in the Adult CNS

When brain and spinal cord of higher vertebrates mature, axonal growth becomes increasingly restricted. This lack of spontaneous axonal growth limits ►regeneration and repair after acquired neurological injury. The failure of adult CNS regeneration is not due to an intrinsic lack of regenerative ability because axons are able to extend if a permissive environment is provided, such as a peripheral nerve explant [6]. This has led to the hypothesis that the local environment provided by the adult CNS determines the degree of spontaneous axonal growth. Aside from a low availability of neurotrophic factors in the mature CNS and injury-induced scar formation, the presence of growth inhibitors seems to be a major factor in limiting axonal extension. It is assumed that these inhibitory proteins provide connective stability in the mature CNS, however, the lack of axonal regeneration after injury represents a considerable clinical challenge.

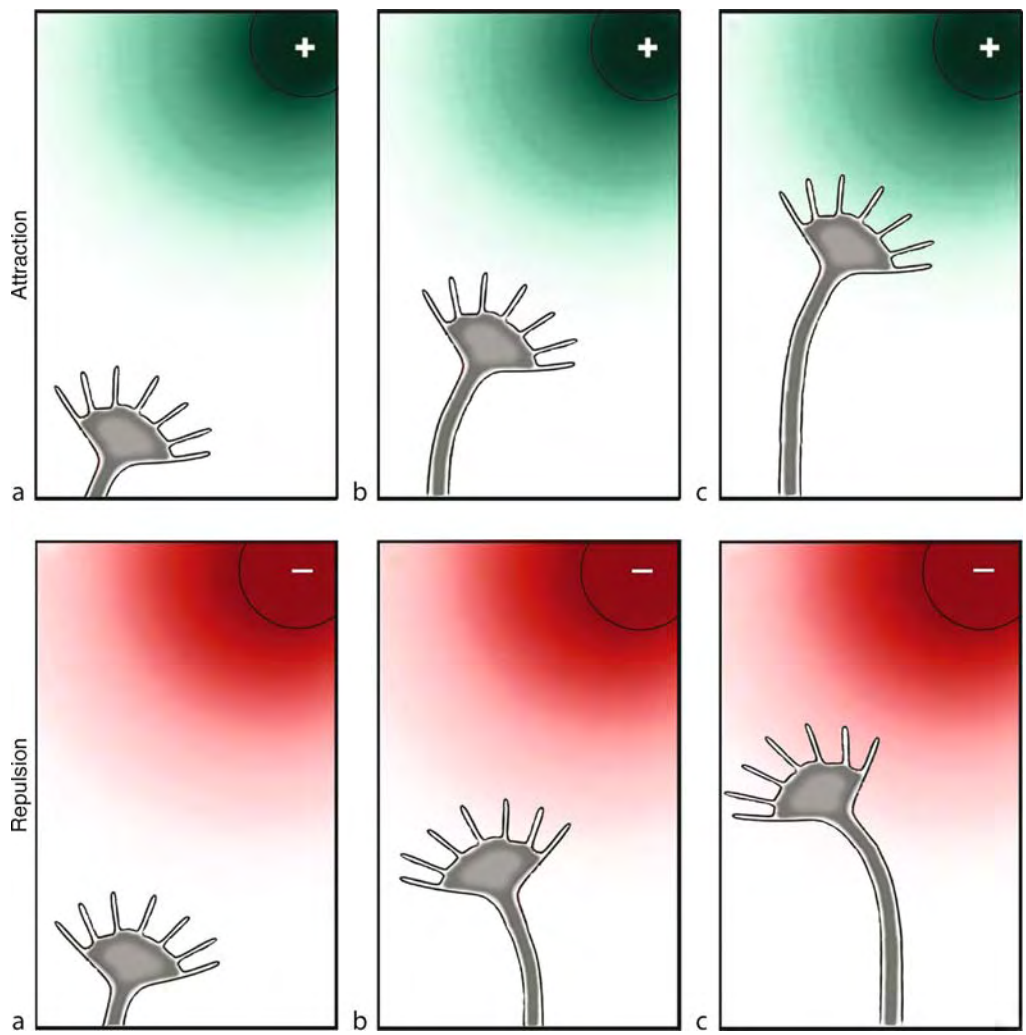
The limited regrowth of the injured adult CNS in higher vertebrates, as opposed to the PNS or the immature CNS, is in part due to the appearance of inhibitory proteins associated with oligodendrocytes and myelin. Although the failure of the mature CNS to regenerate was already reviewed by Ramon y Cajal in 1928, it was not until the 1990s when the pioneering work of Martin Schwab and coworkers led to identification and isolation of inhibitory components of CNS myelin [7,8]. The finding of the inhibitory property of CNS myelin was supported by the observation that injured axons in young mammals fail to regenerate at an age when oligodendrocytes and myelin appear in white matter. Accordingly, if myelin formation and oligodendrocyte differentiation were prevented by x-irradiating the spinal cord in rats, severed corticospinal axons were able to regenerate at a much higher age.

Purification and biochemical characterization of the inhibitory constituent of rat CNS myelin revealed two active protein fractions with molecular weights of 35 and 250 kD. These very potent neurite growth inhibitors were called NI-35 and NI-250, respectively. *In vitro* assays showed that the application of ►NI-35/250 proteins to cultured neurons causes growth cone collapse and strongly inhibits neurite outgrowth. Experiments using an antibody directed against the inhibitory fraction of myelin, called IN-1, permitted axons to regenerate in the CNS environment. When injected into living animals with spinal cord injury, the IN-1 antibody treatment allowed long-distance growth of injured axons and compensatory sprouting of intact fibers. These structural changes were accompanied by improved functional recovery.

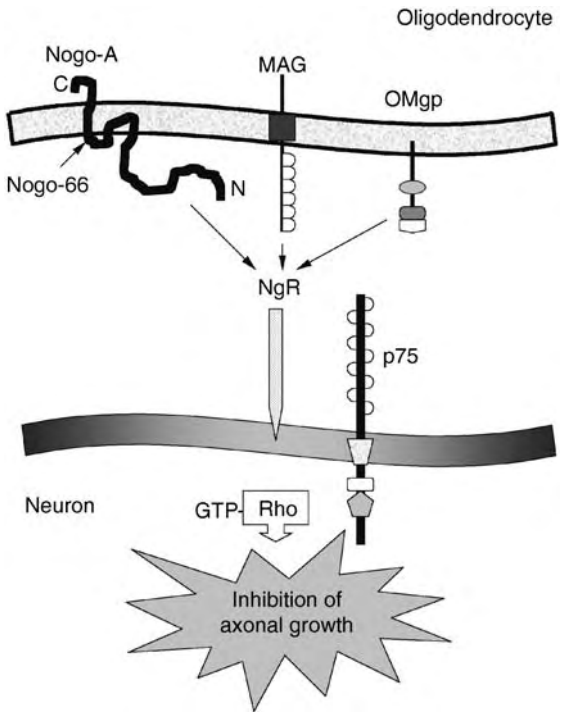
The antigen of IN-1, ►Nogo, was cloned and three distinct isoforms were identified, with Nogo-A being the predominant CNS isoform. Nogo-A likely

corresponds to NI-250, while Nogo-B may correspond to the NI-35 protein fraction. Nogo-C is the shortest splice variant of the full-length Nogo-A sequence. All three isoforms belong to the family of reticulon proteins. Nogo-A mediates its inhibitory activity via an amino-terminal domain and an extracellular 66 amino acid sequence (Nogo-66). Both Nogo-66 and the amino-terminus of Nogo-A have been shown to induce growth cone collapse and inhibit axonal extension. Accordingly, the application of an antagonist for the axonal Nogo-66 receptor (NgR, a multisubunit receptor complex [7,9]) was found to prevent the growth inhibitory effects of Nogo-A and promote sprouting of severed axons, re-formation of synapses in target areas and enhanced functional recovery.

It is interesting to note that, besides Nogo-A, other neurite growth inhibitory myelin proteins might also bind to the NgR complex, including oligodendrocyte-myelin glycoprotein and myelin-associated glycoprotein. Myelin-associated glycoprotein, a transmembrane molecule and comparatively minor constituent of myelin, binds to the NgR complex with high affinity and prevents neurite outgrowth. Knockout mice deficient of myelin-associated glycoprotein display behavioral disturbances and anatomical findings confirmed its role in maintaining axon stability and regulating



**Growth Inhibitory Molecules in Nervous System Development and Regeneration. Figure 1** Navigation of a growth cone responding to chemoattractive and chemorepulsive guidance cues. As the growth cone approaches a target emitting an attractive signal, it responds by turning and growing toward the target (upper panel, a–c). If the growth cone perceives a signal as repulsive, it will grow away from its source (lower panel, a–c).



**Growth Inhibitory Molecules in Nervous System Development and Regeneration. Figure 2** A number of major inhibitors of neurite growth, including the extracellular domain of Nogo-A (Nogo-66), myelin-associated glycoprotein, and oligodendrocyte-myelin glycoprotein are associated with CNS myelin. All three molecules interact with a multisubunit receptor complex comprising the Nogo receptor (NgR) and p75. The signal transduction cascade involves Rho GTPase, a member of the Rho family of small guanosine-5′-triphosphate (GTP) binding proteins. Rho is active in the GTP-bound state and involved in gene transcription, regulation of cytoskeletal structure, cell fate, and survival (adapted from [7]).

axonal outgrowth. Interestingly, myelin-associated glycoprotein is not only expressed by CNS oligodendrocytes but also by PNS Schwann cells. To explain that the PNS nevertheless provides a growth-permissive environment, it has been proposed that myelin-associated glycoprotein is cleared more rapidly after injury to peripheral nerves.

Aside from Nogo, oligodendrocyte-myelin glycoprotein, and myelin-associated glycoprotein, a fourth group of inhibitory proteins, chondroitin sulfate proteoglycans, can also be associated with myelin. Yet, these extracellular matrix components are mostly found in reactive astrocytes. Reactive astrocytes are responsible for the formation of a glial scar after CNS injury, which represents a major barrier to regenerating axons [10]. Because expression of chondroitin sulfate-carrying proteoglycans increases after CNS injury, recent studies have investigated the potential for destroying scar tissue or preventing its formation in the first place for promoting axonal regeneration. On the other hand, chondroitin sulfate-carrying proteoglycans assume a role as axon guidance molecules during development. This again illustrates the multifarious roles of repulsive and ▶growth inhibitory molecules in the developing and mature CNS.

## Therapy

The complex distribution of guidance molecules and the orchestrated balance between their repulsive and attractive actions on growing neurites allows the formation of highly complex neuronal circuits. The identification of guidance and inhibitory molecules is particularly exciting for the discovery of new therapeutic strategies to promote regeneration of axons after injury. Strategies that are currently explored include altering the response of growing axons to inhibitory molecules by abrogation of the inhibitory property of myelin or preventing glial scar formation by pharmacological means. Many neurite growth inhibitory molecules exert redundant actions thus providing a back-up plan for nervous system stability. Thus, it seems likely that a combinatorial approach directed against several growth inhibitory proteins and the simultaneous addition of growth-promoting signals might be most promising. These new therapeutic avenues will be essential for promoting axonal regeneration and functional recovery following CNS injury.

## Growth-associated Protein

Protein, involved in regulating the processes required for outgrowth and/or elongation of the injured axon.

►Neuronal Changes in Axonal Degeneration and Regeneration
►Regeneration

## GTPases

### Definition

Members of a large diverse family of enzymes that bind and hydrolyze guanosine triphosphate (GTP), also known as guanosine-5′′-triphosphate. GTPases play an crucial role in the signal transduction from the intracellular domain of many transmembrane receptors including neurotrophic receptors.

►Neurotrophic Factors in Nerve Regeneration

## Guanylate Cyclase

### Definition

Guanylate cyclase is a lyase enzyme that converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). There are both soluble and membrane bound forms of guanylate cyclase.

## Guidance Cue

### Definition

Guidance cue is any type of molecule that influences growth cone pathfinding. There are four main types of guidance cues: long-range attractants (diffusible attractants), long-range repellents (diffusible repellents), short-range attractants (substrate-bound attractants), and short-range repellents (substrate-bound repellents). These cues can provide positional information for axon guidance. In the developing embryo, the various guidance cues act together to coordinate the pathfinding of growing neurites influencing the proper wiring of the mature nervous system.

►Growth Cones

## Guillain-Barré Syndrome

### Definition

A type of idiopathic polyneuritis in which autoimmunity to peripheral nerve myelin leads to a condition characterized by chronic demyelination of the spinal cord and peripheral nerves.

## Gustation

### Synonyms

Both the Oxford English and the American Heritage dictionaries define gustation as “the act or faculty of tasting,” thus defining the concepts of gustation and taste as synonymic. However, as described in the following text, the term “gustation” has recently been used to define a broader concept [1] which includes, but is not limited to, taste

## Definition

Gustation is the multisensory process that allows for the selection of nutrients and rejection of irritating and/or toxic compounds. The process starts when a motivated animal searches and detects a desired food, usually using visual and/or olfactory cues. When consumption is initiated, flavor, the unitary sensory perception resulting from the taste, odor, texture and temperature of a substance that is placed in the mouth, will be a central contributor in the decision-making relative to ingestive behavior [2].

Feeding decisions are also impacted by the physiological context in which they are made and, thus, are not entirely stimulus-dependent. We know today that the central nervous system detects a multitude of peripheral neural and humoral signals reflecting several aspects of homeostatic balance, namely gastrointestinal status, current energy needs and availability, and energy stores. The regulation of energy homeostasis and maintenance of stable body weight depends on the integration of these signals with orosensory feedback, and the ability to respond adequately through the modulation of both energy expenditure and food intake [3].

The appearance and familiarity of a particular food, given the memory of the orosensory, olfactory and post-ingestive effects of previously encountered identical or similar substances, will influence the decision of ingestion [4]. Emotional, cognitive and social factors are also relevant. These observations underline that, when trying to understand food seeking and ingestion, one should consider not only sensory and homeostatic factors but also others such as motivation, learning and decision-making [5,6].

Data obtained by recording neural ensemble activity in awake animals has demonstrated not only that neural populations, distributed across several cortical and subcortical brain areas, can encode the multisensory properties of intra-oral stimuli, but also that this coding is modulated by physiological state [3]. Consequently, it has been proposed that gustatory processing must be considered in a multimodal perspective, combining the several sensory, homeostatic, affective and learning processes that occur in association with taste receptor activation. According to this view, gustation results from a distributed neural process by which information conveyed to the brain through specialized taste, oral somatosensory, olfactory and gastro-intestinal neural pathways is integrated with humoral signals, thus allowing the organism to feed in accordance with the maintenance of adequate energy homeostasis [1,7].

## Characteristics

### Peripheral Gustatory System

The peripheral gustatory system extracts multisensory information from foods placed in the mouth, and conveys this information through multiple neural pathways to brainstem structures. Taste receptor cells (TRC's), are responsive to the type and quantity of chemicals dissolved in the saliva and allow for the detection of several primary taste qualities: salt, sweet, bitter, umami (savory taste of amino acids), and sour (acidic). Information about most relatively water-insoluble compounds, as well as food texture, weight and temperature, is primarily transduced by specialized somatosensory neurons with endings distributed throughout the oral epithelia [1]. When this system is impaired, symptoms such as ►ageusia, ►hypogeusia, ►hypergeusia or ►dysgeusia or ►hyposmia are frequent. The subjective complaint of 'loss of taste' is commonly associated to hyposmia given perception of flavor.

#### *Taste Receptor Cells*

In vertebrates, TRC's are found in specialized taste organs – the taste buds. Mammalian taste buds are onion-shaped cell clusters that are embedded at the surface of several intra-oral structures, mainly the palate and tongue, where they cluster in macroscopic structures named gustatory papillae. TRC's extend distally into the bud pore where they present microvillar processes to contact with sapid chemical stimuli in the mouth. Taste receptors are transmembrane structures found on these microvilli and are the basis for the chemosensory properties of TRC's since, upon detection of a specific stimulus, they will activate intracellular transduction cascades to initiate the process of gustatory neural signaling [8].

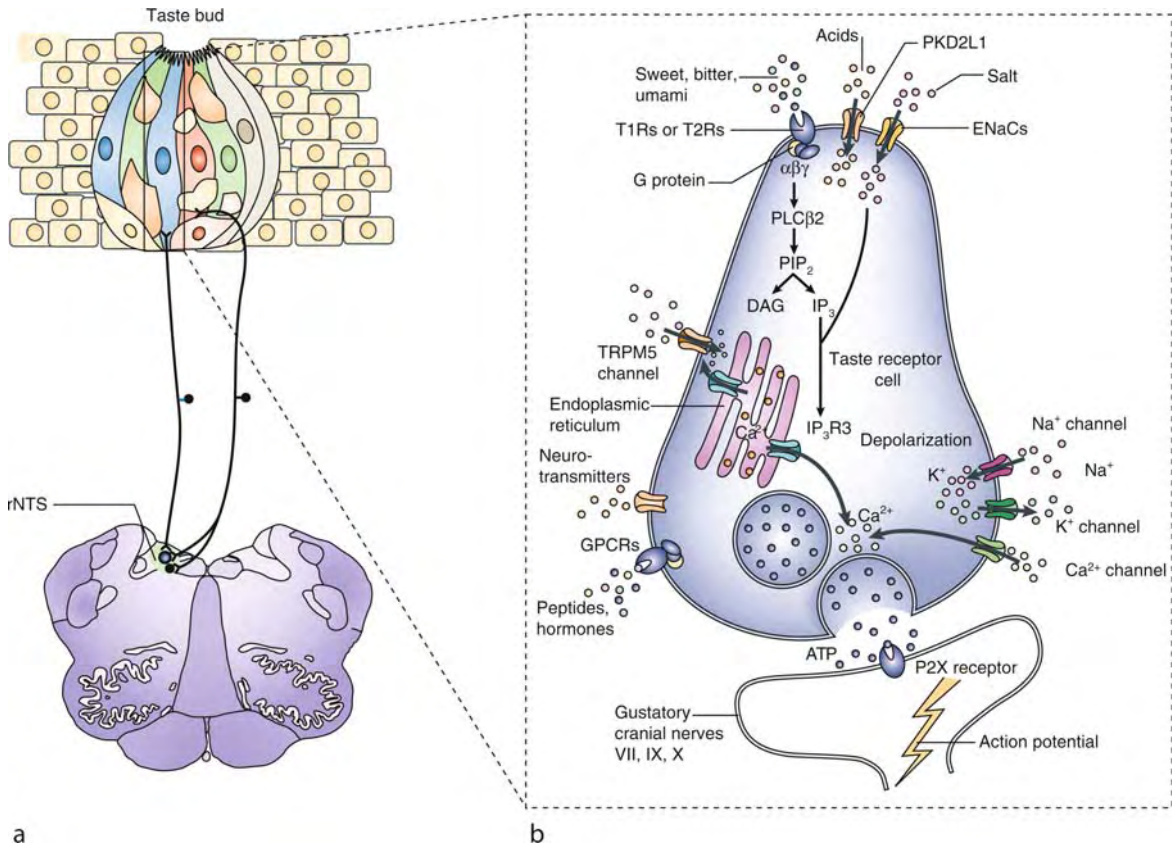
Proteins belonging to the G-protein-coupled receptor (GPCR) superfamily have been established as receptors for sweet tastants (T1R2/T1R3 receptors), amino acids (T1R1/T1R3 receptors) and bitter tastants (T2R receptors). The predominant downstream signalling pathways for these receptors require two common elements: TRPM5, a transient receptor potential ion channel that is activated by intracellular calcium, and phospholipase PLCβ2. There is also evidence implicating gustducin, a G-protein almost exclusively expressed in TRC's, in bitter taste transduction. Sour and salt (NaCl) taste qualities seem to rely on a different set of receptors and signaling pathways. Recently, cells expressing a member of the TRP ion channel family, the polycystic-kidney-disease-like ion channel PKD2L1, were shown to be necessary for sour taste transduction. While the molecular mechanisms for human peripheral salt taste transduction are more controversial, in rodents an amiloride-sensitive sodium channel, ENaC, accounts for part of the transduction of NaCl [8].

Taste receptors for sweet, bitter, umami and sour have been found to be present in largely segregated populations of cells. Additionally, perception of a particular taste quality, more than the property of

a specific tastant–taste receptor interaction, seems to reflect the selective activation of the TRC population expressing a particular taste receptor which is, in itself, sufficient to generate specific behavioral programs [8]. It therefore seems clear that, at the TRC level, sweet, bitter, umami and sour taste pathways are segregated (Fig. 1).

### *Peripheral Gustatory Nerves*

TRC's transmit information to the Central Nervous system (CNS) through primary sensory neurons that terminate centrally in the nucleus of the solitary tract (NTS) of the medulla. Taste buds are innervated by primary sensory neurons from branches of the facial (VIIth), glossopharyngeal (IXth) and vagal (Xth) cranial nerves. The chorda tympani and greater superior petrosal branches of the facial nerve carry sensory axons of cells in the geniculate ganglion and innervate taste buds respectively in the anterior tongue and palate. Sensory axons of the ►glossopharyngeal nerve, with cell bodies in the petrosal ganglion, terminate in taste buds in the posterior tongue (lingual branch) and



**Gustation. Figure 1** Illustration of a taste bud, taste receptor cell and associated neurons. (a) Depiction of a taste bud embedded in epithelial tissue. TRCs sample the intra-oral space through the taste pore, where they are connected by tight junctions that separate the membrane of each TRC into two distinct domains: the apical membrane, in direct contact with the external milieu, and the basolateral membrane, below the tight junctions and bathed by interstitial fluid. TRCs are color-coded according to "best-response" to a specific tastant quality. Primary gustatory neurons project ipsilaterally to the rNTS. (b) Diagram of a TRC and respective synapse with a primary gustatory neuron. The apical membrane of the cell contains receptors for tastants dissolved in the saliva. G-protein-coupled receptors (GPCRs) for sweet, bitter and umami tastant detection activate intracellular signal transduction cascades involving PLCβ2 (a phospholipase C) and TRPM5, a transient receptor potential ion channel on the basolateral membrane. Ion channels involved in salt (ENaCs) and, possibly, sour (PKD2L1) tastant detection are also shown in the apical cell membrane. Other GPCRs and ion channels, shown on the TRC basolateral membrane, are responsive to peptides, hormones and neurotransmitters that modulate responses to tastants. TRC activation culminates in the release of neurotransmitters, namely ATP, from intracellular vesicles to synapses with primary gustatory nerves, here shown with a post-synaptic purinergic P2X receptor. Note that taste receptors and signal transduction molecules described above are not necessarily expressed in the same TRC (see text for details) (adapted from Simon et al. Nat Rev Neurosc, 2006).

pharynx (pharyngeal branch). The nodose ganglion of the vagus nerve contains primary gustatory neurons with axons that integrate the pharyngeal, superior laryngeal and internal laryngeal branch of the vagus nerve to innervate taste buds in the epiglottis, larynx and oesophagus [1].

In addition to taste fibers, the vagal and glossopharyngeal nerves contain general sensory fibers from the oral and upper digestive mucosa, as does the trigeminal (Vth) cranial nerve, allowing for the transduction of information relating to the temperature and texture of ingested stimuli. The vagal nerve also carries visceral sensory nerve fibers from the gastrointestinal (GI) tract and abdominal viscera.

Some intra-oral somatosensory nerve endings have chemosensing properties, as exemplified by the responses of the thermo-sensitive TRPV1 and TRPM8 channels respectively to capsaicin (found in chilli peppers), producing a burning sensation, and menthol, producing a cooling sensation. Trigeminal fibers are also activated by high concentrations of the same chemical stimuli that define some primary tastants, such as NaCl, usually producing irritating sensations. On the other hand, physical variables may affect TRC taste transduction function, as evidenced by thermal modulation of sweet taste intensity. Thus it becomes clear that, even at the periphery, input to the gustatory system is inherently multisensory [1].

## Central Gustatory Neural Pathways

The central taste pathway has strong anatomical and functional connections with the viscero-sensory system, which transmits information about the internal state of the organism, particularly at the NTS, where peripheral taste neurons synapse on second order ascending taste neurons. In rodents, second-order projections arising from the NTS ascend mostly ipsilaterally as a component of the central tegmental tract terminating in the parabrachial nuclei (PbN) of the pons. In turn, the PbN projects to the parvicellular subdivision of the ventral posterior medial nucleus of the thalamus (VPMpc), which then projects to the primary gustatory cortex (GC) in the insular cortex. In primates, there is a direct projection from the NTS to the thalamus, bypassing the PbN [9] (Fig. 2).

### *Nucleus of the Solitary Tract*

Chemosensory information, derived from all taste-responsive cranial nerves, converges on the rostral division of the NTS (rNTS). Trigeminal somatosensory inputs from oral branches of the fifth nerve also project to regions of NTS innervated by primary sensory taste neurons. A second subdivision of the nucleus, the caudal NTS (cNTS), is the main target of visceral (vagal and glossopharyngeal) afferent inputs. These convey information from baroreceptors, chemoreceptors, osmoreceptors and nociceptors from thoracic and abdominal viscera, including the GI system.

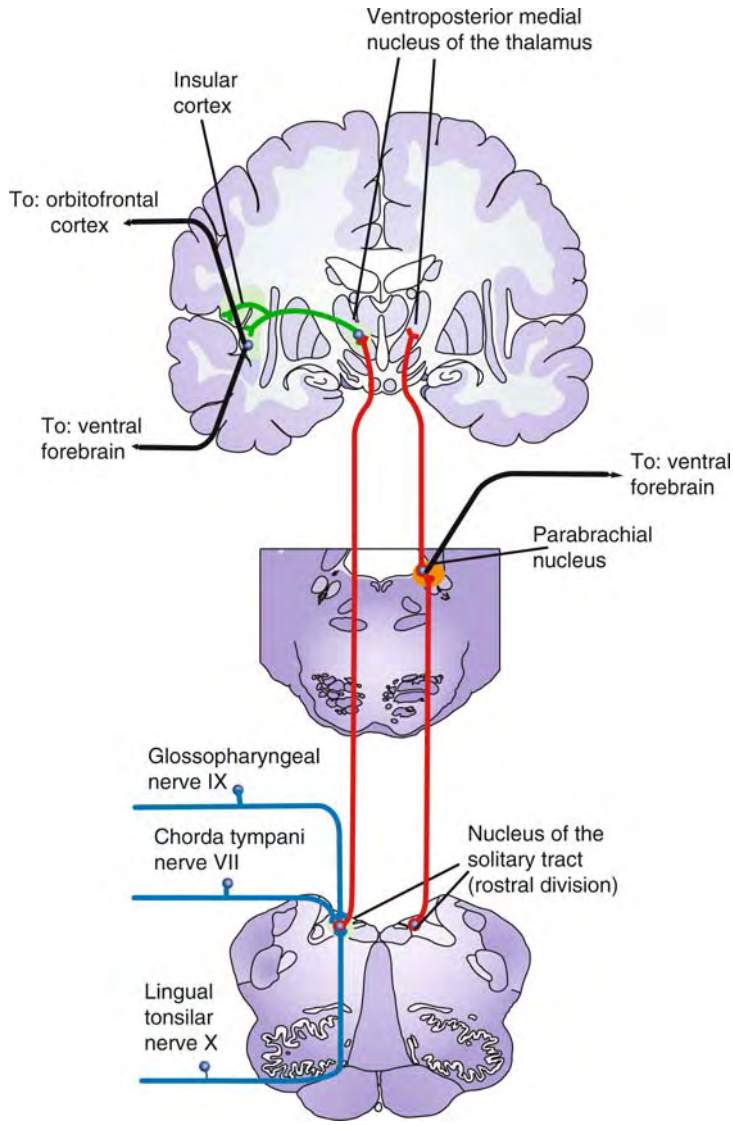
Trigeminal stimulants with irritating effects can modulate taste responses in the rNTS, as does afferent vagal activity such as that produced by gastric distention. The rNTS is also a target of descending forebrain projections from the GC, prefrontal cortex, central nucleus of the amygdala (AMYce), lateral hypothalamus (LH), bed nucleus of the stria terminalis and substancia innominata. In fact, electrical stimulation of the GC has been shown to modulate processing and transmission of neuronal responses to tastants in the rNTS. The NTS thus offers the first opportunity for neural signals derived from the somatosensory and GI systems and other CNS centers to modulate incoming taste information [1].

Taste stimulation activates the afferent limb of a variety of somatic motor and visceromotor reflexes (appetitive or aversive) that accompany eating and drinking. The NTS has local medullary connections with a number of brainstem motor nuclei, either directly or through interneurons in the reticular formation, such that chronic decerebrate rats display both acceptance and rejection behaviors to oral stimulation with tastants. These projections to adjacent somatic and visceral premotor/motor areas are responsible for reflexes involved in chewing (motor nucleus of the trigeminal nerve), tongue movement (hypoglossal nucleus), salivation (superior and inferior salivatory nuclei), swallowing (nucleus ambiguus) and GI motility and secretion (dorsal motor nucleus of the vagal nerve) [9].

### *Parabrachial Nuclei*

The parabrachial complex is a collection of nuclei located in the dorsolateral aspect of the pons. The PbN is physically divided into medial and lateral subdivisions by fibers of the superior cerebellar peduncle. In rodents, ascending neural pathways from the rNTS include an obligatory synapse in the ipsilateral medial division of the PbN. Ascending visceral afferent projections arising from the cNTS terminate primarily in nuclei of the lateral subdivision [9].

Similarly to the rNTS, the PbN is a target of descending forebrain projections and taste-responsive neurons in this location have been shown to be modulated by electrical stimulation of forebrain sites. From the PbN, third order neurons project to several forebrain systems, forming two gustatory projection systems. The thalamocortical system, with synapse in the VPMpc nucleus of the thalamus, terminates in the GC. The ventral forebrain system includes PBN projections to several structures in the limbic forebrain, namely the LH, AMYce, bed nucleus of the stria terminalis and substancia innominata, thus establishing a subcortical loop between brainstem primary gustatory



**Gustation. Figure 2** Anatomy of the principal central gustatory pathways. Taste-specific information is conveyed by cranial nerves VII, IX and X (blue lines) to the rNTS (rostral division of the nucleus tractus solitarius) in the medulla. In primates, fibers (red lines) from second-order taste neurons in the rNTS project ipsilaterally to the VPMpc (parvicellular part of the ventroposterior medial) nucleus of the thalamus. Shown in orange is the PbN (parabrachial nucleus) of the pons that, in rodents, is a relay for rNTS afferents and projects third-order fibers to the VPMpc. Thalamic efferents (green lines) project to the insula, defining the primary gustatory cortex (GC) which, in turn, projects (black lines) to the orbitofrontal cortex (OFC), sometimes defined as a secondary cortical taste area. Cortical gustatory regions also project to areas of the ventral forebrain, such as the amygdala, that in rodents, also receive ascending gustatory projections from the PbN, (adapted from Simon et al, Nat Rev Neurosc, 2006).

areas, namely the NTS and PbN, and motivational and reinforcement-related areas in the ventral forebrain, such as the mesolimbic dopaminergic system.

In primates, including humans, NTS projection fibers have not been shown to project to the PbN and synapse directly in the VPMpc. Thus, input to the PbN is essentially viscerosensory, the bulk of the projections from PbN are directed towards the ventral forebrain and the VPMpc receives most of its gustatory input directly from the NTS [9].

### *Parvicellular Ventroposterior Medial Nucleus of the Thalamus*

The VPMpc is the relay for orosensory information in the dorsal thalamus. Ascending gustatory projections to the thalamus are bilateral such that VPMpc neurons

will respond bilaterally to combinations of chemosensory and/or somatosensory oral stimulation.

### Gustatory Cortex

In macaques the primary GC, as defined by VPMpc thalamic efferent projections, corresponds to the frontal operculum and adjoining insula, extending rostrally to the caudolateral orbitofrontal cortex (OFC). In rodents, VPMpc projects to the agranular insular cortex, which is exposed on the lateral convexity of the brain just dorsal to the rhinal fissure. In addition, there are projections from the LH and AMY to the cortex that overlap the inputs from VPMpc.

The caudolateral OFC, sometimes defined as a secondary taste cortical area, receives converging projections from the GC and primary olfactory cortex, relevant for the perception of flavor, and is also connected to visual areas in the inferior temporal cortex [2,10] (Fig. 2).

Cortical chemoresponsive neurons (in the GC and OFC) have descending projections to subcortical structures in the ventral forebrain that also receive ascending projections from PbN and NTS. The insula (INS), where the GC is found, projects to the AMY, which in turn projects to the basal forebrain, LH, substantia nigra pars compacta (SNpc) and ventral tegmental area (VTA), the latter being the origin of the mesolimbic dopaminergic projection to the Nucleus Accumbens (NucAcb), a part of the ventral striatum. In turn, the OFC projects to the ventral striatum, LH and AMY, and these subcortical structures are also mostly interconnected. The described connections constitute part of a highly complex circuit that is proposed as the basis for the integration of multisensory gustatory input with factors relating to homeostatic and reward signaling, general arousal, directed motivation and neuronal effector mechanisms for motor, autonomic and endocrine responses [4–7].

## Gustatory Coding in the Central Nervous System

There are at least two opposing views regarding the neuronal representation of taste. The labeled-line model proposes that individual cells are tuned to respond to single taste modalities while in the across fiber models overlapping populations of cells and fibers are proposed to encode information relating to each taste quality. Some authors have also argued that temporal coding has a part to play in representing taste-specific information in both the NTS and cortex. While in the periphery the labeled-line model seems to reflect the coding scheme [8], it is nonetheless clear, from neural recordings in both rodents and monkeys, that NTS and GC taste neurons are preferentially broadly tuned, suggesting that the CNS codes for each taste quality via distributed population responses [1,7].

In addition to chemosensory-specific broadly tuned neurons, the GC contains neurons that integrate taste, somatosensory and olfactory information. In the monkey, OFC neurons also exhibit multisensory responses, with cells responding to combinations of taste, olfactory, somatosensory and visual stimuli [10] while, in the rat, they have been shown to rapidly modulate their firing rate as a function of spontaneous licking clusters, as well as in response to tastants. Given the described broad tuning and multisensory responses of single neurons in multiple brain sites, the existence of a distributed central gustatory code is likely to reflect the coding scheme in these higher centers [1].

Modulation of gustatory responses in higher brain centers by the animal's physiological state is also well documented. Lower firing rates during satiety phases is suggested by functional neuroimaging findings of decreased activity levels in the LH, OFC, AMY and INS when satiation is compared to hunger or thirst. Electrophysiological investigations performed on alert monkeys are consistent with imaging studies and have revealed a large population of neurons in the OFC, AMY, and LH that respond to food when the animal is hungry but whose activity is greatly reduced when the animal becomes satiated. Recently, it has also been shown that satiety-modulated responses of individual neurons in the LH, OFC, AMY and GC differ across the feeding cycle, with increases and/or decreases in firing rate at each phase of the cycle (satiety or hunger). However, when single neuron responses are combined as a population, they translate with much greater accuracy the neuronal processes controlling feeding behavior across hunger-satiety cycles, with population firing rates correlating with a behavioral measure of the animal's motivation to feed [3]. The importance of considering a distributed gustatory code was thus demonstrated.

## Conclusions

The current obesity epidemic and the prevalence of eating disorders such as anorexia and bulimia nervosa have made the understanding of how the central nervous system regulates feeding behaviors a central theme in biomedical neuroscience research. The central gustatory system, viewed as a distributed brain circuit that integrates peripheral sensory information from multiple sensory modalities with neuroendocrine and gastrointestinal homeostasis-related signals, is thus a central concept in ingestive behavior research. A systems level approach, integrating neurophysiology from multiple brain areas in awake and freely-feeding animals with complimentary neurochemical and/or metabolic measurements, is essential to allow for further advances in this field, especially when this approach is used in conjunction with genetic or pharmacologic manipulations.

►Circumvallate Papillae

# Gustatory Receptor

## Definition

Gustatory receptors are chemoreceptors in lingual taste buds that signal in response to the different basic tastes.

Transmission within the gustatory system occurs via the facial, the glossopharyngeal and vagal (VII, IX and X) cranial nerves.

## Synonyms

Alpha-gustducin; α-Gustducin; Alpha subunit of gustducin

## Definition

The term gustducin is sometimes used to indicate the α subunit of a heterotrimeric G protein. However, the polypeptide should be correctly referred to as α-gustducin or to the α subunit of gustducin, a regulatory heterotrimeric guanine nucleotide ►(GTP) binding protein (G protein). α-Gustducin is defined by the nucleotide sequence of its gene (Official full name: guanine nucleotide binding protein, α transducing 3 (gnat-3)), or mRNA (GenBank accession number, X65747) or by the amino acid sequence of the polypeptide (Swiss-Prot accession number, P29348).

## Characteristics

### Quarternary Structure of α-Gustducin

α-Gustducin forms together with the inhibitory G protein α subunits, Gαz, and the ►transducins, one major family of G protein α subunits. Other families are $G_s$, $G_o$, $G_q$, and $G_{12}$. It assembles with the β/γ dimer into a heterotrimeric G protein. As all other G protein α subunits, α-gustducin cycles between a GTP bound and a GDP bound form. Activation by receptors leads to GDP–GTP exchange. The GTP bound form can interact with cellular effector molecules. The GDP–GTP exchange also triggers the release of the β/γ dimer that can also engage in signaling functions. Intrinsic ►GTPase activity hydrolyzes GTP to GDP and terminates the activation cycle. α-Gustducin displays a GTPase domain and a helical domain. The N-terminus and the GTPase domain contain the interaction sites for receptors, effectors, and the β/γ dimer while the helical domain may engage in modulating effector activity. Like other $G_i$ protein α subunits, α-gustducin appears to be acylated close to the N-terminus by myristate and possibly by palmitate [1]. These modifications appear to be critical for membrane association of the polypeptide.

### Discovery and Expression of α-Gustducin

α-Gustducin has been discovered by an attempt to identify the G protein α subunits involved in vertebrate ►taste transduction [2]. Degenerate oligonucleotides used as primers in polymerase chain reaction amplification protocols with rat taste tissue cDNA allowed the identification of an mRNA of about 1.7 kb encoding a novel G protein α subunit of 354 amino acids, i.e., α-gustducin. The mRNA for α-gustducin has been found specifically in taste tissue, i.e., in a subset of ►taste receptor cells in lingual epithelium but not in nonsensory lingual epithelium or various other tissues. ►Taste receptor cell specific *α-gustducin* gene expression is apparently regulated by an 8.4 kb segment that contains a 1.4 kb minimal ►promoter and an upstream ►enhancer element [3]. α-Gustducin received its name from the close sequence homology to the visual G protein subunits, the ►α-transducins, and its putative role in ►gustation. Later on, more detailed studies detected expression of α-gustducin in various tissues that are not involved in gustation, such as the ►olfactory and ►vomeronasal epithelium, intestine, colon, airways, and spermatozoa.

### The Functional Roles of α-Gustducin in Taste Transduction

Convincing evidence for a role of α-gustducin in taste transduction comes from studies of gene-targeted mice. These animals showed impaired behavioral and electrophysiological responses to the bitter stimuli denatonium benzoate and quinine as well as to the sweet stimuli sucrose and SC45647, whereas their responses to the sour stimulus, HCl, and salty stimulus, NaCl, were not affected [4]. Moreover, transgenic expression of rat *α-gustducin* driven by the 8.4 kb promoter fragment in gustducin null mice fully rescued the impaired responses to both bitter and ►sweet taste stimuli of these animals [3]. These results strongly suggest that α-gustducin plays a crucial role in sweet taste and ►bitter taste, but not in salty taste (►Salt taste) or ►sour taste. The role of α-gustducin in bitter taste was also strongly supported by a combination of physiological recordings and immunohistochemistry, demonstrating that many but not all taste receptor cells containing α-gustducin responded to bitter stimuli [5]. Further support comes from *in situ* hybridization and immunohistochemistry studies showing that α-gustducin colocalizes with TAS2R bitter ►taste receptors or TAS1R sweet ►taste receptor subunits but not with candidate salty or sour taste receptors. Together these findings also firmly support the long held conjecture that sweet and bitter taste are elicited through activation of ►G protein-coupled receptors while salty and sour taste are thought to be elicited through activation of membrane ►ion channels. Later, two-bottle preference and brief-access taste tests as well as nerve recordings in wild-type and *α-gustducin* knockout mice together with histochemical studies that colocalized α-gustducin and the umami receptor subunit TAS1R1 in taste receptor cells indicated a role for α-gustducin also in ►umami taste.

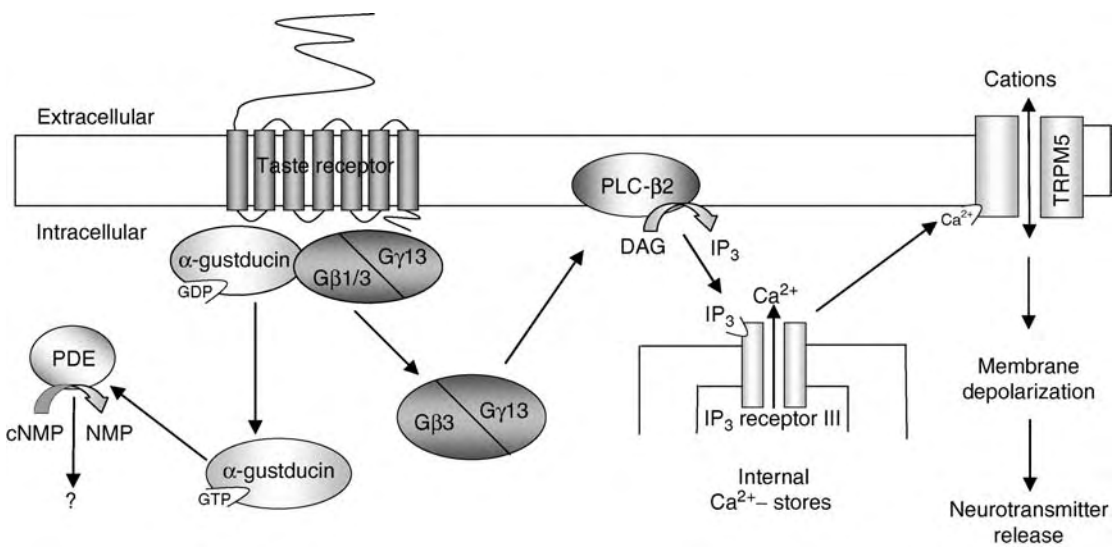
## Signal Transduction of Gustducin

Although above data clearly point to a critical role of α-gustducin in taste, its signal transduction properties are less understood. The high homology of α-gustducin to the α-transducins of visual transduction suggested that both G proteins may be functionally similar or even equivalent. This assumption was reinforced by the notion that the sequence homology was particularly high in regions that mediate coupling to the receptor or effector molecules. In fact, recombinant α-gustducin purified from insect cells closely resembled ►α-transducin with respect to the interactions with the receptor, bovine ►rhodopsin, the effector, bovine retinal cyclic GMP

G

phosphodiesterase, and bovine brain and retinal G protein β/γ-dimers. Also, the rhodopsin-catalyzed GDP–GTP exchange rate and the intrinsic GTPase activity of both G proteins were very similar. This functional similarity is supported by the presence of α-transducin in taste receptor cells and the finding that transgenic expression of α-transducin under the *α-gustducin* gene promoter in a α-gustducin null background partially rescued the taste deficits of these animals [6]. On the basis of these structural and functional similarities, it has been proposed that α-gustducin functions in taste transduction in analogy to α-transducin that modulates phosphodiesterase activities in visual transduction. This assumption was supported by the identification of two types of phosphodiesterases in taste tissue and the demonstration that α-gustducin couples to ►calmodulin-sensitive type I phosphodiesterases in vitro. In parallel, it has been demonstrated that several bitter compounds decreased cyclic nucleotide levels in taste tissue preparations, an effect that depended on the action of α-gustducin. This pathway could alter the activity of cyclic nucleotide regulated kinases or gated ion channels. Although evidence has been obtained for the presence of cAMP, ►protein kinase A, and a ►cyclic nucleotide gated channel in taste tissue, the physiological importance of taste stimulus-decreased cyclic nucleotide levels has not been uncovered yet (Fig. 1).

Various other studies (reviewed in [7]) demonstrated that bitter substances stimulated the generation of ►inositol trisphosphate ($IP_3$) fully consistent with the observations that α-gustducin colocalizes with type III ►$IP_3$ receptor in taste cells and that a specific phospholipase C (PLC) inhibitor blocked the response. Polymerase chain reaction amplification experiments of taste tissues with degenerate primers identified the β2 isoform of PLC. Antibodies against PLC-β2 blocked the denatonium-stimulated rise in $IP_3$. Finally, *PLC-β2* gene-targeted mice lost or substantially impaired their responses to bitter, sweet, and umami stimuli, demonstrating the crucial role of this enzyme in taste transduction. The PLC-β2 isoform appears to be activated by the β/γ subunits of $G_{i/o}$-type G proteins, i.e., G protein families to which also α-gustducin belongs. PLC-β2 shows, however, little sensitivity for activation by G protein α subunits. Differential screening of cDNA libraries from single taste receptor cells for the β/γ subunits that couple to α-gustducin resulted in the isolation of Gβ1 and Gβ3 and of the novel G protein γ subunit, γ13. Antibodies raised against these three G protein subunits blocked the response of mouse taste tissue preparations to the bitter substance denatonium benzoate. As the action of the anti-β3 antiserum appeared to be more robust than that of the anti-β1 antiserum, it has been suggested that the predominant gustducin composition in taste tissue may be α-gustducin/Gβ3/Gγ13 and that α-gustducin couples taste receptors via β1/γ13 or β3/γ13 to PLC-β2 activation (Fig. 1). Recently, another member of the gustducin-initiated signal transduction cascade has been identified, i.e., the ►transient receptor potential channel TRPM5. TRPM5 appeared to be sensitive to several cellular components, but particularly to the rapid changes in the intracellular calcium concentration. The importance of TRPM5 was demonstrated by



**Gustducin. Figure 1** Proposed role of α-gustducin in taste transduction. For details, see text. cNMP, cyclic nucleoside monophosphate; NMP, nucleoside monophosphate; PDE, phosphodiesterase; DAG, diacyl glycerol; $IP_3$, inositol trisphosphate.

gene targeting experiments in mice that showed loss of or largely diminished responses to bitter, sweet, and umami stimuli (Fig. 1).

## Coupling of α-Gustducin to Taste Receptors

Biochemical studies using competing blocking peptides and bovine taste membranes or solubilized fractions thereof found that various bitter substances coupled α-gustducin to phosphodiesterases [8]. This action depended also on the presence of purified β/γ subunits. The data suggested that the unknown bitter taste receptors present in the membrane preparation are members of the superfamily of G protein-coupled receptors and physically interacted with the G protein α subunit. Later on, direct activation of α-gustducin has been monitored through an activation-dependent change in protease sensitivity. Following cloning of the bitter taste receptors, it has been demonstrated that stimulation of the receptor mTAS2R5 by its agonist cycloheximide led to α-gustducin activation in an *in vitro* system reconstituted from insect cell membranes. In similar experiments also a number of human bitter taste receptors have been coupled to the G protein α subunits of $G_{i1}$, $G_o$, and ►transducin. This suggests that not only α-gustducin but also other $G_i$-type subunits couple to bitter taste receptors. Characterization of the interaction of the receptor with α-gustducin revealed that the carboxy-terminal 44 amino acids of the G protein α subunit as well as the ultimate C-terminal region were of importance. In line with this finding, a chimeric G protein comprising of the N-terminal region of Gα16 and the aforementioned 44 amino acids of α-gustducin allowed the functional coupling of many bitter taste receptors to PLC in transfected cell lines [7]. In similar experiments, a G protein chimera containing five carboxy-terminal amino acid residues common to α-gustducin, transducin-1 and -2, and $G_{i\alpha1}$ and $G_{i\alpha2}$ coupled the sweet taste receptor to PLC activity. Together, the findings suggest that α-gustducin is intimately involved in taste transduction but that aspects of taste signaling rely on other G protein α subunits.

## α-Gustducin in nontaste Tissues

In addition to its role in taste transduction, evidence is emerging that α-gustducin fulfils additional functions [9,10]. α-Gustducin expression has been observed in the nasal and vomeronasal epithelium, in cells that resemble solitary ►chemosensory cells of nonmammalian vertebrates. These cells also express some bitter receptors, but apparently no sweet or umami receptor subunits. The findings suggest that, in analogy to its role in the warning function of bitter transduction, α-gustducin, in the nasal respiratory epithelium, protects the animals from the aspiration of noxious substances. A similar role it may have in ►chemoreceptor-like laryngeal cells and cells of the airway epithelium.

Within the gastrointestinal tract, α-gustducin has been detected in brush cells of the stomach, duodenum, and pancreas. Also other taste signaling molecules have been found in these tissues and intestinal cell lines, suggesting that information about the chemical content of the alimentary canal is being sampled and used to regulate gastrointestinal physiology. The clearest example currently available may be the role of α-gustducin in sweet taste receptor-mediated glucose absorption through apical glucose transporter 2.

Other sites of α-gustducin expression are the spermatozoa, suggesting a role for this polypeptide also in reproduction. Most likely, in the near future, researchers will detect α-gustducin in more tissues and unravel the numerous aspects of its physiological importance.

►Gustducin

## Gut Activities

### Definition

Gut activities are commonly subdivided into motility, digestion and absorption. The main gut function is to digest food materials and absorb nutrient substances into the bloodstream. Motility refers to gut movements, mixing gut contents and propelling the contents along the gut. Digestion and absorption can be more effectively performed by the proper assistance of these movements.

## GVS

►Galvanic Vestibulospinal Responses

## Gymnophiones

### Definition

Gymnophiones are one of three orders of living amphibians (order Gymnophiona). These amphibians may also be referred to as "apodans" or "caecilians."

These are relatively rare (compared to the number of species in the other two groups, the anurans and urodeles) and very specialized organisms. Gymnophiones lack limbs and limb girdles and tend to have shortened, compact skulls. These are adaptations for the lifestyles as burrowing fossorial creatures or organisms adapted for wet semiaquatic habitats. Less is known about this group of amphibians than any other.

►Evolution of the Brain: Amphibians

## Gyrification

### Definition

Gyrification refers to the formation or gyri (Greek for bent or curved) by folding the cortex in the cerebral hemispheres into convolutions.

## Gyrus Rectus

### Synonyms

►Straight rectus

### Definition

A long gyrus situated on the basal surface of the frontal lobe and running parallel to the olfactory tract and terminating, towards the brain, in the parolfactory sulcus.

►Telencephalon

## Habenula

### Definition

The habenula (from Greek = habenulare, small rein) consists of the medial and lateral habenular nuclei, which are situated in the dorsal diencephalon of all vertebrates. The habenular nuclei together with the habenular commissure and pineal gland are also referred to as epithalamus. The habenular nuclei convey limbic forebrain information (from posterior septum, pallidum, lateral hypothalamus) to regulatory midbrain nuclei (interpeduncular nucleus, raphé, ventral tegmental area, laterodorsal and pedunculopontine tegmental nuclei). The habenular nuclei are thought to be involved in stress, maternal behavior, reward, and learning.

## Habit

### Definition

Daily activities or routine acquired to adjust oneself to environment. It is maintained by repeated automatically for a long period of one's life.

►Long-Term Memory

## Habit Formation

►Learning and Motivation

## Habituation

### Definition

Habituation is a simple form of non associative memory, common to all sensory systems, which is observed in animals, including humans. It consists of a progressive decrease in behavioral and physiological responses to a given stimulus, initially significant, which accompanies the repeated exposure to this stimulus in absence of occurrence of any biological reinforcing event. The decrease in the subject's response is clearly specific to the stimulus to which the animal was repeatedly exposed, since the same response remains releasable by an other sensory cue. Habituation allows filtering of weakly significant informative cues or predictable events and seems to involve higher-order processing, as opposed to receptor adaptation. Habituation can be distinguished from adaptation or fatigue by dishabituation (response is immediately recovered by a novel or noxious stimulus) or by examining the rate of recovery following different interstimulus intervals. It thus is a reversible process, the habituated stimulus keeping the possibility to become again significant, for instance by conditioning.

►Learning
►Sensory Plasticity and Perceptual Learning
►Learning and Motivation

## Habituation/Dishabituation Test

### Definition

In the habituation/dishabituation test, the investigation of a stimulus, such as an odor, decreases on repeated presentation of the stimulus as the response habituates.

If a different stimulus is then presented, and if it can be discriminated from the habituated stimulus, the amount of investigation it elicits will be increased, i.e. the response dishabituates. This is a sensitive test of the ability of an animal to discriminate two stimuli, which has the advantage that no prior training is required.

However, a disadvantage of the task is that the animal needs to be motivated to investigate the stimuli. For instance, male mice will readily investigate and discriminate urine from female mice in different

reproductive states in a habituation/dishabituation test, but not artificial odors or odorants that have no meaning to them.

►Memory – Odor

## Habituation of Taste Neophobia

### Definition

Non-associative learning that leads to increased consumption of familiar tastes that were not followed by aversive visceral consequences in previous presentations.

►Conditioned Taste Aversion

## Hair Cell Organ

►Electroreceptor Organs

## Hair Cells

### Definition

The mechanoelectrical transducers of the auditory, vestibular and lateral-line systems of all vertebrate species.

►Cochlea
►Peripheral Vestibular Apparatus

## Hair Cells of Vestibular System

### Definition

Signal detecting sensory neurons in the cupula of the semicircular canals and the epithelium of the macula. These neurons are equipped with cilia on the apical surface that detect movements of the endolymph and the otolith and are contacted on the basal surface by afferent fibers of the VIIIth cranial nerve. The displacement of the cilia in preferred and non-preferred directions provokes a graded depolarization and hyperpolarization of the cells respectively, and a concomitant change of transmitter release.

►Peripheral Vestibular Apparatus

## Hairy Skin

### Definition

Skin covering the major portion of the body excepting the palms of hands, soles of the feet, the lips and borders of the genital and anal regions.

## Half-center

### Definition

A neuron or group of neurons that forms one half of a half-center oscillator. A half-center oscillator consists of two neurons or groups of neurons that are connected by reciprocal inhibitory connections, so that when one half-center is active activity in the other half-center is suppressed. A half-center oscillator can produce patterns of alternating activity that switch between the two half-centers in response to a general tonic excitation of both half-centers.

►Central Pattern Generator

## Hallucinogens

David E. Nichols
Department of Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN, USA

### Synonyms

Psychedelics; Psychotomimetics; Entheogens

## Definition

A precise definition of hallucinogens that would be universally accepted probably cannot be agreed upon. In the most general sense, hallucinogens produce an altered state of consciousness (ASC). They increase the intensity and lability of affective responses, and produce profound distortions of perceptual processes, including visual, auditory, somesthetic, and olfactory modalities. Marked alterations in mood, thought, and sensory perception also occur, including changes in the experience of time, space, and self that are rarely experienced otherwise except in dreams.

## Characteristics

Many different types of chemical classes are capable of producing altered states of consciousness. Although some of them occasionally have been referred to as hallucinogens, the focus in this essay is on those molecules whose primary mechanism of action is mediated by effects on serotonergic neuronal systems: the serotonergic hallucinogens.

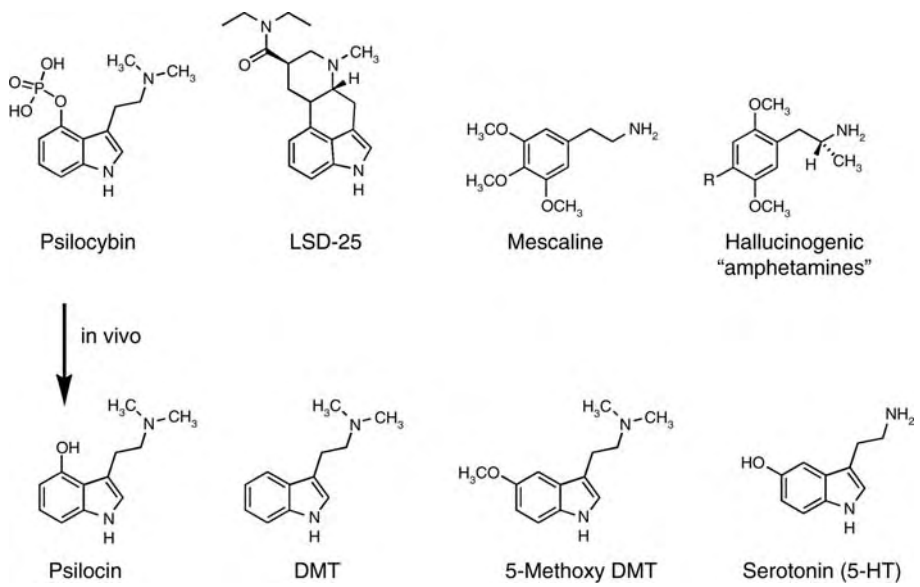
Hallucinogens are comprised of a group of prototypical compounds that includes mescaline, psilocybin, and LSD (Fig. 1).

Mescaline and psilocybin occur in nature, and are representatives of the ►phenethylamine and ►tryptamine classes of hallucinogens, respectively. They have a long history of folkloric use. LSD is a semisynthetic material prepared from lysergic acid, which is obtained by the hydrolysis of ►ergot alkaloids produced by species of the ergot fungus, *claviceps*.

Documented human use of hallucinogens dates back more than two millennia, and archeological artifacts suggest a role for them that predates written records. The vast history of human experience with hallucinogens was derived from the ingestion of plant-derived materials. Traditionally, hallucinogens were employed in sacramental and ritual contexts appropriate to a particular culture. Within the past century, however, the chemical constituents of these plants have been identified and studied. Armed with that knowledge, modern organic chemistry has provided potent synthetic hallucinogens for research that have become widely available and often have been used in nontraditional ways.

### Altered States of Consciousness

Quantifying altered states of consciousness was problematic in the early years of hallucinogen research. Today, however, there are validated instruments for assessing various aspects of consciousness. For example, Dittrich developed a questionnaire that is now widely used to measure altered states of consciousness (ASCs) produced by hallucinogens. The common constellations of effects produced by hallucinogens measured with this instrument lie in three primary dimensions: (i) "oceanic boundlessness" (OB), referring to positively experienced ego dissolution; (ii) "anxious ego-dissolution" (AED), including thought disorder and loss of self-control; and (iii) "visionary restructuralization" (VR), referring to perceptual alterations and altered meaning of percepts. Recent brain imaging studies have demonstrated that the degree to which each of these key dimensions of ASCs



**Hallucinogens. Figure 1** The chemical structures of the serotonin agonist type hallucinogens. Mescaline served as the lead compound for hundreds of other substituted phenethylamines, including the so-called hallucinogenic amphetamines. The natural neurotransmitter serotonin is illustrated for comparison to the indole-based hallucinogens, which include various tryptamines, as well as LSD.

is manifested is correlated with functional alterations in prefrontal, temporal, and parietal cortical regions, as well as the thalamus and basal ganglia.

Hallucinogens also produce dose-dependent cognitive impairments, including deficits in attention, working memory, and associative learning, while leaving executive functions essentially intact. Serotonergic hallucinogens also impair high-level but not low-level motion perception and reduce binocular rivalry rate and rhythmicity in a manner that parallels subjective changes in consciousness.

In general, the intensity of alterations of consciousness produced by hallucinogens is dose-dependent. High doses and/or particular circumstances can, however, lead to the perception of a completely nonordinary reality, transporting the user to unknown realms and worlds of apparent physical substance and reality. Responses to hallucinogens can vary widely, however, depending on the individual and the circumstances of use. Mood changes can range from pleasure to bliss, and feelings of oneness with the universe, to extreme anxiety, fear, and paranoid ideation more typical of a psychotic state. See [1] for a recent review.

## Chemical Structures

The classical serotonergic hallucinogens are comprised of a basic amino group, separated by two carbon atoms from an aromatic system. This motif reflects the fact that tryptophan and tyrosine are the biosynthetic precursors for serotonin and the other monoamine neurotransmitters. The two major classes of serotonergic hallucinogens are the phenethylamines and the tryptamines. The tryptamines can further be divided into the simple tryptamines and the tetracyclic ergolines that include LSD and related lysergic acid amides (Fig. 1).

## Phenethylamines

The simplest phenethylamine hallucinogen is mescaline, which occurs naturally in the peyote cactus, *Lophophora williamsii*. It is the only naturally-occurring phenethylamine hallucinogen presently known. Although it has relatively low potency, mescaline has served as a molecular template for the chemical synthesis of hundreds of structural modifications. These substituted phenethylamines have been essential to understanding the structure-activity relationships of this class, as well as being instrumental in mapping the topography of the 5-$HT_{2A}$ receptor binding domain.

An early modification of the simple phenethylamines involved adding an alpha-methyl group to the side chain. These compounds are often referred to as "hallucinogenic amphetamines." They are more potent than the corresponding phenethylamine and generally have a longer duration of action. Most phenethylamines are much more potent than mescaline, with durations of action ranging from a few hours to 24 h or more.

## Tryptamines

The tryptamines bear close structural resemblance to the neurotransmitter serotonin. A number of these substances are found in nature, but a number of synthetic compounds also have been synthesized and tested. The simplest is *N,N*-dimethyltryptamine (DMT), which is found in a number of plant species, and also has been detected in human cerebrospinal fluid. It is not active orally due to degradation by monoamine oxidase (MAO) in the liver, and is usually smoked or injected, with brief but powerful effects lasting 15–30 min. Ayahuasca, or yagé, is an orally active preparation containing DMT that has been used by Indians of the Amazonian basin in Brazil. It is a decoction made from two plants, *banisteriopsis capii*, a source of beta-carboline alkaloids, and DMT-containing species such as *psychotria viridis*. The beta-carbolines include harmine, harmaline, and tetrahydroharmine, and are reversible MAO-A inhibitors. It is believed that ayahuasca has pharmacological activity because the harmala alkaloids inhibit the MAO in the liver that would normally deaminate DMT following oral ingestion.

Another naturally-occurring tryptamine, 5-methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT), is found in *virola* species that grow in central and South America. The exudate from the inner bark surface of these trees is dried and finely ground to produce a powerful snuff called epená. The effects of 5-MeO-DMT are very short lasting, usually less than 30 min.

Psilocybin, a phosphorylated tryptamine, is produced by species of the *psilocybe* fungus ("magic mushrooms"). In contrast to DMT and 5-MeO-DMT, psilocybin is orally active, and has a 4–6 h action. Serum phosphatases remove the *O*-phosphate from psilocybin to reveal psilocin, the actual pharmacologically-active molecule [2].

## LSD and Other Ergolines

The tetracyclic ►ergoline *N,N*-diethyllysergamide (lysergic acid *N,N*-diethylamide; LSD; LSD-25) is the most potent of the known hallucinogens. A 0.10 mg oral dose of the tartrate salt produces effects lasting 8–10 h. LSD is semi-synthetic, prepared by the condensation of (+)-lysergic acid with diethylamine. Lysergic acid itself is obtained through basic hydrolysis of ergot alkaloids (e.g. ergotamine), which are obtained from any of a variety of *Claviceps* (ergot) species.

## Pharmacology in Animals

The early recognition that both LSD and serotonin were constructed with the same tryptamine scaffold led to hypotheses that LSD affected brain serotonin neurotransmission. Not surprisingly, studies in the 1950s clearly demonstrated that hallucinogens had profound effects on brain serotonin systems. After radioligand binding techniques were developed in the

1970s it was discovered that hallucinogens bound with high affinity to specific serotonin receptor subtypes and subsequently that all the chemical classes of hallucinogens activate serotonin 5-$HT_{2A}$ receptors, a Gαq-coupled member of the G-protein-coupled receptor family.

## Serotonin Receptor Mechanisms

Early on it was found that LSD and tryptamine hallucinogens suppressed cell firing in the dorsal raphe nucleus, a group of midbrain cell bodies with extensive serotonergic projections to the forebrain. The correlation between raphe cell firing and general level of vigilance, and the cessation of firing during REM sleep, were intriguing phenomena that seemed consistent with raphe cells as targets for the hallucinogens. Nonetheless, some molecules that suppressed raphe firing were not hallucinogenic, and conversely, some hallucinogens did not directly suppress raphe cell firing.

Behavioral studies in animals ultimately revealed that blockade of the 5-$HT_{2A}$ receptor abolished the effects of hallucinogens. These receptors were found localized postsynaptically on cortical cells. Clinical studies recently have demonstrated that the selective 5-$HT_{2A}$ receptor antagonist ketanserin essentially abolished the psychopharmacological effects of psilocybin in human volunteers, the most compelling and conclusive proof of 5-$HT_{2A}$ receptor mediation of the effects of hallucinogens [3].

Nevertheless, experimental studies in animals indicate that LSD and other tryptamines may have subtle psychopharmacological properties that could be attributed to their agonist actions at other receptors. Although the phenethylamine hallucinogens appear to act solely or principally at serotonin 5-$HT_{2A}$ receptors, they also potently activate 5-$HT_{2C}$ receptors, an effect with unknown consequences.

All of the tryptamines, including LSD, in addition to being agonists at 5-$HT_{2A}$ and 5-$HT_{2C}$ receptors, also are agonists at the 5-$HT_{1A}$ receptor subtype. Stimulation of somatodendritic serotonin 5-$HT_{1A}$ receptors attenuates raphe cell firing, with the consequence that tonic 5-HT activation at all levels of forebrain is reduced; it would be surprising if that effect had no psychopharmacological consequences.

From a pharmacology perspective LSD is unique among the hallucinogens. It is a nonspecific pharmacological agent, with potent agonist actions at a variety of other monoamine receptors, including the 5-$HT_4$, 5-$HT_5$, 5-$HT_6$, and 5-$HT_7$ receptors, as well as the dopamine $D_2$-like family of receptors. It has been speculated that the high potency of LSD, compared to other hallucinogens, results from some as yet unknown synergistic effect at one of these ancillary receptors. Nevertheless, sufficient data exist to make the argument that activation of the 5-$HT_{2A}$ receptor is a necessary, but perhaps not sufficient condition for producing hallucinogenic effects.

## Receptor Signaling

The 5-$HT_{2A}$ receptor is principally coupled to $G\alpha_q$ proteins, stimulation of which leads to activation of PLC, and the production of ▶diacylglycerol (DAG) and inositol phosphates as second messengers. Nonetheless, a good correlation does not exist between behavioral effects in animal models and the ability to activate this signaling pathway. It has been suggested that a better correlation may exist between hallucinogenic potency and the production of arachidonic acid [4]. This signaling appears to arise through a complex pathway coupled to the 5-$HT_{2A}$ receptor by $G\alpha_{i/o}$ proteins [5]. In addition, at short times after receptor activation, the endocannabinoid ▶2-arachidinoyl glycerol (2-AG) is also produced, although there is no apparent relationship between 2-AG production and hallucinogenic activity.

Activation of 5-$HT_{2A}$ receptors by hallucinogens also leads to increased extracellular levels of glutamate, and enhances delayed glutamate release from thalamocortical terminals [6]. This glutamate spillover was found to be mediated by blockade of Kv1.2-containing K + channels [7]. One model proposed by these authors suggests that a retrograde messenger is produced that is capable of blocking these channels. Arachidonic acid, one of the second messengers produced by 5-$HT_{2A}$ receptor activation, blocks Kv1.2 in expression systems and at least one member of the high-voltage-activated Kv3 family.

The mechanistic picture that seems to be emerging is that postsynaptic activation of 5-$HT_{2A}$ receptors in cortical pyramidal cells leads to production of second messengers that cause membrane depolarization (which does not lead to cell firing), as well as the release of eicosanoids (e.g. arachidonic acid) that may serve as retrograde transmitters to enhance network activity in the prefrontal cortex through a phasic increase in glutamate spillover [8].

## Anatomical Locus of Action

After postsynaptic 5-$HT_{2A}$ receptors were identified as the likely primary target for hallucinogens, a search for these sites in the brain revealed that they were highly expressed on apical dendrites of cortical pyramidal cells, particularly in layer V of the cortex. High expression also was observed on interneurons that were presumably inhibitory GABAergic fibers. 5-$HT_{2A}$ receptor stimulation promotes cortical arousal and substantially increases the gain of layer 5 pyramidal neurons in rat PFC [9]. In addition, 5-$HT_{2A}$ receptors are expressed in areas of the thalamus and the reticular nucleus of the thalamus. Expression in all of these areas is consistent with a mechanism that involves disruption of sensory gating and corticothalamic circuits [1, 10].

PET imaging studies in humans using $H_2O$-PET have shown increased blood flow in the frontomedial cortex extending into the anterior cingulate, dorsolateral,

insular, and temporal cortices (Fig. 2). Decreased blood flow was observed in areas important for gating or integrating cortical information processing such as bilaterial thalamus, right globus pallidus, bilateral pons, and cerebrum. Psilocybin alters brain activation in such a way as to increase cognitive and affective processing in the context of reduced gating and reduced focus on external stimulus processing (unpublished data from F.X. Vollenweider). Interestingly, the discriminative stimulus produced by LSD in rats has been found to be localized within the anterior cingulate cortex.

## Gene Activation

A number of genes have been identified that are upregulated by LSD. Recently one group has proposed that upregulation of Krox20 (egr2) may be a specific effect of hallucinogens, at least in the mouse. Interestingly, they also demonstrated that upregulation of this transcript results from activation of a Gαi/o G protein, also implicated in the studies of arachidonic acid production by Kurrasch-Orbaugh et al. [4], cited earlier.

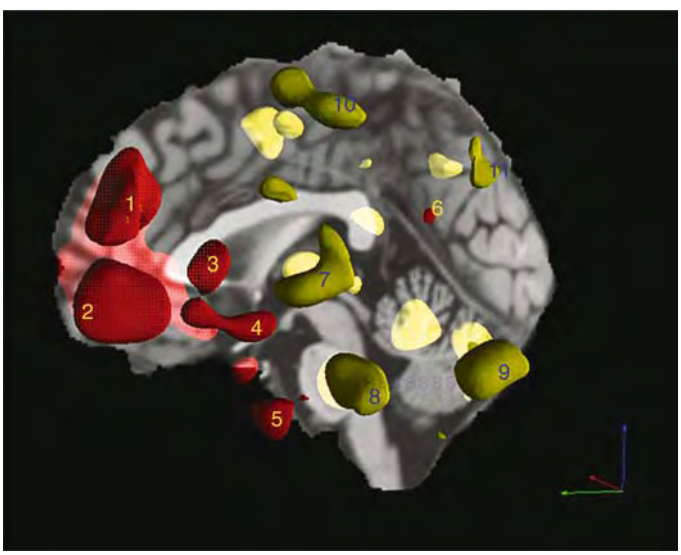
## Therapy

In the 1950s and early 1960s, LSD was hailed as a powerful new technology with the potential to revolutionize psychiatry. There were more than a thousand published clinical studies of over 40,000 subjects. Unfortunately, these clinical studies were poorly designed, poorly controlled, and poorly analyzed, with inadequate post-treatment follow-up. In the absence of well designed studies, the only conclusion that can safely be drawn is that we do not presently know what medical value LSD or other hallucinogens might have.

There was, however, one well-documented use of hallucinogens as therapeutics in the treatment of dying cancer patients. Discovered somewhat serendipitously by Chicago internist Eric Kast, this work ended in several studies at the Baltimore State Hospital. When LSD was included in a program that included only a modest amount of counseling, some degree of benefit was produced in 60–70% of patients, measured as a reduced need for pain medication and improved mood.

## Conclusions

Serotonergic hallucinogens, the classical psychedelic compounds, have profound effects on human consciousness. These substances have been used ceremonially for many centuries in many cultures. Neurochemists and behavioral neuroscientists have identified agonist actions at specific subtypes of serotonin receptors, primarily the 5-$HT_{2A}$ receptors, as being the primary mechanism of action for the behavioral effects of psychedelics. More recent clinical studies of human volunteers have confirmed that the psychedelic effects of hallucinogens



**Hallucinogens. Figure 2** An illustration of the effect of psilocybin on brain activity in healthy human volunteers as indexed by changes in cerebral blood flow (CBF) using $H_2O$-PET. Red shows relative increases, and yellow indicates relative decreases in regional brain activity. Marked increases in activity are seen in areas important for cognitive and affective processes such as the frontomedial cortex extending into the anterior cingulate (1 and 2); the dorsolateral (3), insula (4), and temporal poles (5), and the left posterior cingulate (6). Decreased flow was observed in brain areas important for gating or integrating cortical information processing such as bilateral thalamus (7), right globus pallidus and bilateral pons (8), and in cerebellum (9). Psilocybin also reduced neuronal activity in components responsible for higher order visuo-spatial processing such as precuneus (11) and angular gyrus, as well as in supplementary eye fields of the pre-motor area (10) (unpublished data from F. X. Vollenweider).

such as psilocybin are largely attributable to the activation of 5-$HT_{2A}$ receptors. The study of serotonergic hallucinogens has been informative as to the neurobiological substrates of altered states of consciousness and likely mechanisms contributing to some psychiatric disorders such as schizophrenia. Further research in this area could lead to the identification of novel pharmacotherapeutics, potentially including therapeutic effects of the hallucinogens themselves in certain conditions.

# Haloperidol

### Definition

Drug with antipsychotic properties that is used in hyperactive or manic patients and in animal models of schizophrenia.

# Halteres

### Definition

Fast-moving (rotating) club-like righting organs of flies; working much like gyroscopes.

►Evolution of the Vestibular System

# Hamartoma

### Definition

A focal malformation that resembles a neoplasm in the tissue of its origin.

►Neuroendocrinology of Psychiatric Disorders

# Hand Path

### Definition

The set of positions of the hand that connects two points in space.

►Motor Control Models

# Hand Trajectory

### Definition

The 3D position as a function of time between two points in space.

►Motor Control Models

# Handedness

## Definition

The tendency to prefer using one hand and not the other for a particular task or set of similar tasks.

►Motor Cortex – Hand Movements and Plasticity

# Haploinsufficiency

## Definition

The condition when one functional copy of a gene (the other copy is non-functional) is not enough to prevent the manifestation of a mutant phenotype.

# Haplotype

## Definition

A combination of alleles along part of or the entire chromosome that are transmitted together. Haplotype can also refer to a set of single nucleotide polymorphisms along a single chromatid that tend to be inherited together. Haplotype information is used to identify the genes or genetic susceptibilities underlying certain disorders, and is available through the International HapMap Project.

# Haptics

Lynette A. Jones
Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

## Synonyms

Active touch; Stereognosis

## Definition

Haptics refers to the sensory inputs arising from receptors in skin, muscles, tendons, and joints that are used to derive information about the properties of objects as they are manipulated. Haptic sensing therefore involves both the tactile and proprioceptive sensory modalities [1]. The tactile inputs come from slowly and rapidly adapting ►cutaneous mechanoreceptors in the palmar and dorsal skin of the hand that encode the surface features and shapes of objects as they are explored, whereas the proprioceptive inputs come from receptors in muscles, tendons and joints that respond to changes in muscle length and the forces generated by muscles. These proprioceptive signals provide the central nervous system with information about joint angles, the rate of joint movement and the forces generated on contact, all of which can assist in perceiving the properties of objects held in the hand. It is this active process of manual exploration in which there is a close interplay between finger movements and tactile perception that distinguishes haptics from tactile sensing. The latter term is often referred to as passive touch.

## Characteristics

### Higher Level Structures

Sensory information from cutaneous receptors in the hand and from muscles that control finger movements is conveyed via afferent nerve fibers to the dorsal root ganglion neurons which lie on the dorsal root of a spinal nerve. In the spinal cord, the large diameter axons that mediate touch and proprioception diverge from the smaller diameter afferent fibers that subserve temperature and pain and they follow different pathways to the brain. Tactile and proprioceptive information is segregated anatomically and transmitted to the cerebral cortex via the central axons of dorsal root ganglion cells that enter the spinal cord. These axons ascend directly to the medulla in the dorsal column-medial lemniscal system. At higher spinal levels, the dorsal columns divide into the gracile fascicle that ascends medially and includes fibers from the ipsilateral sacral, lumbar and lower thoracic segments, and the cuneate fascicle that ascends laterally and contains fibers from the upper thoracic and cervical segments. Axons in these fascicles terminate in the gracile and cuneate nuclei in the medulla and from there cross to the other side of the brain stem and ascend to the ventral posterior lateral nucleus of the thalamus in a fiber bundle known as the medial lemniscus. The neurons in the thalamus that receive these inputs from the dorsal column medial lemniscal system send axons to the primary somatosensory cortex in the postcentral gyrus. Most of the thalamic input terminates in areas 3a and 3b and the cells in these areas project to areas 1 and 2. Sensory information from receptors in the skin is transmitted to areas 3b and 1, and proprioceptive information is received in areas 3a and 2. There are extensive interconnections between these four primary

sensory areas, and they send projections to the secondary somatosensory cortex on the superior bank of the lateral sulcus [2]. The four areas within the human somatosensory cortex each contain a full map of the body, with different types of information represented in each area. Parts of the body with high densities of sensory receptors, such as the finger tips and the thumb, have disproportionately larger areas of cortex devoted to processing their sensory signals.

The small diameter fibers from temperature and pain receptors in the skin terminate on second-order neurons in the dorsal horn of the spinal cord and the axons of these neurons cross the midline to form the anterolateral system. The axons involved in transmitting information about pain and temperature are segregated and are arranged somatotopically as they ascend the spinal cord. There are both direct and indirect connections from the anterolateral system to the thalamus via the reticular formation in the medulla and the pons [2]. From the thalamus, there are projections to the primary somatosensory cortex, the dorsal anterior insular cortex and the anterior cingulate gyrus.

## Higher Level Processes

Haptic sensing is focused on perceiving the physical properties of external objects rather than internal tactile sensations and as the hand is the primary organ through which the external world is explored tactually, the study of haptic perception primarily involves the hand. The distinction between haptic and tactile sensing, or active and passive touch, is based on the active component of the former, namely that the hand is voluntarily moved across a surface or an object with purposive movements to obtain specific information. For some properties, such as the perception of roughness of a surface or the detection of minute surface irregularities, it appears to matter little whether the hand moves over a stationary surface (haptic sensing) or the surface is moved across a stationary hand (tactile sensing), all that is important is that there is relative motion between the skin and the surface. For other properties, such as the perception of weight, hand movements greatly facilitate perception, as reflected in the increased sensitivity to changes in weight when an object is lifted as compared to when it rests on the passive hand [1]. In this context, peripheral proprioceptive feedback resulting from the active movement provides an additional source of information about the object. A further source of information about force comes from the cortically generated motor command transmitted to the muscles involved in supporting the weight. Internal correlates or copies of these commands, known as ►corollary discharges, are sent to a number of the sensory areas in the cortex and are involved in the perception of force [3].

Active movements affect the transmission of cutaneous signals through the dorsal column-medial lemniscal pathway by diminishing or gating the sensory inputs. As a result, detection thresholds for cutaneous inputs increase and the perceived magnitude of vibrotactile stimuli is reduced during voluntary movements, although discrimination thresholds remain unchanged [4]. Given the superiority of haptic sensing over tactile sensing in many tasks, it seems paradoxical that movement modulates the transmission of self-generated tactile inputs to the primary somatosensory cortex. It has been proposed that as the rate and type of information acquired during haptic exploration is controlled by the individual, movement speed may be significantly diminished at critical times to minimize the influence of sensory gating. Any disadvantage associated with haptic sensing may then be counteracted by the individual's exploration strategy [4].

## Function

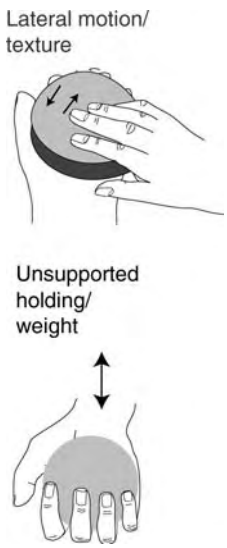
The ability to perceive the attributes of objects is essential to many domains of hand use, from using a tool to typing on a keyboard [1]. As the hand makes contact with an object an initial appraisal of its properties is required so that the grasping forces generated are appropriate for holding the object in a stable grasp. These prehensile forces are adapted to the weight of the object, the friction between the skin of the hand and the object being grasped and the object's shape and size, all of which may be sensed haptically [5]. Afferent information from cutaneous mechanoreceptors in the fingertips therefore plays a crucial role in regulating grasping forces as an object is manipulated. The mechanoreceptors also detect when an object begins to slip between the fingers so that there is an automatic increase (within 70 ms) in grip force that results in a more stable grasp. In the absence of tactile feedback from the fingers, due to peripheral or cortical lesions, the prehensile capacities of the hand are severely compromised.

When considering the dimensions along which an object may vary, a distinction is often made between material properties such as surface texture and thermal diffusivity, and geometric properties, such as shape and size [6]. Some properties such as weight are a function of both material and geometric features, with object density (a material attribute) and volume (a geometric attribute) being contributing factors. Material properties are generally processed more effectively and rapidly by the hand than geometric properties, which often require serial exploration of the object in order to acquire the relevant information. As most common objects vary along a number of different dimensions, people can identify small objects haptically very accurately and quickly (within 1–2 s) [7]. In contrast, it is considerably more difficult to recognize two-dimensional raised outline drawings of common objects haptically. These objects are typically raised

two-dimensional contours and so there is no change in three-dimensional shape and little variation in material properties to assist identification.

Analyses of the hand movements used by people as they manually explore an object indicate that the hand-movement patterns used vary for different properties. These movement patterns or exploratory procedures (EP) have been documented from analyses of hand movements as people manipulate objects to learn about a particular property [8]. A specific exploratory procedure is chosen depending on the property that the person is instructed to explore. For example, the hand is generally moved back and forth across a surface (lateral motion EP) if information about surface texture is of interest, whereas if the weight of the object is being judged, the hand lifts the object from its supporting surface (unsupported holding EP) as illustrated in figure 1 [9].

It has been noted that the exploratory procedure that people voluntarily use to find out about a specific property (i.e., hardness, texture, thermal properties) is the most precise way of learning about that attribute. Exploratory procedures do, however, vary in their execution time, relative precision and generality, that is, the total number of object properties that a single EP can extract. For example, a contour following EP that is used to determine the global or exact shape of an object also provides information about its thermal properties, surface texture, volume, hardness and weight, whereas a lateral motion EP provides cues only about texture, hardness and temperature [8].



**Haptics. Figure 1** Two exploratory procedures (EPs) and the associated object properties. Adapted with permission from [9].

## Pathology

Deficits in haptic object recognition are frequently associated with elevated sensory thresholds on tactile sensory threshold tests such as ►two-point discrimination and pressure sensitivity. Many of these people have injuries to the peripheral nerves innervating the hand or lesions in the primary somatosensory cortex, and the damage to the peripheral or central nervous systems results in a loss of the basic sensory information required to identify an object haptically. Impairments in haptic object recognition can also occur in the absence of primary sensory loss. In these cases, which are usually associated with lesions in the posterior parietal lobe, sensory thresholds on the hand are normal or only mildly impaired, but there is a profound deficit in recognizing objects haptically. A number of terms are used to describe these impairments in haptic object recognition consequent to cortical damage, including astereognosis, ►tactile apraxia and ►tactile paralysis. The deficits appear to result from difficulties in tactile shape perception and inefficient manual exploration strategies. Analyses of the hand movements used by individuals with posterior parietal lobe lesions as they explore objects haptically indicate that there is a reduction in the frequency and regularity of finger movements as compared to normal healthy people, and that the exploration space used to find out about an object is more expansive than that used normally [10]. Lesions in the posterior parietal lobe therefore affect the capacity to make precise controlled finger movements and to plan these movements efficiently, both of which are essential to haptic object recognition.

►Autonomic Function in Space

## Head Movements

### Definition

A component of many different behavioral patterns, such as gaze shifting, an essential part of orienting behavior. They participate in both compensatory and active gaze shifts. Examples of the former are head movements induced by passive rotation of the body. They are controlled by the vestibulo-collic reflex and help to stabilize the line of sight in space.

During active, rapid gaze shifts, the contribution of the head strongly depends on functional properties of the oculomotor system. For example, primates with immobilized heads can move the eyes by up to 50° from a centered orbital position while cats can do it only up to 25°. Correspondingly, primates engage head movements in gaze shifts only if the angular distance between fixation point and the target is greater than 15–20°. In cats, this smallest gaze error is about 3–5°, and the association of eye and head movements (eye-head synergy) is more compulsory than in primates. In animals trained to make rapid eye-head gaze shifts for a reward, maximal head velocities attained during the largest movements are very high (e.g., 400–450°/s in humans, 250–300°/s in rhesus monkeys and 250–500°/s in cats). Because of their speed and because of a positive correlation of peak velocity with movement amplitude such movements are called "head saccades," by analogy with saccadic eye movements. It should be noted that untrained animals often make non-saccadic head movements when their motivation to redirect the gaze to a new target is low. Head movements are also engaged in the tracking of objects moving at low velocity.

## Head-Related Transfer Function (HRTF) in Audition

### Definition

Mathematical descriptions of the manner in which the ears, face, and head affect the amplitude and phase of sound waves at each ear. HRTFs are computed for each ear for a variety of locations in space, by inserting tiny microphones into the ear canals and moving a speaker emitting wide band signals. After removing the contributions of the microphones and speaker, the filtering effects of the head, face, and ear are left.

Arbitrary sound waves can then be filtered by HRTFs corresponding to a given location in space, and played back to the subject over headphones to generate a veridical perception of a sound coming from that location – the sound is said to have been presented in "virtual auditory space."

►Neuroethology of Sound Localization in Barn Owls

## Headache

Sylvia Lucas
University of Washington Medical Center, Seattle, Washington

### Synonyms

Cephalagia; Pain in the head

### Definition

Headache is a term indicative of an experience of pain or discomfort in the cranial regions of the head, but more broadly can include the face and facial structures, and the neck. It is one of the most common medical complaints of humans.

### Characteristics

In an attempt to classify headache into meaningful clinical entities, the International Headache Society (IHS) has organized headache disorders into operational diagnostic categories [1]. These specific definitions of headache types allow the clinician to determine a diagnosis for a patient with a headache complaint and subsequently provide the most effective treatment. The classification system has been particularly useful in the clinical and basic research setting in that it is more likely that the same headache type is studied.

Headaches are divided into two major categories: primary headache disorders (categories 1–4) in which the headaches themselves are the disease process and include ►tension-type headache, ►migraine, and ►cluster headache; and secondary headache disorders (categories 5–12) in which headache is likely to be a symptom based on an underlying structural, infectious or inflammatory etiology. The secondary headache disorders are extensive and may include headache caused by mass lesions, meningitis, subarachnoid hemorrhage, or vasculitis among many other possible entities (see below).

## The International Classification of Headache Disorders (Overview of Main Categories)

### *The Primary Headaches*

***Migraine***

Tension-type headache

Cluster headache and other ►trigeminal autonomic cephalagias

Other primary headache

Adapted from the International Headache Consortium of 2004.

### *The Secondary Headaches*

Headache attributed to head and neck trauma

Headache attributed to cranial or cervical vascular disorder

Headache attributed to non-vascular intracranial disorder

Headache attributed to a substance or its withdrawal

Headache attributed to infection

Headache attributed to disturbance of homeostasis

Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cranial structure

Headache attributed to psychiatric disorder

Adapted from the Headache Classification Subcommittee of the International Headache Society, 2004

The clinical history is of the utmost importance in differentiating primary versus secondary headache. Perhaps the most useful data is the length of time the patient has had the headache. A long history of headache, particularly if episodic and occurring in other family members, is more indicative of a primary headache. A short history of headache with accelerating frequency may generate greater concern for a secondary headache and prompt diagnostic testing such as brain imaging. Other red flags might be change in character or development of a new type of headache especially if there are underlying medical conditions predisposing to secondary headache such as cancer, abnormal neurologic exam findings, prolonged ►aura, fever or stiff neck.

The primary headache syndromes are divided into episodic and chronic classifications based on headache frequency. Typically, episodic headache occurs less than 15 days/month and chronic headache is defined as being present greater than 15 days/month for 4 or more hours per day.

Adapted from the International Headache Consortium of 2004.

### *Common Primary Headache Syndromes*

***Migraine***

The most common primary headache disorder that brings a person to the attention of a physician is migraine, a common episodic disorder characterized by attacks of head pain, as well as accompanying autonomic, neurologic, and gastrointestinal features (see below).

## Diagnostic Criteria for Migraine Headache Without Aura

1. At least five attacks fulfilling criteria A through D
2. Headache lasts 4–72 h (untreated or successfully treated)
3. Headache has at least two of the four characteristics
   (a) Unilateral location
   (b) Throbbing, pulsating quality
   (c) Moderate or severe intensity
   (d) Physical activity increases pain (such as bending over or climbing stairs)
4. During headache attack, at least one of the following occurs:
   (a) Nausea or vomiting
   (b) Photophobia or phonophobia
5. Organic disorder is excluded

Adapted from the Headache Classification Subcommittee of the International Headache Society, 2004.

The word migraine is derived from the Latin term hemicrania and its derivatives: migranea, emigranea, megrane, megrim to describe a one-sided headache. Though only 60% of patients describe migraine pain as unilateral (40% describe bilateral or global pain), this is part of a syndrome in which pain may be throbbing, pounding or pulsatile, moderate to severe in intensity, and worsens with physical activity. Autonomic features such as nausea and vomiting and gastroparesis are frequently seen. Less often, diarrhea, nasal congestion, lacrimation, rhinorrhea or diarrhea may be symptoms. Photophobia and phonophobia are commonly experienced with migraine, and with the temporal development of the headache, many patients experience cutaneous allodynia, a hypersensitivity of the scalp, hair, face or teeth thought to be a manifestation of central sensitization.

Migraine is prevalent in ~12% of the population of industrialized countries [2] and has a 1-year prevalence of ~18% in women and 6% in men. Hormonal issues are thought to play a major role in the increased prevalence of migraine during women's reproductive years. The highest incidence in girls is around the age of menarche at 13–14 years, whereas in boys it is earlier at ~8–10 years old. Migraine is associated with menses in 60% of women

sufferers (menstrual-associated migraine) though it can occur at other times as well. Improvement during the latter two trimesters of pregnancy and resolution or dramatic decrease in frequency and intensity after menopause, suggest that the higher prevalence of migraine during reproductive years is an estrogen withdrawal phenomenon.

### Migraine with Aura

Approximately 12–18% of patients with migraine have aura, a focal, reversible neurologic deficit which develops over several minutes and lasts less than 60 min. Though aura typically happens before the head pain occurs, it may precede, accompany or rarely follow the headache. In many people, aura can occur without accompanying headache as a migraine equivalent. Migraine, migraine with aura, or migraine equivalents can occur as different headache syndromes in the same person.

Eighty percent of aura is visual, primarily scintillating scotoma often described as a small shimmering half-circle of light which may have rick-rack or triangular edges (fortification spectra) in either visual field. The aura typically develops by growing and moving across the visual field until resolution. Other visual auras have been described as tunnel vision, black spots or holes, colored spots or stars. Less frequent auras include paresthesias, numbness, weakness, aphasia, or hemiplegia. These symptoms can happen independently of one another, or can develop in series. In children a common migraine equivalent is cyclical vomiting. Confusion or other cognitive dysfunction may present as a migraine equivalent or as part of a migraine syndrome.

Aura is not to be confused with a migraine prodrome, in which 50% of people who develop migraine will be able to identify symptoms typically preceding their headache syndrome, such as food cravings, sleep disturbance, yawning, personality changes, or altered sensation over areas where pain develops.

### Tension-Type Headache

Episodic tension-type headache is perhaps the most prevalent of the primary headache disorders, with a 1-year prevalence ranging from 38–74% [3]. Though common, it is a mild to moderate headache by definition (see below).

#### Diagnostic Criteria for Tension-Type Headache

1. At least ten previous headache episodes fulfilling criteria B to D
2. Headache lasting from 30 min to 7 days
3. At least two of the following pain characteristics:
   (a) Pressing/tightening (nonpulsating quality)
   (b) Mild or moderate severity
   (c) Bilateral location
   (d) No aggravation by walking stairs or similar routine physical activity
4. Both of the following:
   (a) No nausea or vomiting
   (b) Photophobia and phonophobia are absent or one but not the other is present
5. No evidence of organic disease

Adapted from the Headache Classification Subcommittee of the International Headache Society, 2004.

Therefore, most persons with this headache do not seek medical care and may choose to self-treat with simple analgesics. It is bilateral in location, squeezing, pressing or vice-like in character and nausea or vomiting is not part of this syndrome.

### Cluster Headache

Pain in this primary headache syndrome is thought to be the most severe of the primary headache syndromes. It is described as boring, burning, tearing, or "hot poker in the eye" excruciating pain. An attack of cluster headache has a rapid onset of 5–10 min to peak pain intensity and lasts from 15 min to 3 h, most typically 45–90 min. Cluster is strictly a unilateral, primarily quadrant headache which is retro-orbital or supra-orbital in location and may radiate into the temple. It is accompanied by autonomic features such as ipsilateral lacrimation, conjunctival injection, or nasal congestion and rarely accompanied by nausea, photophobia or phonophobia (see below).

1. At least five attacks fulfilling B-D
2. Severe unilateral, orbital, supraorbital and/or temporal pain lasting 15–180 min, untreated
3. Headache associated with at least one of the following signs, which have to be present on the pain side:
   (a) Conjunctival injection and/or lacrimation
   (b) Nasal congestion and/or rhinorrhea
   (c) Forehead and facial sweating
   (d) Miosis and/or ptosis
   (e) Eyelid edema
   (f) A sense of restlessness or agitation
4. Frequency of attacks: from 1 every other day to 8/day
5. No evidence of organic disease

Adapted from Headache Classification Subcommittee of the International Headache Society, 2004.

Commonly, attacks occur at least once every 24 h, but it is not unusual to have several attacks throughout the day. They may occur at the same time each day or night with nocturnal attacks most likely to happen 60–90 min after sleep onset. A cluster period may last several weeks, most often 6–12 weeks with many months, sometimes years between clusters. Interestingly, during a migraine patients prefer a dark, quiet room in which to rest or sleep. A cluster headache is a "pacing" headache during which restlessness, walking, rocking, even violent behavior is

seen [4]. The gender predilection in cluster is also different with a male: female ratio of 4:1.

## Treatment of Primary Headache Disorders

Effective headache treatment begins with the correct diagnosis, an evaluation of the impact of headaches on a person's daily life, and whether there are any modifiable behaviors or triggers. Migraineurs, for example, may be physiologically more susceptible to certain internal or external stimuli, which can increase the probability of developing migraine. These may include hormonal changes, dietary factors such as alcohol consumption, falls in barometric pressure, sensory stimuli such as bright, shimmering or fluorescent lights, stress, too little or too much sleep or strong smells such as perfume, cigarette smoke or diesel fumes. Avoidance of known triggers may be useful in some migraineurs.

One of the most predictable triggers of migraine in women is the menstrual period. Menstrual-associated migraine (MAM) occurs in 60% of women migraineurs ~2 days before to 3 days after onset of menses. Migraines during this time period appear to be longer in duration and may be more difficult to treat compared to migraines occurring at other times of the month. However, the predictability of the headaches may offer preventive treatment options.

Treatment of migraine is usually acute (abortive) though in patients with frequent headache preventive (prophylactic) therapy may be indicated as well. Acute treatment may be divided into specific and non-specific modalities based on current knowledge of migraine physiology. Migraine is associated with brainstem activation, which may generate or modulate the migraine process. Pain probably results from activation of meningeal and vascular nociceptors in the trigeminovascular complex. Trigeminal sensory afferent terminals contain inflammatory neuropeptides such as calcitonin gene-related peptide, substance P and neurokinins which are released during activation and cause the dilation and plasma extravasation. The neurogenic inflammation can be blocked by drugs that are 5-HT agonists [5].

Specific targeted therapies are based on inhibition of neurotransmitter release at receptors thought to play an important role in the development of the headache pain and its associated features [6,7]. The serotonin receptors 5-HT 1B and 5-HT 1D function as autoreceptors that control the release of 5-HT and other transmitters and are the molecular targets for the class of drugs known as the "triptans." Sumatriptan was the first available drug in this category. Sumatriptan and other marketed triptans (zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan and eletriptan) have relatively high efficacy with a tolerable side effect profile. The ergot alkaloids and derivatives such as dihydroergotamine (DHE) are also thought to exert their anti-migraine activity at these receptors, though bind at other 5-HT, adrenergic, and dopaminergic receptors as well [8].

The putative mechanism of action of triptans and the ergot alkaloids is to block the release of proinflammatory neurotransmitters at the level of the trigeminal nerve terminal (5-HT 1D receptor) thus preventing neurogenic inflammation. However they also cause vasoconstriction of meningeal arterioles through a 5-HT 1B effect. In addition, they may also have a central effect in the brainstem through receptor binding in the trigeminal nucleus caudalis.

They are contraindicated in patients in whom vasoconstriction of coronary, peripheral or intracerebral arteries might lead to ischemic events.

Non-specific therapies consist of simple analgesics such as aspirin, acetaminophen or paracetamol, combination analgesics such as aspirin, acetaminophen and caffeine, opioids, or nonsteroidal anti-inflammatories. Other non-specific headache medications may contain butalbital or isometheptene [8].

Characteristics of the headache such as rate of pain evolution, intensity and severity of the headache, associated symptoms such as nausea or vomiting, and disability during the headache will determine whether specific or non-specific therapies will be effective, and which route of administration (i.e. oral versus injectable) is preferable.

## Other Headache Disorders

### *Chronic Daily Headache*

►Chronic daily headache (CDH) is a headache syndrome in which headache occurs more than 4 h/day, more than 15 days/month. CDHs include transformed migraine, chronic tension-type headache, new daily persistent headache or hemicrania continua [9]. The most common CDH seen by headache specialists is Medication Overuse Headache (MOH) also known as rebound headache. This headache tends to be a constant, diffuse headache that is present upon awakening or shortly thereafter though more severe headache can be present. Typically MOH is caused by overuse of abortive medications used to treat headache and can present as headache with escalating frequency. The development from episodic headache to daily headache may take weeks or months. Any acute agents may cause MOH such as opiates, barbiturates, benzodiazepines, simple and combination analgesics, triptans and ergot derivatives. It is thought to be a withdrawal syndrome and may develop in persons who use the medication as little as two to three times a week on average. Treatment is to taper or stop the causative agent.

### *Idiopathic Stabbing Headache (Ice-Pick Headache)*

This headache is characterized by stabs of sudden, sharp severe ice-pick-like pains located in the parietal, temple, or orbital regions of the head. The episodes

**Headache. Table 1** Clinical features of some of the short-lasting primary headaches

| | Cluster | Paroxysmal hemicrania | SUNCT | Idiopathic stabbing headache | Trigeminal neuralgia |
|---|---|---|---|---|---|
| M:F ratio | 4:1 | 1:1 | 5:1 | F > M | F > M |
| Pain quality | Lancinating | Pulsating | Stabbing | Stabbing | Sudden stabbing |
| Pain intensity | Excruciating | Excruciating | Severe | Severe | Excruciating |
| Pain location | Orbital temporal | Orbital temporal | Orbital temporal | Head (any part) | V2-V3 (V1 rarely) |
| Attack duration | 15–180 min | 1–30 min | 5–240 s | <1 s | <1 s to 2 min |
| Attack frequency | 1–8/day | 3–30/day | 1/day to 30/h | Few to many/day | Few to many/day |
| Autonomic phenomena | Moderate | Moderate | Extensive | _ | _ |

*F*, Female; *M*, Male, *SUNCT*, short-lasting neuralgiform headache attacks with conjunctival injection and tearing

usually last less than a second and can occur several times a day sometimes in clusters throughout the year. ►Ice-pick headaches usually occur in people who also have migraine, cluster or other trigeminal autonomic cephalalgias. If frequent, indomethacin can be used as preventive treatment.

### *Occipital Neuralgia*

This is a continuous dull aching, sometimes throbbing pain often superimposed by sharp stabbing pain in the distribution of the unilateral, sometimes bilateral greater occipital nerve. Occipital pain, which may radiate to the vertex, can often be reproduced by applying pressure over the occipital nerve. Causative factors may be trauma, compression or entrapment of the nerve or possibly excessive contraction or hypertonus of the cervical musculature. Definitive treatment is with local nerve blocks of the greater occipital nerve.

### *Pseudotumor Cerebri (Idiopathic Intracranial Hypertension)*

Idiopathic increased intracranial hypertension (ICH) is the most common presentation of ICH. More common in women than in men, it often occurs in young women in their 20's and is often associated with obesity. It may or may not be associated with papilledema on fundoscopic examination, but typically CSF examination to measure opening pressure is high (>200–250 mm$H_2O$). This is a chronic headache with a quality similar to tension-type headache and may be unilateral, bilateral, occipital or frontal. It may be worse in the morning and there may be transient visual obscurations, tinnitus, diplopia or nausea. Hypotheses on the pathophysiology of ICH include increased CSF formation, decreased CSF absorption and increased venous pressure. Definitive treatment is usually weight loss, though lumboperitoneal or ventriculoperitoneal shunt placement or optic nerve fenestration may be used to prevent the visual loss or blindness that may be the outcome of untreated ICH.

### *Trigeminal Autonomic Cephalalgias (TACs)*

These are short-lasting headaches with unifying features of pain in the trigeminal nerve distribution (usually V1) and autonomic involvement of the cranial parasympathetic nervous system (for example, lacrimation, conjunctival injection, nasal congestion, rhinnorhea). The TACs include cluster, paroxysmal hemicrania, hemicrania continua and short-lasting unilateral neuralgiform headache with conjunctival injection (SUNCT). The hemicranias are indomethacin-responsive headaches, whereas cluster and SUNCT are not ([10]; Table 1).

### *Trigeminal Neuralgia (Tic Douloureaux)*

Idiopathic trigeminal neuralgia (TN) typically presents in older patients with a slight preponderance in women. Secondary TN may be related to structural causes such as multiple sclerosis, aneurysm or arterial compression. TN is thought to be caused by irritation of the trigeminal nerve and presents as a lancinating, knife-like stabbing or electrical shock-like pain in the distribution of the trigeminal nerve. It is most commonly unilateral with episodes lasting seconds to 2 min several times a day. It can be provoked by chewing, talking, brushing the teeth or a breeze touching the face. An MRI of the base of the brain should be performed initially to rule out structural or compressive causes. ►Tic douloureux may be treated with antiepileptic drugs such as carbamazepine, baclofen or ablative procedures.

## Hearing Aids

Pamela Souza
Department of Speech and Hearing Sciences, University of Washington, Seattle, WA, USA

H

### Synonyms

Hearing instrument; Amplification

### Definition

A hearing aid is an electronic device worn in the ear to amplify sound. Within the hearing aid, a microphone converts acoustic energy to electrical energy. The signal is amplified, and a receiver converts the electrical signal back to acoustic energy. Power is provided by a small battery. Digital hearing aids combine electronic components with a computer chip. In a digital aid, the input electrical signal is sampled. Amplification and associated sound processing are then accomplished by manipulating the digital code before reconverting to acoustic energy.

### Characteristics

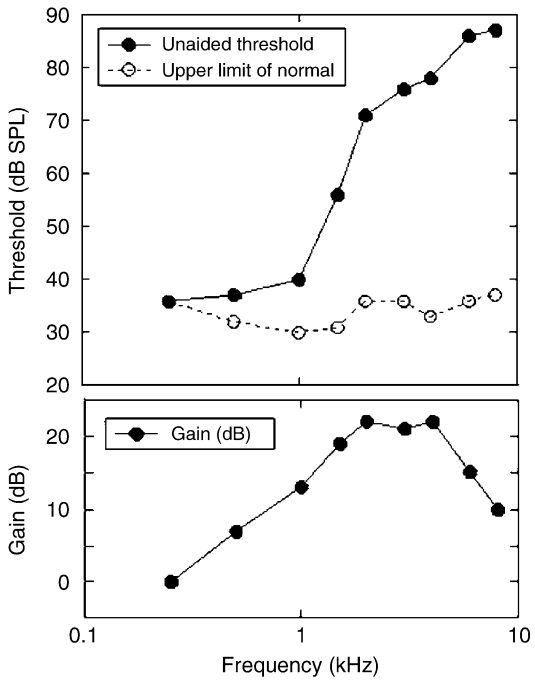
#### Frequency Response

Amplification is applied differentially across ►frequency. This can be thought of as a mirror of the patient's ►audiogram, whereby frequencies where the listener has greater amounts of hearing loss are compensated for with greater amplification. Various aspects of the hearing aid response can be quantified, including the aided ►output and aided ►gain. A typical hearing aid response provides increasing gain at high frequencies with a peak at 3000 Hz to mimic the natural ►resonance of the open ear. Hearing aid gain is often expressed as gain measured at the maximum volume control position, with peak gain ranging from about 30 dB for an aid suitable for mild hearing loss to as much as 80 dB for power hearing aids. In practice, most listeners wear the aid at a lower volume setting, and will receive 5 to 15 dB less than maximum gain. The specific gain at each frequency is determined by applying one of several available target calculations to the listener's audiogram. The various calculations are designed to optimize speech intelligibility [1], audibility [2] or to normalize loudness [3].

As ►sensorineural hearing loss introduces ►recruitment in addition to threshold elevation, the compensatory gain at each frequency is less than the amount of hearing loss at that frequency. An example is shown in (Fig. 1).

## Maximum Output

All hearing aids have a physical output limit based on the capacity of the receiver and battery. The maximum output is specified as the output level with an input of 90 dB SPL measured in a 2cc coupler. Maximum output can be as high as 130–140 dB SPL in some power hearing aids. Most hearing aids also incorporate an adjustable maximum output value set by the hearing aid fitter. The reduced limit maintains sound at levels below the listener's discomfort level and prevents additional hearing damage from unintended high sound levels. Output limiting is accomplished either by peak clipping or by compression limiting; a technique whereby reduced gain is applied to input levels that would otherwise exceed the desired maximum output. Of the two methods, peak clipping results in significantly greater signal distortion.



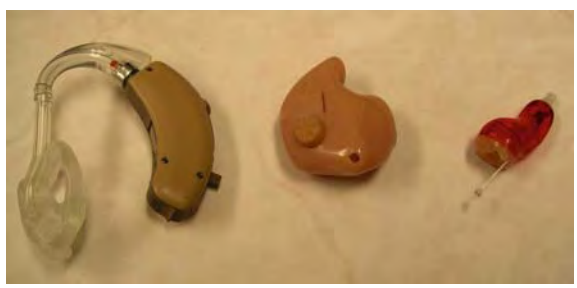
**Hearing Aids. Figure 1** Illustration of hearing aid gain. In the top panel, filled circles show a representative hearing loss, expressed as the dB SPL level that is just audible to the listener at each frequency. Normal hearing (open circles) is shown for comparison. The bottom panel shows the amount of gain required to compensate for threshold elevation. Note that the amount of gain at each frequency is not equal to the threshold elevation. For example, hearing threshold at 2 kHz is about 35 dB above the maximum criterion for normal sensitivity, but the prescribed gain is only 22 dB.

## Lower Level Components

### Case

The size and shape of the hearing aid depend on a number of factors, including the listener's ear canal, age, communication needs, dexterity, and cosmetic preferences. In behind-the-ear aids, the electronic components are contained in a small plastic case that fits behind the outer ear and is coupled by means of plastic tubing to a custom-fit acrylic or silicone ►earmold. With in-the-ear aids, all components are contained within a hard plastic shell that fits within the ►concha. In-the-ear aids vary in size. The smallest hearing aids, completely-in-the-canal aids, are inserted deeply within the ear canal and are usually not visible to a casual observer. Fig. 2 shows some different styles of hearing aids. Each style has advantages and disadvantages.

The larger styles are more powerful and can offer more options, such as user controls. The smaller styles may be more convenient or cosmetically appealing for some users. Behind-the-ear aids are most appropriate for children, because the earmold can be changed frequently to accommodate their growing ears. Behind-the-ear aids with "open" earmolds reduce occlusion and improve sound quality and physical comfort, but are suitable only when the wearer has good low-frequency hearing. Disposable hearing aids contain an integrated battery and are designed for one-time use. However, disposable hearing aids fit only a limited range of hearing losses and ear canal sizes. Finally, a small percentage of individuals with ►conductive hearing loss may use bone conduction hearing aids, in which sound vibration is transmitted mechanically to the ►cochlea via a small titanium screw surgically implanted in the ►temporal bone, or by a vibrating case held to the mastoid with a spring tension metal headband.



**Hearing Aids. Figure 2** Examples of different styles of hearing aids. From *left to right*: behind-the-ear hearing aid with earmold; in-the-ear aid, and; completely-in-the-canal aid.

### Venting

A ►vent that transverses the medial to distal portion of the aid or earmold may be used to allow airflow into the ear and prevent pressure discomfort. The vent also has an acoustic effect by allowing low frequency sounds to leak out of the ear, thus amplifying the high frequency sounds to a greater extent. The larger the vent, the more reduced the low-frequency amplification.

### User Controls

External volume adjustments may include a volume wheel, push button or remote control that allows the wearer to control volume level. The range of hearing aid gain available via the volume control is preset by the hearing aid fitter. Multimemory hearing aids either select automatically or allow the user to select among preset acoustic programs for different listening situations, using a button on the hearing aid or a remote control. These might include programs for listening to speech in quiet, speech in noise, telephone, or music, or programs that emphasize intelligibility or loudness comfort. The programs may vary in frequency response, volume adjustment, or microphone characteristics. For example, speech recognition is optimized with a rising frequency response that emphasizes high-frequency consonants, whereas a flatter frequency response that maintains the treble-bass relationship is more appropriate for music listening.

### Telecoil

With many hearing aids, placing an object such as a telephone receiver close to the microphone causes acoustic feedback. Changes in receiver position or connecting the receiver to a plastic or foam coupler may reduce the chance of feedback. Some digital hearing aids can numerically "cancel" the feedback by adding a signal of opposing phase or eliminate it by attenuating a narrow frequency region surrounding the feedback. Some hearing aids can be switched manually or automatically to an induction loop input that picks up electromagnetic energy from the telephone receiver. However, digital cellular phones emit distortion that may impair their use with telecoils. The extent of the problem depends on the amount of energy emitted by the cellular phone and how resistant a particular hearing aid is to that interference. In the United States, the Federal Communications Commission has implemented regulations that should improve this situation in a few years. In addition to telephone use, a telecoil can also be used to wear the hearing aid in combination with personal or group assistive listening systems.

## Function

Modern hearing aids do more than just amplify sound. Increasingly, they use sophisticated sound processing to manipulate various aspects of speech and noise signals.

### Linear and Nonlinear Gain

Linear hearing aids apply a constant gain, regardless of the input level. This is problematic because the high gain required to make low-intensity sounds audible may increase the level of high-intensity sounds to the point of discomfort. If the gain is reduced to make high-intensity sound comfortable, low-intensity sounds may be inaudible. Newer hearing aids use nonlinear gain called wide-►dynamic range compression. With this processing, the level of the input signal is continually monitored, and low-intensity sounds are automatically amplified more than high-intensity sounds. The goal is that all sounds received by the listener will be heard at comfortable levels. This scheme is also intended to compensate for the loss of the nonlinear cochlear amplifier provided by the outer hair cells in normal-hearing individuals. The speed with which gain is adjusted as the input level changes may range from a few ms to several seconds. In multichannel hearing aids, the gain adjustment is made separately in each of several overlapping frequency bands. Multichannel hearing aids can more easily accommodate differences in dynamic range across frequency.

### Noise Reduction

Difficulty hearing in background noise is the most common complaint of listeners with hearing loss. Hearing aids deal with this problem in several ways:

Digital noise reduction algorithms analyze the ►spectral and/or temporal pattern of the sound within each frequency band to determine whether the incoming signal is speech or noise. Sound categorized as noise is either attenuated or digitally cancelled by summing with an opposite phase signal. These systems are most effective when the noise is very different from the speech; for example, ventilation or road noise, which have little level variation. Digital noise reduction is less effective when the "noise" is another speaker, due to difficulty differentiating between similar varying signals.

Directional microphones can be used to reduce the level of extraneous sound sources. In an omnidirectional hearing aid, all sounds are amplified without respect to the direction of the sound source. Directional microphones amplify sounds from some directions more than others. The directional microphone can be comprised of a single directional microphone or a pair of electronically linked omnidirectional microphones. As the listener will usually turn to face the speaker, a common arrangement is a directional microphone by which sound from the front of the listener is amplified to a greater extent than sounds to the rear. More sophisticated directional microphones use adaptive processing in which directionality is combined with digital sampling. They attempt to determine whether sounds from various directions are speech or noise and orient the maximum amplification in the direction of the speech. Other

H

directions are attenuated to reduce surrounding background noise. Automatic hearing aids self-select between omnidirectional and directional responses. As directional microphones require a minimum distance between microphone ports, this feature is not available on smaller hearing aids, such as completely-in-the-canal aids.

### Therapy

Obtaining a hearing aid usually involves several visits. First, hearing is measured to evaluate whether the individual is a candidate for hearing aids. Generally, there is an inverse relationship between hearing sensitivity and the potential for significant hearing aid benefit, such that listeners with more hearing loss notice a greater improvement with the hearing aid. Exceptions include listeners with profound hearing loss, who have little ►residual hearing or for whom broadened ►auditory tuning restricts the ability to recognize amplified speech [4]; these individuals may be candidates for cochlear implants. If amplification is warranted, the listener's communication needs and preferences are determined. The listener's dynamic range may also be measured. A silicone impression is taken of the listener's ear(s). ►Binaural amplification is preferable when both ears are impaired, unless one ear cannot be fitted due to the type of pathology. Binaural aids improve speech recognition and localization over ►monaural amplification.

The timing of obtaining a hearing aid is also important. Young children, in particular, need early auditory input to facilitate development of auditory nerve fibers [5]. Adults with acquired hearing loss who have bilateral hearing loss but are fitted with only one hearing aid may also experience a loss of auditory function over a period of years. This phenomenon has been termed late onset auditory deprivation, and probably has more to do with the dominant contribution of the aided ear than with true deprivation of the unaided ear [6,7].

At the second visit, the hearing aid controls are adjusted. Most hearing aids are programmed using a standard hardware interface in combination with a software framework that is common across all hearing aid manufacturers. Each manufacturer provides programming cables and software modules for their products. The ►potentiometer controls on analog aids are adjusted with a small screwdriver. The hearing aid response is then measured to ensure that it will compensate adequately for the amount of hearing loss. This can be done in situ using a probe microphone, which is a small microphone coupled to a plastic tube. Alternatively, the hearing aid response can be measured in a 2cc coupler to mimic the ear canal volume medial to the tip of the hearing aid. A correction factor is then applied to the coupler values to obtain the predicted in-ear response [8]. The coupler technique is often preferred when testing children because it requires less cooperation from the patient. At this visit, the listener also receives instruction in care, cleaning and effective use of the hearing aid. Like any electronic device, hearing aids are susceptible to moisture, heat, or impact and care should be taken to avoid these factors. Often a third visit is scheduled after a trial period to evaluate hearing aid performance and make any necessary adjustments. A series of standardized questionnaires are available to assess wearer satisfaction and benefit after the trial period.

## Heart Rate

### Definition
Heart rate is the number of contractions of the ventricles per unit of time, and is usually expressed as beats per minute. In clinical practice, the normal range of the resting heart rate in adults is regarded as between 60 and 100 beats per minute as measured by palpation of the pulse. However, the heart rate varies widely depending upon factors such as level of activity and psychological state. Additionally, even under constant conditions, the heart rate normally oscillates in concert with the respiratory rhythm.

## Hemagglutination

### Definition

Hemagglutination is a clumping of red blood cells usually present as 1% suspension which contain a red blood cell attachment protein (hemagglutinin) on their surface. A large number of viruses hemagglutinate a wide variety of red blood cells each virus favoring certain cells from certain animals. Used as a quick, quantitative assay for certain viruses.

## Hemianopsias

### Definition

Losses of vision in halves of the visual field. Bitemporal hemianopsias result from selective lesions of the ►optic chiasm in which fibers from the nasal halves of the ►retina (representing the temporal halves of the visual field) cross to the contralateral side. Complete homonymous hemianopsias result from total destruction of one ►optic tract, such that, e.g., destruction of the right tract results in a left hemianopsia because fibers from the left nasal and right temporal halves of the retinas are destroyed. Incomplete homonymous hemianopsias result from partial lesions of the ►optic radiation or ►primary visual cortex.

►Optic Tract
►Primary Visual Cortex
►Retina
►Visual Field

## Hemiballism

### Definition

Ballismus is large amplitude and violent chorea. It is rare and usually occurs as hemiballismus after a lacunar infarct in the contralateral subthalamic nucleus. Hemiballismus tends to slow down into chorea over time and its treatment is similar to that of chorea. Hemiballismus can also occur iatrogenically after contralateral subthalamotomy or subthalamic nucleus deep brain stimulation surgery as part of the treatment for Parkinson disease.

►Chorea
►Parkinson Disease
►Subthalamic Nucleus (STN)

## Hemichorea

### Definition
►Chorea on one body side.

## Hemilabyrinthectomy

### Definition
Global exstirpation of the labyrinth of one side, resulting in distinctive lesion symptoms.

## Hemiparesis

### Definition
►Paresis on one body side.

## Hemiplegia

### Definition
Paralysis (loss of muscle strength) in limbs and sometimes face on one body side, usually resulting from lesions to descending motor tracts, such that the site of lesion determines the distribution of paralysis.

## Hemisensory Defect

### Definition
Defect of sensory sensation on one side of the body.

## Hemispatial Neglect

### Definition
In its full-fledged form, hemispatial neglect typically results from damage of the right inferior ►parietal lobule (IPL; ►Brodmann areas 39 and 40). Patients deviate their head and eyes to the side of the lesion and frequently neglect objects in contralateral visual space, but occasionally the body half as well ('personal neglect'), entailing a lack of spontaneous movements of that half ('motor neglect'). Occasionally, neglect concerns only objects in far space ('extrapersonal neglect') or near objects ('peripersonal neglect'). However, neglect may also result from damage of the ►frontal eye field (FEF), inferior ►area 6, polysensory area of the ►superior temporal sulcus, ►cingulate gyrus and other, even sub-cortical structures. The symptoms, whose expression and combination depend on the precise extent of the damage, include attentional deficits, visual mislocalization and disorientation, topographical and spatial-memory deficits, ►constructional apraxia, and - possibly - alterations of temporal motor programming. Elementary visual and somatosensory functions may be preserved, but if compromised as well, the hemineglect may be so severe that patients do not recognize the opposite body side as their own. In less severe, more restricted cases, patients will not attend to objects in the opposite field of view, e.g. not draw opposite sides of objects.

[3]Memorial Hospital of Carbondale, Southern Illinois Health Care, Carbondale, IL, USA

### Definition
Brain regions in the left and right cerebral hemispheres do not contribute equally to mental functions [1]. Here

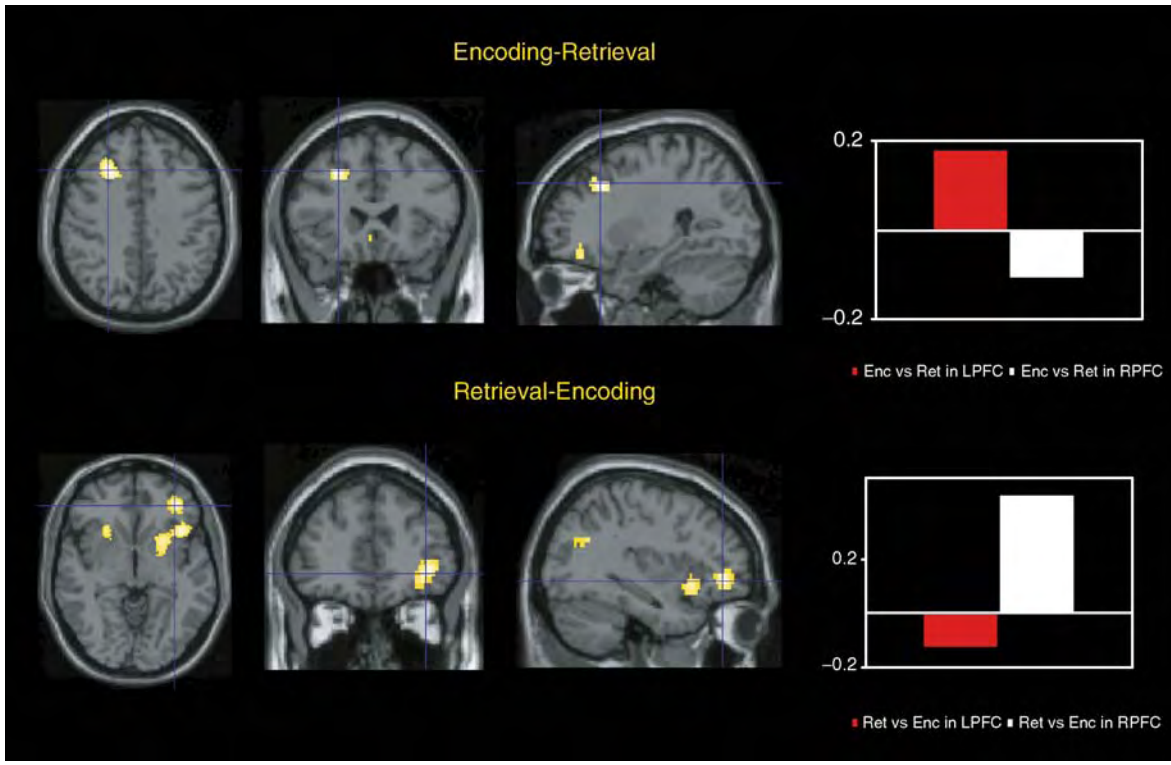
we will be concerned with asymmetries of declarative long-term memory processes, in particular ►episodic memory processes [2]. Memory is a relatively recent addition to the list of functions that appear to differentially depend on right or left hemisphere regions. With the advent of ►functional neuroimaging techniques, it has become possible to separately examine how the brain is activated when new information is encoded into memory and how it is activated when that information is subsequently retrieved. Based on the results of early functional neuroimaging studies, episodic encoding and retrieval were found to be asymmetrically mediated by regions within the left and right frontal cortices [3]. This laid the foundation for the HERA (hemispheric encoding/retrieval asymmetry) model [4], which postulates that regions in the left prefrontal cortex are more active than right prefrontal regions during episodic memory encoding whereas regions in the right prefrontal cortex are more active than left prefrontal regions during retrieval from episodic memory.

It should be stressed that the model does not claim that right prefrontal regions are of no relevance to encoding, and vice versa for the left prefrontal cortex and retrieval. Such a claim would clearly be inconsistent with the available evidence. Instead, the HERA model states that certain left prefrontal regions are differentially more engaged during encoding than retrieval compared to what is true for the homologous region in the right hemisphere. Conversely, relative to specific left prefrontal regions, certain right prefrontal regions are more activated during retrieval than encoding (Fig. 1).

Thus, the HERA model is concerned with the modulation of brain activity in select left and right prefrontal cortical regions by processing demands. This was made explicit in a recent definition of the HERA model [5]:

1. (Enc in left PFC − Ret in left PFC) > (Enc in right PFC − Ret in right PFC)
2. (Ret in right PFC − Enc in right PFC) > (Ret in left PFC − Enc in left PFC)

where Enc refers to encoding-related regional activity, Ret to retrieval-related regional activity, and PFC to the prefrontal cortex. Thus, according to this definition,



**Hemispheric Asymmetry of Memory. Figure 1** *Top*: Three different views of activity in the left prefrontal cortex during episodic memory encoding. The graph indicates that the difference between encoding and retrieval (Encoding – Retrieval) is greater in the left than in the right prefrontal cortex. *Bottom*: Three different views of activity in the right prefrontal cortex during episodic memory retrieval. The graph indicates that the difference between retrieval and encoding (Retrieval – Encoding) is greater in the right than in the left prefrontal cortex.

tests of the HERA model require that both encoding-related and retrieval-related brain activity be monitored in the left and right prefrontal cortex, with other variables held constant (e.g., mnemonic information such as verbal vs. pictorial). Although it is generally agreed that claims of asymmetric hemispheric contributions require such direct process-comparisons, to date, very few studies have adhered to this definition in tests of the HERA model.

## Characteristics

### Functional Basis for the Asymmetry

It has been proposed that the left and right hemispheres differ in terms of mnemonic functions [1]. The left hemisphere, since long associated with language processes, seems to be more specialized for semantic (elaborative) processes, whereas the right hemisphere maintains a veridical record of past events and is able in a recognition test to correctly classify presented test items as belonging to a previous study list. This view of hemispheric specialization can be related to assigned functional roles of the left and right prefrontal cortex during episodic encoding and retrieval, respectively.

Increased left prefrontal activity during episodic encoding has been related to elaborative, semantic processes. This may, for example, involve reflecting upon the meaning of presented information, relating it to what one already knows about a certain topic, or other higher-order meaning-based processes. It has been shown that instruction to focus on deeper, semantic aspects of verbal information during encoding is associated with increased left prefrontal cortex activity and higher subsequent retrieval [2]. This association between left prefrontal activity during encoding and elaborate semantic processes is in good agreement with the suggestion that the left hemisphere is specialized for interpreting events [1].

Right prefrontal activity during episodic retrieval has been linked to a specific neurocognitive set, termed episodic retrieval mode (►REMO [2]). This mental state is a necessary pre-condition for episodic retrieval. It can be triggered by a question (e.g., *What did you do last night?*) or an instruction (*Try to think back to the list I presented previously and say if these words were part of that list!*). These triggers have the effect that the person, for a limited period of time, enters REMO and thereby treats information (e.g., words in a word list) as clues for remembering past events (the previous presentation of these words). If a person is not in REMO, words or other similar clues have little chances of evoking past memories (unless very strongly associated with a past event). Thus, retrieval of episodic information seems to require processes mediated by right frontal regions, which is consistent with the theory that the right hemisphere can be linked to veridical retrieval of past events [1].

### Why did the Asymmetry Emerge?

The current thinking on the functional basis for asymmetry in memory, as described above, makes quite good sense, but it is far from settled. Even more unclear is the answer to the question of why the asymmetry emerged. Naturally, this is a general issue that goes beyond asymmetry in memory per se. One of several possibilities is that the asymmetry is a response to a competition for cortical space [1]. As more and more mental capacities were developed during the course of evolution, what was initially a bilateral function was successively turned into a lateralized function.

The cortical space hypothesis does not imply that the "dormant" region in the non-active hemisphere no longer has the capacity to perform the relevant computations – it simply states that it is possible to unilaterally perform the task with the more specialized hemisphere. By this view, a task that typically has an asymmetric functional basis can under certain circumstances start to recruit the normally less-active hemisphere. Support for this type of reorganization comes from findings of recruitment of *right* frontal cortex regions during performance of a semantic task by a patient with a left-sided frontal lesion [6], and findings of a bilateral activation pattern during the performance of normally asymmetric tasks after brain damage.

### Reduced Asymmetry in Memory

Asymmetry in memory may, thus, be conceived of as a sign of efficient processing in cognitive and neural terms. It is well established that several diseases and conditions are associated with impaired cognitive processing. Does this mean that the asymmetry in memory may be reduced or even eliminated in certain subject populations? The answer appears to be affirmative. One striking example of reduced asymmetry in memory comes from normal aging. Many elderly, even though not suffering from dementia or similar pathological conditions, show a reduction in cognitive performance [7]. Interestingly, functional imaging studies that have compared brain activity for younger and older adults indicate that elderly tend to display a more bilateral activation pattern whereas younger adults show a more asymmetric activation pattern [8]. This age-related reduction in asymmetry is captured by the ►HAROLD model [8].

The reductions in both cognitive performance and asymmetric activation patterns may be linked such that a more bilateral activation pattern can be seen as a compensatory response. There is some support for this notion. One example comes from a study that compared elderly with a declining or a stable level of memory performance over time [9]. These elderly were selected from a large database that comprises elderly that show the typical age-related decline in cognitive performance, as well as elderly that maintain a very high

level of cognitive performance in old age [7]. Of main interest was to see whether elderly with a declining level of cognitive performance would show a reduction in asymmetry. Such a result would link asymmetry reduction to a need for compensation. The groups of declining and stable elderly were studied with functional brain imaging while they performed a test of incidental episodic encoding. As expected, both groups were found to activate left prefrontal cortex. However, in addition, the declining group activated the corresponding right prefrontal region. This provided support for the hypothesis that reduced asymmetry in memory can be linked to a need for functional compensation. Further support for this hypothesis was provided from ►structural imaging, showing that the declining group had reductions of grey and white matter in select brain regions.

### Symmetry as well as Asymmetry in Memory

The focus of this essay has been on processes that operate during encoding or retrieval and tend to activate distinct and asymmetric brain regions. However, there are also several regions, in the left and right hemisphere, that are commonly activated during encoding and retrieval [10]. In other words, there are sites in the brain where "encoding meets retrieval." This point should be stressed to avoid erroneous simplifications of the sort "encoding is located in the left hemisphere."

### Other Asymmetries of Memory

While the focus of this essay has been on asymmetries between encoding and retrieval, the most studied and best known asymmetry of memory is between memory for verbal and non-verbal information. Neuropsychological studies of patients with lateral or medial temporal lobe damage has associated left-sided damage with disruptions of verbal memories (e.g., word-pair recall, story recall, verbal recognition), whereas right-sided damage has been associated with disruption of non-verbal memories (e.g., corsi blocks, face recognition, maze-learning). This kind of asymmetry has been observed in healthy adults using functional neuroimaging approaches, and functional neuroimaging has revealed an asymmetry between verbal and non-verbal memories in the frontal lobes, in regions close to those hypothesized by the HERA model to be differentially involved in encoding and retrieval (see [5]). Thus, it seems quite possible that there exists both material-based (e.g., verbal vs. non-verbal) and process-based (e.g., encoding vs. retrieval) asymmetries in the brain [5].

### Summary and Conclusion

Functional neuroimaging studies of declarative memory processes have provided strong support that certain encoding and retrieval processes engage different brain regions, notably in the prefrontal cortex. At least in part, this difference in brain activity can be accounted for in terms of hemispheric asymmetry, such that encoding more strongly engages left frontal regions and retrieval right frontal regions. The association of encoding and elaborative processes with the left hemisphere is consistent with a role for this hemisphere in interpreting and structuring information, and the association of retrieval and retrieval mode with the right hemisphere is consistent with the idea that this hemisphere is specialized for veridical processing which would benefit, for example, episodic recognition memory [1].

## Hering–Breuer Reflex

Ikuo Homma
Department of Physiology, Showa University School of Medicine, Tokyo, Japan

### Synonyms

Inspiratory inhibitory reflex

### Definition

Inspiration is inhibited by the vagal afferent.

### Characteristics

Research in the field of respiratory physiology has been carried out for several centuries. Numerous findings and terms have been designated as the name of the finder. One such named term, "Hering–Breuer reflex," has been a steadfast term in the respiration control system. In 1868, two striking papers, written by Ewalt Hering and Joseph Breuer, were introduced to the world. Although today the idea and the work do not seem surprising in our modern world, these works were extraordinary at that time in the mid-nineteenth century.

Ewalt Hering (1834–1918) studied medicine at Leipziz University, Germany, and he worked in the basic research field. He was immensely interested in visual physiology and continued to study the subject throughout his life for his life work. In 1865, he became a professor at the University of Vienna. Joseph Breurer (1842–1925) studied medicine at the University of Vienna and worked as a clinician. During his clinical practice, he had the idea that breathing was accomplished under a self-regulatory mechanism. His clinical professor introduced him to E. Hering who had just joined the University of Vienna as a research professor. Interestingly, as the research work on breathing had been carried out by J. Breuer, many refer to their findings as the "Breuer–Hering reflex" rather than the "Hering–Breuer reflex." E. Hering moved to a position in the Physiology Department of Prague University in 1869, and there he promoted the work of the respiratory control system. He encouraged his student, Henry Head (1861–1940), to investigate the neural control of breathing. Head's paper (1889) prompted widespread interest in the Hering–Breuer reflex, and he proposed a term, "Head's paradoxical reflex." It may be said that the widespread recognition of the Hering–Breuer reflex is the result of the work by Head.

The living body is a conglomeration of many substances; it is differentiated into various systems to take change of numerous functions. Two factors are necessary for survival of the systems: integrity of the intrinsic systems and supply of extrinsic materials. Food (including water) and air are among the extrinsic materials. Every organ utilizes food and oxygen in its metabolic process. Man can survive for weeks without food and for days without water. However, man can not even survive for minutes without oxygen. There are three oxygen transport routes: the inlet of oxygen to the lung, oxygen transport in the blood, and oxygen transport in the cell. Air is transported to the lung from the outer environment by rhythmical expansion and shrinkage of the lungs. Such a simple system had not

come to scientists' attention until the mid-seventeenth century. Even William Harvey, who is well known for his circulation research, described that the lung is a pump for accelerating the blood flow between the pulmonary artery and vein. It was not until the time of Antoine Lavoisier in the mid-eighteenth century that the pumping of the lung was considered as a function for oxygen inhalation. It was later (early in the nineteenth century) brought out by Le Gallois and Pierre Flourens that the center for pumping is located in the medulla oblongata. However, the mechanism of the generation of respiratory rhythm, the pumping change from inspiration to expiration, and from expiration to inspiration remained unclarified. At this same period, Francois Maggendie elucidated the difference between afferent and efferent nerve fibers. It was also suggested that the center of the respiratory nervous system receives inputs from the vagus, trigeminal nerve, spinal nerve, and the higher center of volition, and it sends outputs to the respiratory muscles. The idea is seemingly modern; however, the idea was that normal inspiration is generated by $CO_2$-activated vagal afferents. Inspiration diluted $CO_2$ in the lung, which in turn shut off the inspiration.

This simple conception of how rhythmic inspiratory and expiratory phases are produced had been entirely inadequate until the view based on the particular facts discovered by Hering and Breuer (1868) came into the world. They found that when an animal's trachea is clamped at the end of expiration and air is prevented from entering the lung, the animal gave a great inspiratory effort that was prolonged for a while. When clamping the trachea at the end of inspiration and interrupting the expulsion of air from the lung, rhythmic respiratory efforts that were alternated by inspiratory and expiratory efforts were interrupted for a while until the interruption was broken. These effects were completely abolished by the bilateral sectioning of the vagus nerve. After bilateral ►vagotomy, slow rhythmic respiratory efforts went on independently whether or not inflation or deflation of the lung was prevented. From these experiments, they recognized that the vagus nerve might carry two different types of afferents. Inflation of the lung stimulates one type of nerve ending of the vagus nerve to terminate inspiration and initiate expiration. On the other hand, deflation of the lung stimulates another type of afferent to terminate expiration and initiate inspiration. The former phenomenon was called the "Hering–Breuer inflation reflex" and the later, the "Hering–Breuer deflation reflex." As previously mentioned, the works of Hering and Breuer gained notoriety late in the century largely in part due to the work of Hering's student Henry Head. The latter phenomenon is also called the "Head paradoxical reflex."

How does the Hering–Breuer reflex correspond to the position of respiratory physiology today? We now have the term "inspiratory off-switch mechanism," which was derived from the Hering–Breuer inflation reflex. In the twentieth century, with the progress of science and technology, we are able to record electrical activities of muscles and nerves, which could not be done in the nineteenth century. The activities recorded from the main inspiratory muscle, the ►diaphragm, or from the ►phrenic nerve, which innervates the diaphragm, show the same trajectories with and without lung inflation. This indicates that the Hering–Breuer inflation reflex, in other words, the inspiratory inhibitory reflex becomes available at the end of inspiration. Breuer described that the inspiratory effort increases when an animal's trachea is clamped to disturb lung inflation. The trajectories of inspiratory motor output with and without inflation did not differ, but they did differ according to whether or not the inspiratory off-switch occurred early. Receptors are necessary to induce reflexes. It is well known that the receptor operating in the Hering–Breuer inflation reflex is the pulmonary stretch receptor (PSR) and the activity is conducted in the vagus nerve. PSR is a mechanoreceptor that responds to mechanical stimulation. There are two types of mechanoreceptors distinguished by the difference in adaptation. One is the slowly adapting receptor and the other is the rapidly adapting receptor. PSR belongs to the former, the slowly adapting receptor, and it is not adaptable to stimulation. The appropriate stimulation for PSR is stretching, which is activated during inflation of the lung. The Hering–Breuer inflation reflex is just the reflex induced by the activation of PSR. However, inspiratory inhibition does not occur until the afferent activities from PSR increase and reach a certain level. Inspiratory inhibition suddenly occurs when the afferent activities reach the threshold. The abrupt inhibition is called "inspiratory off-switch." However, the inhibition is induced even after bilateral vagotomy. Tidal volume and inspiratory time increases after vagotomy. That is to say that the inspiratory off-switch occurs when the central inspiratory output reaches the threshold for inspiratory inhibition. The inspiratory off-switch is induced by a summation of activities of the central inspiratory output and vagal afferent activity. This research has been performed in animal experiments. In humans, the PSR is too weak to induce the reflex. The Hering–Breuer inspiratory inhibitory reflex does not occur until the lung inflation reaches 1.5-fold the eupneic tidal volume. In addition to PSR, there are other stretch receptors in skeletal muscles. The receptors are densely distributed in the intercostal muscles. The stretch receptor in intercostal muscles has been shown to induce the same kind of reflex as the Hering–Breuer inflation reflex.

You can find the term Hering–Breuer reflex in every textbook of physiology.

From the clinical viewpoint, the Hering–Breuer reflex is also important in that the reflex tends to prevent excessive distention of the lung during inspiration, which may cause injury to the alveoli, and prevents the collapse of the lung during expiration.

Hering and Breuer's description of "self-regulation" of breathing remains as a general timeless hypothesis, and the term Hering–Breuer reflex will be carried on in the new millennium.

## Hering's "Law of Equal Innervation"

### Definition

It postulates that the eyes move in a conjugate fashion (i.e., simultaneously in the same direction and by roughly the same amount), because synergistic muscles of both eyes receive the same signal. It was formulated with two corollaries attached to it: (i) The principle of equal innervation is due to the existence of appropriate anatomical connections, and (ii) The appropriate anatomical connections are innate.

## Herpes Virus

### Definition

Herpes viruses are a family of large DNA-containing, enveloped viruses. Eight human herpes viruses are recognized and can be classified into three sub-families α, β and γ viruses based on their genomic organization, virus host range, and other biologic properties. Herpes viruses are transmitted through direct contact and induce disease by destroying affected tissues. For example, both herpes simplex virus and varicella-zoster virus are α herpes viruses and infect primarily epithelial cells, thus causing mucocutaneous infections. All herpes viruses induce latent infections after primary infection. Latent viruses are usually retained in certain types of cells, such as in sensory neurons for herpes simplex virus and varicella-zoster virus.

►Immune System and Pain

## Herpes Zoster

### Definition

Also known as "shingles," herpes zoster is a reactivation of varicella zoster virus infection from a ganglion within the nervous system. Reactivation usually produces a skin rash that includes fluid-filled blisters.

Commonly affected sites of reactivation include the skin area (dermatome) innervated by the corresponding dorsal root ganglion of the spinal cord or area of the face innervated by the Trigeminal ganglion. Although reactivation can be painful, pain is more common after blisters have healed, and is called "postherpetic neuralgia." Diagnosis can be made presumptively from the dermatomal distribution of the rash, or confirmed by Tzanck smear or polymerase chain reaction (PCR) assay on scrapings of tissue from the base of a blister.

►Dorsal Root Ganglion (DRG)
►Neuropathic Pain
►Trigeminal Nerve

## Heteroassociative Memory

### Definition

A neural network that stores input–output pattern pairs to recall a stored output pattern by receiving a noisy or incomplete version of a stored input pattern paired with that output pattern. In each of the pairs, an input pattern should differ from an output pattern.

►Associative Memory

## Heterodimerization

### Definition

The binding of two different protein subunits, such as G protein-coupled receptors, to form a single functional unit. The pharmacological properties of the heteromeric receptor are generally different from a receptor composed of two identical subunits. Heterodimerization appears to be a mechanism for increasing the diversity of receptor pharmacology.

►G-Protein Coupled Receptors (GPCRs) in Sensory Neuron Function and Pain

## Heterologous Expression

### Definition

The process of expressing a foreign protein in cell line or type that does not usually make the target protein.

This is most often done to determine the functional consequences of introducing amino acid mutations into proteins or to assess the specific interactions among proteins. For example, heterologous expression has been extensively used to study the molecular mechanisms of ion channel function and modulation. Commonly used cells include immortalized mammalian cells derived from tumors, or amphibian oocytes (i.e. unfertilized eggs).

►Sodium Channels

## Heterologous Expression System

### Definition

Heterologous expression systems comprise prokaryotic organisms (e.g. E. coli) and eukaryotic cells (e.g. yeast, HEK293, Xenopus oocytes) that are used to functionally express foreign genes or cDNAs.

## Heteromodal

►Multimodal Integration

## Heterospecific

### Definition

►Conspecific

## Heterostasis

### Definition

Under varied condition of an organism, adaptation has to change the homeostatic state. Hans Selye named this changed state to be heterostasis.

►Homeostasis

## Heterosynaptic Depression

### Definition

When high-frequency stimulation is applied to one of the two independent pathways innervating the same postsynaptic cells, synaptic depression is sometimes induced in the other nontetanized pathway. This type of synaptic depression is called heterosynaptic depression.

## Hibernation

Arjen M. Strijkstra
Department of Chronobiology, University of Groningen, Groningen, The Netherlands

### Synonyms

Wintering (to hibernate = to winter)

### Definition

Hibernation: (a set of) adaptive behavior(s) which allow animals to survive winter by minimizing their exposure to harsh winter conditions.

### Characteristics

#### On the Word Hibernation

The word ►hibernation (Latin: "*Hibernare*") refers to "behavior used in wintertime." It indicates behaviors that animals use during their surface absence in winter. However, hibernation is often used for the long-lasting inactive low body temperature (hypothermic) state, which euthermic hibernators (e.g., mammals and birds) have during hibernation. This seems incorrect since hibernation in euthermic animals almost always contains other vital behaviors, which require euthermic conditions at least. A better behavioral term for the inactive state is ►torpor (Latin: "*Torpere*," being "stiff or numb"), which indicates inactive behavior with low reactivity.

#### Why Hibernate?

Most animals cannot escape winter conditions (e.g., by migration) and thus have to endure them. Hibernating animals seclude themselves in a secure and shielded place (hibernaculum, e.g., a burrow, a den) for as long as possible, avoiding problems of outside exposure, e.g., predation risk, the high energy expenditure of activity in the cold, and the low energy yield of foraging. Hibernation thus increases survival by minimal exposure.

#### Which Animals Hibernate?

Hibernation is widespread in the animal kingdom. Insects hibernate. Heterothermic vertebrates such as amphibians and reptiles also hibernate. Hibernation in heterothermic animals includes finding a suitable hibernaculum, minimization of activity, suppression of metabolism and coping with the ambient temperature conditions. In extreme cases, this may include being able to freeze solid and thaw after winter, e.g., in frogs. During the freezing process, frogs massively mobilize blood sugars, which are transported into cells to high concentrations. This minimizes cell damage by preventing growth of ice crystals during freezing. Other cryoprotective processes also have been described (e.g., preventing icicle nucleation, supercooling).

Euthermic animals, birds (e.g. Poorwills, Goatsuckers) as well as mammals (e.g. Bears, Ground squirrels, Syrian hamsters) [1], also hibernate. Many small mammals and birds do not completely refrain from surface activity in winter, but use short daily torpor bouts to cope with harsh winter conditions instead (e.g. Djungarian hamsters, Deermice, Willow Tits).

Strategies including reduced activity and torpor are not exclusive for winter conditions, but are also used to survive summer drought (estivation), to survive food shortage (e.g., fasting induced torpor) or may even be considered a part of normal euthermic life (e.g., Hummingbirds, Bats).

#### Benefits of Hibernation

A primary benefit of hibernation is elongation of lifespan by avoiding winter conditions. However, since some hibernators already start hibernation in summer at high temperatures, there are probably additional benefits in avoidance of surface activity before winter. This may be related to avoiding summer drought or predation risk.

Additional benefits may be related to the positive effects on lifespan by torpor. The more time a euthermic hibernator spends in torpor, the longer it lives. Furthermore, euthermic hibernators generally live longer than non-hibernating euthermic species of similar size.

## Costs of Hibernation

Doing nothing comes at a cost. Hibernation prohibits reproduction. When not active above ground, animals will have problems to finding a mate. Additionally, hibernation physiology is incompatible with reproduction and gonads are regressed in deep hibernators. Furthermore, animals will not be able to forage while inactive. This means that animals have to prepare energy stores before hibernation, which takes time, effort and risk of surface activity, and in many cases major physiological adaptations.

Although one can not say that one species suffers more from hibernation than another, euthermic hibernators appear to face particularly dramatic changes [1]. Since euthermic animals have a high metabolic rate, the need for extreme energy stores and energy savings for hibernation appears essential. Additionally, euthermic animals have to cope with the loss of stable high body temperature.

Furthermore, doing nothing may have costs in itself: several tissues need to be used to be maintained. This is the case for body tissues, such as muscle, bone, and gut, although hibernators appear to deal with this very well. Disuse of the brain may however lead to behavioral consequences as well ("use it or lose it").

## Mammalian Hibernation

Even within the mammalian hibernators a tremendous variety in hibernation and torpor patterns occurs. Hibernation behavior depends on life history characteristics and physiological limitations of the species, as well as on environmental conditions. Hibernation may thus differ between species, between populations, between sexes, between age classes, between individuals, and between years. However, it is possible to indicate general patterns of hibernation based on torpor timing.

## Patterns of Torpor

Three basic patterns in torpor timing occur in mammals: (i) continuous torpor, (ii) short torpor bouts on a daily basis, and (iii) long multi-day torpor bouts interspersed with short euthermic phases (i.e., arousal episodes, inter-bout arousals). These patterns can be mixed, but most torpor patterns fit the division into these three types.

## Continuous Hibernation

The classical view on hibernation – hibernation with continuous torpor – has been observed in few mammalian species. Bears are large animals with a low mass-specific metabolic rate (i.e., metabolic rate per gram of body weight), large fat storage capabilities and high thermal capacity and insulation. This allows bears to hibernate continuously at a relatively high body temperature of >28°C.

Fat-tailed lemurs can hibernate with long torpor bouts interspersed with euthermic phases, but also continuously. Their continuous hibernation is linked to regular torpid body temperatures of >30°C, which occur by external heating during daytime: if these temperatures are not reached, long torpor bouts with euthermic phases occur [2]. This suggests that there may be a temperature limitation in the possibility to maintain a continuous natural torpid state.

## Daily Torpor

Many small species show short torpor bouts on a daily basis in winter, allowing them to forage on a daily basis. The daily torpor bouts are timed in the inactive phase of day and are governed by the internal biological daily (►circadian) timing system. Daily torpor is short (<12 h per day) and has an apparent lower temperature limit of about 15°C in all species [3]. Daily short bouts of torpor may also be observed in early stages of deep hibernation.

## Deep Hibernation

Deep hibernation with long multi-day torpor bouts interspersed with euthermic phases represents the most extreme form of hibernation. Deep hibernators reduce their metabolic rate to a fraction (1–2%) of basal metabolic rate and allow body temperatures to drop close to 0°C [3], or even slightly below. Duration of torpor bouts varies between 1 and 2 days to >30 days, and depends on species, body size and temperature. Larger hibernators usually have longer torpor bouts, higher torpor temperatures result in shorter torpor bouts. Below 0°C, torpor bout duration remains similar (or becomes much shorter).

## Obligate and Facultative Deep Hibernation

Obligate hibernators have an internal programmed drive to hibernate. These species (e.g., ground squirrels, European hamster) have an internal annual program governed by an elusive seasonal timing system, possibly mediated by a signal in the blood stream [4]. Ground squirrels will hibernate in an approximate 300-day (►circannual) cycle in the absence of any seasonal information. Obligate hibernators such as ground squirrels are the most extreme hibernators. In preparation for hibernation they become insulin insensitive and obese. Entering hibernation, they become anorexic, and hibernate for up to 7–9 months per year. They rely mainly on body fat reserves as energy supply. During hibernation they have a series of long torpor bouts of >10 days in which sub-zero body temperatures may be reached.

Facultative hibernators are triggered to hibernate by ambient conditions: temperature and photoperiod (►photoperiodism). Syrian hamsters hibernate after a change of day length (photoperiod) from long days (>13 h light, "summer") to short days (<10 h light, "winter"). This is governed by the internal daylength measurement system, using ►melatonin. Melatonin is a hormone produced by the ►pineal organ in the brain. Suppression of melatonin by light confines high melatonin levels to darkness. Melatonin presence thus indicates the length of darkness and thereby day length. A subsequent lowering of ambient temperature will trigger hibernation. Facultative hibernators are less extreme hibernators, having short torpor bouts and long euthermic phases. Furthermore, they may heavily rely on food stores as energy supply during hibernation.

## Torpor Physiology

Torpor starts with behavioral inactivity, followed by metabolic suppression, and subsequent hypothermia (►natural hypothermia). First, animals typically assume a sleep posture. Torpor is started from an inactive sleep-like state: electrical brain activity (electroencephalogram, EEG) suggests sleep, with regular alternations of the two sleep stages ►rapid-eye-movement (►REM) and ►non-REM sleep [5]. During this inactivating sleep, whole body oxygen consumption is reduced by 90% or more within the hour. This metabolic reduction leads to lower temperature of the body, cooling passively. Thus, animals reduce metabolism by fast active suppression, which is indicated by high ►$Q_{10}$ values. A $Q_{10}$ value is the change in rate of a process caused by a 10°C temperature change. For passive physiological processes $Q_{10}$ values range between 2 and 3, for regulated changes (such as in metabolic suppression entering torpor) $Q_{10}$ values may be >10.

The metabolic suppression is associated with reduced activity of rate limiting enzymes, reducing the entry of fuel substrates into the respiratory chain and the tri-cyclic-acid (Krebs) cycle. Blocking these pathways suppresses production of cellular energy (adenosinetriphosphate: ►ATP). In torpor, a suppressed ATP production does not lead to cell death. Somehow, energy production and consumption are balanced by a co-occurring reduction of cellular energy demanding processes. At temperatures below 18°C DNA read-off and protein production are negligible [6].

Although metabolism is minimal, this does not indicate deregulation. Thermoregulation is functional. Torpid mammals accurately regulate respiration, heart rate, cardiac output, blood pressure, oxygen delivery to tissues, even though blood/tissue pH (level of acidity) and $CO_2$ (carbon dioxide) clearance may be regulated differently. Torpid animals are reactive to external stimuli and will arouse from torpor spontaneously or by disturbances [1].

## Thermoregulation

Hypothermia during torpor is not an uncontrolled pathological situation which can only be reverted by external heating. Homeostatic (►homeostasis) thermoregulation is functional, although in torpor entry and steady state torpor, thermoregulation operates around different setpoints (►rheostasis). Bears regulate body temperature above 28°C in continuous torpor, daily torpor animals defend a body temperature of about 15°C, and deep hibernators defend a body temperature of about 0°C, even when ambient temperature is much lower.

Thermoregulation is vital to maintain in hypothermic torpor, because the animal has to rewarm eventually to resume euthermic life. Thermoregulatory function resides in the brain, in ►hypothalamic and ►brainstem nuclei and ►hippocampus [7]. Involvement of several ►neurotransmitter and ►neuropeptide systems (adenosinergic, cholinergic, noradrenergic, serotonergic, histaminergic and opioid [1,8]) in torpor and arousal regulation have been indicated.

## Arousal From Torpor

Rewarming starts with signals from the brain stem and hypothalamus. These lead to heat production by a specialized organ designed to generate heat: brown fat. The brown color is caused by the many blood vessels which transport the heat away from the tissue, and the densely packed mitochondria. Brown fat is located around the major arteries linking the heart to the brain.

Brown fat efficiently generates heat by uncoupling membrane pump action from its normal cellular energy (ATP) producing function using specialized uncoupling proteins. Heat is generated fast in the heart and brain region. When the brain is sufficiently warm, it can mobilize additional heat production by shivering. Depending on the starting temperature and size of the animal, the rewarming process may take about 30 min to several hours.

## Why Arouse Regularly From Deep Torpor?

During continuous torpor and daily torpor, (near) euthermic temperatures regularly occur. Deep hibernation apparently requires regular euthemia. The cost of the euthermic phases is extremely high compared to torpor, but the function appears difficult to find.

The basic idea is that torpor accumulates a problem of some kind. Several hypotheses have been forwarded ranging from the need to empty the bladder, restore blood fuels, and restore cell products (mRNA, proteins), to the need for brain maintenance and repair. Since the most vital regulatory functions (e.g., thermoregulation) reside in the brain, hypotheses related to maintenance of brain function are attractive.

### The Brain and Torpor Entry

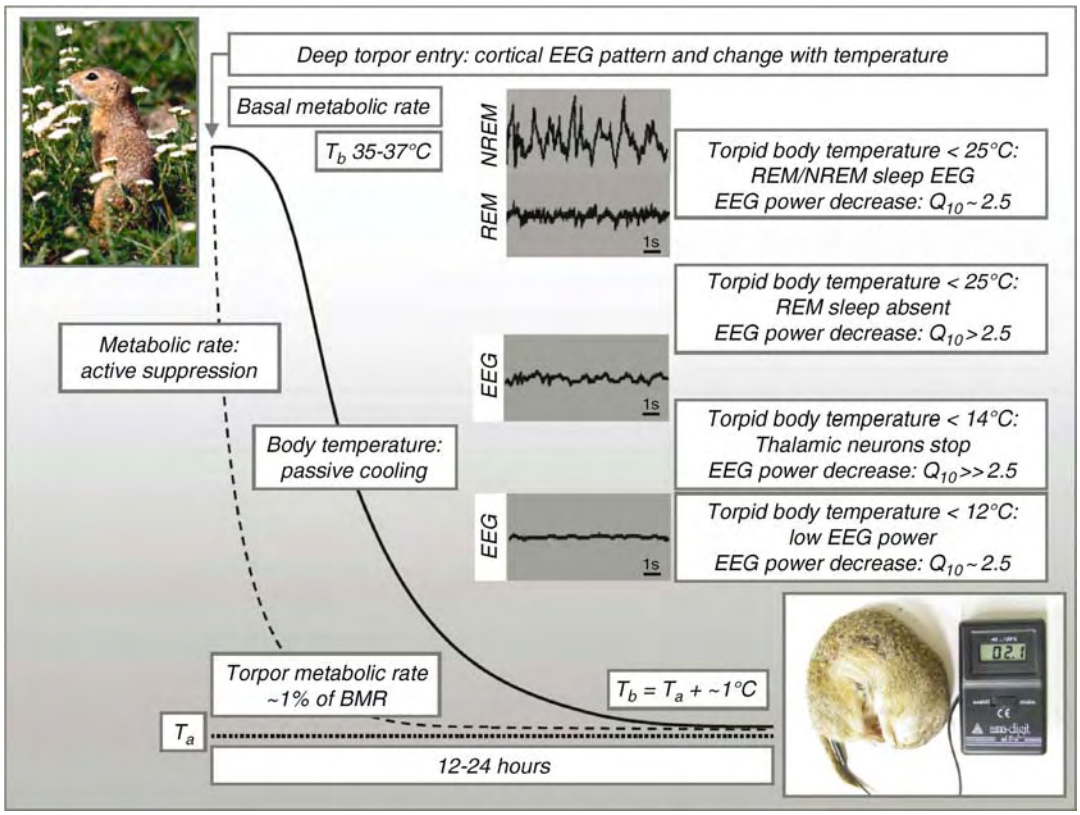
During cooling, brain activity patterns change (Fig. 1). Electroencephalographic (EEG) power is reduced in steps: at 25°C, rapid-eye-movement (REM) sleep patterns disappear (preventing defining of sleep states) and EEG power starts to drop faster than passive at a $Q_{10}$ of >3. At 15°C, EEG power drops massively, mediated by the cessation of thalamic neuronal firing. Below 10°C, the EEG suggests brain death. Only in deeper brain regions important for thermoregulation (e.g., hypothalamus, hippocampus) low electrical activity can still be measured. In general, torpor constitutes a phase of extreme brain inactivity, depending on temperature [5,7].

### The Brain After Torpor

During rewarming, effects on brain activity are reversed. Thalamic neurons start firing again around 15°C and cortical EEG returns to (approximately) normal above 25°C. However, subtle EEG differences indicate carry-over effects of torpor in subsequent euthermia (►euthermia, ►normothermia). Initially, REM and NREM sleep-like firing patters of thalamic neurons could be found simulataneously, which was never observed in any other sleep situation. Furthermore, ►slow-wave activity (SWA: power of the slow 1–4 Hz (delta) frequencies of the NREM sleep EEG, indicating the level of simultaneous hyperpolarization (relative inactivity) of cortical neurons, synchronously "burst-firing") is high after torpor. This depends on duration of torpor (long torpor has high SWA increases) and the temperature during torpor (high torpor temperature has low SWA increases). This indicates that deep torpor affects functional neuronal connectivity in the brain [5].

### Torpor is Not Deep Sleep

Torpor induces high SWA, i.e., deep sleep. This indicates that torpor may resemble a kind of wakefulness, but certainly not a kind of sleep. Furthermore, after deep



**Hibernation. Figure 1** Schematic representation of deep torpor entry from a euthermic body temperature ($T_b$) to a deep torpor body temperature just over ambient temperature ($T_a$) in a deep hibernator, the European ground squirrel (*Spermophilus citellus*). Active metabolic suppression (dotted line) from basal metabolic rates (lowest euthermic metabolic level) at euthermia is followed by a passive body temperature decrease (solid line). The 10 s EEG traces initially resemble NREM and REM sleep; REM sleep is lost below 25°C. At lower temperatures the EEG shows progressive changes in power with different rates, indicating regulated activity changes ($Q_{10}$ > 2–3) and passive changes ($Q_{10}$ ~ 2–3), ultimately resembling a flat line below ~10°C.

torpor, the increased SWA is not attached to sleep regulation processes. Preventing SWA expression during euthermia by ►sleep deprivation or caffeine did not postpone the expression of SWA, which would be expected if the torpor induced SWA is similar to wakefulness induced SWA. In contrast to deep torpor, sleep deprivation did postpone SWA expression after daily torpor in Djungarian hamsters. Thus, the hypothesis that daily torpor may represent some kind of wakefulness can not be refuted yet.

### Torpor Affects Neuronal Status

The carry-over effects of torpor on subsequent euthermic EEGs suggest repercussions of inactivity. Indeed, neurons show marked cyclic reversible changes in neurons (i.e., reduced dendritic trees, synaptic contacts and neurotransmission capacity) over torpor and subsequent euthermia [5].

In torpor, the microtubule-associated protein "►tau" shows phosphorylation on locations indicative for the switch between physiological and pathological states of the neuroskeleton in aging and Alzheimer's disease. Interestingly, this is rapidly reversed in euthermic phases. Although this phosphorylation is associated with decreased brain function in humans, in hibernation this may contribute neuroprotective action [9].

### Hibernation Affects Brain Function

Although many vital functions appear not affected by torpor, memory performance is. Ground squirrels forget spatial memory and operational conditioning due to low temperature torpor [10]. During hibernation, learning during euthermic phases may be enhanced. This indicates that the hibernating brain is plastic [9], although the functional reason for this is probably not related to learning.

Circadian function also is affected by hibernation. Ground squirrels have reduced amplitude in daily (circadian) body temperature and activity rhythms. This is reflected in the expression of a circadian output signal (arginine vasopressin) in neurons in the ►suprachiasmatic nucleus (►SCN), the neural substrate of the circadian clock.

### Medical Relevance

Considering the enormous physiological changes a mammalian hibernator goes through, torpor may be an important model system for medical problems related to cellular metabolism, for which hibernators may possess evolutionarily validated solutions.

Ground squirrels and marmots become insulin insensitive before hibernation, adding 50% of their body weight in fat in several weeks, mimicking obesity. When the animal starts hibernation, the obese state is changed to an anorexic state. Apparently, hibernators possess cellular programs to battle obesity and metabolic syndrome.

Deep hibernators can maintain torpor for 10–20 days at near freezing temperatures without apparent damage to internal organs. This greatly contrasts the time window of less than 24 h for successful transplantation of cold-stored human organs. Hibernators are a model system for research on increasing this time window.

Acute problems of cardiac arrest and stroke are related to local circulatory arrest and reperfusion in the brain. The damage is caused by low cellular energy supply, which occurs rapidly in the brain. Mild hypothermia is beneficial for the neurological outcome of circulatory arrest patients. Hibernators combine hypothermia with metabolic suppression, which may further reduce neuronal damage [8].

Hibernators have phosphorylation of the microtubule-associated protein tau resembling that of Alzheimer's disease (AD) and aging. Torpor leads to memory impairments and dampening of circadian rhythms, behavioral symptoms of AD and aging. Even if torpor does not lead to neurofibrillary tangles and cell death, torpor is a natural model system for tau phosphorylation and dephosphorylation [9].

### Suggested Reading

This brief overview of hibernation does not allow for full coverage and references for all behavioral and neurological issues. Besides some original papers, the reference list contains books and review papers that can be helpful as an entry into the hibernation literature.

## Synonyms

HIF-1α: ARNT Interacting Protein; Member of PAS Superfamily 1; Basic-Helix-Loop-Helix-PAS Protein MOP1; HIF-1β: Arylhydrocarbon Receptor Nuclear Translocator (ARNT)

## Definition

HIF-1, the ►hypoxia-inducible factor-1, is a transcription factor which is activated under conditions when cellular oxygen consumption exceeds the oxygen supply, or in other terms cellular hypoxia. HIF-1 activity leads to metabolic adaptation and cellular survival during situations in which oxygen is limited, typically found in inflamed tissues. A characteristic feature of inflamed tissue is the invasion of white blood cells producing different inflammatory mediators. Additionally to hypoxia, proinflammatory cytokines are potent activators of HIF-1 and some proteins involved in the inflammatory process are regulated by HIF-1 itself. Furthermore, HIF-1 seems to be necessary for hypoxia induced apoptosis. Therefore, HIF-1 activity plays an important role during maintenance and possibly termination of inflammation. At present HIF-1 inhibitors are in clinical trials as anti-cancer drugs, but HIF-1 inhibition should also be an attractive approach to fight rheumatoid arthritis or neuroinflammation.

## Characteristics

### Quantitative Description

HIF-1 is a heterodimeric transcription factor consisting of an oxygen-labile α-subunit and an oxygen-resistant β-subunit. The human α-subunit is a single chain of 826 amino acids with a calculated molecular mass of approximately 92.5 kD, although the apparent molecular weight in Western blot experiments is somewhat higher in the range of 110 kD. The single copy gene is located on chromosome 14q21-q24. The β-subunit has been identified as the arylhydrocarbon receptor nuclear translocator, the dimerization partner of the dioxin-receptor. HIF-1β/ARNT consists of 789 amino acids, has a molecular mass of approximately 91 kD and is encoded on chromosome 1 in the region of 1q21.

Typical HIF-1 target genes are the genes encoding most of the glycolytic enzymes to enhance anaerobic glycolysis, the glucose transporter-1 and -4 to facilitate glucose uptake during oxygen deprivation, the vascular endothelial growth factor (VEGF) and the transforming growth factor-β3 (TGF-β3) to induce angiogenesis, the insulin-like growth factor-2 (IGF-2) and transforming growth factor-α (TGF-α) to promote cell proliferation, heme oxygenase-1 (HOX-1) and NO-synthase-2 (NOS-2), both involved in regulating vascular tone, the ceruloplasmin, transferrin and the transferrin-receptor critical for iron metabolism, the carboanhydrase 9 for pH regulation and the well-known erythropoietin (EPO) increasing erythropoiesis and acting as a neuroprotectant [1]. Indeed, HIF-1α and the active HIF-1α/β dimer were discovered in context with hypoxic EPO expression [2] and the EPO gene was the prototype of hypoxically regulated genes for years. More recently it became obvious that HIF-2, an isoform with a more restricted tissue distribution, is much more important for hypoxia dependent EPO expression than HIF-1, as well in the kidney as in hepatoma and neuroblastoma

cell lines and in cortical astrocytes. In any case, the number of validated target genes regulated by HIF transcription factors is increasing steadily.

## Description of the Structure/Process

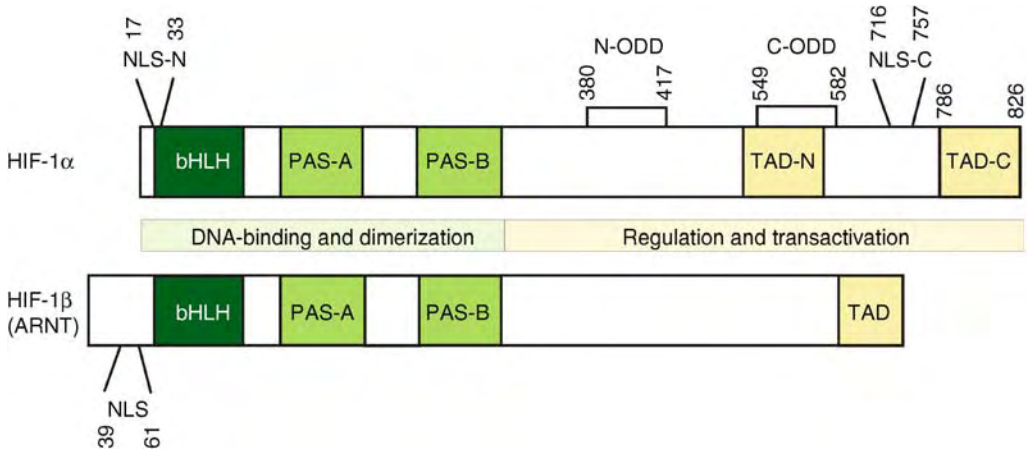
In the presence of oxygen, the α-subunit of HIF-1 is immediately hydroxylated by HIF-specific prolyl hydroxylase domain proteins (PHDs). PHDs are a family of HIF prolyl 4-hydroxylases, currently consisting of 3- or 4 members (PHD-1,-2, -3; and perhaps -4), hydroxylating specific proline residues (p402 and p564) in so-called oxygen dependent degradation domains of the HIF-1α protein (N-terminal- and C-terminal oxygen dependent degradation domain, N-ODD and C-ODD) (Fig. 1).

The PHDs serve as cellular oxygen sensors, since their enzymatic activity depends on the availability of molecular oxygen. Hydroxylated HIF-1α is recognized by the von-Hippel-Lindau protein, the substrate-recognition subunit of an E3 ubiquitin ligase complex. Subsequently, hydroxylated HIF-1α is polyubiquitinated and thereby tagged for proteasomal degradation [3]. Thus, HIF-1α remains undetectable under normoxic conditions, the averaged half-life is extremely short (minutes). In hypoxia PHD-activity is reduced due to limited amounts of oxygen and HIF-1α becomes no longer hydroxylated. Although overall translation is clearly reduced under hypoxic conditions, HIF-1α translation is apparently not affected. This might be due to the use of an internal ribosomal entry site (IRES) within the HIF-1α mRNA, rendering the translation to be cap-independent.

The hypoxically stabilized HIF-1α subunit has then to be translocated into the nucleus. The nuclear destination is achieved by use of the C-terminal NLS (NLS-C) which is most probably of bipartite type and the classical α/β importin system since most α-importins bind HIF-1α at the NLS-C domain. The NLS-N, in contrast, seems to be of minor importance for nuclear translocation. Within the nucleus, HIF-1α dimerizes with HIF-1β *via* PAS-A and PAS-B domains and associates with additional transcriptional cofactors (e.g., CBP/p300) *via* transactivating domains (TAD-N and TAD-C). Within this complex, HIF-1 recognizes and binds to HIF-1-responsive elements (HREs) within promoter or enhancer regions of hypoxia regulated genes by use of the basic helix-loop-helix motifs (bHLH). The order of the described processes is not strictly as written, many processes happen simultaneously or the order is not clear. As a result, the formed protein-DNA complex directs the RNA-polymerase 2 to initiate transcription. Therefore, HIF-1 functions as a classical transcription factor, but it is of note that repressive effects have been reported too.

## Higher Level Structures/Processes/Conditions

Beside this main regulatory pathway, there exist some additional pathways to regulate the HIF-1α protein amount. For instance, protein acetylation by ARD-1 has been reported to destabilize HIF-1α *via* enhanced



**HIF-1 and Neuroinflammation. Figure 1** Schematic drawing of HIF-1α and HIF-1β proteins. Abbreviations are: N-ODD and C-ODD: Amino-terminal and carboxy-terminal oxygen dependent degradation domains; NLS-N and NLS-C: Amino-terminal and carboxy-terminal nuclear localization signals/sequences; PAS-A and PAS-B: Protein domains critical for dimerization, first identified in drosophila period protein, the arylhydrocarbon receptor and in the drosophila single-minded protein; TAD-N and TAD-C: Amino-terminal and carboxy-terminal transactivating domains; bHLH: Basic helix-loop-helix motiv for DNA-binding. Figure adopted from Semenza GL, Agani F, Iyer N, Jiang B-H, Leung S, Wiener C and Yu A (1998) Hypoxia-Inducible Factor 1: From Molecular Biology to Cardiopulmonary Physiology. CHEST 114:40S-45S and extended.

interaction with pVHL and ubiquitination. The HIF-1 inhibitor YC-1 (3-(5′-hydroxymethyl-2′-furyl)-1-benzylindazole) reduces the amount of hypoxically induced nuclear HIF-1α by a so far unknown mechanism. Nevertheless it has been shown that macrophage derived nitric oxide (NO) can lead to nitrosylation of cystein 533. This posttranslational modification within one ODD of HIF-1α prevents its destruction. Despite the regulation *via* protein stability of the α-subunit, HIF-1 activity can be regulated in many other different ways. One prominent and probably important possibility is the hydroxylation of asparagine 803 of the α-subunit by an asparaginyl hydroxylase named factor inhibiting HIF-1 (FIH-1). This action prevents p300 and CBP to interact with HIF-1α and, most likely, the transcriptional initiation complex cannot be established. In this context it is of note that HIF-1α becomes nitrosylated in the presence of NO at cystein 800 (beside the above mentioned nitrosylation at cystein 533) which improves its interaction with p300 leading to increased transcriptional activity. Furthermore, HIF-1α as well as HIF-1β are subject to lysine-sumoylation but the functional consequences are currently unclear due to contradictionary reports.

## Regulation of the Structure/Process/Conditions

There are several interconnections between hypoxia, respectively HIF-1, and neuroinflammation. The systemic inflammatory response syndrome (SIRS) is characterized, besides other malfunctions, by large inflammatory changes in the brain causing fever, cardiovascular and neuroendocrine responses. At the sites of inflammation the cellular metabolism is changed, resulting in a disequilibrium of energy supply and demand. This situation is leading to inflammation-associated tissue hypoxia and local metabolic acidosis and thus stabilization and activation of HIF-1. As an early event the recruitment of inflammatory cells, particulary myeloid cells such as neutrophils and monocytes to the place of inflammation is observed. In animals with a conditional HIF-1α knockout no such myeloid cell infiltration was found. A closer look at the HIF-1α knockout myeloid cells revealed a decreased glycolytic rate and finally drastically reduced ATP levels within these cells. This in turn has negative effects on myeloid cell aggregation, motility, invasiveness and bacterial cell killing [4].

Bacterial infections and lipopolysaccharide (LPS) activate HIF-1α under normoxia in many different cell types, including the above mentioned immune cells. Activated macrophages produce a large number of proinflammatory cytokines, including IL-1,IL-4, IL-6, IL-12 and TNF-α and knockout experiments revealed that the production is HIF-1α dependent and that TLR-4 is necessary for LPS mediated activation of HIF-1α (TLR-4 belongs to the pattern recognition receptor-family and is critical for the proinflammatory response) [5]. Considering that proinflammatory cytokines itself are potent inducers of HIF-1α, the initial inflammatory response of the immune cells augments the overall HIF-1 activation in the inflamed tissue. Nevertheless, IL-1 is not solely expressed by immune cells. Astrocytes and microglia have been demonstrated to produce IL-1β under hypoxic conditions in a HIF-1-dependent manner. This is most likely the explanation, why peripheral, circulating leukocytes are attracted by the hypoxic brain. However, it has been shown that IL-1 and its type 1 receptor are necessary for progressive neurodegeneration upon a mild hypoxic/ischemic injury [6]. Focused on the immune cells, it has been reported that LPS increases the glucose uptake in neutrophils. A closer look revealed a HIF-1 and p38 dependent Glut-1 (glucose transporter-1) translocation from the interior to the cell surface to be the cause for the enhanced glucose uptake [7]. However, Glut-1 is a HIF-1 target; its expression is increased under hypoxia, which is of special importance, since the facilitated glucose shuttling across the blood-brain barrier (BBB) is achieved by this transporter. Considering VEGF as a HIF-1 target too, it becomes obvious that HIF-1 activation has dramatic effects on the BBB, since VEGF enhances the vascular permeability. Furthermore, VEGF is produced by virtually all cell types of the brain upon the onset of hypoxia or the stimulation with IL-1. But not only the effect on BBB function of VEGF is of importance, VEGF is the principal mediator of angiogenesis in normal and tumor tissues. Particularly malignant gliomas show strongly elevated HIF-1α amounts and VEGF expression. The resulting tumors are highly vascularized. Recently it has been shown that HIF-1α inhibition by either overexpression of a dominant-negative HIF-1α isoform or by siRNA leads to decreased HIF-1α and VEGF protein amounts in glioma cells and the tumor growth of identically transfected cells in an animal model was reduced [8]. Additionally, it could be proven that direct injection of HIF-1α-siRNA into preexisting gliomas grown *in vivo* in mouse flanks reduced tumor volume by 50% compared to negative controls [9]. These works presented the proof of principle that HIF-1α inhibition could be a successful intervention in glioma tumor therapy. Besides that, it might be a promising approach to test the anti-inflammatory effects of HIF-1α inhibition in an animal model.

Another aspect, by which the interconnection of HIF-1 and neuroinflammation becomes evident, is neuroprotection by erythropoietin (EPO) [10]. EPO is, as mentioned above, a HIF-1 and HIF-2 target. The most prominent site of production is the adult kidney but astrocytes and neuronal cells have been shown to produce EPO too. The regulation is somewhat different in these tissues. In the kidney, EPO mRNA levels decline after long hypoxic conditions whereas EPO mRNA levels in the cerebrum remain high. This may reflect different functions of EPO. Kidney derived EPO should

elevate the number of red blood cells, whereas neuronal/astrocyte derived EPO acts neuroprotective. It is of note that HIF-1α levels do not decline after prolonged hypoxic exposure of the brain and this may be the cause for maintained EPO production. Similar to the kidney, it has been shown that IL-1β, IL-6 and TNF-α reduce EPO expression in astrocytes. It should be noted that neuronal cells are also capable of producing EPO, but the effects of proinflammatory cytokines on these cells have not been investigated so far. In summary, the onset of hypoxia induces the expression of EPO thereby enhancing neuroprotection. This holds true as long as the hypoxic insult does not induce the production of proinflammatory cytokines. In this case the neuroprotection by endogenous produced EPO is lost.

## "Higher" Sensory Cortices

### Definition

Those parts of the cerebral cortex to which the early sensory cortices send their output-signals.

## Higher Thalamic Sensory Processing

►Visual Role of the Pulvinar

## High-pass Filtering

### Definition

A filter that passes only those frequency components in the high end of the spectrum.

►Signals and Systems

## Hindbrain

### Definition

The region of the brain between the spinal cord and the midbrain. Comprised of the medulla oblongata and the pons. It contains the nuclei of many cranial nerves. Among its functions are control of the viscera, movements of the jaws and tongue, and a number of sensory systems.

►Evolution of the Spinal Cord

## Hindbrain Segments

### Definition

Vertebrate hindbrain development is characterized by segmental patterning at both cellular and genetic levels. During the ontogenesis the hindbrain neuroepithelium in all vertebrates is organized at the gross morphological level as a series of segments, the rhombomeres. Combinations of genes encoding transcriptional factors and cell signalling molecules are expressed in patterns corresponding to various inter- and intra-rhombomeric boundaries and are believed to define the identity of cells within each rhombomere.

►Functional and Neurochemical Organization of Vestibulo Pathways

## Hip Strategy

### Definition

A fixed support (feet in place) reaction to antero-posterior postural perturbation where the predominant stabilizing action involves active generation of hip torque. The "pure" hip strategy (i.e. where there is little or no ankle activation) can be learned under special conditions, but seldom (if ever) occurs during natural behavior.

►Postural Strategies

## Hippocampal Complex

### Definition

The hippocampal complex consists of the hippocampal formation (which comprises the hippocampus proper (cornu ammonis), the dentate gyrus, and the subiculum) and the adjacent parahippocampal gyrus (which includes the entorhinal, perirhinal, and parahippocampal cortices).

## Hippocampal Formation

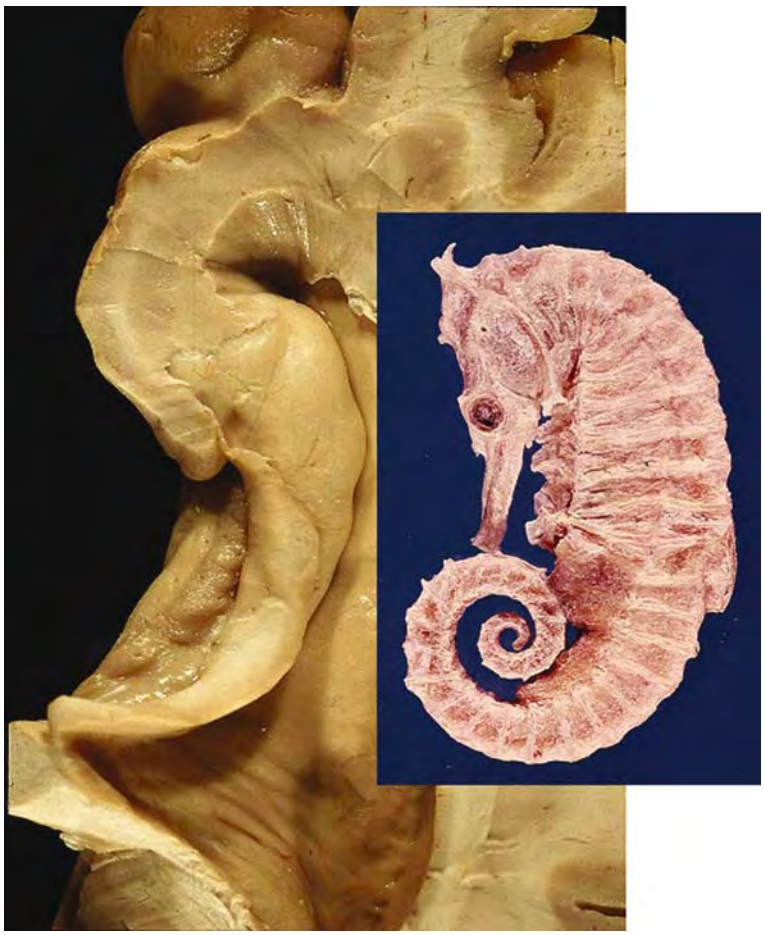
### Definition

The hippocampal formation is a macroscopically defined cortical structure, present in the brain of all mammals. It derives its name from hippocampus (seahorse), which is easily appreciated in case of the human macroscopic structure – located in the inferior horn of the lateral ventricle of the medial temporal lobe – that resembles a seahorse (Fig. 1).

It belongs to the so-called allo (old) cortex and as such is part of the *cerebral cortex* and it is closely linked to a restricted number of cortical areas, which are collectively referred to as the *para-(next to)-hippocampal region*. The hippocampal formation is reciprocally connected with a wide variety of higher order *association cortices* representing all sensory domains as well as with number of *limbic* subcortical structures. Functionally it forms a key-component of the medial temporal lobe memory system, mediating conscious or *declarative memory*.



**Hippocampal Formation. Figure 1** Dissection of the right human temporal lobe, providing a view into the inferior horn of the lateral ventricle, showing the position and extent of the hippocampal formation left). On the right a picture of the seahorse (*Hippocampus* sp.) is given, indicating the overall structural resemblance between the two structures.

## Characteristics

### Anatomical Organization

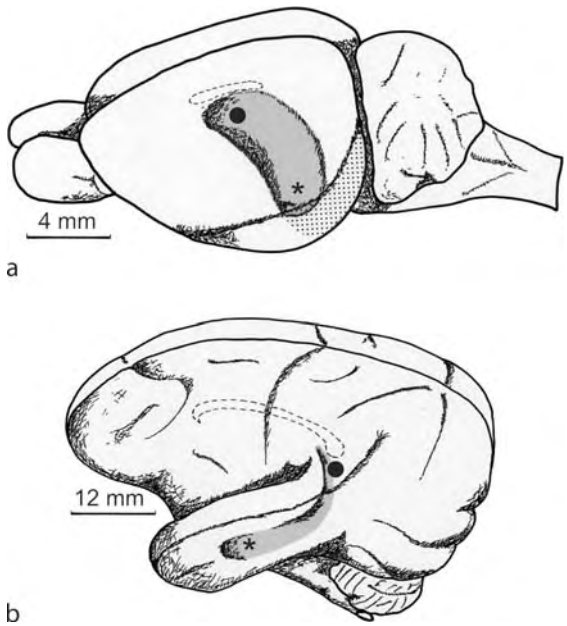
The precise orientation and curvature of the hippocampal formation and thus its overall position in the brain may vary between different species. In species with a clearly developed temporal lobe, the hippocampus is more ventrally and anteriorly (humans and monkeys) positioned, compared to the situation in for example the rat, where the hippocampus looks more like a c-shaped structure positioned in the caudal third of the hemisphere (Fig. 2).

However, this difference in position does not alter the major characteristics and the topological relations between the hippocampus and the parahippocampal structures. Nor does it influence the fact that the most anterior/ventral portion of the hippocampus has a close spatial relationship with the *amygdala*.

The wiring of the hippocampal formation, both intrinsically as well as extrinsically, is well-preserved in most species studied, such that a generalized description suffices. The hippocampus has two major pathways connecting it to the rest of the brain. The first pathway is mediated through reciprocal connections with the parahippocampal region, more in particular the *entorhinal area*, connecting the hippocampal formation with a wide variety of higher order association cortices representing all sensory domains. The second pathway, which mainly, but not exclusively, links the hippocampus to subcortical structures, makes use of the *fornix*.

The hippocampus consists of three major subdivisions, which can be easily recognized in all species (Fig. 3).

The first field, the *dentate gyrus*, is a c-shaped three-layered cortical structure which is characterized by a

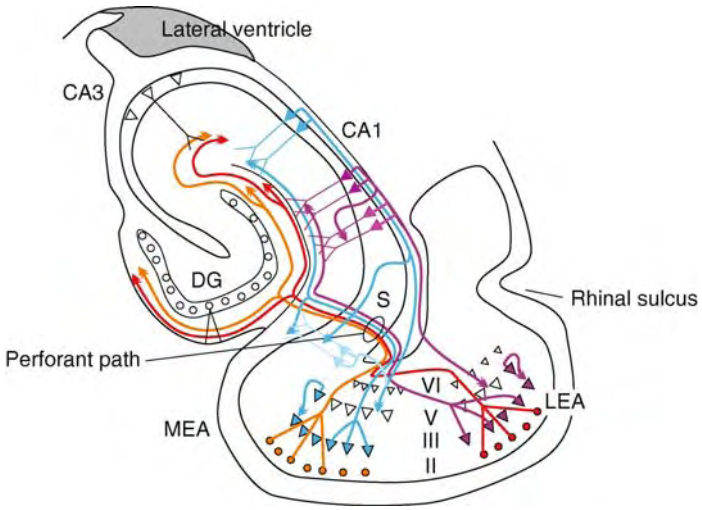


**Hippocampal Formation. Figure 2** Schematic representation of the position of the hippocampal formation in the hemisphere of the rat (a) and the monkey (b). As indicated the rodent hippocampus is positioned quite posterior in the brain such that the longitudinal feature is C-shaped, having its most dorsal pole as its most dorso-medial extension. The hippocampus in the primate, in contrast, is located in the medio-ventral part of the temporal lobe. Presumed homologous areas of the hippocampal formation, i.e. dorsal and posterior versus ventral and anterior are indicated with dot and star symbols respectively. (Reproduced and modified with permission from Witter et al. (1989) Prog Neurobiol 33:161–254).

densely packed cell layer, mainly consisting of granular cells, i.e. cells with a round soma, and a apical dendritic tuft and no or only sparse basal dendrites. Enclosed in this c-shaped cortical blade, is a polymorphic cell group generally referred to as the hilus of the dentate gyrus. The second subfield is the Ammon's Horn or Cornu Ammonis, generally abbreviated as CA-field. The CA-field is generally subdivided into CA1, CA2, and CA3. The third subdivision is the subiculum. Like the dentate gyrus, the Ammon's horn and the subiculum have an overall three-layered structure, comprising a superficially positioned fiber layer, a cell layer, mainly consisting of *pyramidal* cells with various soma-sizes, and a deep polymorph layer. The most deeply located white matter is called the alveus and the fibers that travel in the alveus are continuous with the *fornix*.

The original descriptions of hippocampal circuitry emphasized the so-called trisynaptic circuit comprising an exclusive unidirectional pathway from the entorhinal area to the distal dendrites of the granular cells in the dentate gyrus, which in turn give rise to the mossy fiber pathway to the proximal part of the apical dendrites of CA3 pyramidal cells. These CA3 neurons finally convey their output by way of the Schaffer axon collaterals to the apical and basal dendrites of pyramidal cells in CA1. The notion of connectivity along the long axis as an integral feature of the hippocampal organization has been added. Finally, the subiculum has been added on a crucial position within this circuit.

A striking feature of the cortico-parahippocampal-hippocampal circuit is that the hippocampal formation does not have extensive direct connections with the cerebral cortex. This communication is largely mediated by way of the *parahippocampal region*. Of this region, the perirhinal cortex (peri = around the *rhinal sulcus*) and postrhinal cortex (post = behind the rhinal sulcus), maintain the highest number of cortico-cortical connections, including connections with all major sensory realms, such as visual, auditory, somatosensory, and gustatory cortices (note that the postrhinal cortex as described in rodents, cats, dogs, and guinea pig most likely is homologues to the *parahippocampal cortex* of primates). Also, massive connections exist with the other two major higher-order association domains, the parietal and prefrontal cortices, but connections with the motor cortex are less prevalent. The perirhinal and postrhinal/parahippocampal cortices, in turn, provide a major input to the superficial layers II and III of the entorhinal area, and these layers further receive inputs from olfactory structures, the amygdala, and from the remaining two components of the parahippocampal region, i.e. the *pre- and parasubiculum*. Neurons in entorhinal layers II and III, which are the recipients of this wide variety of inputs, give rise to the major cortical input to the hippocampus, the so-called *perforant pathway.* This name is derived from the traditional descriptions by Ramon y Cajal who noted that fibers from the entorhinal cortex perforate the underlying white matter and the cortical lamina of the subiculum, to gain access to the dentate gyrus molecular layer. In order to understand the potential functioning of the system, it is critical to point out that the perforant pathway projection harbors two different systems. Layer II cells distribute their axons to most, if not all of the dentate gyrus, as originally described, but also to CA3. It is now well established that cells in one particular subdivision of the entorhinal area, generally referred to as lateral entorhinal area distribute their axons exclusively to the most distal portions of the dendrites of dentate and CA3 cells. The other entorhinal subdivision, referred to as medial entorhinal area, sends its projection to the middle portions of the apical dendrites of cells in dentate and CA3. This laminar organization implies that a single dentate or CA3 neuron receives both pathways. The second pathway connecting entorhinal area to hippocampal formation originates from layer III cells and



**Hippocampal Formation. Figure 3** Schematic representation of the intrinsic connectivity of the hippocampal formation and its main connectivity with the *entorhinal area*. The entorhinal area is subdivided into lateral (LEA) and medial subdivisions (MEA). Layer II projections from both subdivisions (red and yellow respectively) target different dendritic segments in DG and CA3. Layer III projections (purple and blue respectively) target different populations of neurons in CA1 and subiculum. Connections between CA1 and subiculum as well as projections from both back to LEA and MEA are in register, as are the connections between deep and superficial layers of both entorhinal subdivisions.

distributes to CA1 and the subiculum. In contrast to the laminar pattern as described for the lateral and medial layer II components, axons of layer III cells only target restricted groups of the available neurons in CA1 andthe subiculum. The unidirectional projections from CA1 to the subiculum show a strikingly similar selective organization. This results in a pattern of connectivity such that neurons in CA1 and subiculum that share either inputs from the lateral entorhinal area or from the medial entorhinal area are interconnected (Fig. 3). Field CA1 and the subiculum constitute the major output structures of the hippocampal formation. This output is distributed by way of projections back to the deep layers of the entorhinal area and these projections are organized such that they reciprocate the input pathways from the superficial layers of the entorhinal area [1].

The *fornix* is a major fiber bundle that connects the hippocampus to the hypothalamus, in particular the ►mammillary bodies. The fornix carries fibers that originate from CA3, CA1, and subiculum, although parahippocampal cortices, in particular the pre- and parasubiculum and to a much lesser extent the entorhinal cortex contribute fibers. The CA3 fibers mainly distribute to the *septal area* and the contralateral hippocampal formation. Fibers from CA1 and subiculum en route to the *mammillary bodies*, issue collaterals to the *septal area*, the ventral *striatum*, and the *amygdala*. The fornix also carries the fibers from CA1 and subiculum targeting parts of the *prefrontal cortex*. The fornix is not a pure output pathway since projections from the septal area to the hippocampus and in part to the entorhinal area travel by way of the *fornix* as well. These septal afferents provide the hippocampal formation with most of its *cholinergic* inputs. The fornix also forms one of the input routes for the noradrenergic, serotonergic, and dopaminergic innervation to reach the hippocampal formation. Aminergic fibers also enter the parahippocampal region through a ventral route, through the parahippocampal region. Additional innervation from midline *thalamic* structures as well as from the *anterior complex of the thalamus* travels in part by way of the fornix. Finally, the commissural connections between the left and right hippocampi also partially travel by way of the fornix [1].

## Functional Organization

Together, the overall cortical-hippocampal circuitry indicates the presence of functionally different, parallel circuits. One of the pathways carries inputs through the perirhinal cortex-lateral entorhinal area into and away from the hippocampus, whereas the second mediates transfer of information from and to the parahippocampal/postrhinal cortex-medial entorhinal area. These two pathways differ with respect to the types of information being transferred in that the first most likely deals with information about items ("what" information), whereas the second deals more with context ("where" information). In view of the anatomical organization outlined above it has thus been suggested that in the hippocampus these two pathways converge at the level of the dentate gyrus

and CA3, whereas they are kept more or less separate at the level of CA1 and the subiculum. This suggests that the hippocampal formation comprises two functionally different systems of which the dentate/CA3 system most likely mediates the rapid and efficient storage and recall of conjunctive (associated) information [2].

Structurally, the hippocampal formation looks apparently homogeneous along its long axis. However, the dorsal/posterior portion of the hippocampus receives its major cortical input from the more sensory-related or exteroceptive lateral and caudal portions of *the entorhinal area*, whereas the ventral/anterior hippocampus receives inputs from more ventromedial parts of the entorhinal cortex, which most likely convey information that reflects the interoceptive status of the individual. In addition, direct reciprocal connections with the amygdala are limited to the ventral/anterior and intermediate levels of the hippocampus and are absent for the dorsal/posterior portion of the hippocampal formation [1]. Behavioral data in support of this notion are the findings that in rats the dorsal hippocampus is critical for the initial learning and long-term memory of spatial information, whereas the ventral hippocampus appears not to be essential [3]. Recently, brain imaging studies have revealed that in humans also functional differences are present between anterior and posterior portions of the hippocampal formation; however the precise nature of these differences is still an issue of debate [2].

There is an overall emphasis on the role of the hippocampal formation in learning and memory processes and a related emphasis on the corticocortical connectivity. However, the hippocampal formation also communicates with a number of subcortical structures, including the *ventral striatum* and the *amygdala*. In the ventral striatum, interactions may take place between hippocampal, amygdaloid and prefrontal information, leading to the selection of appropriate behavioral strategies, for example in learning paradigms. The functional relevance of the reciprocal connections between the amygdala and hippocampus are likely an essential component of our motivational system providing the hippocampal formation with a marker for relevance to a particular memory episode and providing the *amygdala* with easy access to previously stored information. Finally, normal functioning of the hippocampal formation, and more generally its interactions with the cortex, depend strongly on a functional *septal complex*, and the *cholinergic* inputs that originate from it [4].

## Clinical Relevance

The hippocampal formation plays a critical role in mediating memory for relevant relationships among conjunctions or associations unique to a particular episode [2]. Damage to the hippocampal formation is a hallmark of patients suffering from (early phase) Alzheimer's disease and patients suffering from *temporal lobe epilepsy*. In both groups of patients, damage is not confined to the hippocampal formation, but quite commonly includes additional damage in the *parahippocampal cortex* as well as diverse levels of cortical degeneration, depending on the state and severity of the disease. The resulting memory deficits seen in these patients are most likely the result of malfunction of the hippocampal-parahippocampal-cortical route. In contrast, short lasting ischemic accidents reportedly result in damage confined to the hippocampal formation, in particular to CA3 and CA1, resulting in an amnesic syndrome as well [5]. Perinatal asphyxia, a shortage of oxygen for a short period around birth results in damage of the hippocampal formation that has been suggested to be related to cognitive memory impairment and schizophrenia [6]. Hippocampal functions are strongly dependent on stress and in case of posttraumatic stress disorder both the volume and functional integrity of the hippocampal formation are diminished [7].

The *fornix* provides the hippocampus with another pathway, beside the cortical route, to communicate with a host of subcortical brain structures, including the mammillary bodies. The hippocampal-mammillary connection is part of the traditionally described *limbic or Papez* circuit, which includes the mammillothalamic tract connecting the mammillary bodies to the *anterior complex of the thalamus*, which in turn project to large portions of the *limbic cortex*, including anterior and posterior *cingulate cortex*, and pre- and parasubiculum. All these structures, in turn, provide input to the hippocampal formation, either directly, or indirectly by way of the entorhinal area. The role of the fornix-pathway in learning and memory is as yet poorly understood. Lesions of the fornix, although rare, have been described and result in impairment in recall, but not in recognition memory [8]. Lesions of the main target of the fornix, i.e. the mammillary complex in animals do not result in marked memory deficits. In Korsakoff's patients, which do show a marked anterograde as well as retrograde memory deficit, the mammillary bodies show a marked decrease in volume. However a comparable atrophy of the mammillary bodies is observed in cases of Wernicke's encephalopathy that do not present amnesic symptoms. The differentiating lesion between the two groups is the *anterior complex of the thalamus* [9]. Interestingly, there is now convincing evidence that in cases of ►diencephalic amnesia the critical lesion disconnects the mammillary bodies from the anterior nuclei [10].

## Definition

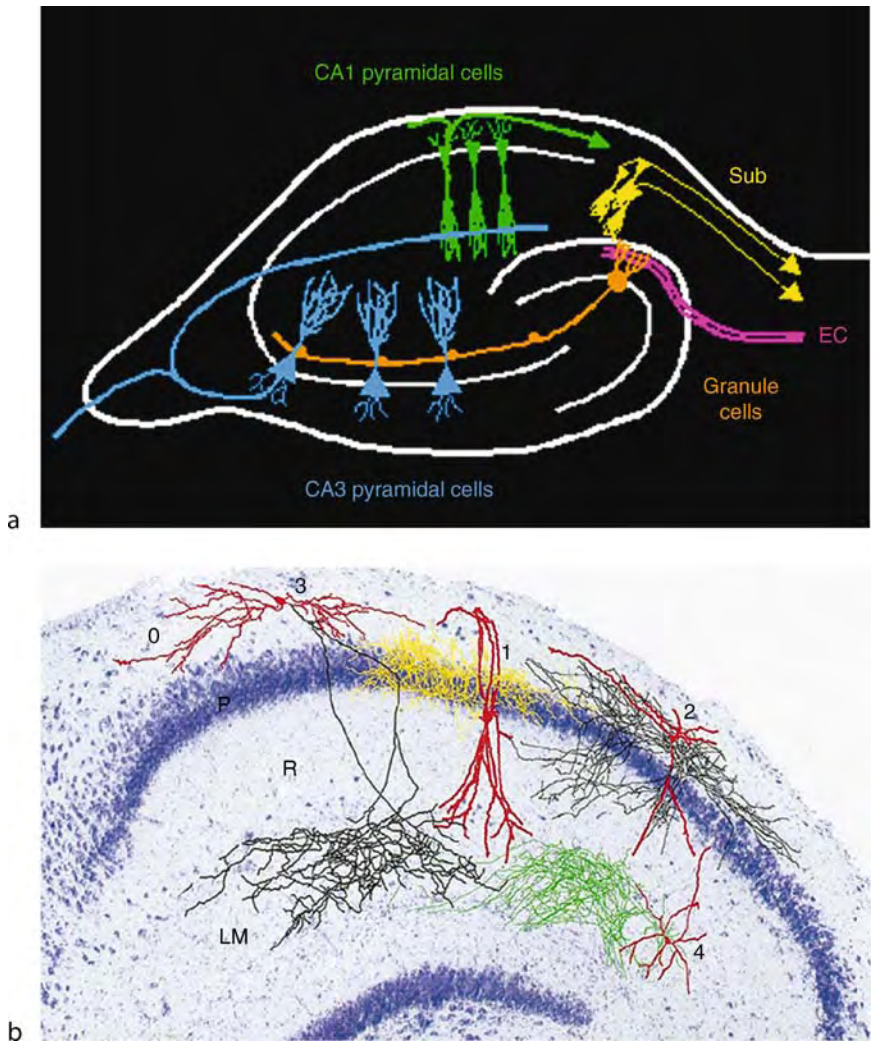
The hippocampus is a primitive cortex that plays a central role in memory processes. It is endowed with a relatively simple organization that has served as a template for the determination of cellular and network mechanisms. The sequential maturation of hippocampal neurons and synapses has been extensively investigated and its principles confirmed in other brain structures. The hippocampus is amongst the most vulnerable brain structure to seizures and cerebrovascular infarcts, and studies on hippocampal insults provided most of our understanding on the mechanisms that underlie major neurological disorders.

## Characteristics

### The Hippocampus has a Laminar Organization

The hippocampus is an important brain structure of the limbic system located in the temporal lobe. It is composed of three major fields (Fig. 1a) the dentate gyrus, the Ammon's horn with the CA1, 2, and 3 fields, and the subiculum. This simple cortex is composed of one main layer of glutamatergic granule cells and pyramidal neurons and a large variety of GABAergic interneurons distributed within the main cellular layer and the neuropile. The principal input of the hippocampal formation has its origin in the ►entorhinal cortex and targets mainly granule cells. Within the Ammon's horn, there is a tri-synaptic glutamatergic circuit that links dentate gyrus to CA3 (via mossy fibers), CA3 to CA1 (via Schaffer' collaterals), and CA1 to subiculum. The main output from the hippocampus originates in the subiculum and projects via the cingulum and fimbria fornix to other limbic areas (including the contralateral hippocampus and the entorhinal cortex). GABAergic interneurons compose a large variety of neuron classes located within the main cellular and neuropile layers (Fig. 1b), which differ by electrophysiological (intrinsic membrane properties and temporal firing patterns) and morphological (location, axonal distribution, peptides



**Hippocampus: Organization, Maturation, and Operation in Cognition and Pathological Conditions.**
**Figure 1** Hippocampal network and neuronal types. (a) Schematic representation of an hippocampal section depicting the different fields and the main excitatory network. Afferents from entorhinal cortex (EC) innervate mainly dentate granule cells. The axons of the later innervate CA3 pyramidal neurons, which in turn innervate CA1 pyramidal cells. Axons from CA1 pyramidal neurons innervate the subiculum (Sub), which constitutes the main output gateway of the hippocampal complex. (b) Photomontage depicting a CA1 field Nissl stained (blue) and biocytine reconstructed interneurons. Axonal trees (in different colors) allow the identification of different interneuron classes, some innervating depict the terminals the cell body of principal neurons (in yellow) and other targeting neuropile layers (in black or green).

that they express) features, and can schematically be segregated into three groups: (i) interneurons responsible for the feedback inhibition of principal cells, group represented mainly by basket cells and axo-axonic cells. They innervate the cell body and axonal initial segment of principal neurons, respectively, and are innervated by axon collaterals emerging from the later. (ii) interneurons responsible for the feed-forward inhibition of principal cells (e.g., bistratified neurons and O-LM (*oriens-lacunosum moleculare*) cells), which innervate the dendrites of principal neurons and are innervated by excitatory axons that also innervate the later. (iii) interneurons innervating other interneurons, which compose a complex population of diverse cell types (e.g., back-projecting cells). Interneurons play a central and differential role in modulating the precise input–output transformation during the generation of behaviorally relevant network oscillations (see later).

## The Hippocampus is a Central Structure for Learning and Memory Processes

The hippocampus, with the entorhinal cortex, has an essential role in the formation of new memories (episodic or autobiographical memory) and participates with

the temporal lobe memory system in declarative memory. Damage to the hippocampus results in profound difficulties in forming new memories. Thus, in the classical "HM patient case" report [1], removal of medial temporal lobes, including entorhinal cortex and hippocampus led to severe anterograde amnesia. Though this type of lesions might also affect the access to memories prior to the damage (retrograde amnesia) relatively older memories were spared. These and other observations suggest that memory consolidation requires a transfer from the hippocampus to other brain areas. Other types of memories (e.g., procedural, semantic) do not require the contribution of the hippocampus.

Studies in experimental animals revealed the presence of "►place cells," in both the hippocampus and the entorhinal cortex [2], that fire when the animal is within a particular location. The majority of these neurons are sensitive to head direction and direction of travel.

In addition, interactions between olfactory cortices and the hippocampus support sensory discrimination functions ("►odor cells"). The olfactory input accesses the hippocampal formation via a polysynaptic pathway mediated by the lateral and rostral entorhinal cortex.

Context-dependent cells that alter their firing pattern according to the animal's past (retrospective) or expected future (prospective) have also been described. It was proposed that the entorhinal cortex contains a directionally oriented, topographically organized neural map of the spatial environment [2]. Recent studies in epileptic patients with deeply implanted electrodes have revealed place cells, thus reinforcing the suggestion that in human as in rats the hippocampus might act as a cognitive map involved in the representation of environmental plan, which plays an important role in spatial memory tasks.

Extensive investigations on cellular substrate of memory processes suggest that a brief period of enhanced stimulation generates a persistent increase of the synaptic response [3]. The mechanisms underlying this long-term potentiation (LTP) of synaptic efficacy are thought to include a NMDA-receptor-mediated postsynaptic rise of calcium that triggers a cascade of signals leading to a postsynaptic increase of the density of AMPA receptors. However, it is not yet clear whether the changes that underlie maintenance of LTP also underlie memory consolidation.

## The Hippocampus Generates Behaviorally Relevant Network Driven Oscillations

Synchronous firing of ensembles of neurons has been found in many regions of the brain. It is though that a temporal organization of activity is required for neuronal integration, coincidence detection, and discrimination of information. Behaviorally relevant neuronal oscillations occur at different frequencies. In the hippocampus, three types of oscillations have been described [4]: (i) theta oscillations (4–10 Hz), which are linked to body movements, memory tasks, and rapid-eye-movement sleep. They involve CA1 pyramidal neurons and mainly place cells during navigation. Interestingly, dendrite-innervating O-LM and bistratified cells discharge with highest provability at the trough of the pyramidal layer theta whereas the perisomatic interneurons (basket and axo-axonic) discharge on average at earlier phases of the theta cycle. (ii) sharp-wave-associated high-frequency ripples (120–200 Hz) of around 100-ms duration; they occur during slow-wave sleep and consummatory behaviors and concerned mainly pyramidal neurons. Basket cells and bistratified cells increase their frequencies of discharge during these ripple episodes while the firing of O-LM cells was suppressed. (iii) gamma oscillations (30–800 Hz) that occur at different brain states. They often coexist with theta oscillations.

H

## Basic Rules in the Maturation of the Hippocampus

### GABAergic Interneurons and Synapses Mature Before Glutamatergic Ones

Relying on BrdU dating techniques, several studies have identified several developmental gradients – earlier maturation of CA3 than CA1, late postnatal development of the fascia dentate, lateromedial gradient, etc. GABAergic interneurons divide and mature before principal neurons. Granule cells of the fascia dentate develop at later stages suggesting that the gate control of the Ammon's horn is not operative until a relatively late stage. GABAergic synapses that impinge on other GABAergic neurons and on pyramidal glutamatergic neurons are also established first. Therefore, GABAergic currents will provide most of the activity at an early developmental stage. This gradient has been confirmed in various species including primates in utero [5,6].

### GABA Exerts Paracrinic Actions on Neurons Prior to Synapse Formation

Immature neurons express functional receptors prior to the formation of synapses [5]. These receptors act as sensors of extracellular GABA as reflected by the large tonic currents generated by GABA receptor antagonists that also reduces significantly neuronal migration. This has important implications as GABA-acting drugs notably antiepileptic ones affect neuronal migration and constitute potential sources of heterotopic neuronal assemblies.

### GABA Excites Immature Neurons Because of a Higher $[Cl^-]_i$

GABA excites immature neurons consequently to a higher intracellular concentration of chloride ($[Cl^-]_i$) that has been confirmed and extended to all brain structures and animal species investigated, suggesting that this feature has been preserved throughout evolution. GABA generates sodium action potentials, calcium currents and removes the voltage dependent $Mg^{2+}$

blockade from NMDA channels at an early stage [6]. The developmental reduction of $[Cl^-]_i$ and the excitatory to inhibitory shift is mediated by the delayed maturation of a chloride extruder. Early excitatory actions of GABA provide the source of calcium increase needed for neuronal growth and synapse formation while avoiding toxic actions of glutamate. An interesting illustration of this sequence is shown by the abrupt drop of $[Cl^-]_i$ that occurs immediately before delivery (Fig. 2) [7]). This transient shift to inhibitory GABA is mediated by maternal hormone oxytocin released to start labor. This mechanism has a neuroprotective action as oxytocin augments the resistance of neurons to anoxic insults [7]. Therefore, the fetus is informed that delivery is to commence and protected from labor-associated insults by the hormone. This has important clinical implications notably in relation to preterm deliveries. GABA exerts also important trophic roles in neuronal and network construction [5]. Therefore, the regulation of $[Cl^-]_i$ has a major impact on brain development.

### *The Immature Hippocampal Network Generates a Primitive Universal Pattern*

Immature rodent hippocampal neurons generate until the 2nd week postnatal a pattern called giant depolarizing potentials (GDPs). This pattern is the first synapse-driven pattern in the hippocampus and consists of large polysynaptic events that provide most of the activity as long as a substantial proportion of GABAergic synapses are excitatory [6]. Similar patterns have been observed in a wide range of structures and animal species. GDPs are generated by depolarizing GABA that removes the voltage-dependent $Mg^{2+}$ block from NMDA channels, thus generating large synaptic currents that activate most neurons in the population [6]. GDPs are primitive events that are replaced by behaviorally relevant patterns. Prior to GDPs, nonsynapse-driven patterns have been described; their generation relies primarily on voltage-gated currents.

## Pathology

### *Epilepsies*

#### *Excitatory GABA Plays a Central Role in Epileptogenesis of the Developing Brain*

The incidence of seizures is highest at an early developmental stage in humans and in immature experimental animals. The excitatory actions of GABA contribute at early developmental stages to seizure generation as shown by the observation that GABA receptor antagonists can fail to trigger seizures and often aggravate them in immature neurons. Excitatory GABA also plays a central role in the consequences of seizures. Thus, in human epileptic slices removed during surgical interventions, GABA excites a substantial number of neurons because of a persistent increase of $[Cl^-]_i$ [8]. A similar return to immature actions of GABA that has been reported after a variety of insults is due to downregulation of the main chloride cotransporter KCC2. In vitro, in a preparation that includes the two intact hippocampi, propagation of seizures from one hippocampus to the other transforms the latter to a permanent epileptogenic mirror focus. Activation of GABA and NMDA receptors is essential in that process, as antagonists of these receptors prevent this change. GABA excites neurons in the newly formed mirror focus, confirming the central role of $[Cl^-]_i$ in epileptogenesis [5]. Thus, epileptogenesis recapitulates ontogenesis: clearly, alterations of $[Cl^-]_i$ and GABA

actions are key elements in epilepsies and other neurological disorders.

### *The Hippocampus is a Key Player in Temporal Lobe Epilepsies*

The hippocampus is amongst the most susceptible brain structures to seizures and is affected in temporal lobe epilepsies (TLE), amongst the most frequent drug-resistant type of epilepsies. Hippocampal sclerosis, the most common pathological substrate of TLE, is characterized by neuronal loss (both pyramidal neurons and GABAergic interneurons) and gliosis, axonal sprouting (mainly of mossy fibers; (Fig. 3), and granule cell dispersion. Studies using first the kainic acid model of TLE and then the pilocarpine model have provided most of present understanding as to how seizures

(c) Electron microscopy micrograph from a chronic epileptic rat. Dendrites of a granule cell (overstained in green) are contacted by three giant mossy boutons (m). (d) Histograms depicting the mean density of mossy boutons in the inner molecular layer in control and chronic epileptic (30 days after kainate treatment) rats. (e) In epileptic rats, recurrent mossy fibers act through the activation of glutamate receptors of AMPA and kainate types. Miniature excitatory postsynaptic currents (mEPSC) were recorded in granule cells of chronic epileptic rats in the presence of 1 µM TTX, 10 µM bicuculline (Bicu), and 40 µM D-APV (to block voltage-gated fast sodium channels, $GABA_A$, and NMDA receptors, respectively). Slow events (asterisk) are mediated by glutamate receptors of kainate type, because they are blocked by 10 µM SYM 2081. Fast events (filled circle) are mediated by AMPARs, because they are SYM 2081 resistant and abolished by 100 µM GYKI 52466. Bars = 500 µm (a, b), 100 µm and 10 µm (d) (for more information, see [9]).

produce neuronal cell loss and reactive sprouting. With the seizure-induced death of hilar mossy cells, mossy fiber axons redirect new collaterals to the inner molecular layer of the dentate gyrus and innervate granule cell dendrites, thus creating a hyperexcitable recurrent circuit that predisposes the hippocampus to paroxysmal firing. In addition, various GABA neurons – notably the O-LM interneurons – degenerate leading to a loss of inhibition on the apical dendrites of the principal cells. Therefore, a partial chronic destruction of the inhibitory drive – particularly that impinges on the dendrites of principal cells – plays an important role in TLE. In addition, newly formed aberrant mossy fiber synapses differ from control ones: thus, although control mossy fiber granule cells synapses operate by AMPA receptors only, newly formed mossy fiber synapses in the epileptic tissue are operated partly by kainate receptors [9] (Fig. 3). Therefore, the epileptic state is characterized not only by a synaptic reorganization but also by a change of the receptor type, thus conferring unique properties to the network. To sum up, the plasticity that is endowed in hippocampal synapses is also largely responsible for the major implication of this structure in epilepsies.

### *Anoxo-Ischemic Insults*

In experimental animal models, brief episodes of global ischemia destroy selectively CA1 pyramidal neurons and various interneurons. Quite similar pathological insults have been reported following anoxic episodes in humans, suggesting that this region is also susceptible to interruption of oxygen and glucose. Underlying mechanisms include an excitotoxic release of glutamate that leads to cell death. However, although NMDA receptor antagonists reduce the damage in experimental animals, the mechanism and signaling cascade involved have not been elucidated.

### *Alzheimer Disease*

It is widely accepted that the hippocampus as assessed by MRI volumetric analysis is atrophied early in Alzheimer disease patients and in patients with age-associated memory impairment [10]. Consequently, deficits on short-term and anterograde memory are the first clinical manifestations observed in patients with Alzheimer's disease that lose the estimation of time and place even in familiar locations and experience confusion. Hippocampus atrophy may also occur in other forms of dementia, like Lewy body dementia, frontotemporal lobe degeneration, and vascular dementia.

## Synonyms

Post-translational modification of lysine groups on histone tails; Acetylation of nucleosomal histones; Histone code

## Definition

►Histone acetylation defines a post-translational modification of histone proteins, which are the major component of the basic unit of ►chromatin called the ►nucleosome. Histone modifications and the ►methylation of specific regions of DNA modulate transcription by modifying chromatin structure and thereby define a mechanism of regulation of gene expression called ►epigenetics.

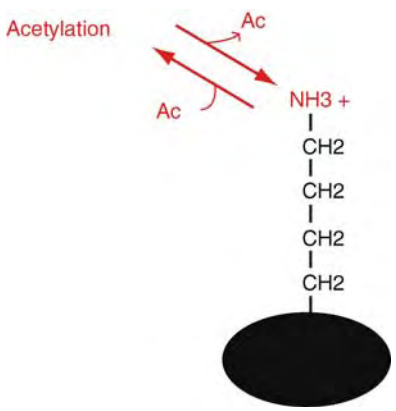
Acetylation is the transfer of acetyl groups to the epsilon position of lysine residues in the tail of nucleosomal histones (Fig. 1). It is important to distinguish this modification from N-alpha-acetylation of eukaryotic structural proteins that occurs on alanine, serine, and methionine residues, and is catalyzed by N-acetyl-transferases.

Histone acetylation is catalyzed by a family of enzymes called histone acetyltransferases (HATs) and it is functionally correlated with transcriptionally competent chromatin. The removal of acetyl groups is catalyzed by a family of enzymes called histone deacetylases (HDACs or HDs) and is functionally correlated with transcriptionally inactive chromatin. Hence the ratio of HDAC to HAT activity determines the level of histone acetylation, one of the major epigenetic mechanisms regulating the inheritable pattern of gene expression on the progeny cells, without altering the DNA sequence. It is important to mention that although the core nucleosomal histone proteins H2A, H2B, H3 and H4 were originally identified as substrates for these regulatory enzymes, recent studies have reported an increasing number of non-histone cellular proteins that are also subject to acetylation of lysine residues [1].

## Characteristics

### Histone Modifications

Reversible acetylation of selected lysine residues in the N-terminal tails of core histone proteins represents an efficient way to regulate gene expression [2]. In general, the removal of acetyl groups (i.e. histone deacetylation) mediated by HDACs keeps the positive charges on histone tails, promotes close contact of histone tails with negative charged DNA, and thereby prevents the accessibility of ►transcription factors and results in gene repression, characteristic of ►heterochromatin (Fig. 2). In contrast, the transfer of acetyl groups (i.e. histone acetylation) catalyzed by HATs neutralizes the positive charge on the N-terminal histone tails, loosens histone-DNA contacts and allows the access of



**Histone Acetylation in the Developing Central Nervous System. Figure 1** Acetylation and deacetylation of lysine residues. Histones are acetylated and deacetylated due to transfer or removal of acetyl groups on the epsilon position of lysine residues in the histone tails.

transcription factors and RNA polymerase II, thereby increasing transcriptional activity. This modification is associated with transcriptionally competent chromatin, which is structurally defined by a relaxed state (i.e. ►euchromatin) (Fig. 2).

Besides acetylation, the N-terminal tails of nucleosomal histones undergo several additional post-translational modifications that will not be extensively discussed in this chapter. They include methylation, phosphorylation, ►sumoylation, ►ubiquitination and ►citrullination. In addition, the same post-translational modification can either favor or repress gene expression, depending on the positional information. Methylation of lysine residues in the tail of histone H3, for instance, is associated with active transcription, if it occurs on lysine 4 and with repression, if it occurs on lysine 9 or 27. Therefore, the positional and combinatorial arrangement of distinct histone modifications on any given gene defines the "histone code," which is essential in the induction of specific patterns of ►epigenetic inheritance.

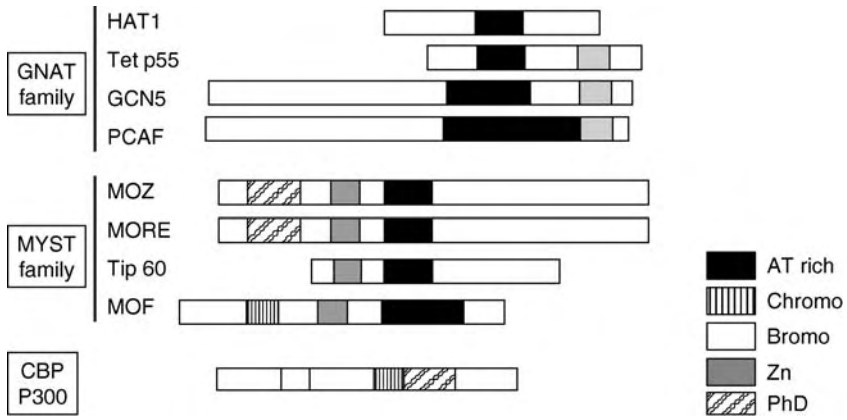
## Enzymatic Activities Responsible for Histone Acetylation

The HAT family of mammalian histone acetyltransferases is composed of a growing number of family members, including GNAT, MYST and CBP/p300 families [3]. The GNAT (GCN-5-related-N-AcetylTransferases) family of HATs are characterized by sequence and functional similarity to the yeast gene Gcn5 and include members with a high degree of substrate specificity, including PCAF (Fig. 3). The MYST family (from the name of its founding members MOZ, Ybf2, Sas2 and Tip60) of acetyltransferases, shares with the GNAT family a region characterized by acetyl-CoA recognition and binding. One of the MYST members (i.e. MOZ) has been implicated in ►chromosomal translocations associated with oncogenic transformation.

P300 and CBP are structurally related and their homologues have been reported in a wide variety of multicellular organisms, including Drosophila and ►*C. elegans*, but not in yeast. These enzymes play a critical role in development especially of the nervous system, as shown by the phenotype of knockout mice.

## HAT Regulation of Gene Expression

Histone acetyltransferases like p300 and CBP have the ability to promote gene expression, by binding to specific transcription factors, as well as with basal components of the transcriptional machinery. Thus, HATs are part of co-activator complexes that render the chromatin accessible to transcription factors and to ATP-dependent chromatin remodeling complexes, thereby allowing efficient transcription by RNA pol II.



**Histone Acetylation in the Developing Central Nervous System. Figure 3** Histone acetyltransferases. Schematic representation and classification of distinct HAT family members. Note the structural similarities of the distinct domains that define each of the classes of HATs (adapted from [2]).

## Enzymatic Activities Responsible for Histone Deacetylation

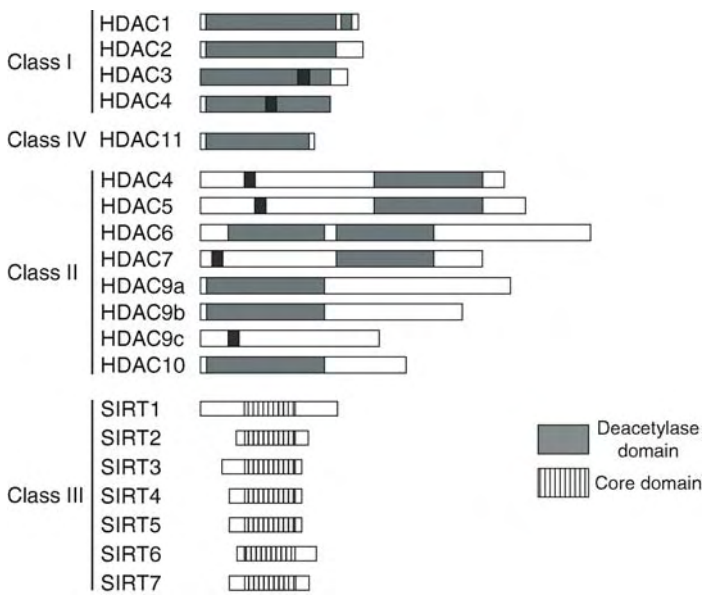
HDACs are highly conserved enzymes from yeast to human [4,5]. Based on homology, mammalian HDACs can be broadly grouped into four major classes (Fig. 4). Class I is composed of small (377–488 amino acids) nuclear proteins, with a broad tissue expression pattern and includes the isoforms: HDAC-1, -2, -3 and -8. Class II is composed of cytosolic proteins of larger size (590–1215 a.a) with tissue-specific pattern of expression and includes: HDAC-4, -5, -6 -7, -9 and -10. Class III is composed of the NAD-dependent family of sirtuin proteins (SIRT1–7). These molecules are sensitive to the redox state of the cell and are inhibited by a different category of pharmacological inhibitors than the previous two classes. Class IV is composed of a single member, HDAC11, an isoform with the catalytic domain and conserved amino acid sequence of the active site of class I HDAC and the expression pattern limited to brain, heart, muscle and kidney, characteristic of class II HDACs.

## HDAC Regulation of Gene Expression

HDACs down-regulate gene expression by forming repressive complexes with transcription factors and co-repressors, thereby modifying chromatin structure and recruiting additional protein complexes involved in histone and DNA methylation. HDAC-complexed co-repressors include: Sin3, SMRT (Silencing Mediator of Retinoic and Thyroid hormone receptors), Groucho/TLE, N-CoR (Nuclear Co-Repressor), and Co-REST (RE1 Silencing Transcription factors). These complexes are recruited to the ►promoter region of target genes by specific transcriptional inhibitors [6].

## Histone Acetylation in the Neuronal Lineage

Increasing evidence has shown that the level of histone acetylation has critical and varied functions during CNS development, such as cell fate specification and maturation. Neural stem cells (NSCs) are capable of self-renewal and have the ability to generate neurons, astrocytes and oligodendrocytes in an orderly manner. The plasticity of NSCs relies, at least in part, on the relatively relaxed chromatin structure of genes that are essential in maintaining the undifferentiated state (i.e. ►Sox2), as a result of histone acetylation. The progressive lineage restriction of these cells, requires a careful coordination with the exact timing of fate specification. An example of coordinated lineage progression modulated by chromatin modifications is the control of neurogenesis. In NSC cells and in multipotential progenitors, neuronal gene expression is prevented by the presence of repressive complexes containing the transcription factor REST, the co-repressor Co-REST and the histone deacetylases HDAC1 and 2 [7]. REST is a powerful repressor with the ability to recruit mSin3/HDAC1/2 complexes with its N-terminus and Co-REST/HDAC1/2 complexes with its C-terminus. The co-repressors, in turn, have the ability to recruit additional chromatin modifiers associated with gene silencing, thereby maintaining neuronal genes silent. This model explains why treatment of multipotential



**Histone Acetylation in the Developing Central Nervous System. Figure 4** Histone deacetylases. Classification and sequence domains of the four classes of HDACs (adapted from [4,5]).

progenitors with HDAC inhibitors relieves REST-dependent repression and allows the expression of neuronal target genes [7].

During embryonic development, neuronal gene expression occurs when the inhibitory effect of REST is removed due to proteasomal degradation and transcriptional inactivation. By contrast, in adult neural stem cells REST-dependent neuronal gene expression has been linked to the conversion of ►REST from a repressor to an activator, due to a small double stranded non-coding RNA containing the REST specific RE1 sequence [7]. Regardless of the mechanism of REST inactivation, both embryonic and adult neural precursor share a similar mechanism of activation of neuronal gene expression that requires histone acetylation. Among the genes that promote neuronal differentiation and are regulated by histone acetylation, three basic helix-loop-helix (bHLH) transcription factors have been identified: ►NeuroD, ►Neurogenin (Ngn) and ►Mash1. This explains why treatment of embryonic or adult neural progenitors with HDAC inhibitors enhances neurogenesis at the expenses of gliogenesis and suggests that the neurogenic effect of HDAC inhibitors can be attributed, at least in part, to the direct activation of pro-neural transcription factors.

The REST-dependent modulation of neuronal gene expression in neural cells and multipotential progenitors, however, is very different from the one occurring in differentiated non-neuronal cells. In contrast to neural progenitors where silencing of REST target genes relies principally on histone deacetylation, in non-neuronal cells REST target genes are stably repressed by additional epigenetic modifications, including DNA methylation, tri-methylation of lysine 9 and stable chromatin condensation. This explains why treatment with HDAC inhibitors is not sufficient to induce REST-targeted gene expression in non-neuronal cells.

## Histone Acetylation in the Astrocytic Lineage

The differentiation of astrocytes from precursor cells has been defined by the expression of the intermediate filament protein glial fibrillary acidic protein (GFAP). Most of our current understanding of the epigenetic modulation of astrocytic differentiation is derived from studies on the regulation of the ►*Gfap* promoter. It was originally proposed that this gene was not expressed in undifferentiated embryonic precursors because of DNA methylation of the ►*Gfap* gene. Later studies confirmed these early findings and defined the presence of specific DNA methylation sites corresponding to binding regions for the transcription factor STAT in the ►*Gfap* promoter, as well as in the promoter of genes encoding signaling components of the ►JAK-STAT pathways. This was consistent with a vast literature supporting the astrogliogenic potential of extracellular factors enhancing the JAK-STAT signaling pathway, such as ►LIF and ►CNTF. It was later defined that ►*Gfap* promoter activation by STAT1/3 requires the recruitment of the histone acetyltransferases p300 and CBP [8]. Further, proneural transcription factors, such as neurogenin 1, prevented astrogliogenesis by inhibiting the formation of transcription factor/co-activator complexes. The importance of the HATs in astrocytic differentiation was further confirmed by the evidence that p300 is also recruited to the ►*Gfap* promoter by SMAD1, a downstream effector of the astrogliogenic signal bone morphogenetic proteins (►BMPs). Therefore histone acetylation is clearly important for astrocytic differentiation because multiple astroglial signals regulate GFAP expression by recruiting the HATs (CBP/p300) to specific regions of the promoter.

## Histone Acetylation in the Oligodendrocytic Lineage

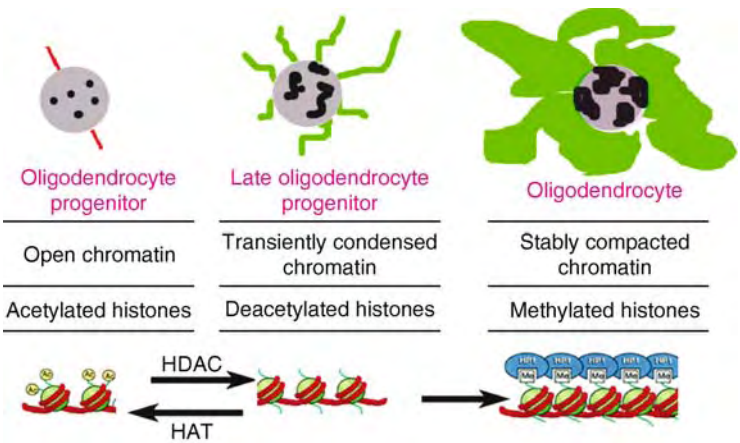
By analogy to the differentiation of neurons and astrocytes, it was proposed that histone acetylation could similarly regulate ►myelin gene expression during the differentiation of progenitors ino myelin-forming cells. Transcriptional inhibitors, in complex with histone deacetylases and co-repressors, were identified on the promoter of myelin genes in oligodendrocyte progenitors. For instance, transcription factors Hes5 or Nxk2.2, in complex with the co-repressor Sin3A, were shown to recruit HDAC1 to the proximal region of the myelin basic protein (MBP) promoter. Similarly, the transcription factor Myt1, in complex with Sin3B, was shown to recruit HDAC1/2 to the proteolipid protein (PLP) promoter. This led to a model of myelin gene expression consequent to the displacement of the repressive complexes containing HDAC. The inference from this model was that treatment with HDAC inhibitors should promote myelin gene expression. In contrast to the prediction, the administration of HDAC inhibitors, such as trichostatin A (TSA) or valproic acid (VPA), prevented the differentiation of cultured progenitors into highly branched myelin gene expressing cells. Similar results were obtained *in vivo*, after systemic administration of HDAC inhibitors to neonatal rats and in ► *hdac1* mutant zebrafish.

These surprising results revealed the need for alternative models that could explain the role of HDAC during oligodendrocyte progenitor differentiation. It is now well accepted that histone deacetylation is an essential event during a specific temporal window of progenitor differentiation. Global histone deacetylation occurs after cells have exited the cell cycle and is functionally related to decreased levels of inhibitors of morphological differentiation (i.e. stathmin) and of myelin gene expression (i.e. Id4) (Fig. 5). This model explains why pharmacological or genetic manipulations favoring histone acetylation prevent the differentiation of progenitors into myelin forming cells [9]. This arrested oligodendrocyte differentiation is

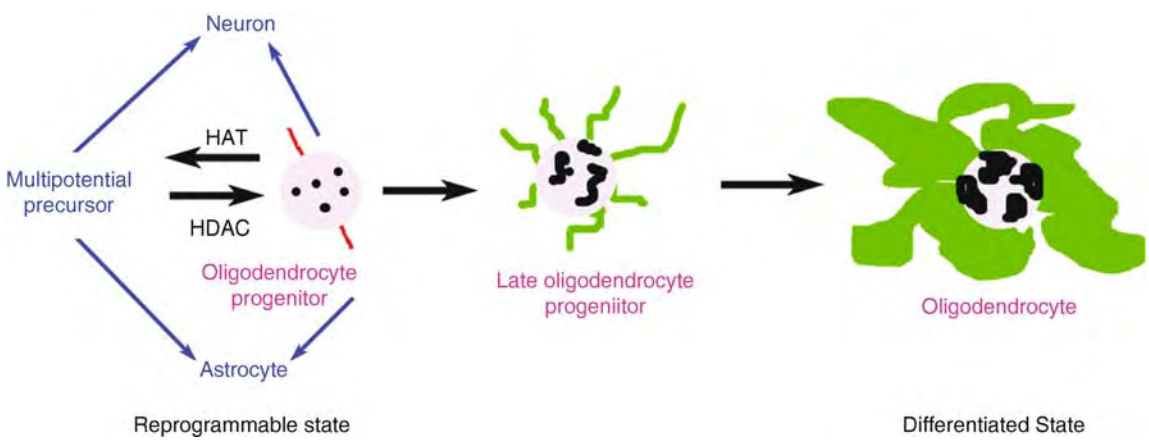
associated with the re-expression of markers of the undifferentiated state and is therefore suggestive of the reversal of oligodendrocyte progenitors to a multipotential state.

Together, these studies have suggested a model of oligodendrocyte differentiation as a multi-step process, characterized by the progressive epigenetic repression of inhibitory molecules, which is initially dependent on histone deacetylation. This model is also in agreement with early ultrastructural studies on the developing corpus callosum of neonatal rats reporting the progressive increase of chromatin compaction in the nuclei of oligodendrocyte progenitors during differentiation.

In addition, this model predicts differences in the ability of oligodendrocyte lineage cells to be "reprogrammed" (Fig. 6). Progenitors are "reprogrammable" cells because the chromatin of genes affecting self-renewal is regulated by reversible HAT/HDAC-dependent post-translational histone modifications. Differentiated mature oligodendrocytes, in contrast, are not reprogrammable cells because the genes that are involved in the maintenance of the undifferentiated state are transcriptionally silent, due to more stable epigenetic modifications [10].



**Histone Acetylation in the Developing Central Nervous System. Figure 5** Model of progressive protein compaction during oligodendrocyte progenitor differentiation. Note that the HDAC dependent histone deacetylation in progenitors is the first and reversible step towards chromatin compaction, that is later followed by more permanent chromatin condensation, due to additional epigenetic modifications.



**Histone Acetylation in the Developing Central Nervous System. Figure 6** Two-step model of oligodendrocyte progenitor differentiation. Note that the transition between early and late progenitors is characterized by reversible modifications of nucleosomal histones, mediated by the activity of HAT and HDACs. This is a highly plastic and reprogrammable stage of development, which is later followed by a more stable chromatin compaction, characteristic of the differentiated state.

### Concluding Remarks

Epigenetics defines all the modifications of chromatin components that can affect gene expression. Transcriptionally active chromatin requires an open conformation that is dependent on the presence of acetyl groups on lysine residues in the tail of nucleosomal histones. When the acetyl groups are removed (by HDACs), chromatin is in a closed conformation and this renders the DNA inaccessible to specific transcription factors and results in transcriptional repression. These post-translational modifications of histones modulate the pattern of gene expression in distinct cell types, thereby modulating lineage specification and timing in the developing central nervous system.

## History-Dependent Properties of Skeletal Muscle

David C. Lin
Programs in Bioengineering and Neuroscience, Washington State University, Pullman, WA, USA

### Definition

History-dependent muscle properties refer to the fact that muscle force not only depends entirely upon the instantaneous ►kinematic conditions, but also upon the occurrence of prior movements.

### Characteristics

#### Quantitative Description

A fundamental concept in the functional characterization of skeletal muscle contractile properties is that the force generated by the muscle depends upon the ►kinematics of the movement, namely the length and velocity of the muscle. Thus, muscle mechanical properties are generally defined by the way force varies with muscle length (i.e. the force–length relationship) and velocity (i.e. the force–velocity relationship). The measurement of mechanical properties is usually made by controlling the particular ►kinematic variable of interest and measuring the force produced by the muscle. Moreover, the measurement of mechanical properties is usually performed after imposition of a steady-state isometric condition (constant length and activation) for a relatively long duration. However, prior movement before the measurement of force under the controlled ►kinematic condition influences that measurement. This essay reviews how movement history influences the mechanical properties of muscle, the mechanisms by which this dependency occurs, and the functional importance of history-dependent muscle properties.

The observation that prior movements affect muscle properties has been shown under the simplest mechanical condition of an isometric contraction. If an isolated muscle is isometrically activated at a specific length, muscle force will reach a steady-state. If the same muscle

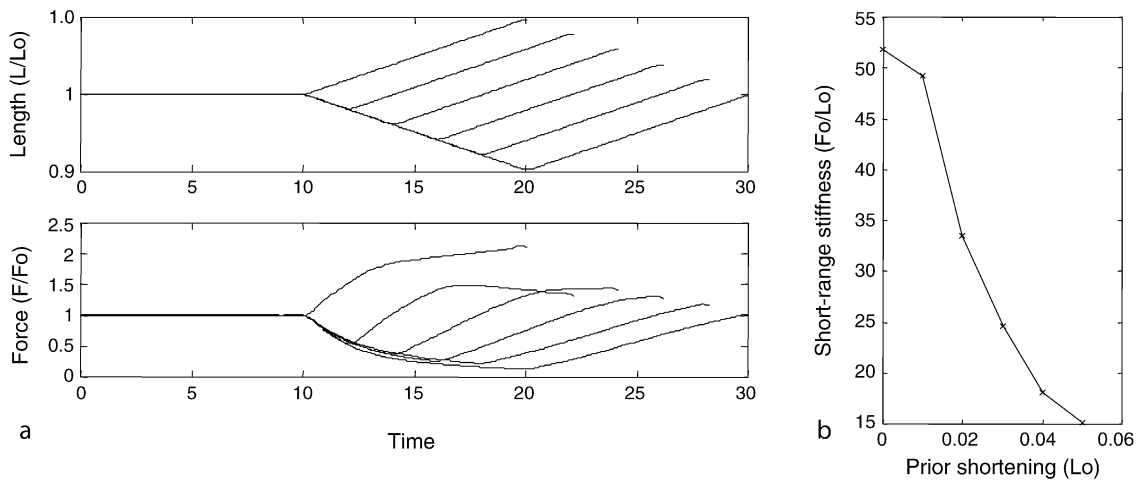
is again activated, but this time at a shorter length, and then stretched to the previous length, the steady-state force will be greater than the force that was measured during the first condition. This phenomenon has been called "permanent extra tension," because the lengthening caused more isometric force to be generated at the same length [1]. Muscle shortening has the opposite effect; isometric force is decreased following a shortening if the muscle is activated before the movement. Furthermore, the lengthening and shortening effects cancel out if a shortening-lengthening movement takes place; however, a lengthening-shortening movement will produce a decrease in isometric force [2].

Another mechanical property of functional importance is stiffness, or how muscle force changes in response to a change in length (i.e. $\Delta F/\Delta L$). The formal mechanical definition of stiffness assumes that the measurement of force and length should be with both force and length in a steady-state (►static) condition. This definition of stiffness would be equivalent to the slope of the well-known force-length relationship. However, the measurement of stiffness can be made under more dynamic conditions, or by measuring the changes in force and length during a movement. This measurement is useful for understanding the importance of mechanical properties related to motor function, especially in the maintenance of posture (see Function). Further, this measurement is useful for determining the number of attached myosin heads to actin binding sites (i.e. ►crossbridges; see Lower level components), which provides a basis for the experimental observations. This review will focus on the dynamic measurement of stiffness.

The measurement of stiffness during movement conditions has often been made by the imposition of a constant velocity length change because any velocity dependent forces should not change during the movement. Early studies of this type showed that muscles exhibited a "short-range stiffness" behavior, where length changes less than ~1% of the muscle length produced force changes that were in proportion to the length changes (Fig. 1) [3].

In other words, the muscle behaved as a linear, highly stiff spring for small length changes. When the muscle was lengthened beyond the short-range stiffness range, the muscle "yielded," or the stiffness decreased considerably and quickly. The mechanism for yielding behavior is probably due to the disruption of muscle ►crossbridge interactions during the lengthening movement, resulting in fewer attached ►crossbridges, which provide stiffness (see Lower Level Processes). Furthermore, if a yielding stretch is imposed and followed by an isometric period, the stiffness is reduced during subsequent lengthening [4]. Prior shortening also reduces muscle stiffness expressed during subsequent stretches, and the reduction in stiffness depends upon the amount of shortening (Fig. 1) [5]. In summary, any prior movement, whether it be shortening or lengthening, significantly reduces muscle stiffness, and this will influence the reaction to disturbances to posture and the amount of force generated in cyclic movements (see Function).

The amount of muscle yield, or the dramatic reduction in stiffness following a large stretch, depends upon the prior movement history. As the amount of shortening increases prior to a large stretch, the yielding behavior is reduced until the response becomes linear spring-like (with a reduced stiffness) throughout the stretch (Fig. 1) [5]. The significance of this observation



**History-Dependent Properties of Skeletal Muscle. Figure 1** The force response (a) and stiffness (b) measurements of chemically skinned cat soleus single muscle fibers at 22°C for six amounts of shortening prior to a lengthening. Muscle length and force are normalized by the initial length ($L_o$) and force ($F_o$). Short-range stiffness ($\Delta F/\Delta L$) was measured over the first 25 ms (1.25% of $L_o$) of lengthening for each case of prior shortening.

is that spinal reflexes arising from ►muscle spindles are affected by prior movement in a parallel fashion, and this influences the modulation of mechanical properties of muscle by reflex control (see Higher Level Processes and Function).

## Higher Level Structures

The mechanical properties of muscle interact with spinal reflexes to form a feedback system. The components of this feedback system are the sensory organs within the muscle, the distributed connections from the sensory organs to motoneurons innervating the muscle from which the sensory signal arises (and to motoneurons of other muscles as well), and muscle as a force-generating element. One of the best studied and strongest reflexes arises from ►muscle spindles, which are sensitive to changes in length. Specifically, the Ia reflex loop is a monosynaptic pathway in which muscle lengthening causes an increased ►spindle afferent firing rate, which in turn causes further excitation of the motoneurons innervating the same muscle. In terms of function, the Ia reflex is a key pathway involved with the maintenance of posture.

## Lower Level Components

The interaction of the contractile proteins myosin and actin to form ►crossbridges is responsible for the generation of force. In addition, the mechanical properties of an individual ►crossbridge are responsible for giving muscle its macroscopic mechanical properties. Specifically, muscle stiffness arises from the summed stiffness provided by all attached ►crossbridges. In fact, stiffness measured by the application of small stretches is often assumed to be proportional to the number of attached ►crossbridges.

## Higher Level Processes

An important higher level process which interacts with history-dependent mechanical properties of muscle involves the feedback provided through spinal reflexes. Namely, it has been shown that as muscle starts to yield during a lengthening movement, the Ia reflex compensates for the yield by recruiting additional motoneurons innervating the same muscle. The net effect is to preserve stiffness properties, so that the muscle with reflexive feedback is spring-like throughout the duration of a lengthening movement [6]. However, it is important to note that ►muscle spindle responses are also movement history-dependent, probably due to the properties of the ►intrafusal muscle fibers that surround the sensory region of the ►spindle [7]. Thus, both muscle and ►spindle properties are affected by prior movement in concert, and complementary effects are important to understanding their functional significance (see Function).

## Lower Level Processes

The formation and detachment of ►crossbridges is a cyclic process that is influenced by the mechanical conditions under which the muscle is exposed. In relation to movement history-dependent properties, prior shortening or lengthening is thought to promote ►crossbridge detachment (or inhibit crossbridge attachment), thereby decreasing the total stiffness of the muscle [8]. Thus, the interaction of movement with ►crossbridge kinetics is the mechanism by which movement history-dependent properties occur.

## Function

Movement history-dependent muscle properties have the potential to be influential both in reactions to postural disturbances and in voluntary movements, especially cyclic movements. During locomotion, specific muscles undergo cycles of shortening-lengthening movements while being active. In the cat gait cycle, the *triceps surae* muscle group is active while the muscles are shortening just prior to foot strike, and continue to be active while they are lengthening after foot strike. As the prior shortening prevents yielding during the subsequent lengthening, the muscle group behaves more spring-like [9], and this may assist in storing and returning potential energy during foot strike.

For reactions to postural disturbances, the mechanical properties of muscle combined with the spinal reflex response determine the initial response to maintain the desired posture. In early studies of muscle-reflex properties, it was demonstrated that the initial high stiffness state (short-range stiffness) was maintained throughout an imposed lengthening (see Higher Level Processes). The implication of this observation is that any change in muscle length following a postural disturbance would evoke a change in muscle force appropriate to resisting that change. However, the interaction of spring-like muscle-reflex properties and the mass of a limb segment could result in an oscillatory response and potential for instability. Further studies addressed this issue by using mass loads with the muscle-reflex system, and found that the magnitude of the stiffness properties decreased following the initial movement caused by a perturbation. The decrease in stiffness allowed any oscillations of the mass to be damped out more quickly than if the stiffness had remained at the initially high magnitude [10].

Movement history-dependent properties provide an explanation for the postural experiments with mass loads. Namely, the initial mechanical response to the perturbation was dominated by the high stiffness of the muscle-reflex system. This would allow the limb segment (i.e. mass load) to return quickly to its initial position, but with a large velocity comparable to a mass-spring oscillator. However, the initial movement of the limb decreases the stiffness of the muscle and

reduces the reflex response. Both of these effects would decrease the stiffness of the muscle-reflex system and enhance the dampening out of oscillations [10].

In summary, movement history-dependent effects of muscle properties have important functional consequences for both voluntary movements and postural maintenance. Namely, modulation of stiffness properties by prior movement enhances the ability of muscle alone and muscle with reflex action to interface with its primary mechanical load, the mass of the limbs.

# Histrionic Personality Disorder

►Hysteria

# HIV-associated Dementia (HAD)

## Definition

In persons infected with human immunodeficiency virus (HIV), even at the early stage of the disease, HIV enters the brain. HIV along with its pathogenic proteins damages the neurons by activating pro-inflammatory mediators, or through their direct actions. This leads to the development of cognitive disability in those patients, and the condition is described as HAD. Other terms such as AIDS-dementia complex, HIV encephalopathy are also used to describe HIV- associated dementia.

# Holism

## Definition

The idea that systems must be considered as organic wholes rather than analyzed in terms of the behavior of parts, including at least social systems, organisms, people, and sometimes cells.

►Reductionism (Anti-Reductionism, Reductive Explanation)

# Holonomic Constraint

## Definition

A geometric constraint of a mechanical system restricting just the positions (rather than the velocities) of the particles.

►Mechanics

# Homeobox

## Definition

Homeobox genes encode transcription factors with DNA binding homeodomains. Homeobox genes are required for patterning, regional specification and terminal differentiation. Homeobox transcription factors bind to TAAT/ATTA consensus binding sequences.

Many homeobox genes are members of genes families, such as the *Hox*, *Dlx*, and *Pax* genes.

## Synonyms

Constant internal environment of an organism; Constant "milieu intérieur" in the biological system

## Definition

It is the mechanism(s) in the living organism for maintaining its internal environment at a constant level, or within narrow limits of the most adequate level, for its survival.

## Characteristics

### History of the concept

In the human body and in the living organism most cells are surrounded by extracellular fluid, so that for living cells to function well and to survive, it is most important to maintain and control the internal environment.

In 1878, a French physiologist, Claude Bernard, introduced the idea of constant *milieu intérieur* (the internal environment) in the body, explaining the importance of the extracellular fluid in which an organism is bathed, separated from the internal environment [1]. He wrote, "It is the fixity of the internal environment that is the condition of free and independent life. All the vital mechanisms, however varied they may be, have only one object, that of preserving the constant conditions of life in the internal environment." (Translation taken from [2].)

This concept was first termed as "homeostasis" by an eminent American Physiologist, Walter B. Cannon, and expanded in his famous book, The Wisdom of the Body [3], published in 1932. Cannon defined the word as "the coordinated physiological processes by which maintain most of the steady states in the organism."

Homeostasis means that in the biological system the internal environment is maintained at a constant level or between narrow limits that are the most adequate levels for the living organism. Changes in the system do occur (e.g., changes in the outside temperature or invasion of toxic substance from infection), but the body eventually achieves "normal" conditions through various functional changes.

### Process Regulation

#### *Processes to Achieve and Maintain Homeostasis*

In normal and healthy conditions we can maintain fairly constant levels of many body variables, such as the body temperature, blood pressure, levels of respiratory gases, glucose and other chemicals in the blood, ion concentration in the extra-cellular fluid, etc. When changes of these parameters occur due to changes in the external and internal environment, multiple functions operate in the body in order to achieve a "constant" or "physiological" state. These multiple functions are termed "►homeostatic mechanisms," or the homeostatic control system.

The mechanism for achieving a homeostatic state is through a ►feedback system. Each system is comprised of a sensor (or sensors) that must detect changes from a set point or reference point and the effector system.

A ►set point is the range of values to maintain physiological or "normal" condition in the system. When a sensor detects a change from a set point, error signals are sent to the brain or organs. These signals bring a series of reactions so that the system will be brought back to a set point level, as will be illustrated later.

The nervous system and the endocrine system play a major role in controlling and maintaining homeostasis. Some sensors are situated in the brain, such as in the hypothalamus, the pituitary gland. ►Baroreceptors, ►chemoreceptors, and volume receptors in the periphery as well as in the brain also act as sensors. In addition, the endocrine organs like the pancreas and the adrenal gland have sensors. The control system for bringing back the homeostatic state and maintaining it in most physiological conditions in the body is the negative feedback system. (The positive feedback system changes variables further by setting up a chain of responses, and does not operate for maintenance of homeostatic state. In physiological states, the positive feedback system operates only in certain specific cases, e.g., gonadal hormones causing ovulation.)

## Functions

There are many examples of homeostasis in the living system. In order for an organism to survive in a varied environment, a cell must receive oxygen and nutrients from the extracellular fluid, and move carbon dioxide and waste materials to the extracellular fluid to be carried away. In humans, the respiratory system brings oxygen into the body and removes carbon dioxide out of the body; the digestive system brings nutrients into the body, and excretes waste materials, the circulatory system carries oxygen and the nutrients to various organs including the brain, and takes away waste materials from the tissues; the renal system removes waste materials from the blood and reabsorbs certain ions to maintain the adequate levels of ions in the blood and tissue fluid, etc. Thus, the overall effect accomplished by many body functions is to maintain an environment adequate for all cells and organs to function.

### *Specific Examples*

#### *Body Temperature*

In warm-blooded animals and humans, body temperature is maintained around 37°C most of the time. When the body temperature is elevated, for instance during severe exercise, sensors in the brain called thermoreceptors, detect a change from its normal temperature and send error signals to the structures in the central nervous system that control the autonomic and somatic systems. This causes the autonomic nerves to cause sweating, dilation of the blood vessels in the skin and the body temperature drops. In the cold environment, sensors send the error signals to cause constriction of skin blood vessels, shivering, and erection of hairs in hairy animals (goose bumps in humans). It is often stated that the autonomic nervous system plays an important role in achieving homeostasis, but, as seen in the above example, shivering involves the somatic system, i.e., the skeletal muscle contraction. The behavioral changes, such as putting more clothes on in the cold environment, etc., is also an important part of the homeostatic responses involving the whole body system. In cold-blooded animals, such as salamanders, the body temperature cannot be regulated as mammals, so that the regulation is accomplished solely by behavioral responses. During the cold night their body temperature drops, and in the morning these animals lie in the sun until the body temperature is raised so that they can move around. In long lasting changes, e.g., exposure to the hot or cold climate, the endocrine system, such as the adrenal medulla (for heat production) and the thyroid gland (against cold in animals) is also involved.

#### *Blood Pressure*

Changes in blood pressure are sensed by baroreceptors in the periphery, near the carotid artery in the neck and the arch of aorta near the heart. When the pressure is too high or too low, they send signals through their afferent nerves to the brain regions, mostly the medulla, to activate the autonomic nervous system response. This brings changes in blood vessels to dilate or constrict, and changes in heart rate and force of contraction, thus restoring the blood pressure to the normal range, 80–120 mmHg (which is called baroreceptor reflex). The response also involves release of epinephrine and norepinephrine from the adrenal glands.

#### *Blood Sugar*

In maintenance of blood sugar at adequate levels, at around 100 mg per 100 ml, specialized cells (beta cells) in the islets of Langerhans in the pancreas detect changes in the glucose level in the plasma. When the glucose level is elevated after a meal, secretion of ►insulin from beta cells increases while that of ►glucagon, produced by alpha cells in the pancreas, decreases so that the blood sugar level is returned to its normal level.

#### *Hormones*

In physiological conditions, the adequate level of various hormones is maintained. Sensors are located at various levels in the endocrine system, in the endocrine organs, the anterior pituitary gland and the hypothalamus. They detect changes in plasma levels of certain hormones, ions or metabolites. If the level is deviated grossly from the "normal" level of that particular hormone, error signals are sent to the appropriate regions in the brain. Depending on the particular situation

they act on the hypothalamus, altering secretion of ►releasing- or release-inhibiting hormones, or signals are delivered to the anterior pituitary gland, causing secretion of tropic hormones to increase or decrease, or directly act on peripheral endocrine glands to alter their hormone synthesis and release.

In many homeostatic controls both nervous and endocrine systems work together. For example, when there is a large amount of blood loss, baroreceptors and volume receptors situated in the periphery (vascular system and the heart) as well as in the brain send error signals to the central nervous system, and they increase blood pressure through the action of the autonomic nervous system and cause a release of epinephrine from the adrenal gland. At the same time, secretion of ►vasopressin (antidiuretic hormone, ADH) from the posterior pituitary gland is greatly increased so that water loss from the kidney is prevented by this hormone action. Release of renin from the kidney also occurs. Thus, through many mechanisms the blood pressure, blood volume and the body fluid are returned to their "normal" level.

### Pathology

#### *Changes in Homeostasis: "Heterostasis"*

Maintenance of the homeostatic state is important for the survival of an organism for the long run. However, in the biological system it does not mean that the "ideal" condition for an organism is maintained all the time. In many cases, adaptation has to change the homeostatic state. Such an idea was originated from Hans Selye in the early 70s [4].

After studying many stressful situations in the organism, Hans Selye proposed the state newly established by adaptation, called "►heterostasis." This state is necessary for survival of an organism against potential dangers. According to Selye, heterostasis means "the new establishment of the new steady state by exogenous stimulation of adaptive mechanisms through development of and maintenance of unusual defensive tissue reaction."

# Homeostatic Mechanism

### Definition

Homeostatic mechanisms are the multiple functions that operate in the organism in order to achieve and maintain homeostasis.

►Homeostasis

# Homeostatic Regulation

### Definition

The tendency of the nervous system (and all biological systems) for self-correction when the properties are altered in some way. For example, when the firing properties of a neuron or synapse are altered, over a period of time new proteins are synthesized that restore the neuron or synapse back towards their original properties.

# Homeostatic Regulation of Sleep Need

►Sleep Homeostasis

# Homeotic Genes/Hox Genes

### Definition

Evolutionary highly conserved genes, containing a homeobox. Hox genes are clustered along the chromosome in complexes, their relative location within the complex is reflected by the expression along the anterior–posterior body axis. Mutations in Hox genes lead to the alteration of segmental identity.

## Homogeneity

### Definition

The property of a uniform material body for which there exists a configuration in which the trivial translations between neighborhoods happen to be material isomorphisms.

►Mechanics

## Homogeneous Transformation
