These are (i) the six transmembrane (6TM) domain channels which are gated by voltage or in a few cases by both $Ca^{2+}$ and voltage or by $Ca^{2+}$ alone; (ii) the two transmembrane (2TM) or ►inward-rectifier $K^+$ channels and (iii) the four transmembrane (4TM) or two pore domain (K2P) ►leak $K^+$ channel(s).

## The Six Transmembrane Domain K Channel Family

The 6TM family comprises a number of different subfamilies (Table 1) such as the voltage-gated $K_V1$–4 family of channels, which underlie functional ►delayed-rectifier channels and ►A-type $K^+$channel(s). These channels open when the membrane is depolarized. Also in this family are the $K_V7$ (KCNQ) and $K_V10$–12 (EAG) channels (including hERG, which are of particular interest due to their role in certain sudden death syndromes). These are low-threshold voltage-gated channels which are often regulated by G protein coupled receptors such as ►muscarinic acetylcholine receptors and have a non-inactivating component open close to the resting membrane potential of the cell. Finally, in this family are the $Ca^{2+}$ and $Na^+$ activated $K^+$ channels ($K_{Ca}1$–5). These $K^+$ channels can be divided into three broad groups. These are the large conductance maxi-$K^+$ channels (or ►BK channels) corresponding to the *slo* family of $K^+$ channels, the small-conductance or ►SK channels (corresponding to SK1-SK3) and the intermediate conductance $K^+$ channels, corresponding to SK4 channels. Within the 6TM family, the pore-forming

N

α subunits form tetramers. Heteromeric channels may be formed within subfamilies (e.g. $K_V1.1$ with $K_V1.2$; $K_V7.2$ with $K_V7.3$).

## The Two Transmembrane Domain K Channel Family

The 2TM domain family of $K^+$ channels is also known as the inward-rectifier $K^+$ channel family. Current flows through them more easily in an inward direction because they are blocked by intracellular polyamines and/or $Mg^{2+}$ ions at depolarized voltages. This family includes the strong inward-rectifier $K^+$ channels ($K_{IR}2$), the G-protein-activated inward-rectifier $K^+$ channels ($K_{IR}3$) and the ►ATP-sensitive $K^+$ channels ($K_{IR}6$, which combine with sulphonylurea receptors (SUR)) (see Table 2). Like the 6TM family, the pore-forming a subunits of the 2TM family form tetramers. Heteromeric channels may be formed within subfamilies (e.g. $K_{IR}3.2$ with $K_{IR}3.3$).

## The Four Transmembrane Domain $K^+$ Channel Family

The 4TM family of $K^+$ channels (TWIK, TREK, TASK, TALK, THIK and TRESK channels, Table 3) are the most recently identified $K^+$ channel family and underlie ►leak currents open at all voltages and expressed heterologously throughout the nervous system. They are regulated by a wide array of ►neurotransmitters and biochemical mediators. The primary pore-forming α subunit contains two pore domains (hence K2P) and so it is envisaged that they form functional dimers rather than the usual $K^+$ channel tetramers. There is some evidence that they can form heterodimers within subfamilies (e.g. $K_{2P}3.1$ with $K_{2P}9.1$).

## Structural Features of $K^+$ Channels

Whilst the structural properties of the different $K^+$ channel families vary considerably, one region, the pore (P) region (and within this region the selectivity filter particularly), is highly conserved between $K^+$ channels. The P region forms a hydrophobic hairpin loop in the membrane, within which is located the selectivity filter of the channel that confers $K^+$ selectivity. The selectivity filter has a highly conserved sequence, usually TYGYG. This region allows $K^+$ channels to be both extremely selective in which ions they allow to pass, yet still allow extremely fast transport rates, close to the aqueous diffusion limits (see Fig. 2).

The unique structure of the selectivity filter, in particular the arrangement of these five conserved residues which have their carbonyl oxygen atoms aligned towards the center of the selectivity filter pore, forms "customized oxygen cages" which mimic the arrangement of water molecules around $K^+$ ions. The $K^+$ ions can then enter the selectivity filter easily by diffusion. Sodium ($Na^+$) ions (although smaller) have a different arrangement of water molecules around them in solution and so do not enter the selectivity filter so easily. The selectivity filter also allows multiple ion occupancy, i.e. more than one $K^+$ ion (from two to two and a half on average) can sit in the selectivity filter at one time. The positively charged ions repel each other and ions are pushed through the

channel, usually down their concentration gradient so that $K^+$ ions flow from inside the cell to the outside [6,7].

Other regions of $K^+$ channels vary more widely from family to family and gene to gene. These include the regions of the channel that sense stimuli which act to alter the activity of $K^+$ channels (such as voltage, $Ca^{2+}$, phosphorylation, activated G protein subunits, etc), regions of the protein concerned with gating and regions which form protein/protein interactions with other proteins. For example, the fourth transmembrane domain (S4) of voltage-gated $K_V$ channels contains many positively charged amino acids and this is thought to be the region that senses changes in membrane voltage. However, exactly how this region then responds to the voltage change it senses is an area of intense debate [see 8]. For a subgroup of $K_V$ channels the intracellular N terminus region is mobile and interacts with the channel pore when the channel is open leading to current ►inactivation (termed N-type inactivation). Functionally, this is seen as fast inactivation characteristic of ►A-type $K^+$ currents (►$I_A$) (see below).

## $K^+$ Channel Auxiliary Subunits

Most primary α subunits of $K^+$ channels interact with auxiliary subunits which can act to alter both channel function and channel expression levels at the cell membrane. For example, $K_V$ β1 and β2 subunits accelerate inactivation when co-expressed with certain $K_V1$ channel subunits. Furthermore $K_V5$, $K_V6$, $K_V8$ and $K_V9$ subunits do not form functional channels when expressed alone but act as auxiliary subunits to modify the function of $K_V2$ channel subunits when co-expressed with these (see Table 1). In most cases, the detailed role and importance of auxiliary $K^+$ channel subunits has still to be established. Perhaps the most well known of $K^+$ channel auxiliary subunits described to date

are the sulphonylurea receptors which form multimeric complexes with $K_{IR}6$ channels to give functional ATP-sensitive $K^+$ channels.

## Functional Properties of Neuronal $K^+$ Channels

The large number of $K^+$ channel genes, the possibility of heteromeric combinations and the existence of both auxiliary subunits and post-translational modifications such as phosphorylation, when taken together, suggest that the potential number of functional $K^+$ channel types in neurons is extremely large. Despite this, only a comparatively small number of distinct $K^+$ channel currents have been characterized to date, suggesting that many channel combinations have properties that differ from each other only subtly. This often makes it extremely difficult to be certain which subunit combinations underlie which functional currents seen in particular neurons. Nevertheless a few functional profiles are seen in many neuron populations. These include delayed-rectifier $K^+$ currents ($K_V$), ►A type currents ($K_A$), ►M currents, Ca-activated K currents and leak K currents.

*Delayed rectifier*, $K_V$, currents (e.g. $K_V1.1$, $K_V3.1$, $K_V3.2$ homomers) are the main $K^+$ current in many excitable cells (Fig. 3). Once a threshold voltage is reached, their conductance increases upon membrane depolarization rising sigmoidally and they inactivate slowly. From one cell to another (or one protein to another) they have diverse kinetics, pharmacology and voltage-dependence but they are usually sensitive to relatively low concentrations of ►tetraethylammonium ions (►TEA). Their activity controls action potential depolarization and hence the duration of the action potential (Action potential).

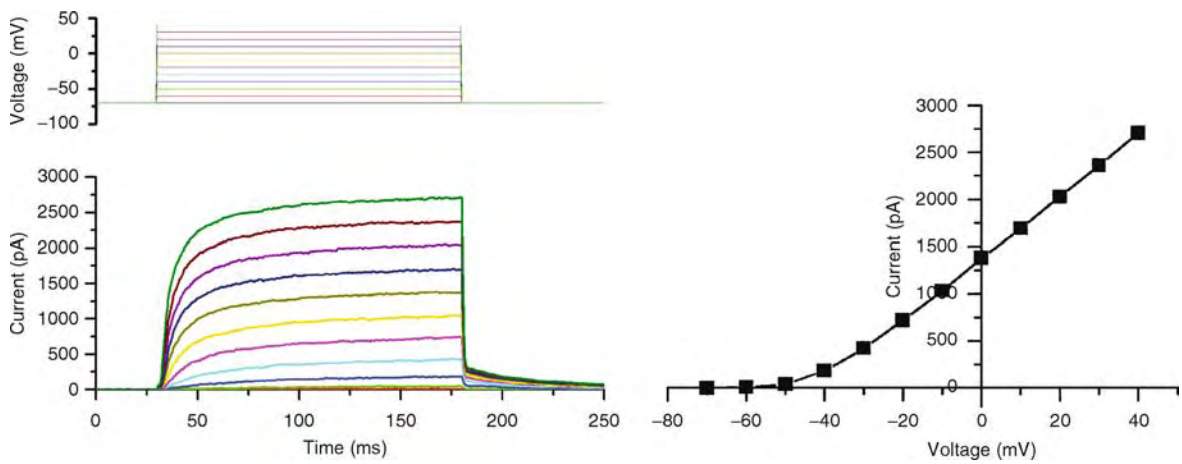
►*Transient $K^+$ currents* such as ►$K_A$ currents or ►$K_D$ currents (e.g. $K_V1.2$, $K_V1.4$, $K_V3.4$, $K_V4.2$ homomers) are usually found in cells in addition to delayed rectifier currents. Their conductance also increases with depolarization but they characteristically inactivate quickly, albeit with varying timescales when comparing one to another. They are often selectively localized within a neuron and have a role in regulating the interspike interval in a train of action potentials, thus their activity helps to determine the latency to the first action potential spike.

The *M current* is encoded by members of the $K_V7$ or KCNQ subfamily (usually seen as $K_V7.2$ and $K_V7.3$ heteromers in neurons). The current gets its name because it is inhibited following activation of muscarinic acetylcholine receptors. The M current is a sustained current which activates slowly at subthreshold voltages and normally keeps the neuronal membrane hyperpolarized. However, suppression of the current following muscarinic receptor activation leads to membrane depolarization. The current controls spike frequency accommodation; thus typically on depolarization, one might see a few spikes before the M current activates fully to act as a break to further firing.

*$Ca^{2+}$-activated $K^+$ currents* are activated following a rise in intracellular $Ca^{2+}$. BK currents have a role in action potential depolarization whilst SK currents contribute to after hyperpolarizations which control the action potential firing rate.

*Leak $K^+$ currents* are open at all voltages (i.e. they are not voltage gated) and contribute to the cell membrane potential and neuronal excitability. K2P channels often underlie leak $K^+$ currents and these channels are highly regulated by agents such as neurotransmitters and other physiological mediators, thereby constantly tuning neuronal excitability.

So, why are there so many different $K^+$ channel subunits and different $K^+$ current functional profiles?



**Neuronal Potassium Channels. Figure 3** Left hand side – a family of $K^+$ currents through $K_V1.1$ potassium channel homo-tetramers expressed in HEK cells, evoked by step depolarizations in membrane potential. Right hand side – the peak current is plotted against the voltage for each step. Note that current is activated at voltages positive to −50 mV.

The most likely explanation is that different neurons express different subsets of $K^+$ channels in order to uniquely tailor their responses to particular synaptic inputs. For example, neurons that are required to fire at extremely high frequencies (such as neurons in the auditory brainstem nuclei [9] are often found to have high expression levels of $K_V3$ channels. These particular channels activate and deactivate extremely quickly which allows the membrane potential to depolarize quickly following an action potential, ready to depolarize again very rapidly as required for high frequency firing. Studies into the expression levels of $K^+$ channels are mapping their distinct distribution throughout the central nervous system [e.g. 10]. This differential distribution of $K^+$ channels underlies the differential neuronal responses seen throughout the central nervous system to synaptic inputs.

### Synonyms

Neurogenic pain

### Definition

Neuropathic pain is defined as a "Pain arising as a direct consequence of a lesion or disease affecting the

somatosensory system" [1]. The term "disease" refers to identifiable disease processes such as inflammatory, autoimmune conditions or channelopathies, while lesions refer to macro- or microscopically identifiable damage. The restriction to the somatosensory system is necessary, because diseases and lesions of other parts of the nervous system may cause nociceptive pain. For example, lesions or diseases of the motor system may lead to spasticity or rigidity, and thus may indirectly cause muscle pain. These pain conditions are now explicitly excluded from the condition neuropathic pain.

## Characteristics

### Epidemiology of Neuropathic Pain

Chronic neuropathic pain is common in clinical practice, greatly impairs the quality of life of patients and is a major economical health problem. Estimates of point prevalence for neuropathic pain in the general population are as high as 5%, a quarter of them suffering from severe pain. Moreover, a recent prospective cross-sectional survey in 13,000 chronic pain patients with both nociceptive and neuropathic pain types who were referred to pain specialists in Germany revealed that 13% of these patients suffer from the two classical neuropathic disorders, ►post-herpetic neuralgia (PHN) and painful diabetic neuropathy, and 40% of all have at least a neuropathic component to their discomfort (especially patients with chronic back pain and ►radiculopathy) [2]. Comorbidities such as poor sleep, depressed mood and anxiety are common in neuropathic pain and have a significant impact on the global pain experience.

### Classification

#### *Disease/Anatomy-Based Classification*

It is common clinical practice to classify neuropathic pain according to the underlying etiology of the disorder and the anatomical location of the specific lesion. The majority of patients fall into four broad classes (Table 1): painful peripheral neuropathies (focal, multifocal or generalized, e.g. traumatic, ischemic, inflammatory, toxic, metabolic, hereditary), central pain syndromes (e.g. stroke, multiple sclerosis, spinal cord injury), complex painful neuropathic disorders (complex regional pain syndromes, CRPS) and mixed pain syndromes (combination of nociceptive and neuropathic pain, e.g., chronic low back pain with radiculopathy).

### Painful Peripheral (Focal, Multifocal, Generalized) Neuropathies

The anatomical distribution pattern of the affected nerves provides valuable differential diagnostic clues as to possible underlying causes. It is therefore common clinical practice to group painful neuropathies into symmetrical generalized polyneuropathies, affecting

many nerves simultaneously, and into asymmetrical neuropathies with a focal- or multifocal distribution or processes affecting the brachial or lumbosacral plexuses. One important subgroup of polyneuropathies is characterized by a predominant, or in some cases even isolated, involvement of small afferent fibers (i.e. unmyelinated C-fibers and small myelinated Aδ-fibers). In many cases, autonomic efferent small fiber systems are also affected. Different etiologies may lead to small fiber polyneuropathies, but up to 20% of cases, however, are of unknown cause. It is important to realize that conventional electrophysiological techniques like NCS (nerve conduction study), SEP (somatosensory evoked potential), etc. only assess the function of myelinated peripheral axonal systems and the contribution of small fibers will be missed. Therefore, especially in small fiber neuropathies, alternative diagnostic procedures have to be used, like ▶quantitative sensory testing (QST).

## Central Pain Syndromes

Central pain is defined as chronic pain following a lesion or disease of the central nervous system. The cause of pain is a primary process within the CNS (central nervous system). The highest incidence is observed after spinal cord injury, lesions in the lower brainstem and thalamus. An involvement of spinothalamo-cortical pathways seems to be crucial for the development of central pain, whereas isolated lesions of the lemniscal system are never associated with pain. Many kinds of lesions can induce central pain. The most common are cerebrovascular lesions, multiple sclerosis (MS) and traumatic spinal cord injuries (SCI). Central pain often develops with a latency of weeks or months after the inciting event.

## Complex Painful Neuropathic Disorders

In addition to the classical neuropathic syndromes like painful diabetic neuropathy, postherpetic neuralgia or phantom limb pain are certain chronic painful conditions that share many clinical characteristics. These syndromes were formerly called reflex sympathetic dystrophy, M. Sudeck or causalgia and are now classified under the umbrella term complex regional pain syndromes (CRPS). CRPS are painful disorders that may develop as a disproportionate consequence of trauma typically affecting the limbs. CRPS type I usually develops after minor trauma with no obvious nerve lesion at an extremity (e.g. bone fracture, sprains, bruises or skin lesions, surgeries). CRPS type II develops after trauma that typically involves a large nerve lesion.

## Mixed Pain Syndromes

Both nociceptive and neuropathic processes contribute to many chronic pain syndromes and these different mechanisms may explain the qualitatively different symptoms and signs that patients experience. In particular, patients with chronic low-back pain, cancer pain and CRPS seem to fit into this theoretical construct.

### *Mechanism-Based Classification*

In neuropathic pain a disease/anatomy-based classification is often insufficient. Despite obvious differences in etiology, many of these diseases share common clinical phenomena; for example, touch-evoked pain in postherpetic neuralgia and painful diabetic neuropathy. Conversely, different signs and symptoms can be present in the same disease; for example, pain paroxysms and stimulus-evoked abnormalities in postherpetic neuralgia. Classification on the basis of location also has its shortcomings, as neuroplastic changes following nervous system lesions often give rise to sensory and pain distributions that do not respect nerve, root, segmental or cortical territories. These observations have raised the question whether an

entirely different strategy, in which pain is analyzed on the basis of underlying mechanisms [3], could provide an alternative approach for examining and classifying patients, with the ultimate aim of obtaining a better treatment outcome [4,5].

## Signs and Symptoms in Neuropathic Pain

Patients with neuropathic pain demonstrate a variety of distinct sensory symptoms that can coexist in combinations. Bedside sensory examination should include touch, pinprick, pressure, cold, heat, vibration, and temporal summation ([6], definitions in Table 2).

Responses can be graded as normal, decreased or increased to determine whether negative or positive sensory phenomena are involved. Stimulus-evoked (positive) pain is classified as dysesthetic, hyperalgesic or allodynic, and according to the dynamic or static character of the stimulus. Touch can be assessed by gently applying cotton wool to the skin, pinprick sensation by the response to sharp pinprick stimuli, deep pain by gentle pressure on muscle and joints, cold and heat sensation by measuring the response to a thermal stimulus, for example by thermo-rollers kept at 20 or 45°C. Cold sensation can also be assessed by the response to acetone spray. Vibration can be assessed by a tuning fork placed at strategic points (interphalangeal joints, etc).

## Pathophysiological Mechanisms in Patients

### *Peripheral and Central Sensitization of Nociceptive Neurons*

Abnormal nociceptor sensitization and abnormal spontaneous afferent activity has been demonstrated in many peripheral nerve injury models. Partial nerve lesion is associated with dramatic changes in the regulation of receptors and channels in damaged as well as undamaged primary afferent neurons. These neurons develop spontaneous activity (ectopic discharge) and an increased sensitivity to chemical, thermal and mechanical stimuli. Ectopic impulse generation following nerve injury is associated with enhanced expression and changes in the distribution of certain voltage gated

**Neuropathic Pain. Table 2** Definition and assessment of negative and positive sensory symptoms or signs in neuropathic pain

| | Symptom/Sign | Definition | Assessment bedside exam | Expected pathological response |
|---|---|---|---|---|
| Negative signs and symptoms | Hypoesthesia | Reduced sensation to non painful stimuli | Touch skin with painters brush, cotton swab or gauze | Reduced perception, numbness |
| | Pall-hypoesthesia | Reduced sensation to vibration | Apply tuning fork on bone or joint | Reduced perception threshold |
| | Hypoalgesia | Reduced sensation to painful stimuli | Prick skin with single pin stimulus | Reduced perception, numbness |
| | Therm-hypoesthesia | Reduced sensation to cold/warm stimuli | Contact skin with objects of 10°C (metal roller, glass with water, coolants like acetone) | Reduced perception |
| | | | Contact skin with objects of 45°C (metal roller, glass with water) | |
| Spontaneous sensations/pain | Paraesthesia | Non-painful ongoing sensation (ant crawling) | Grade intensity (0–10) | – |
| | | | Area in $cm^2$ | |
| | Paroxysmal pain | Shooting electrical attacks for seconds | Number per time | – |
| | | | Grade intensity (0–10) Threshold for evocation | |
| | Superficial pain | Painful ongoing sensation often of burning quality | Grade intensity (0–10) | – |
| | | | Area in $cm^2$ | |

**Neuropathic Pain. Table 2** Definition and assessment of negative and positive sensory symptoms or signs in neuropathic pain (Continued)

| | Symptom/Sign | Definition | Assessment bedside exam | Expected pathological response |
|---|---|---|---|---|
| Evoked pain | Mechanical dynamic allodynia | Normally non painful light moving stimuli on skin evoke pain | Stroking skin with painters brush, cotton swab or gauze | Sharp burning superficial pain |
| | | | | Present in the primary affected zone but spread beyond into unaffected skin areas (secondary zone) |
| | Mechanical static allodynia | Normally non painful gentle static pressure stimuli at skin evoke pain | Manual gentle mechanical pressure at the skin | Dull pain |
| | | | | Present in the area of affected (damaged or sensitized) primary afferent nerve endings (primary zone) |
| | Mechanical punctate hyperalgesia | Normally stinging but not painful stimuli evoke pain | Manual pricking the skin with a safety pin, sharp stick or stiff von Frey hair | Sharp superficial pain |
| | | | | Present in the primary affected zone but spread beyond into unaffected skin areas (secondary zone) |
| | Temporal summation | Repetitive application of identical single noxious stimuli is perceived as increasing pain sensation (Wind-up like pain) | Pricking skin with safety pin at interval <3 s for 30 s | Sharp superficial pain of increasing intensity |
| | Cold allodynia (hyperalgesia) | Normally non (slightly) painful cold stimuli evoke pain | Contact skin with objects of 20°C (metal roller, glass with water, coolants like acetone) | Painful often burning temperature sensation |
| | | | Control: contact skin with objects of skin temperature | Present in the area of affected (damaged or sensitized) primary afferent nerve endings (primary zone) |
| | Heat allodynia (hyperalgesia) | Normally non (slightly) painful heat stimuli evoke pain | Contact skin with objects of 40°C (metal roller, glass with water) | Painful burning temperature sensation |

sodium channels in primary afferent neurons, leading to a lowering of the action potential threshold [7].

As a consequence of peripheral nociceptor hyperactivity, dramatic secondary changes in the spinal cord dorsal horn also occur. Partial peripheral nerve injury leads to an increase in the general excitability of spinal cord neurons. This so-called central sensitization is probably due to activity in pathologically sensitized C-fibers, which sensitize spinal cord dorsal horn neurons by releasing glutamate and the neuropeptide substance P. Neuronal voltage-gated calcium channels that are located presynaptically at spinal nociceptive terminals are up-regulated after peripheral nerve injury and play an important role in the process of central

sensitization by mediating the release of glutamate and substance P. If central sensitization is established, normally innocuous tactile stimuli become capable of activating spinal cord pain signaling neurons via Aß-low threshold mechanoreceptors [8] [see ►Hyperalgesia and Allodynia]. By this mechanism, light touching of the skin induces pain (i.e. mechanical allodynia).

### *Changes in the Brain*

Most animal experiments have concentrated on the dorsal horn as the location of central sensitization. However, in rodents, sensitized neurons are also found in the thalamus and primary somatosensory cortex after partial peripheral nerve injury. Furthermore, MEG, PET and functional MRI studies demonstrate fundamental changes in somatosensory cortical representation and excitability in patients with phantom limb pain, CRPS and central pain syndromes as well as experimental pain models. Interestingly, these changes correlate with the intensity of the perceived pain and disappear after successful treatment of the pain.

### *Deafferentation: Hyperactivity of Central Pain Transmission Neurons*

Although the above convincingly supports a role for peripheral and central sensitization in the generation of neuropathic pain, in some patients there is a profound cutaneous deafferentation of the painful area with no significant ►allodynia. Assuming that the ►dorsal root ganglion cells and the central afferent connections are lost in such patients, their pain must be the result of intrinsic CNS changes. In animal studies, following complete primary afferent loss of a spinal segment, many dorsal horn cells begin to fire spontaneously at high frequencies. There is some evidence that a similar process may underlie the pain that follows extensive denervating injuries in humans. Recordings of spinal neuron activity in a pain patient whose dorsal roots were injured by trauma to the ►cauda equina revealed high frequency regular and paroxysmal bursting discharges. The patient complained of spontaneous burning pain in a skin region that was anesthetic by the lesion (anesthesia dolorosa).

### *Inflammation in Neuropathic Pain*

After nerve lesion, activated macrophages infiltrate from endoneural blood vessels into the nerve and dorsal root ganglia, releasing pro-inflammatory cytokines, in particular tumor necrosis factor alpha (TNF-α) [see ►Immune System and Pain]. These mediators induce ectopic activity in both injured and adjacent uninjured primary afferent nociceptors at the lesion site.

In patients with inflammatory neuropathies, such as vasculitic neuropathies or HIV neuropathy, deep proximal aching and paroxysmal pain are characteristic phenomena. COX2 (cyclooxygenase 2) and proinflammatory cytokines were found to be up-regulated in nerve biopsy specimens of these patients. In the affected extremities of CRPS patients, the fluid of artificially produced skin blisters contain significantly higher levels of IL-6 and TNF-α as compared with the uninvolved extremity.

## Quantitative Sensory Testing as a Diagnostic Tool in Neuropathic Pain

The modern theoretical concept of a mechanism-based therapy assumes that a specific symptom predicts a specific underlying mechanism [3]. However, this approach carries certain important caveats. Clinical experimental studies indicate that a specific symptom might be generated by several entirely different underlying pathophysiological mechanisms. Therefore, a specific symptom profile rather than a single symptom might be required to predict the underlying mechanism. To translate these ideas into the clinical framework, it is important to characterize the somatosensory phenotype of a patient as precisely as possible. A standardized quantitative sensory testing protocol (QST) was introduced by the German Research Network on Neuropathic Pain, including 13 parameters and encompassing thermal as well as mechanical testing procedures for the analysis of the somatosensory phenotype. To judge plus or minus symptoms in patients, an age- and gender-matched data-base for absolute and relative QST reference data for several body regions in healthy human subjects was established. The precise phenotypic mapping with QST is an important step to establish a future mechanism-based drug therapy of neuropathic pain. If the symptoms are closely related to mechanisms, clinical assessment of the symptoms may give an idea of the concert of the distinct mechanisms that operate in one individual patient. This knowledge may lead in the future to an optimal poly-pragmatic therapy with drugs that address the specific combination of mechanisms in each patient.

## Present Medical Treatment

The number of trials for peripheral neuropathic pain has expanded greatly in the last few years [9]. In summary, the medical management of neuropathic pain consists of five main classes of oral medication (serotonin/norepinephrine modulating antidepressants, sodium-blocker-anticonvulsants, calcium-modulator-anticonvulsants, tramadol and opioids) and two categories of topical medications mainly for patients with cutaneous ►allodynia and ►hyperalgesia (capsaicin and local anaesthetics). For central neuropathic pain, there are limited data. Since more than one mechanism is at work in most patients, a combination of two or more analgesic strategies to address multiple mechanisms will generally produce greater pain relief. Therefore, in most patients a stepwise process using successive

monotherapies is not appropriate. Early combinations of two or three drugs form different classes is the general practical approach.

## Neuropathy

### Definition

Any peripheral nerve disease, which usually causes weakness and numbness (see ►peripheral neuropathy).

## Neuropeptide S (NPS)

### Definition

A twenty-residue peptide expressed in a few discrete nuclei in the brainstem (pericoerulear area and parabrachial nucleus). The name arises because its N-terminal residue is a Serine (S), which is conserved across vertebrate species. NPS receptors (formerly, GPRA receptors) are distributed widely throughout the brain. Infusion of NPS in the brain has anxiolytic-like properties and induces wakefulness.

►Hypocretin/Orexin
►Neuropeptides
►Ventrolateral Preoptic Nucleus (VLPO)

## Neuropeptide Y (NPY)

### Definition

A 36 amino acid neuromodulator well known as a contributor to the regulation of feeding. In the context of circadian rhythm regulation, it is important because it is synthesized in neurons of the intergeniculate leaflet (IGL) that project to the suprachiasmatic nucleus (SCN) via the geniculohypothalamic tract (GHT). NPY is released from GHT terminals in the SCN and acts as a neuromodulator mediating the ability of certain nonphotic environmental stimuli to modulate circadian rhythm phase.

### Synonyms

Neuromodulators; Neurotransmitters

### Definition

►Neuropeptides are small proteins produced in and released from neurons. They exert potent membrane effects on both adjacent neurons (i.e., synaptic) and glia (i.e., paracrine) and can be released from neurons

to gain access to the hypothalamo-pituitary-portal vessels (i.e., neuroendocrine) or general circulation (i.e., endocrine). Within the limbic system, these small chains of amino acids exert potent behavioral effects that can be divided into several categories, motivation, appetite, fear and anxiety, arousal, memory, addiction and aggression to name but a few.

## Characteristics

### Quantitative Description

No one rule is agreed upon by the scientific community. Neuropeptides are considered to be proteins consisting of fewer than 100 amino acids, although some investigators would assign such status to peptides comprised of fewer than 50 amino acids. Clearly these biologically active factors are produced as part of a larger pre-prohormone that, following translation of the encoding mRNA, undergoes numerous catalytic modifications resulting in the assembly of the bioactive components in secretory granules. Along the way, biochemical adjustments to the amino acid backbone that are essential for expression of full biologic activity are completed, including N- and C-terminal modifications and in some cases unique changes to single amino acid structure such as bromination and surprisingly in the case of the peptide ghrelin the addition of an octanoyl group [1]. In general, neuropeptides are thought to be extremely labile and the termination of their biological activity is a combination of uptake (of bound peptide to cognate receptor) or enzymatic processing by cell surface proteases abundant in the neuropil. Many but not all the identified neuropeptide receptors are members of the G-protein classes of biologically active receptors; however, some neuropeptides bind directly to ion channels, membrane spanning guanylyl cyclases or tyrosine kinase-like growth factor receptors. While direct actions of neuropeptides can be demonstrated on the more classically described neurotransmitters (e.g., acetylcholine, norepinephrine, dopamine, glutamate, GABA), important interactions of neuropeptides with other neuropeptide producing neurons are clearly the basis for the pharmacological and in some cases the demonstrated physiologically relevant actions of the peptides. Since neuropeptides are unique products of single genes, molecular engineering technologies [2,3] have allowed for the development of informative animal models in which the peptide itself or its receptor are selectively ablated in either the embryonic stage (and thus throughout life, gene knockouts) or at any stage during postnatal development (selective gene ablation, Cre-LOX strategies) using a technique that can be initiated without the deleterious effects of loss of the neuropeptide during fetal development. These technologies also allow for continuous or regulated over-expression of the neuropeptide by insertion of a transgene that is constitutively expressed or induced chemically for either short or long periods of time. These technologies have clearly established the importance of these "non-classical" neurotransmitters in a wide variety of neural events and provided insight into therapeutic strategies for the treatment of CNS disorders.

### Higher Level Structures

It is impossible in the space allotted to catalog all the currently identified neuropeptides, their localization in limbic structures or their multiple and diverse biologic actions. One peptide will be used as an example for each class of characteristic biologic effects exerted by neuropeptides within limbic structures.

Motivation is a behavior intimately linked to reward. The endogenous opioid systems including the neuropeptides beta-endorphin and the enkephalins are important neural factors that organize learned responses and provide signals that impact motivation [4]. Aversive stimuli are also transmitted by neuropeptides, including CCK-8 and oxytocin. Included in motivation is a component of memory and the role of vasopressin in this behavior has been demonstrated in experimental animals and humans. This neuropeptide surprisingly affects both the consolidation and recovery of memory and contributes, via actions in the medial septal nuclei, to the emotional components of memory including aggression.

By far the most comprehensively cataloged behavioral response to neuropeptides within limbic structures is appetite, although it is difficult to separate appetitive behaviors from the additional limbic actions of many of these neuropeptides such as arousal state, anxiety and even addiction. Currently there are more than 50 neuropeptides that have been characterized for their effects on appetite (Table 1).

These can be divided into those that elicit hunger and those that contribute to ►satiety. While the actions of these "feeding peptides" are exerted in many distinct limbic structures, it is in the medial-basal hypothalamus where the primary interactions take place, in particular in the arcuate nuclei, the ventromedial hypothalamic nuclei and the lateral hypothalamic nuclei. Cells in these areas integrate ascending neuronal input from brainstem structures such as the nucleus tractus solitarius (in particularly the vagal afferent relaying information relevant to ongoing and metabolic state), from temporal lobe structures including hippocampus and amygdala and from circumventricular organs such as the subfornical organ, area postrema and organum vasculosum lamina terminalis.

Circulating hormones derived from the gut and adipocytes activate cells in blood brain barrier free sites and in some cases directly affect the activity of neurons in these hypothalamic nuclei, informing these integrative centers of the fed/fasted state of the individual.

**Neuropeptides. Table 1** Neuropeptides acting in limbic structures to alter feeding behaviors

| Stimulators | Inhibitors |
|---|---|
| Agouti-Related Peptide (AGRP) | Adrenomedullin |
| Dynorphin | Amylin |
| Beta-Endorphin | Anorectin |
| Galanin | Bombesin |
| Ghrelin | Brain-derived neurotrophic factor (BDNF) |
| Growth Hormone Releasing Hormone | Calcitonin Gene Related Peptide (CGRP) |
| Hypocretins/Orexins | CART |
| Melanin Concentrating Hormone (MCH) | Cholecystokinin (CCK) |
| Neuropeptide Y (NPY) | Ciliary Neurotrophic Factor (CNTF) |

| | Thyrotropin Releasing Hormone (TRH) |
| | Urocortin |

Metabolic factors themselves such as plasma glucose and free fatty acids are also sensed by neurons in these "feeding centers" and it is neuropeptides that then transmit the appropriate signals to motivational centers in brain organizing the appropriate response to ambient nutrient availability [5,6]. Central to this organization are neurons in the arcuate nucleus, which provide the critical organization of these inputs. Neuropeptide Y (NPY) and agouti-related peptide (AGRP) are produced in the same arcuate neurons and these two neuropeptides are central to the stimulatory drive for feeding [2]. They are inhibited by circulating leptin, a peptide derived from adipocytes and by insulin levels. High circulating levels of free fatty acids also exert inhibitory effects on NPY/AGRP neurons [6]. Peptide $YY_{3–36}$ is a gut hormone released in response to feeding that potently inhibits NPY/AGRP neurons [7]. On the other hand ghrelin, an octanoylated peptide produced in the gastric mucosa, is released during the fasted state and exerts direct, stimulatory actions on these neurons [1]. Thus the peripheral tissues can directly regulate motivation and appetite via metabolic and hormonal factors.

Also located in the arcuate nucleus are neurons that express the pro-opiomelanocortin (POMC) gene and, after post-translational processing of the encoded mRNA package for synaptic release, the neuropeptide alpha-melanocyte stimulating hormone (alpha-MSH). This peptide binds to a family of melanocortin receptors expressed on neurons in the feeding center and exerts potent anorexigenic actions, thus reducing the motivation for food seeking behaviors. These POMC neurons

are stimulated by insulin and leptin [2,6]. They are inhibited by NPY produced in adjacent neurons and binding of alpha-MSH to its melanocortin receptors is antagonized by AGRP. The integrative nature of these neuronal systems is further demonstrated by the ability of alpha-MSH to inhibit the activity of the NPY/AGRP neurons. Thus, even simply within the small population of arcuate neurons, a push-pull mechanism exists for the integration of feeding signals from the periphery. Neurons in the adjacent lateral hypothalamic area (LHA) contribute to the integration. These neurons produce the neuropeptides orexin A and orexin B (products of the same gene, also called hypocretin 1 and hypocretin 2). They are activated by NPY and inhibited by POMC. Important efferent projections from these LHA neurons innervate reward centers and brain stem satiety centers [8]. These neurons are also responsible for the behavioral arousal (locomotor activity, autonomic nervous system activation) that accompanies food seeking and eating [3].

The orexin neurons in LHA appear to play a central role in the reward aspects of food [9] and they are influenced by recognized interactions of the ascending dopaminergic pathways from the ventral tegmental area (VTA) to the nucleus accumbens (NAc). GABA-ergic neurons from the NAc project to the orexin neurons in LHA. Thus the neuropeptide systems of the "feeding centers" in medio-basal hypothalamus are intimately associated with brain reward circuitry in limbic structures.

## Lower Level Components

As mentioned above, orexin neurons in the LHA also control behavioral arousal and are essential for normal sleep-wakefulness. Administration of exogenous orexin into the brains of experimental animals results in increased cardiovascular function (increased sympathetic outflow resulting in increased mean arterial pressure and heart rate) and in increases in spontaneous locomotor activity, including ambulatory and grooming behaviors. The behavioral arousal observed in response to pharmacological application of orexin predicted the result of loss of orexin neurons during the development of ►narcolepsy/cataplexy in animal models and humans [3].

Anxiety and fear behaviors may also play a role in the limbic responses to changes in the endocrine and metabolic state. This is best illustrated by the actions of another hypothalamic neuropeptide, corticotropin-releasing hormone (CRH) on food intake and avoidance behaviors. The main function of CRH is expressed in anterior pituitary gland where it exerts primary control of the production and release of adrenocorticotropin (ACTH). ACTH in turn stimulates glucocorticoid (cortisol in humans, corticosterone in lower mammals) production in the adrenal gland. In addition to their mixed catabolic and anabolic effects in peripheral tissues, glucocorticoids feedback into the hypothalamus to control CRH release. In the absence of glucocorticoid negative feedback, the activity of CRH neurons increases and appetite is suppressed (the anorexigenic action of CRH). Behaviors characterized by fear and anxiety increase as well, due to the limbic actions of CRH. Alternatively, when glucocorticoid levels are high, such as in multiple models of stress and anxiety, CRH neurons are suppressed and appetite increases.

Social recognition and maternal behaviors are also regulated by the actions of neuropeptides in limbic structures. In an extensive series of studies, Thomas Insel and colleagues demonstrated the importance of the neuropeptide oxytocin in the organization and maintenance of affiliative behaviors in rodents [10]. Additional studies by Insel and others established the importance of oxytocin in the organization and imprinting of maternal behaviors.

Neuropeptides also play important roles in the organization of survival responses to changes in an animal's external environment including physical and emotional stressors. Neuropeptides that exert important metabolic actions, particularly those that stimulate feeding (e.g., NPY, orexin) are also potent activators of the sympathetic response to stress. Oxytocin, in addition to acting on social behaviors, is one of the most important neurotransmitters controlling sodium balance and therefore fluid and electrolyte homeostasis, which in itself is essential for the appropriate responses to stress.

## Structural Regulation

As detailed above, neuropeptides are pivotal factors in the assembly and integration of interoceptive and exteroceptive information. Neuropeptide producing neurons are targets of ascending and descending neural networks and furthermore are the detectors of hormonal and metabolic information. A highly organized system of communication is being discovered in which neuropeptides interact with other neurotransmitters systems in brain to organize the appropriate responses to those changes in the internal and external milieus. Not only do these neuropeptide systems control behavior and autonomic responses in normal physiology, they serve as potential targets for therapeutic interventions in disease [7].

## Pathology

Loss of the expression of individual neuropeptides or their receptors results in distinct pathologies, reflective of the physiological role played by those peptidergic systems of communication within limbic structures. Failure of the gonadotropin releasing hormone (GnRH) neurons to migrate into the hypothalamus during development results not only in hypogonadism (loss of GnRH action in pituitary gland), but also the absence

of characteristic gender based behaviors. Obesity caused by failure of satiety factors to inhibit neurons in hypothalamic feeding centers occurs when leptin receptors are mutated or absent [6]. Behavioral arousal is severely compromised when orexin neurons in the lateral hypothalamic area begin to disappear during the onset of narcolepsy.

## Therapy

Neuropeptides are relatively easy to mass-produce by classic synthetic chemistry or recombinant technologies. Subtle modifications in peptide structure can be made, resulting in increased or decreased biological activity and thus neuropeptides are attractive compounds for the development of super-active agonists or potent antagonists. While the problem of access into the neuropil must be overcome when designing peptide analogs for therapeutic actions within limbic structures, some synthetic neuropeptides readily access the brain or at least act on blood brain barrier free sites to affect limbic function. New strategies are being developed to facilitate delivery of synthetic neuropeptides into the brain and thus take advantage of their inherent activities to treat various pathologies. Particularly in the behaviors associated with feeding, these studies show strong promise. Indeed, $PYY_{3-36}$ has been shown to be an effective anorexic agent in human trials because of its ability to cross the blood brain barrier and activate the neuropeptide systems in limbic centers that inhibit feeding while inhibiting those neurons that produce ►orexigenic neuropeptides [7]. The potential to reverse the catastrophic consequences of loss of orexin neurons during the development of narcolepsy/cataplexy [3] by treatment with a blood brain barrier permeant analog of the neuropeptide has stimulated intense interest in not only the physiologic actions of the neuropeptide itself, but also the convergence of feeding signals and arousal state in general.

## Synonyms

Polypeptide; Energy homeostasis; Energy state; Appetite regulation; Food intake; Hypothalamus

## Definition

►Energy balance refers to the homeostasis between positive and negative energy states in an organism and is controlled by the regulation of food intake and energy expenditure. In higher organisms, these processes are regulated by the brain, where the hypothalamus assumes an important role. The hypothalamic circuitry involved includes ►peptide chemical messengers. These neuropeptides can be orexigenic, stimulating increased energy intake and tending to decrease energy expenditure, or anorexigenic, reducing energy intake and promoting increased energy expenditure. Here, we discuss the main hypothalamic neuropeptides that modulate the central circuitry involved in energy

homeostasis, and their integration of peripheral peptide and protein hormone signals of energy balance.

## Characteristics

### Neuropeptide Modulation of Hypothalamic Circuitry

Early experiments investigating the role of the hypothalamus in energy balance focused on the ventromedial nucleus (VMH) and the lateral hypothalamic area (LHA). Lesions to the VMH in rats resulted in ►hyperphagia and increased weight gain, while lesions to the LHA caused anorexia and weight loss. The "dual centre hypothesis" thus proposed that the VMH and LHA were the hypothalamic ►satiety centre and feeding centre, respectively [1]. However, this hypothesis is now believed to be overly simplistic. Lesions to the VMH and LHA may have interfered with intra- and extra-hypothalamic neural pathways passing through these regions. Furthermore, lesions at other hypothalamic regions can also influence energy balance.

The regulation of energy balance is now thought to involve a number of hypothalamic nuclei and extra-hypothalamic brain regions. These include the area postrema and subfornical organ, which are ►circumventricular organs (CVO) that mediate communication between the brain and peripheral appetite signals [2]; the nucleus tractus solitarius (NTS) of the brainstem, which receives inputs from vagal sensory afferents, and is capable of mediating some feeding responses [3]; the amygdala, which contributes an emotional component to the acquisition, storage, and recall of experiences with food; the nucleus accumbens and ventral tegmental area, which processes motivational and reward-mediated behaviors [4]; and the neocortex, which integrates taste, olfactory, visual, memory, and social factors that influence food intake [5].

The information regarding the nutrient and energy levels in the body is communicated to the brain, via neural and endocrine signals. The arcuate nucleus (ARC) of the hypothalamus plays an important role in integrating these signals. The ARC projects within the hypothalamus to the VMH, LHA, paraventricular nucleus (PVN), and dorsomedial nucleus (DMH) [6]. Communication within the hypothalamus is mediated by several classes of chemical messengers, including the amino acid and biogenic amine transmitters, cytokines, cannabinoids, and most notably, neuropeptides. These peptide neurotransmitters can act as either orexigenic (Table 1) or anorexigenic (Table 2) signals to stimulate or inhibit food intake, respectively.

A brief discussion of some individual peptides involved in energy balance regulation follows.

#### *Melanocortin Peptides*

Activation of the central melanocortin system reduces food intake and increases energy expenditure. It includes α-, β-, and γ-melanocyte stimulating hormone (MSH), all of which are derived from the proopiomelanocortin (POMC) peptide precursor. POMC expression in the CNS is restricted to the neurons of the NTS and ARC. POMC expression in the ARC is reduced in fasted animals. α-MSH is thought to represent the main melanocortin signal in this circuit. The ARC POMC neurons project to the PVN, DMH, and LH, where the melanocortins are released and act via MC3 and MC4 receptors. α-MSH and β-MSH are the main ligands of the MC4 receptor while γ-MSH is the main ligand at the MC3 receptor. Acute central administration of α-MSH reduces food intake and chronic administration reduces body weight. Genetic modulation of the melanocortin system, unlike most genetic models targeting specific hypothalamic circuits

| PYY | | Y2 | GI tract | ARC |

that regulate appetite, produces significant changes in food intake and body weight. ►Knockout of the MC4 or MC3 receptor results in hyperphagia and obesity in mice, and humans with MC4 receptor or POMC mutations are obese.

### *Corticotrophin-Releasing Hormone (CRH) and CRH-like Peptides*

CRH plays a central role in mediating stress by action on the hypothalamic-pituitary-adrenal axis (HPA). Central administration of CRH also reduces appetite in rodents. However, the anorexigenic effects of the CRH-like peptides, including urocortin (UCN) I–III, are more potent than that of CRH. CRH is expressed in the PVN and UCN is expressed in both the PVN and the LHA. Interestingly, CRH can play a role in initiating food-seeking behavior via the HPA axis.

### *Cocaine- and Amphetamine-Regulated Transcript (CART)*

CART is expressed in several hypothalamic nuclei and codes for a peptide that reduces food intake following ►intracerebroventricular (ICV) injection to the third cerebral ventricle. However, some orexigenic actions of the CART peptide have also been demonstrated. It has been suggested that CART can activate inhibitory autoreceptors that downregulate the anorexigenic CART signaling.

### *Neuropeptide Y (NPY)*

NPY, a member of the pancreatic polypeptide (PP) family, is one of the most potent known orexigenic neuropeptides. It is mainly produced by neurons in the ARC and brainstem and acts at several sites in the hypothalamus, including the PVN, VMH, DMH, LHA, and the perifornical area (PFA), a region of the LHA surrounding the fornix. Central administration of NPY stimulates food intake, which is thought to be mediated via Y1 and Y5 receptors. The greatest effect of NPY on food intake has been observed when administered into the PFA. The orexigenic actions of NPY peak during the appetitive, "food-seeking" phase of feeding. NPY release is enhanced immediately prior to the onset of feeding and gradually decreased as food intake continues. Despite the powerful acute effects of NPY on feeding, neither the overexpression nor knockout of NPY or its receptors causes profound changes in body weight. There appears to be compensatory mechanisms that protect orexigenic signaling in the hypothalamus when NPY signaling is compromised. This is observed in germline mutations of NPY signaling, which take effect throughout the development and growth of the animal. However, this is not true for adult animals, as the targeted disruption of NPY neurons in the ARC of adult mice results in lethal ►hypophagia [7].

### *Agouti-Related Peptide (AgRP)*

AgRP has potent orexigenic effects by its action as an endogenous antagonist of the melanocortin receptors. This suggests that melanocortin signaling is tonic and modulated by AgRP, which is ►co-localized exclusively with NPY in ARC neurons. ARC AgRP expression is greatly increased in fasted animals.

Central injection of AgRP potently stimulates food intake in rodents and can increase food intake for up to one week.

### Melanin-Concentrating Hormone (MCH)

MCH is produced mainly by two groups of LH neurons: Type A MCH neurons co-express CART and send descending projections to the brainstem while Type B neurons do not express CART and send ascending projections to the forebrain. The orexigenic effects of MCH are mediated by MCH1 receptors. Mice overexpressing the MCH gene are more susceptible to high-fat diet-induced obesity. In contrast, animals lacking the MCH or MCH1 receptor genes are lean and are resistant to obesity. Such conditions of MCH deficiency are accompanied by a marked suppression of ARC POMC expression, perhaps responding to counterbalance the decrease in satiety and body weight.

### Orexin

The orexins play an important role in maintaining the arousal system, which has been associated with changes in energy homeostasis. The orexins – Orexins A and B – are also known as the hypocretins and are produced primarily in the LHA but also in the PFA and DMH. The orexigenic effects of Orexin A are more potent than that of Orexin B. Orexin A has equal affinity for the $OX_1$ and $OX_2$ receptor. The $OX_1$ receptor is expressed in the VMH and LHA. The $OX_2$ receptor is expressed in neurons of the PVN, DMH, and ARC, which receives the highest density of LHA orexin fibers. Orexin A delays the onset of satiety, thereby increasing the duration of a meal to prolong feeding behavior. Disruption of orexin signaling by the ablation of orexin neurons or knockout of the prepro-orexin gene produces a hypophagic phenotype, which is partly attributed to the development of narcolepsy in these animals.

### Galanin and Galanin-like Peptide (GALP)

Galanin is expressed in the PVN, DMH, and ARC. GALP expression is restricted to the ARC. The orexigenic effects of galanin and GALP are fat-sensitive. Galanin acts via the Gal1 receptor and the positive feedback circuitry between galanin and dietary fat contributes to large meal sizes. The orexigenic effects of GALP, which are mediated by the GalR2 receptor, are enhanced following a high-fat diet when preceded by a period of hypophagia.

### Opioid Peptides

The opioid peptides (β-endorphin, enkephalin, and dynorphin) are all expressed in the ARC. Dynorphin is also expressed in the PVN and enkephalin in the PVN, VMH, and DMH. The orexigenic actions of the opioids are most commonly associated with β-endorphin, though all opioids stimulate food intake. The opioids preferentially increase fat ingestion over that of proteins or carbohydrates. Central blockade of opioid receptors prevents orexigenic actions of other peptides such as NPY, AgRP, orexin, and galanin.

## Contribution of Peripheral Peptides and Hormones

The central feeding circuitry is influenced by peripheral signals that indicate nutritional state and adiposity level. Peptides and other hormones that are produced and released from the gastrointestinal (GI) tract, pancreas, and adipose tissue play an important role in the short- and long-term regulation of energy balance. These peripheral signals can have central effects by:

1. Stimulation of vagal sensory afferents in the GI tract to signal brainstem nuclei, such as the NTS [8]
2. Stimulation of neurons in CVOs that project to the hypothalamus [2]
3. Transport across the ►blood-brain barrier (BBB) to act directly within the CNS [9]

### Ghrelin

Ghrelin is secreted by the stomach and is the only peripheral factor known to signal to the CNS to increase food intake. It plays a role in meal initiation; circulating ghrelin levels rise immediately before a meal and remain elevated during periods of food deprivation, and rapidly decline following food intake. Ghrelin can have central effects by crossing the BBB, acting via the vagal afferent pathway, and acting at CVOs. In addition, ghrelin is locally produced in the hypothalamus. In the hypothalamus, ghrelin acts at the ARC, LH, and PVN. The effects of ghrelin are mediated by NPY and AgRP release and are most potent in the PVN. In the ARC, ghrelin activates NPY neurons and inhibits POMC neurons.

### Leptin

Leptin is the protein product of the obese (*OB*) gene and plays a significant role in reducing food intake. Leptin is produced in white adipose tissue and levels of circulating leptin are directly correlated with body fat, glucose uptake, and food intake. Humans with congenital leptin deficiency, animals with defects in leptin (*ob/ob* mouse) or the leptin receptor (*db/db* mouse, fatty Zucker rat) are grossly obese. However, this is not a major cause of obesity, since most obese humans are leptin resistant and have elevated leptin levels. Leptin is transported into the brain via truncated forms of the leptin receptor (Ob-Ra, c, or d) and leptin signaling occurs via the long form of the receptor (Ob-Rb). In the ARC, leptin activates anorexigenic POMC neurons and inhibits orexigenic NPY/AgRP neurons. In the LHA, leptin inhibits the orexigenic MCH- and orexin-expressing neurons. Thus, when circulating leptin levels are low during periods of food-restriction or fasting, orexigenic neurons are activated and expression of orexigenic neuropeptides is increased

while anorexigenic neuronal activity and neuropeptide expression is inhibited. Conversely, high plasma leptin levels inhibit orexigenic pathways and activate anorexigenic pathways. Leptin clearly participates in long-term energy balance regulation. The absence of leptin signaling produces drastic changes in the energy state while leptin overexpression produces only mild phenotypic changes; this suggests that leptin is an essential signal indicating the adequacy of energy stores, which is required for the maintenance of vital activities such as reproduction [10].

### Insulin

Insulin is produced by the pancreas and, in addition to its well characterized role in the regulation of blood glucose levels, can act as a circulating adiposity signal. Plasma insulin levels change directly with changes in adiposity so that positive energy states stimulate, and negative energy states decrease, insulin secretion. Little or no insulin is produced in the brain but it can have significant central effects. Insulin moves by transporter-mediated entry into the brain and acts on insulin receptors in the ARC, PVN, and DMH. The actions of insulin in the CNS are anorexigenic. The orexigenic NPY and anorexigenic melanocortin systems are both downstream mediators of insulin signaling. Thus, insulin can increase POMC expression and prevent fasting-induced increases in NPY expression. Insulin is also implicated in the long-term regulation of energy balance as the specific deletion of neurons expressing the central insulin receptor leads to obesity.

### Glucagon-like Peptides (GLP)

The GLP, including GLP-1, GLP-2, and oxyntomodulin (OXM), are anorexigenic peptides released by the gut following food intake. GLP-1 and OXM, but not GLP-2 can affect food intake when administered peripherally. However, all three GLPs inhibit food intake when administered centrally; this is mediated by the GLP-1 and GLP-2 receptors. In addition, central or peripheral administration of GLP-1 potently stimulates insulin release. The anorectic effects of these peptides are mediated by the brainstem, which is reciprocally connected with the hypothalamus.

### Cholecystokinin (CCK)

CCK is secreted by the small intestine following food intake and is the first gut peptide to have been shown to affect food intake. The CCK1 and CCK2 receptors mediating its actions have been cloned and characterized. Its role appears to be restricted to that of a short-term satiety signal contributing to meal termination.

### Pancreatic Polypeptide (PP)

PP, a member of the PP fold peptide family, is released from the pancreas following the ingestion of food and reduces appetite and food intake via the Y4 receptor. However, counter-intuitively, the global deletion of the Y4 receptor produces hypophagic mice with reduced body weight gain. PP can enter the CNS via the area postrema, a CVO rich in the expression of Y4 receptors. However, the central effects of PP are orexigenic, possibly as a result of pharmacological activation of Y5 receptors.

### Peptide YY (PYY)

PYY is released into the circulation from enteroendocrine cells of the gut after a meal. In the circulation, PYY is rapidly converted to the C-terminal $PYY_{3-36}$ fragment, the major circulating form. Peripheral administration of $PYY_{3-36}$ reduces food intake in rodents and humans by activation of ARC neurons. Direct administration of $PYY_{3-36}$ to the ARC also suppresses food intake. This is mediated by the activation of postsynaptic Y2 receptors that directly inhibits anorexigenic POMC ARC neurons and activation of Y2 autoreceptors on NPY/AgRP ARC neurons that suppresses orexigenic tone. However, ICV injection of $PYY_{3-36}$ increases food intake in rodents, presumably due to the pharmacological activation of Y1 and/or Y5 receptors.

## Experimental Methods Employed

Several experimental approaches have been used to demonstrate orexigenic or anorexigenic effects of a peptide:

1. Acute administration of orexigens such as by intracerebroventricular injection or direct microinjection into the specific hypothalamic nuclei stimulates feeding behavior in satiated animals, while anorexigens can prevent feeding following periods of food-deprivation.
2. Chronic administration of orexigens induce hyperphagia and increase body weight gain while chronic administration of anorexigens results in hypophagia and reduced body weight gain.
3. Under conditions of food-deprivation, orexigenic and anorexigenic peptide gene expression is increased and decreased, respectively; while opposite patterns emerge in animals on a high-fat diet.
4. Genetic manipulation at embryogenesis, such as by transgenic peptide overexpression, or a generation of a peptide- or receptor-knockout mouse, rarely results in animals with profound changes in feeding behavior. This implies that the regulation of energy balance is protected by a redundant system that can compensate for compromised orexigenic or anorexigenic signaling systems, during development. However, current evidence suggests that such redundancies are not effective in adult animals.

Thus the homeostatic regulation of energy intake and expenditure is remarkably complex. This is unsurprising given the importance of energy balance to the

survival of the organism. The inbuilt redundancies in the hypothalamic networks that play a key role in this regulation may explain the resistance of obesity to pharmacological interventions based on targeting single chemical signals.

# Neuropharmacology

Paul F. Smith
Department of Pharmacology and Toxicology, School of Medical Sciences, University of Otago Medical School, Dunedin, New Zealand

## Definition

"Neuropharmacology" is the subdiscipline of pharmacology devoted to the study of the action of drugs on the nervous system. This includes the effects of therapeutic drugs as well as recreational drugs and toxins. Neuropharmacology is distinct from related subjects, such as neurochemistry, neurophysiology and neuroanatomy, in that the emphasis is on *drug action*. Whereas the neurochemist and the neurophysiologist study the same cellular machinery of the nervous system as the neuropharmacologist, the latter does so with the chemical structure of drugs and how it affects that machinery, in mind. In this regard, neuropharmacology interacts with medicinal chemistry in order to understand how various molecular structures affect receptors and other drug targets within the cells of the nervous system. No matter how diverse different branches of pharmacology may be, what pharmacologists, including neuropharmacologists, have in common is the desire to understand how exogenous chemical structures manipulate living cells, and the discovery of drugs is of course one of the major routes for the clinical application of neuroscientific knowledge to the management of clinical neurological disorders (see chapters on ►Analgesics, ►Anticonvulsants, ►Antipsychotics for examples).

## A Changing Field…

Despite the neuropharmacologist's emphasis on drug action, more than ever before, neuropharmacology interacts with neurochemistry, neurophysiology and neuroanatomy, as the level of detail available on neural functions becomes ever greater. One obvious example of this is the striking increase in the understanding of the complexity of the biochemical pathways that are affected by drugs. For example, the interactions of ►G protein-coupled receptors (GPCRs) with other proteins and the subunit-specific actions of ►$GABA_A$ receptor agonists, are understood to a degree not possible previously (see chapters on ►Pharmacodynamics and ►Anxiolytics and hypnotics). Hence, for the last decade and a half, there has been a strong molecular influence in neuropharmacology.

## New Waves of Influence…

Neuropharmacology is influenced by progress in every area of biology and medicine. The increasing interest in the effects of growth factors and ►cytokines in the nervous system has led to the investigation of whether some of these endogenous molecules, or their synthetic derivatives, might be of use in the treatment of neurological disease (see chapter on ►Growth factors). At the same time, gene therapy, which traditionally has not been considered to be a form of drug treatment (but which must be according to Goodman and Gillman's definition of a drug as any chemical that affects living processes…) is now being investigated, in some cases instead of, and in other cases, in addition to, conventional drug therapy (see chapter on ►Gene therapy).

Another important theme in recent neuropharmacology has been the recognition of the differences in drug action in the male and female nervous system. While historically, most drugs have been tested mainly in males, even including those such as ►benzodiazepines

that were preferentially prescribed to females, it is now recognized that there is an urgent need to understand the differences between males and females in the action of neurological drugs, and also how drugs affect females differently through the menstrual cycle (see chapter on ►Neuroendocrinological drugs).

Since 1988 when the first cannabinoid receptor was reported, cannabinoid pharmacology has undergone a revolution. The endocannabinoid system has emerged as one of major importance in human biology and in the brain it has been shown to interact with almost every neurotransmitter system. The chapter on ►Cannabinoids reviews the latest developments in this fast moving area of neuropharmacology, including the new therapeutic drugs that are developing from it.

Neuropharmacology includes not only therapeutic drugs, but also recreational and lifestyle-enhancing drugs, and an important topic in this respect is the recreational use of stimulants, such as ►methamphetamine and ►methylenedioxymethamphetamine (MDMA). These drugs are used and abused around the world, and the investigation of how they affect the nervous system is an active area of research in neuropharmacology (see chapter on ►Stimulants).

Finally, some topics are common to all or at least most drugs affecting the nervous system, and the analysis of drug tolerance and dependence is one such topic. Because of the fact that the nervous system adapts to any repeated stimulus, its response to a drug is rarely the same twice, and therefore understanding how its reaction changes over time and how this may be related in some cases, to dependence or addiction, is a critical issue for both therapeutic and non-therapeutic drugs (see chapter on ►Tolerance and dependence).

Neuropharmacology in the twenty-first century is an exciting, compelling discipline that has all of the attractions of other areas of neurobiology, but with a strong focus on clinical applications and drug development for the treatment of the many neurological disorders that continue to afflict society.

# Neurophilosophy

Michael Pauen
Institut für Philosophie, Humboldt-Universität Zu Berlin, Unter den Linden 6, Berlin

Neurophilosophy is an emerging field at the interface between neuroscience and philosophy. It encompasses, first, methodological, conceptual, anthropological, and ethical questions that are of relevance to neuro- and cognitive science. Second, neurophilosophy uses results from these sciences in order to shed light on related philosophical problems.

## The Term "Neurophilosophy"

The term became popular after Patricia Churchland [1] used it as a title for a book and has since then received increasing attention, both in scientific literature and in academic teaching [2]. Still, "neurophilosophy" is not yet a received term for an established branch in academic philosophy like "philosophy of science" or "philosophy of history" with their own journals, academic programs, scientific societies, etc.

Nevertheless, the close connection to empirical science sets neurophilosophy apart from its predecessors, particularly from traditional philosophy of mind, although there is a significant overlap between both fields. Even proponents of ►materialism in the second half of the twentieth century used only placeholders for neural states like the legendary "C-fiber firings" rather than real neurobiological data. Functionalism, a widely accepted view in the 1970's and 1980's, held that a detailed understanding of the brain could not help us to get a significantly better understanding of conscious states. However, with the success of neuroscience, it became increasingly evident that neuroscientific findings *are* relevant for philosophical theories. Likewise, it turned out that neuroscience raises conceptual, methodological, and ethical problems that are of philosophical relevance. Neurophilosophy tries to account for these problems and it makes use of neuroscientific insights in order to solve them.

## What is the Rationale of Neuro-Philosophical Cooperation?

From the philosophical perspective, brain research is of special interest because the brain is the material substrate of those distinctive human abilities and ►properties like consciousness, ►free will, the ►self, cognition, memory, and emotion that have always taken center stage in philosophical thinking. Although even most ►materialist philosophers would insist that there is an important difference between ►*knowledge about* the brain and *knowledge about* certain cognitive abilities, the former knowledge can be of central importance if we want to know more about the details of our cognitive abilities. Given that our current views of these abilities are based on pre-scientific assumptions, it would follow that new empirical findings might lead to a profound revision of these views. Since these abilities, in turn, are substantial for human self-understanding, it is not difficult to see why neuroscience is of particular relevance from a philosophical point of view.

Conversely, there are at least two reasons why neuroscience can take advantage of philosophical work.

First, with the advent of new experimental techniques, particularly with the availability of non-invasive imaging, questions of fundamental relevance for human self-understanding like consciousness, the self, or the free will problem, became subject to neuroscientific research. One might feel tempted to conclude that this enables neuroscience to solve old philosophical problems. On reflection, however, it turns out that, in order to come up with experimental designs or to derive conclusions that are relevant for our self-understanding, we first need clear cut concepts of what it takes to be conscious, self-conscious, or to act freely. This is true, in particular, because we have strong but usually fuzzy and incoherent pre-scientific intuitions concerning these ideas, and philosophers have considerable expertise in transforming such intuitions into coherent concepts. Of course, there may be irresolvable conflicts between competing intuitions; but even then, the ensuing debates about the correct understanding are useful because they clarify the available conceptual and theoretical choices. The second reason why neuroscience can take advantage of philosophical considerations results from the complexity of the brain itself and of the related research programs. As a consequence, any theory that tries to come close to a comprehensive picture of the mind/brain raises fundamental methodological and ►epistemological questions, partly because it has to account for findings from a vast number of disciplines, ranging from molecular biology up to cognitive psychology. Philosophers have discussed these questions for quite some time, thus exposing the advantages and disadvantages of the options at hand in order to make a reasonable choice possible.

## Neurophilosophical Tools

Given that philosophy tries to explore the premises and foundations of empirical knowledge rather than providing such knowledge itself, it should not be surprising that there are neither uncontroversial philosophical results nor established methodologies. If a question becomes tractable by such a methodology or if we can come up with uncontroversial answers, then the question looses its philosophical interest. This is true for neurophilosophy, too. Still, there are certain universally accepted "tools" that are useful in this endeavor. ►*Logic* is, of course, one of them, especially if we try to expose the consequences and implications of a particular view. *Conceptual analysis* is another important tool. In this case, philosophers try to characterize or even define a pre-theoretic concept. In an ideal case, such a definition provides necessary and sufficient conditions for the application of a concept. Since definitions in a strict sense are often hard to come by, we must be content with *characterizations* of the typical way of using a concept. In many cases, intuitions play an important role in our pre-scientific understanding. In order to explore these intuitions, philosophers use thought experiments as "intuition-pumps" [3]. Many of these thought experiments are based on extreme scenarios in order to enable clear distinctions in difficult cases. So if philosophers come up with their notorious Zombies, Zimbos and the like, they do not maintain the empirical possibility of suchlike beings in some distant future; rather, they try to find out how we would classify these strange beings, and knowing that can be quite useful if we want to make conceptual distinctions in less extreme cases.

## The Mind-Body Problem

In what follows, some of the most important neurophilosophical issues will be discussed. The most basic problem, of course, is the notorious mind-body problem which can also serve as an example for the "division of labor" between philosophers and scientists: While scientists try to find out facts about the relation between mind and brain, philosophers have to clarify the conceptual distinctions between the different available options, to expose the theoretical advantages and disadvantages of each of them, and to outline possible empirical evidence that would support or disprove each of these options. In doing so, neurophilosophy clarifies the criteria for the assessment of empirical evidence and limits the number of possible options for the interpretation of this evidence, thus enabling us to make a reasonable choice between these options in light of the available evidence.

Trivially, there are two fundamental alternatives: Either the mental is some kind of physical process or it is not. Monists hold that it is, Dualists hold that it is not. Due to its initial plausibility, psychophysical dualism can be found in many mythological and religious writings including the Bible, but it is also part and parcel of our commonsense beliefs about the mind-body relation. Depending on the ►causal relation between the mental and the physical, philosophers have distinguished different varieties of dualism. Psychophysical parallelism in its original form, as it was defended by Leibniz, holds that there is no psychophysical interaction at all. Mind and body run in parallel like two clocks that remain synchronized without any causal interaction between them, once they have been started together. ►Epiphenomenalism, a theory that was brought forward by T. H. Huxley [34], Jackson [4], Robinson [5], and, in principle, also by Chalmers , states that there is only a one-way causation: Neural events cause mental events, but mental events, in turn, do not cause anything; they are causally inefficacious by-products. Certainly the most widely held dualist view is psychophysical interactionism as it was defended by Descartes. More recently, interactionist views were held by philosophers like Popper but also by neuroscientists like Eccles [32] or [35]. Interactionism holds that mental events like volitional

acts cause physical events like brain processes, and physical events, in turn, cause mental events, like ►perceptions. Philosophers have exposed at some length the implications and problems of each of the available alternatives [7]. In the case of interactionist dualism, psychophysical causation is one of the notorious difficulties because, on this view, mental processes like acts of will would have to interrupt the physical causal chain. This would violate almost uncontroversial doctrines like the principle of the causal closure of the physical realm or the law of the conservation of energy. Dualists have made various suggestions how to solve these problems, but none of them has been universally accepted. Other varieties of dualism face severe problems, too: Parallelism has difficulties to explain the synchronicity between the mental and the physical realm, given that the existence of God is not an acceptable scientific hypothesis. Epiphenomenalism is counterintuitive because mental states, due to their causal inefficacy, cannot be among the causes, why we talk about these very states, react upon them, or even design epiphenomenalist theories about them [8].

However, seen from a neurophilosophical perspective, there is still another objection against dualism as a scientific hypothesis. Presumed that natural science tries to explain empirical facts with reference to natural laws and physical entities, the postulate of a non-physical mind doesn't appear as a sensible scientific hypothesis because it implies that mental facts are not amenable to a naturalistic ►explanation. While this does not rule out that dualism is in fact true, it seems unreasonable for natural science, including neuroscience, to start with such an assumption that would seriously limit its own explanatory scope. Natural science should extend the realm of naturalistic explanations as far as possible rather than beginning with the premise that there are facts beyond explanation in principle.

It would follow that monism is a much more plausible position to take from the viewpoint of natural science. Monists assume that there is only one type of entities. According to current versions of monism there are only physical entities; thus monism is in fact a sort of ►physicalism. In the last five or so decades, philosophers have explored a vast number of varieties of monism that differ with respect to the status of mental states in such a physical world. While identity-theorists think that we can keep our pre-scientific beliefs about causally efficacious mental states as long as we accept that these states are physical states, more radical materialists like eliminativists and ►logical behaviorists think that mental states and the related mentalistic idiom have no place in a scientific picture of the world.

According to eliminative materialism, the existence of mental states like beliefs and desires is more than questionable [1,9,10]. Rather than being subject to immediate access from the first person perspective, these states are postulates of a vernacular theory, usually called "►folk psychology". Folk psychology has originally been introduced by our remote ancestors in order to explain and predict human behavior. In the meantime, we became so much used to this postulate that it now appears to us as if we had immediate access to the postulated mental states.

However, neuroscience will eventually provide a better theory of human behavior that gets along without any reference to beliefs and desires. This theory will replace its primitive precursor, thus eliminating not only folk psychology itself but also mental states as its theoretical postulates. Our successors will substitute the precise terminology of neuroscience for the unclear mentalistic idiom, and in the long run even the alleged "direct access" to mental states from the first person perspective will disappear. Mental states will be "eliminated" because the underlying theory has to be given up, just like phlogiston or caloric were eliminated when their theoretical basis vanished. Eliminative materialism is a substantial part of Patricia Churchland's original version of neurophilosophy [1]. If eliminativism is true, then natural science should be able to solve or better: *dissolve* the mind-body problem. All there is that needs to be explained is the brain, and it would seem that neuroscience is able, in principle, to explain neural processes.

Many philosophers think however that this solution is all too simple. Apart from the fact that it is counterintuitive to think that mental states are only postulates of a theory, eliminativism seems to undermine its own theoretical basis: Eliminativists, after all, have to believe in their own theory, but if their theory is true, then there are no beliefs.

This is one of the reasons why eliminative materialism has lost some support in the recent past. Its strongest monistic competitor is the identity theory which was proposed by Feigl [11], and Place [12] in the 1950s. Identity theorists have no doubt that mental states exist; according to their theory, one could dispense with mental states only at the cost of giving up the corresponding physical states, too. Identity theorists can even insist that mental states are perfectly adequate subjects of scientific inquiry, say in cognitive or volitional psychology. Another advantage of this theory is that it provides a simple solution to the problem of mental causation: If mental states are identical with certain physical states, then they *are* physical states and should have causal powers just like other physical states.

According to the original version of the identity theory, there is a one-to-one relation between types of mental states (say pain) and types of physical states (say some neural type *N*). Thus, each particular token of a

certain mental type (pain) will also be a token of the corresponding physical type (*N*), and vice versa. Talking about a pain state and talking about a neural state of type *N* is talking about one and the same type of states. This is the reason why this variety of the identity theory has been called "type identity."

The most severe objection that appeared almost detrimental to the identity theory in its original form refers to the so called "multiple realizability" of mental states. Organisms and even artificial systems whose physical makeup differs considerably from the human neuroanatomy, so the objection goes, might be able to feel pain. It would follow that, contrary to what type identity theorists would have us to believe, not all pain states are neural states of type *N*, or in general: Mental states of a certain type can exist in the absence of the related physical type.

Solutions to this problem have been proposed in the meantime [13], but it was originally thought that this objection forces us to reject the type identity theory. As a consequence, another variety of the identity theory emerged, namely the so-called "token identity" theory [14]. According to token identity theorists, every token of a certain mental state is identical with a token of *some* physical state. Thus, token-identity theorists postulate a one-to-*many* relation between mental and physical types: Tokens of *one* mental type (pain) can be realized by the tokens of *many* different physical types (neural states *N, O, P,* state *Q* in a silicon chip, etc.). Typically, token identity-theorists subscribe to functionalism [15]. According to functionalism, mental states have a distinctive functional role that can be captured in an extended ►behavioral terminology. Accordingly, being in a pain state is to have certain functional or behavioral properties, e.g. the tendency to say "ouch" under certain conditions, to take painkillers, to think about other ways to get rid of pain, etc. A complete list of these features should be able to capture what we mean if we talk about pain. Consequently, every physical state that performs this functional role would count as a "realizer" of pain because it meets the relevant conceptual criteria.

While it seems that functionalism was successful in providing a solution to the problem of multiple realization, its fundamental premise, namely that mental states can be captured by a distinctive functional role, has been challenged. It seems that, say, our concept of color-experiences cannot be captured by any distinctive functional role, given that it seems perfectly possible to imagine cognitive systems with identical functional roles that have different color-experiences or no color-experiences at all [16]. This assumption has played a major role in the discussion of the so called explanatory gap problem (see below).

One might conclude that all these ►arguments, objections, and counterarguments show that neurophilosophy has failed to provide a solution to its most basic problem. But this would be a misunderstanding of the objectives of philosophy. Of course: Philosophers have to clarify the conceptual criteria for each of the available options, they can even rule out options with severe theoretical disadvantages, but they cannot provide the empirical data themselves. More conceptual clarity and a better understanding of the implications of each of the available options can help us to make a reasonable choice between these options, once the relevant data are available. But since it is one of the distinctive characteristics of neurophilosophy that it relies on empirical data in order to make progress on philosophical problems, it cannot provide a solution before the relevant data are in.

## Particular Questions

### The "Explanatory Gap Problem"

But how could we make progress towards a solution? One obvious strategy is to look for the "neural correlates of consciousness," or better, for strict and specific correlations between distinctive and well-defined mental states on the one hand and distinctive and well-defined neural activities on the other. If there is no evidence for psychophysical interaction and if it is true that eliminative materialism, psychophysical parallelism, and epiphenomenalism are subject to severe theoretical objections, we might be justified to believe that mental states *are* physical states and some version of the psychophysical identity claim is true.

But even then, one might feel somewhat worried. It seems difficult to understand that the different qualia or qualitative properties of mental states, the "way it feels" to be in a pain state or to have a red-experience should be identical with the uniform activity of simple neurons. The worry has already been felt by Locke and Leibniz and it has received increased attention in the recent past. Many philosophers have argued that this worry results from an "explanatory gap" that cannot be closed in principle [4,17,18].

In trying to come to terms with this worry, one should note, first, that the problem does not concern the factual relation between neural activities and mental processes. Asking why neurons bring about consciousness would obviously imply a distinction between the mental and the physical that is incompatible with the claim that mental processes *just are* neural activities. Rather, the question concerns the relation between our *knowledge about* neural activities and our *knowledge about* mental processes, that would allow us to account for problems on the mental level in neurobiological terms.

Normally, we use ►reductive explanations in order to understand problems concerning higher level properties of a complex entity (e.g. heat) in terms of knowledge about the lower level constituents of this entity (e.g. mean kinetic energy of molecules), say the laws that apply to these lower level constituents. Reductive explanations

make it intelligible why an entity with certain lower level constituents has specific higher level features. A higher level property that cannot be reductively explained, in principle, is an ►emergent property.

Reductive explanations have two basic requirements: First an explanation why the constituents have a certain lower level feature (a specific kinetic energy), second a bridge between the higher and the lower level that makes it intelligible why having the lower level feature *really is* having the higher level feature in question (i.e. a certain temperature). Given these requirements, our lower level explanation should help us to understand the presence of the higher level property in question.

Provided that scientific explanations pertain to observable properties rather than to subjective features, any bridge between mental and physical properties would require a determination of subjective mental features in terms of objective observable properties which guarantees that the organism in question really has the mental features that should be explained. Many philosophers think that this is impossible, in principle. In their view, subjective, qualitative properties of mental states cannot be captured by objective properties that are observable from the third person perspective. Two organisms that are identical on the molecular level may have completely different qualitative mental properties. Consequently, a reductive explanation would be impossible, in principle. While some philosophers conclude that some sort of dualism must be true, others hold that the whole question is misguided [19] or that additional knowledge concerning mental states might eventually improve our abilities to operationalize even qualitative mental properties [20] (PS Churchland 1996). If these latter authors are right, scientific progress might eventually lead to a solution of the explanatory gap problem.

## Mental Representation

A quite similar puzzle pertains to the problem of mental representation. Basically, a theory of mental representation has to explain how individual states of a cognitive system can refer to external entities, how they can be "about" something. For a physicalist approach, the theory as to make it intelligible how this is possible in a physical system. According to the "computational theory of mind" which was popular in the 1970's and 1980's, the problem can be solved on the basis of an analogy between the brain and a traditional Von Neumann Computer. Following Fodor [21], mental representations are discrete symbols of an innate "►language of thought." Cognitive operations are formal manipulation-processes of these symbols according to certain syntactic rules (the "program"), and because the semantic content of mental representation is mirrored by their syntactic properties of the symbols, the manipulation processes are sensitive to semantic content.

Many philosophers have criticized that it is implausible to assume the existence of an innate and therefore unchanging language of thought; in addition, it has been doubted whether Fodor can explain in a naturalistically acceptable way how the states of a physical system get their meaning (►naturalization of intentionality). Moreover, it seems that there are ►mental images or "iconic" representations [22] that cannot be accounted for in this theory, in principle, and scientists have pointed out that the architecture of the brain differs in several crucial respects from formal symbol manipulation devices like traditional computers [23].

Connectionism is an alternative that tries to account for these observations. According to this approach, the brain doesn't work like a traditional computer but, rather, it is a layered neural network, and mental representations are not discrete symbols but rather neural activities that are distributed over different areas of the brain [24]. Although is has been questioned whether this theory can account for higher level cognitive processes like logical reasoning, many philosophers have come to believe that it provides a much better basis for an account of mental representation, given that this theory is not amenable to the objections against the computational theory of mind and it better accounts for the neuroscientific facts.

The ►mental model theory is another alternative [25]. While the symbols of a language of thought are only arbitrarily related to their objects, mental models preserve the relations between the objects they represent: If there is an order between certain parameters of an object in the outside world (e.g. hue, temperature, size), this order should be preserved by the model of the object in question. In addition, representations from different aspects of an object or a scene (e.g. size, weight, sound, smell) can be combined in the respective model.

## Self

Philosophers have also addressed several more detailed questions, among them the problem of the self or the problem of free will. Again, such considerations are not intended to replace empirical research; rather they try to specify the criteria that a person has to meet in order to count as self-conscious or free. While these criteria have to capture our pre-scientific intuitions they should also do justice to new scientific findings that may prompt for a revision of our concepts, just like science has prompted us to revise the concept of an atom.

It may be tempting to conceive of the self as a monolithic entity, a kind of "central-observer" that is realized by a single neural process. Since there are good reasons to believe that no such monolithic entity exists, neither on the neural nor on the psychological level, one might conclude that the self is only a fiction [3].

Many philosophers, however, maintain the self cannot be conceived of as a monolithic entity. As David Hume has noted already in the eighteenth century, we don't experience a "self" when we direct our attention inwards. This need not lead to skepticism concerning the self but it should be considered when the conceptual criteria for the ascription of a self or of self-consciousness are discussed. It seems evident that, in order to count as self-conscious, a person needs access, at least in principle, not only to her *present* feelings, experiences, and beliefs, but also to the related states in the past. The second, almost uncontroversial requirement is that a self-conscious person has to recognize these feelings, experiences, and beliefs *as her own* feelings, experiences, and beliefs. And third, she needs some kind of *self-concept,* that is, a more or less stable and coherent idea of those features and abilities that are characteristic for herself.

In addition, it would seem that being a self requires also being an agent [26]. Other issues are more controversial, e.g. whether it is really possible to understand how self-consciousness emerges, how the term "I" refers, and whether first-person access to our own mental states is privileged or even immune to error. Again, empirical findings may call for a more or less fundamental revision of our pre-scientific concepts.

In any case, even if we could determine the criteria for self-consciousness, it would be still another, empirical question, whether or not an actual person, or maybe human beings in general, meet these criteria. This raises questions concerning our autobiographical knowledge, that is, concerning our ability to remember events and experiences in our own past, and to integrate these memories as well as our present experiences into an adequate and coherent picture of our self or into a "self-model" [25,27]. Another empirical issue concerns the cognitive mechanism that is required for recognizing one's own experiences *as* one's own experiences. One promising candidate is the ability for perspective-taking as it has been identified in theory-of-mind research (►theory-theory). It seems obvious that a confirmation of this hypothesis would alter our concept of self-consciousness, demonstrating how empirical findings might lead to conceptual revisions.

## Free Will

One of the most substantial implications of our pre-scientific self-understanding is that we can be held responsible for what we do, at least in principle. Provided that responsibility requires freedom and freedom, in turn, requires the ability to do otherwise, it would seem obvious that there is no free will and thus no responsibility in a determined world. In such a world, everything including our ►actions is determined by natural laws, so only those events *could* have happened that actually *did* happen, and only those actions *could* be performed that actually *were* performed. Conversely, freedom and responsibility would require the absence of determination.

Again, all these statements are based on certain standards for free action, and these standards need justification. Probably the most important question is whether or not freedom and determination are *compatible*. ►Compatibilists think they are, incompatibilists think they are not. Incompatibilists typically argue that freedom requires the ability to do otherwise under identical conditions which is obviously impossible in a determined world. Compatibilists, by contrast, may argue that freedom requires the ability to act according to one's will, and this seems possible even in a determined world. Unfortunately, there are many cases in which we would not say that a person who acts according to her will is free because the person's will lacks freedom. An addict may have the wish to take his drug and act accordingly, but we wouldn't say that he is free because his will is determined by his addiction.

Compatibilists have tried to respond to such objections. According to Harry Frankfurt [28], freedom requires not only that one performs the action that one wishes to perform, but also that one has the wish one really wants to have. Thus, an addict who has the desire to take his drug but despises this desire because he wants to get rid of this addiction, would *not* count as free; conversely, a person who does what she wants and approves her own wishes would be free. Compatibilists have also argued that getting rid of determination does not enhance freedom because an action that is not determined, cannot be determined by the agent either, it's just a random event.

Some philosophers even maintain that the criteria for freedom are such that it is impossible in principle that human actions are free. But even if one does not accept this view, skepticism concerning free will seems to be supported by empirical results from e.g. [29]. According to these experiments, conscious will is controlled by subconscious brain processes that are beyond a person's control. However, these experiments are still subject to a fierce debate. Apart from problems concerning the timing of the relevant mental and neural processes one might doubt that Libet has really investigated genuine decisions given that his subjects had no choice between different alternatives.

In any case, it is possible that future empirical results will show that human agents lack the abilities that are required for free actions. Philosophers have already discussed possible consequences, e.g. for our commonsense understanding of responsibility and for the justification of our legal system. Apart from that, one might suspect that neuroscientific findings may have an impact on the related concepts: If there is evidence that human actions in general fail to meet the traditional

criteria for freedom, there may still be other interesting differences that call for a revision of our current concept of freedom.

Another important issue concerns the role of emotions in action and decision. Experiments and case studies by Antonio Damasio [30] and his group show that emotions play an important role even in what seem to be purely rational decisions. This raises the question whether the traditional distinction between rational and irrational decisions has to be revised.

## Neuroethics

It seems obvious that neuroscience may have severe ethical implications. As a consequence, neuroethics as a specialized discipline has emerged in recent years. One of the reasons for this development is that neuroscience raises a number of specific issues that require a distinctive expertise. By and large, these issues fall into two categories. On the one hand, a "neuroscience of ethics" addresses neuroscientific findings that are relevant for ethics. Those findings concern the neural basis of the human ability to act according to moral standards, but also pathological alterations of the relevant structures that might affect and even destroy these abilities. On the other hand, an "ethics of neuroscience" addresses ethical standards for neuroscientific research and its applications like neuroprosthetics or psychotropic drugs. One example for these drugs is Ritalin which has well established short-term benefits in the case of ADHD (attention deficit/hyperactivity disorder). On the other hand, Ritalin seems to have long-term effects on the brain-structure, and is subject to abuse by healthy persons who seek to enhance their cognitive performance [31]. A clear distinction between treatment and enhancement might be helpful but has yet to be established; in addition, one might ask whether improving cognitive performance by a drug rather than by education or psychotherapy does not alter the way we look at humans in a fundamental way.

Neuroprosthetics, i.e. electronic devices like cochlea implants or electrodes for deep brain stimulation in the case of Parkinson's disease, raise ethical questions because they may have psychological side effects that involve the patient's personality. Unlike conventional prosthetics, neuroprosthetics may be regarded as a part of the person's self, thus changing the very person whose prosthetics they are.

It would seem, then, that there are quite some fields in which neurophilosophy can help to promote scientific progress and to assess the consequences of this development. This requires close cooperation between neuroscience and philosophy but it requires also a clear distinction between those issues that can be treated empirically and those that require genuine philosophical research. Traditional armchair reasoning, by contrast, doesn't appear as a very promising strategy if philosophy wants to play its role in the development of the neuro- and cognitive sciences.

## Synonyms

Sexual neurophysiology

## Definition

The ►sexual spinal reflexes are spinal cord reflexes (consisting of afferent and efferent components) which instigate the genital vasocongestion and neuromuscular tension responsible for sexual arousal (erection in men and vaginal lubrication and elongation in women), the triggering of ejaculation in men, and possibly orgasm in both sexes.

## Characteristics

### Sexual Arousal in Men and Women

Both men and women have erectile tissue in their genitalia. Nerve mediated vasocongestion to the pelvis allows for genital tissue engorgement. In men, penile erection occurs when the sinusoidal spaces (the trabeculae) of the corpora cavernosal bodies fill with blood, expanding them to their anatomical limit set by a surrounding, stocking-like, elastic tunica albuginea. Arterial penile filling, or "tumescence," is further assisted by the cessation of venous outflow from compression of the emissary veins which pierce the tunica. This veno-occlusive mechanism, in conjunction with pelvic floor musculature contraction, increases the intracavernosal pressure making the penis rigid. In women, a similar tumescence of the cavernosal bodies of the clitoris occurs with sexual stimulation along with extensive pelvic vasocongestion (uterine, vaginal, urethral, labial and pelvic ligaments), resulting in swelling of the external genitalia, lengthening of the vagina and the production of vaginal lubrication (a transudate extruded through the vaginal epithelial cells). Physiologically, arousal is primarily a parasympathetic event. The sympathetic nervous system dominates during male ejaculation and probably also at orgasm.

### Ejaculation in Men

Ejaculation is the process of delivery of semen through the penis to the distal urethral opening. ►Seminal emission, the first phase of ejaculation, involves transport of spermatozoa into the prostatic urethra via the ejaculatory ducts in the prostate. The accumulation of fluid immediately proceeds propulsatile ejaculation and contributes to the sensation of *ejaculatory inevitability*. Expulsion, or propulsatile ejaculation, the second phase of ejaculation, propels the seminal bolus distally out the urethral meatus by rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles. Emission is under voluntary control, whereas expulsion is not [1].

### Orgasm in Men and Women

Orgasm is the pleasant physical and mental sensation of sexual climax. While it most often occurs in men with ejaculation, it is not synonymous with it. Orgasm can occur in men and women during sleep, during hypnotic suggestion or even after loss of external genitalia or CNS injury. However, it can still be elusive to some persons with normal physiology despite their best efforts (orgasmic dysfunction). In men, orgasm has been variously described as the result of cerebral processing of ►pudendal nerve sensory stimuli from increased pressure in the posterior urethra and prostate, and from sensory stimuli arising from the veramontanum and contraction of the urethral bulb and accessory sexual organs [1]. Women's orgasm can be described as

a pleasurable peak sensation accompanied by involuntary rhythmic contraction of the pelvic floor, often with concomitant uterine and anal contractions. Most men have post-ejaculatory refractory periods, but women do not [2], allowing for the potential of serial orgasms.

## Characteristics

Experimental evidence demonstrates that the spinal cord contains all the neural circuitry involved in the generation of genital arousal [3]. However, sexual functioning is extremely complicated beyond the spinal cord: all body senses, emotions and social awareness will determine whether an individual person will orient towards sexual activity (the situation is safe, erotic and likely to be sexually rewarding) or lose interest (the situation is unrewarding, unsafe or nonsexual). The brain is the ultimate controller. For example, in healthy men, heightened sexual arousal sends descending signals to the spinal cord allowing for the natural unfolding of the sexual spinal reflexes, with the resultant erection acting as a positive reinforcement. This "supraspinal control" is primarily inhibitory in nature, and needs to be "removed" so excitatory signals can pass through to the spinal cord. In male rats, the anatomical site for the descending inhibitory action has been identified in the rostral pole of the paragigantocellular nucleus bilaterally located in the oblongata [4]. A human infant will have rapid reflex erection or lubrication to touch of the genitalia: when myelination of the spinal nerve tracts is complete the brain can then impose inhibition or facilitation of this reflex at a cortical level. Only men and women with complete spinal cord injury (SCI), i.e. whose cortical control is interrupted by the spinal cord injury itself, can provide data for the practical understanding of the neurology of the spinal reflexes. However, their reaction to their sexual experience will ultimately affect their sexual neurophysiology and function. In humans, recognizing this complex, moment-to-moment mind-body interaction linked to reward and expectation is what distinguishes the sexual reflexes from other more automatic physiological reflexes that are also under excitatory and inhibitory control from the brain.

Autonomic spinal nuclei are activated by excitatory descending projections from the brain. While the traditional concept of sexual responses follows a "hard wired" model with neural connections extending from the brain to the peripheral nerve receptors at the sexual end organs, there are neuroendocrine and other biological factors, as well as other non-CNS pathways that are possibly significant. For example, there is growing evidence of a nociceptive vagal-solitary tract pathway from the vaginocervix region in women with complete spinal cord injuries (so far not identified in men with SCI), consistent with pathways already described in basic rat studies and confirmed by fMRI in the human female [5].

## Organization of the Sexual Reflexes

### Central Control

Brain initiated excitatory descending signals are the result of positive "interpretation" of sexual imagery and fantasy, of visual, auditory and olfactory inputs (including the little known role of pheromones in humans), and of cerebral evaluation of ascending signals from somatic (usually tactile) stimulation from the body (particularly the genitalia, nipples, etc). The control of genital arousal is located in the limbic system (linked to processes of motivation and reward), and the hypothalamus (the coordinating center for complex autonomic responses), and other midbrain structures [3]. This has been supported by various functional imaging modalities done in humans undergoing sexual arousal including positron-emission tomography (PET) and functional magnetic resonance (fMRI) showing activation of the higher cortex, the limbic and paralimbic cortex and other subcortical regions: these studies show that sexual responses require brain areas that integrate cognitive, motivational and autonomic components [6]. Seminal emission and ejaculation are controlled by the paraventricular nucleus (PVN) of the anterior hypothalamus and the medical preoptic area (MPOA).

### Ascending and Descending Pathways

Both the lateral spinothalamic pathway (which terminates in the thalamus) and spinoreticular pathway (which crosses the cord to the opposite side and travels in the lateral spinal columns, terminating in the reticular formation) relay sexual sensory information to the brain. Descending signals from the brain travel in the dorsal and dorsolateral white matter and enter into the spinal gray matter. The spinal interneurons connect the afferent and efferent pathways and coordinate various components of the sexual response [2].

### Spinal Cord and Peripheral Innervation

*The spinal cord* is the integration site for afferent signals from the periphery and descending modulation (excitatory and inhibitory) of interneurons from supraspinal areas. The spinal cord contains neurons projecting to every anatomic genital element participating in the sexual response [2]. S*pinal interneurons* located in and around the intermediolateral cell column and in the medial gray form a column of neurons through segments T12–S1 [2]: these interneurons relay afferent input from the genitalia to efferent somatic and autonomic spinal neurons en route to structures involved in the sexual response. They receive projections from the supraspinal structures and are involved in modulation/coordination of the sexual response.

At the effector organ, locally released nitric oxide (NO) is the primary molecule responsible for genital arousal. Other facilitory neurotransmitters such as vasoactive intestinal polypeptide (VIP) supplying the

arterioles of the corpora results in smooth muscle relaxation and erection in males and tumescence of clitoral tissue in women, whereas noradrenaline and neuropeptide Y (NPY) are the primary inhibitors of genital arousal response. Acetylcholine (Ach) likely acts synergistically with other vasodilators released by nerves or contained within vascular structures in both men and women: sympathetic pathways may produce erection via a cholinergic mechanism [2].

## Spinal Cord Reflex Pathways

### Genital Arousal

Recognition of genital arousal either externally or internally is a combination of both somatic cutaneous sensitivity (pressure, touch, temperature, vibration and pain) and visceral sensitivity of the internal organs (movement of the uterus and ligaments during intercourse, bladder pressure, etc) [2]. Afferent messages travel to the sacral 2, 3, 4 segments along various pathways, depending on the anatomical structure, but in general, touch and temperature signals from the clitoris and glans penis travel along the dorsal nerve which merges into the *pudendal* nerve (S1–S3), touch and vibration (especially from the vagina and cervix) travel via the ►*pelvic nerve* (S1–S3) and potentially via the ►vagus nerve in women (which may be related to vaginocervical stimulation only), whereas deep pressure and viscero receptive stimuli likely travel along the *pelvic* (S1–S3) and ►*hypogastric* (►T12–L1) *nerves* [2]. These afferent signals reach the brain through the ascending pathways.

Descending from the brain, two areas in the spinal cord provide the main transmission of efferent signals, (i) T10–12 and L1–3 segments (sympathetic and other fibers) known to be responsible for relaying the messages responsible for psychogenic or mental arousal respectively, and (ii) sacral 2, 3, 4 (parasympathetic and motor fibers) responsible for reflexogenic arousal (genital vasocongestion and muscular pelvic floor activation).

#### Clinical Correlate: Spinal Cord Injury

Depending on the level and completeness of injury, isolated SCI can disrupt either psychogenic or reflex genital arousal. Reflex arousal results from stimulation of the dorsal nerve, which propagates signals to the sacral spinal cord, synapsing with the parasympathetic efferent neurons whose axons travel back to the corpora cavernosa and pelvic viscera. If the SCI is above this sacral level, the reflex erection is rarely disrupted. Due to loss of tonic inhibitory control that reduces the sensory threshold and onset of erectile responses [7], men with SCI at the cervical level will have preserved, if not enhanced, reflex erection, especially if the lesion is complete [8]. The ability to have reflex erections or vaginal lubrication is lost if the sacral spinal cord is injured or if the pudendal nerve or pelvic nerve is destroyed [8]. The pathways of the sympathetic nervous system can compensate for parasympathetic deficits and preserve erectile function. However, the intense mental concentration needed to maintain psychogenic erection via the sympathetic chain can also provoke seminal emission, leading to unwanted detumescence.

### Ejaculatory Reflexes

Afferent sensory information from the genitalia (primarily the glans penis) travels in the pudendal nerve (within the dorsal nerve of the penis) to the S4 level of the spinal cord. Afferent autonomic fibers within the hypogastric plexus transmit information from the sympathetic ganglia located alongside the spinal cord [1]. The efferent component involves sequential contraction of internal accessory sexual organs, which can be associated with pleasurable sensations. Spinal cord segments extending T10–S4 are involved in the ejaculatory process.

Seminal emission, consisting of sperm transport and seminal fluid formation, is under sympathetic control (T10–12), and closure of the bladder neck (internal urinary sphincter) to prevent retrograde ejaculation is controlled via the sympathetic fibers emerging at L1, 2. The actual process of expulsion (propulsatile ejaculation) of seminal fluid occurs through the intermittent relaxation of the external urinary sphincter. Spasmodic contractions of the seminal vesicles, prostate and urethra (parasympathetic fibers of S2, 3, 4) and rhythmic contractions of the bulbocavernosus, ischiocavernosus, levator ani and related muscles (somatic/motor signals of S2, 3, 4 via the pudendal nerve), propel the seminal bolus distally.

Two other local ejaculatory reflexes have been identified: stimulation of the glans penis brings semen to the posterior urethra (glans–vasal reflex) and a urethromuscular reflex is responsible for propulsion of the semen to the exterior (urethral meatus) [9].

#### Clinical Correlate: Spinal Cord Injury

It is possible to trigger the ►ejaculation reflex through intense penile stimulation with high intensity vibrators (*vibrostimulation*) in about 60–90% of men with SCI lesions above T10 neurological level. No longer under cortical control, the T10–L2 levels can be triggered as a coordinated reflex as long as the afferent and/or efferent signals are intact, or vibrostimulation can activate enough remaining afferent fibers to complete the reflex. If the spinal cord lesion is below T10 with resultant interference of the lumbosacral reflex, then *electroejaculation*, which electrically stimulates (via the periprostatic nerves) the efferent pathways of seminal emission, will invariably work.

### Orgasm

The neurology of orgasm is not fully understood, but likely entails somatic and autonomic components [7].

Orgasm, or components of orgasm, while most often generated from external genital stimulation, are not wholly dependant on such. Orgasm triggered by non-genital stimulation (erogenous zones), or from the brain alone (as in fantasy or during sleep) may be a form of autonomic excitation and release. Furthermore, in spinal cord injured women, the vagus nerve has been identified as a non-spinal cord pathway for orgasm [5]. However, orgasm is primarily triggered by stimulation of the clitoris (and/or anterior vaginal wall) or glans penis and appears to have a reflex component that can be reinforced with practice [2,10]. An experimental model, developed in anesthetized spinalized female rats, mimics the human orgasmic response: assuming the removal of descending inhibitory inputs, the *urogenital reflex* consists of stimulation of the urethra resulting in rhythmic contractions of the vagina, uterus and anal sphincter [7].

Regarding the subjective pleasure component of orgasm (especially in women), there are two arguments: one suggests orgasm is a simple reflex stimulus-response reaction, and the other that sensations identified as orgasm are closely attached to contextual meaning at the time [7]. Confusion between orgasmic etiologies makes the reflex component of orgasm difficult to define. The distinction between genital and non-genital orgasm may help resolve these differences. For example, those men and women with SCI who have intact pain and temperature sensations from the genitalia through the lateral spinothalamic tract, and intact descending corticospinal tracts as demonstrated by voluntary anal contraction, are potentially able to experience *genital* orgasm, whereas loss of these specific ascending and descending reflex pathways do not rule out the potential for *non-genitally* induced (i.e. cerebral or other non-genital erotic zone generated) orgasm [10]. After SCI, orgasm is less likely to be experienced if there is complete disruption of the sacral reflex arc (such as occurs with conus medularis injuries), or if T10–L1 sensation is not intact [2]. Likewise, orgasm can occur despite damage to the sympathetic ganglia, but it is rarely possible after injury to the pudendal nerve.

# Neuropile

## Definition

The integration center within the central nervous system (CNS) surrounding the neuronal cell bodies and composed of a network of axonal and dendritic fibers interconnected by synapses.

# Neuroprostheses

►Computer-Neural Hybrids

# Neuroprotection

## Definition

Any therapeutic intervention that prevents or slows down secondary neurodegeneration. After an acute central nervous system (CNS) injury, and in most chronic neurodegenerative conditions, three types of neurons operate: those damaged by the primary insult that will inevitably die, healthy neurons, and marginally damaged neurons. The last two types, unless protected,

are susceptible to secondary degeneration and death. "Neuroprotection" also refers to therapeutic interventions that reduce the rate of secondary degeneration.

## Introduction: The Concept of "Neuropsychiatry"

A clinician taking care of a patient suffering from Parkinson's disease does not have to treat motor symptoms alone (►tremor, ►akinesia, ►rigor), which belong to the field of neurology, but has to diagnose and treat effective (e.g., depressions) or cognitive symptoms (e.g., ►bradyphrenia, retardation of thinking), which belong to the field of psychiatry. However, it is quite unlikely that he will meet all requirements of both fields because he is either a neurologist or a psychiatrist, and he therefore has learned different ways of thinking and different methods. This reflects the paradox situation in contemporary relationship between neurology and psychiatry: On the one hand neurology and psychiatry are regarded as two different disciplines with different content concerning methodology, diseases, diagnostics, and therapy. On the other hand the boundaries of separation between both disciplines melt away by applying neurological methodology and diagnostics in psychiatric diseases (►CT, ►Spect, ►PET) as well as by the interest of neurology in complex mental functions and psychiatric symptoms in neurological diseases. Particularly in the Anglo-American region this resulted in the foundation of the discipline of "neuropsychiatry": "Although half a century ago neurology and psychiatry seemed to be diverging from a common purpose and sanding as two stools apart, these recent advances have not only seen the stools bridged by a plank, but the whole structure has come gradually to resemble a bench, which for some seems quite comfortable. The last decade has seen not only an exponential growth of knowledge in the field of the neurosciences, but also a resolution of some interdisciplinary rivalry, and laid the foundations of neuropsychiatry for at least the rest of this century [1]." Neuropsychiatry in this sense can best be understood by considering its historical development, which is discussed briefly in the following. One crucial feature of Neuropsychiatry in this sense is that it considers subjective experience of mental states in First-Person Perspective, as distinguished from mere scientific observation of neuronal states in Third-Person Perspective, as crucial.

## Neurology, Psychiatry, and Neuropsychiatry

### *Historic Development of the Separation of Neurology and Psychiatry*

Neurology as an independent discipline has developed at the beginning of the nineteenth century when Parkinson's disease and ►Multiple sclerosis were defined as neural diseases [2] (see also [3]). Following advances in anatomy and pathology in the nineteenth century correlations between the clinical appearance and the pathological–anatomical substrate became possible to an increasing degree; this has been successful in numerous neurological diseases and symptoms (e.g. ►aphasia) and consequently established the field of neurology as an independent discipline of medicine. On the contrary clinical–pathological correlations in psychiatry did not show significant success, which strengthened the separation of medicine/neurology on the one hand and psychiatry on the other. The previously apparent connection between psychiatry and philosophy/humanities [2], the letter dealing with mental states as implicated in psychiatric diseases as mental disorders, additionally supported the separation between neurology and psychiatry.

The application of scientific principles in psychiatry has later been established by Griesinger, Kahlbaum, Kraepelin, and Maudsely who created a consistent nosology and regarded psychiatric diseases as diseases of the brain. Nevertheless correlations between the clinical appearance and the pathological–anatomical substrate still remained unsuccessful. Although in the field of neurology such correlations showed rising success since neurological diseases could be localized anatomically and morphologically in the brain implying that they were regarded as "structural" diseases. The failure of structural localization of psychiatric diseases, in contrast, resulted in their acceptance as "functional"

diseases with "functional" meaning "psychological" and thus mental origin as distinguished from "structural" describing the "organic" and thus neuronal origin [2].This opposition of "structure versus function" and "localization versus nonlocalization" accounted for the separation of neurology and psychiatry in a decisive manner; the neurologist dealt with structural diseases of the brain, the psychiatrist focused on functional diseases of the mind. This leads to the development of neurology and psychiatry as independent disciplines in the Anglo-American region whereas in the German-speaking regions both disciplines have been kept together for a long time in the common discipline of "Nervenheilkunde."

### Changes in the Relationship between Neurology and Psychiatry

Different developments in the last decades question the comparison of neurology and psychiatry. These developments mounted from both the field of neurology and psychiatry, which is described briefly in the following. By the discovery of variability of the brain's neuronal structures, i.e., the plasticity, and the introduction of new imaging techniques (►MRI, PET; see below) neurology changed its appearance: Solely static-structural observations have been replaced by a dynamic-functional anatomy [3]. This "functional neuroanatomy" not only examines different static structures but tries to point out the connections between these structures, to show plasticity of connections and structures as well as the influence of function on structure [1]. The boundaries between anatomy and physiology melt away because of this "functional neuroanatomy," where the contrast of anatomical-static structure and physiological-dynamic function is dismantled and rather regarded as a relationship of mutual complementation: "The boundaries between anatomy and physiology, between form and function, break down at an ultrastructural level. Anatomy is not static. Pharmacotherapy may alter structure as well as function." [3]. The new imaging techniques on the one hand allow to image anatomic structures more exactly and in detail. On the other hand they make it possible to draw a connection between functional changes and anatomic structure – they are a kind of "window for the brain function" [4]. These developments make it possible to look at psychiatric diseases too. The physiologic-functional examination, which is still getting off the ground, could shed new light on the pathophysiology of psychiatric diseases.

The development of psychopharmacology supported the hypothesis already set by Griesinger that mental diseases are diseases of the brain. The question of the mechanisms of the pharmacological effects in the brain by psychopharmacological drugs resulted in an intensive exploration of ►neurotransmitters, ►synapses, and receptors in the brain, which resulted in a better and extended understanding of physiological brain functions. Out of this the discipline of "biological psychiatry" emerged, which tries to correlate psychopathological phenomena with functional and structural changes in the brain [5]. Initially "Biological psychiatry" mainly dealt with synapses, neurotransmitters, and receptors; by examination of the mechanisms of effectiveness one tries to gain insight into the structural and functional events in the brain in psychiatric symptoms and diseases.

Not only in psychiatry changes have happened, but also in neurology. In neurology a rising interest in complex phenomena and behavior, which could not clearly be traced back to reflexes, developed [6]. Here the insufficiency of classic neurology became clear [7] – because of this, mainly in America, the discipline of "behavioral neurology" developed. It deals with complex phenomena like aphasia and ►amnesia and tries to localize these phenomena neurologically and neuroanatomically, respectively [8]. The old method of clinical–pathological correlations (see above) is applied here in a new field of interest, the field of higher-order cognitive phenomena and complex behavior – in doing so the focus is still on structure and the aim of localization [3].

The discipline of "neuropsychology," constantly developing in the last years, too, examines the "correlations between brain function and psychological processes" [9] closely following classical neuropathology [9,10]. The separation between neuropsychology on the one hand and "behavioral neurology" on the other hand is mainly pursued in the USA. In "behavioral neurology" mainly aphasia and amnesia are investigated. The main topic of neuropsychology is to provide objective methods for the examination of psychological function, which then can be applied on the clinical problems as dealt with in "behavioral neurology" and set into relationship to brain structure and function [11]. The "behavioral neurologist" primarily looks at the structures of the brain and secondarily their relation to complex psychological functions. The neuropsychologist, on the contrary, regards primarily the psychological functions and secondarily their relation to the structures of the brain [8]. The neuropsychologist captures affective and cognitive alterations in the Parkinson's disease using standardized tests in an objective manner – the correlation of these results with structures and functions of the brain is left to the neurologist to a large extent. The quantitative, operationalized measurement of psychological functions, the so-called psychometrics [10], is increasingly used in psychiatry too, where psychopathological phenomena are captured quantitatively and objectively by operationalization of the psychopathological symptoms. Thus the psychopathology which previously has often been called nonscientific becomes affiliated with an

"empiric-scientific methodology" [12] thereby gaining scientific status.

The above described developments of different disciplines in the border area between neurology and psychiatry aim to bridge the contrasts between both fields from different directions (biological *psychiatry*, behavioral *neurology*, neuro*psychology*) [3]. All of these three disciplines would explain the above described example of Parkinson's disease differently: The biological psychiatrist localizes the affective and cognitive symptoms in the microstructure of the transmitters, synapses, and receptors; the "behavioral neurologist" localizes the same symptoms in the macrostructures of the brain; the neuropsychologist objectivizes and standardizes psychological functions. All of them place motor/neurological and psychiatric symptoms next to each other and explain them more or less independently from each other – the internal connection of motor and psychological alterations in the Parkinson's disease as experienced by the patient gets lost. Because of this in the following we want to show that neuropsychiatry could be able to demonstrate these internal connections between psyche and motor activity.

### *Neuropsychiatry: Characterization and Definition*

The discipline of neuropsychiatry tries to bridge the gap between neurology on the one hand and psychiatry on the other – in doing so, psychological functions and neurological structures are not only to be observed at the same time but are to be connected internally coherently: "This new orientation of which Jellife spoke, and of which he himself was a notable exemplar, did not involve merely combining neurological and psychiatric knowledge (as every neurologist and psychiatrist does to some extent), but conjoining them seeing them as inseparable, seeing how psychiatric phenomena might emerge from the physiological, or how, conversely, they might be transformed into it – …" [3]. The static-structural, strictly localizing observation of the classic neurology and the "behavioral neurology" will be contrasted by a dynamic-functional approach of the neuropsychiatry. Psychological and motor alterations in the Parkinson's disease are no longer explained separately and independently but are regarded as two expressions of a uniform dynamic-functional structure – the alteration of this structure, and not of the two different symptom complexes as two different phenomena, have to be explained. Thus the "neurologilization" of psychiatric functions [3] is impossible – behavior can not only be observed with neurological methodology, but has to be assessed by integration of neurological and psychiatric knowledge [3].

Biological psychiatry cannot be identified with and reduced to neuropsychology, because it does not exclusively deal with complex macro phenomena of behavior and psychological functions, but with micro phenomena of the synapses, transmitters, and receptors – psychological functions mainly remain beyond observation [13]. While biological psychiatry uses functional neuroanatomy, restricting it to microstructures (synapses), behavioral neurology focuses on macrostructures of the brain though considering them solely in a static, anatomic-structural sense. Neuropsychiatry should aim to combine the dynamic-functional approach with the observation of macrostructures in the phenomena of behavior and higher-order psychological functions. In other terms, neuropsychiatry in this sense would take a middle position between a static-structural, localizing neurology on the one hand and a dynamic-functional, holistic/anti-localizing psychiatry on the other. As a bridge between neuroanatomy and psychopathology, neuropsychiatry has to examine functional and dynamic processes being positioned in between strictly localizable neurological functions and strictly holistic psychological processes [14]. This middle level of neuropsychiatry undermines the traditional opposition of structure versus function and localization versus nonlocalization.

## Function and Neuronal Integration in Neuropsychiatry

### Function and Localization

As already mentioned the contrast of structure versus function and charactzerized the latter as crucial for the discipline of neuropsychiatry. What does the term "function" mean? "Functional" can be understood in two senses [15]: First, "functional" means just nonorganic and thus psychological, as it has been understood in psychiatry. Second, "functional" can be understood in a physiological sense in contrast to anatomic – here "functional" describes dynamic, plastic, and variable physiological processes, being in contrast to the static, anatomic structure; this second meaning of the word "functional" has been used in the characterization of functional neuroanatomy (see above). We want to follow the second and original meaning of the word "functional" [5] and regard the physiologic-functional description as middle level between static-structural pathology and dynamic-functional psychiatry as the specific neuropsychiatric level [14]. Physiologic functions may not correlate with a specific static anatomic structure any more, but they develop in so-called functional systems [7,16]. These systems produce distinct functions by a dynamic constellation of changes between different parts of the brain reflecting what may be called neuronal integration (see below). They are plastic, show a systemic (and not a concrete) structure, and operate by dynamic autoregulation [16]. The realization of function depends then on dynamic systems that include different brain regions, which Luria characterized as "functional systems":

"According to this view a function is, in fact, a functional system (…) directed towards the performance of a particular biological task and consisted of a group of interconnected acts that produce the corresponding biological effect. The most significant feature of a functional system is that, as a rule, it is based on a complex dynamic "constellation" of connections, situated at different levels of the nervous system, that in the performance of the adaptive task, may be changed with the task itself may be unchanged" [16].

The brain here is regarded as a network consisting of different, overlapping functional systems with an internal dynamic, a so-called "neurodynamic" [3], which has already been demonstrated in the form of "resonant oscillator circuits" for the brain [17]. For our example of Parkinson's disease this would mean that the functional interaction of the functional systems of motor action, affect/emotion and cognition and their "interfunctional relation" [18] are altered. The motor action cannot be observed separated from affect/emotion and cognition because of the mutually overlapping systems – between the different functional systems there are so-called "functional knots" [7], enabling the motor action to influence affect/emotion and cognition directly, and reverse.

What does this neuropsychiatric network with its interconnections between the different functional systems imply for the problem of localization versus nonlocalization and consecutively for the separation between neurology and psychiatry? Historically and currently, the discussion of mental processes is often characterized by the opposition of localizationists, who claim for exact localizability of mental processes in structures of the brain, and holists or aquipotentionalists, who believed that all structures of the brain are necessary for mental processes [19]. Both approaches can be considered "psycho morphological attempts" [7], which give priority to either the structural-functional differentiation/specialization of the brain (localizationists) or to the plasticity of the brain (holists) as visible in functional restitution following structural lesions. A dynamic-functional neuropsychiatry regards both positions as different aspects of the organization of the neuronal network without either aspect prevailing or dominating. Neuropsychiatry aims to combine both positions in a concept of "systemic-dynamic localization" [7]. In this concept, a function cannot be localized in a distinct anatomic structure but in a functional system with its functional interconnections. On the other hand no anatomic structure of the brain can be assigned to only one function, but it is always involved in different functional systems simultaneously or successively – Luria calls this "functional pluripotentialism" [7].

This "functional pluripotentialism" the functional overlaps the "functional knots," of the functional systems of affection, cognition, and motor action as well as their connection in the case of the Parkinson's disease. This can be localized neither in a distinct anatomic structure (localizationists) nor in the whole brain (holists) – a distinct kind of alteration of the functional interaction of the functional systems of motor action, affect/emotion, and cognition is represented by the dynamic-functional localization in the Parkinson's disease. This makes clear that traditional contrasts of structure versus function and localization versus nonlocalization, which resulted in the separation of neurology and psychiatry (see above), can no longer be maintained in the present form and could be bridged by a dynamic-functional neuropsychiatry. The middle level between structural localization and functional holism of mental states may be characterized dynamic-functional, which may be realized by what can be called neuronal integration.

## Neuronal Integration

Neuronal integration describes the coordination and adjustment of neuronal activity across multiple brain regions. The interaction between distant and remote brain areas is considered necessary for complex functions to occur, such as emotion or cognition [20]. Neuronal integration focusing on the interaction between two or more brain regions must be distinguished from neuronal segregation [20]. Here a particular cognitive or emotional function or processing capacity is ascribed to neural activity in a single area that is both necessary and sufficient; one can subsequently speak of neuronal specialization and localization. We assume that higher psychological functions as complex emotional–cognitive interactions cannot be localized in specialized or segregated brain regions. Instead, we assume that higher psychological functions require interaction between different brain regions and thus neuronal integration.

For neuronal integration to be possible, distant and remote brain regions have to be linked together, which is provided by connectivity. Connectivity describes the relation between neural activity in different brain areas. There is anatomical connectivity for which we will use the term connections in order to clearly distinguish it from functional connectivity. In addition, Friston and Price [21] distinguish between functional and effective connectivity: Functional connectivity describes the "correlation between remote neurophysiological events," which might be due to either direct interaction between the events or other factors mediating both events. A correlation can either indicate a direct influence of one brain area on another or their indirect linkage via other factors. In the first case the correlation is due to the interaction itself whereas in the second the correlation might be due to other rather indirect factors like for example, stimuli based on common inputs. In contrast, effective connectivity describes the direct interaction between brain areas, it "refers explicitly to the (direct)

influence that one neural system exerts over another, either at a synaptic or population level" [21]. Here, effective connectivity is considered on the population level because this corresponds best to the level of different brain regions investigated here. For example, the ►prefrontal cortex might modulate its effective connectivity with subcortical regions thereby influencing specific functions like for example interoceptive processing. Based upon connectivity, neural activity between distant and remote brain regions has to be adjusted, coordinated, and harmonized. Coordination and adjustment of neural activity might not be arbitrarly but guided by certain principles of neuronal integration [22]. These principles describe functional mechanisms according to which the neural activity between remote and distant brain regions is organized and coordinated as for instance in top-down modulation (see also [23]).

## Top-down Modulation

Top-down modulation might be considered a typical example of specific mechanisms of neuronal integration; it can be described as modulation of hierachically lower regions by those being higher in the hierarchy. Often top-down modulation concerns modulation of neural activity in subcortical regions by cortical regions. For example, premotor/motor cortical regions might modulate neural activity in subcortical ►basal ganglia like the ►caudate and ►striatum [23,24]. Yet another example is top-down modulation of ►primary visual cortex by prefrontal cortical regions, which has been shown to be essential in visual processing [25]. Top-down modulation might be related to the concepts of "re-entrant circuitry" [26] and feedback modulation. These concepts allow for circuiting of information and readjustment of neural activity in one area according to another rather distant area. This provides the possibility of adjusting, filtering, and tuning neural activity in the lower area according to the one in the higher area. For example, top-down modulation allows for attentional modulation of visual input, which makes selective visual perception possible.

We want to focus on the medial prefrontal cortex. Neural activity in both medial prefrontal cortex and ►amygdala has been shown to be involved in emotional processing [27]. Their functional relationship is supposed to be characterized by top-down modulation of the amygdala by the medial prefrontal cortex [28], [29]. Medial prefrontal cortical regions seem to exert also top-down control of neural activity in the ►insula [30] that is densely and reciprocally connected with subcortical medial regions like the ►hypothalamus, the ►periaquaeductal grey (PAG), the ►substantia nigra, and various brain stem nuclei such as the ►raphe nuclei and the ►locus coeruleus [31]. Both the amygdala and the subcortical medial regions are involved in regulating internal bodily functions whereas medial prefrontal cortical regions have been associated with emotional processing [27,32]. The three regions, medial prefrontal cortex, amygdala, and subcortical medial regions, show dense and reciprocal connections [33,34]. Therefore, one might assume modulation between all of them. This might not only include top-down modulation, as illustrated, but also the reverse kind of modulation, bottom-up modulation. In the case of bottom-up modulation a hierachically lower area modulates activity in an area being higher in the hierarchy. For example, subcortical midline regions might modulate neural activity in medial prefrontal cortex via the insula thus concerning the same regions as top-down modulation. Accordingly, bottom-up and top-down modulation might co-occur across the same regions.

Functionally, this co-occurrence of bottom-up and top-down modulation might allow for reciprocal adjustment between emotional and internal bodily processing. Internal bodily processing concerns only stimuli from the own body, so-called internal self-related stimuli. These include, for example, stimuli from autonomic-vegetative or other humoral functions. Whereas emotional processing concerns both internal self-related and thus internal bodily stimuli and external self-related stimuli from the environment. For example, emotional processing might be induced by specific events within the environment which in turn might induce internal bodily stimuli. This is well compatible with the co-occurrence of bodily and emotional symptoms in ►Posttraumatic Stress Disorder (PTSD) where such top-down modulation between amygdala and medial prefrontal cortex is assumed to be altered [35]. The elucidation of specific mechanisms of neuronal integration for higher-order functions and mental states, their control by genetic and social factors, and their changes in psychiatric disorders will be the central task for future neuropsychiatry.

# Neurosemiotics

René J. Jorna
Professor of Knowledge Management & Cognition
Faculty of Economics and Business, University of Groningen, Groningen, The Netherlands

## Definition

Neurosemiotics is about the sign or signal related aspects of synapses, neurons and neural nets [20,29]. Because neurons are the physiological tissue within which the brain or mind resides, neurosemiotics is also about cognition or about humans as information processing and connectionist systems [30].

## Description of the Theory

To understand the complex relationships between signs, signals and semiosis as aspects of semiotics on the one hand and brain and cognition on the other hand, an aid for understanding the distinction in various (ontological) levels of description [5,26,23] is used. The explanation of this conceptual help is followed (Neuro-psychological consequences) by a description of its neuropsychological implications and after that (Neurosemiotics) by an analysis of various categorizations of signs. The article ends (The role of Neurosemiotics) with a determination of the role of neurosemiotics.

## Levels of Description

The intriguing intangible phenomenon of the human mind seems to require various perspectives at the same time. The perspectives depend on certain levels of aggregation, also called levels of description. "Levels are clearly abstractions, being alternative ways of describing the same system, each level ignoring some of what is specified at the level beneath it." [23]. The idea of levels of description for a (cognitive) system has been elaborated most elegantly by Dennett [5,6,7]. He distinguishes three independent levels: (i) the physical (or physiological) stance, (ii) the functional (or design) stance, and (iii) the intentional stance. Other authors [22,23,26] give similar accounts in which, however, the number of levels varies. Newell (1990;26, p.46) says: "Often we describe the same system in multiple ways […]. The choice of what description to use is a pragmatic one, depending on our purpose and our own knowledge of the system and its character." In the following we use Dennett's explanation of levels [5,6].

The physical (or physiological) stance explains behavior in terms of physical properties of the states and the behavior of the system under concern. For its proper functioning the human organism requires a complex interaction of its parts and with the external world. The central nervous system in al its subdivisions and the endocrine system are there to transmit data (signals, information) that reveal the state of one part of the system to other parts. We can also mention the transmission of currents in the synaptive system of neurons. Within the study of brain and cognition, the physiological stance is the endpoint of ontological reduction.

The second level concerns the functional design of a system. At a functional level it is important to know the components of a system, how they are defined and how the components and sub-components are connected. Stated differently, if the input and output of each component are known, then with a certain input at the beginning of the system the resulting behavior (output) can be predicted based on the characteristics of the components. The behavior of a system is conceived of as the result of the interaction between several functional components or processes. The physical structure of the system is not explicitly taken into account, although it surely imposes constraints on the behavior of the system at the higher level. The capacity limitations of human memory, for instance, impose boundary conditions on the complexity of decision making at the higher intentional level.

Thirdly, Dennett distinguishes the intentional stance. Complex behavior that is adapted to the prevailing circumstances, according to some criterion of optimality is said to be rational or intelligent. A behaving system to which we can successfully attribute rationality or intelligence qualifies as an intentional system. It is not necessary for a behaving system to "really" possess rationality or intelligence, as long as the assumption allows us to correctly predict the behavior of the system based on our knowledge of the circumstances in which the system is operating.

One may deal with this level's distinction in two different ways: instrumentalistic and ontological. Dennett [5] has taken the levels distinction in a strictly instrumentalistic way, claiming only pragmatic validity. Summarizing his position twenty years later, he wrote: "As I have put it, physical stance predictions trump design [or functional] stance predictions which trump intentional stance predictions - but one pays for the power with a loss of portability and a (usually unbearable) computational cost." [8]. In contrast to Dennett, authors such as [11,23,26] assign an ontological meaning to each level. The higher levels introduce emergent qualities into human behavior that make no sense if we maintain only an instrumentalistic point of view.

## (Neuro-)Psychological Consequences

Neurons, synapses, neuronal nets are all located at the physiological level. The most important question resulting from the levels distinction is the art of the relationship between the levels. Is the relationship reductionist? Or is

ultimate reduction not possible. If the intentional level can be reduced without loss of information to the functional level and from there to the physiological level we have a reductionist position [3]. If one accepts that levels do exist in a parallel way in which lower levels set constraints for the higher levels also implying that a higher level can be incorporated in various concrete designs at the lower levels (the so called "under-determination" issue) one is non-reductionist, Sometimes this position is called the "emergence" or "supervenient" position. In that case properties and characteristics of levels exist on their own (level) [21].

From a neurological and psychological point of view, the (non-)reductionist position and the level's distinction determine how one sees and therefore studies human beings and how one deals with neurosemiotics. If human beings in all their complexity of behavior and cognition can be reduced to neurons, the study of humans in the long-run equals neuroscience. In that case humans as biological, psychological and social entities will be explained in an analytic and scientific way in terms of the well elaborated lowest domain of neuroscience. Neurosemiotics then is a matter of extremely complex signal analysis (see section 3). However, if behavior and cognition cannot be ultimately reduced and can only be studied at their appropriate level of description, more holistic and emergent descriptions of humans have value on their own. This implies that signs and symbols requiring an autonomous interpretation mechanism are proper object of study, even, or especially, within neurosemiotics.

One consequence of this distinction relates to the possibility of "real" artificial intelligence. If one follows the reductionist line of reasoning resulting in theories, predictions and explanations at the neuroscientific level, it is tempting to argue that the only way intelligence can be mimicked is by doing neuroscience. A neurological basis of "real" intelligence is essential. In contrast with this position one can follow Good Old Fashioned Artificial Intelligence GOFAI [12] which says that intelligent (functional or intentional) systems can "run" on different kinds of "hardware": neurons or chips. In the latter case, the program (Deep Blue 2, see [15] that beat the world champion in chess is an intelligent system, comparable to a human, but wired with different material. However, in the former case the software program is a nice piece of programming, but is not intelligent in the real sense, because it lacks synapses, neurons and similar tissues.

## Neurosemiotics

The discussion of various levels and (non-)reductionism determines the view on neurosemiotics in two respects. First, semiotics in relation to a domain of study can never exist without a precise demarcation of that domain [28]. Second, humans whether they are conceived of as information processing system or as neurological systems are signals, signs and symbols using systems themselves [16]. Therefore, neurosemiotics, largely, is also about our selves. I will first give a definition of semiotics and illustrate its relevance for neurons, then I will introduce and categorize various kinds of "signs" and finally I will discuss semiosis or sign interpretation.

Extending the definition of semiotics (Posner, 1979), a demarcation of semiotics is as follows: "Semiotics is the study of all sorts of sign or symbol processes in the communication and the exchange of knowledge, in the sense of data, between and inside information processing systems, such as humans, other organisms and machines" [17]. Other definitions can be found in [1,9,25,24], to name but a few. In this demarcation a sign is defined as "something that stands for something else" (aliquid stat pro aliquo), which is the same definition as for the notion of representation [18]. In the definition of semiotics three aspects in relation to neurosemiotics are important. First, signals are not mentioned and signs and symbols are equivalent. Second, data, information and knowledge seem to be interchangeable, whereas the usual distinction is that knowledge is interpreted information, which is interpreted data. Third, behind communication and exchange an interpretation mechanism is presupposed.

Within semiotics, various categorizations of semiotic elements are used. For neurosemiotics the following distinctions are relevant: (i) signal and sign, (ii) index, icon and symbol and (iii) sign or symbol sets (see for overviews: [10,14,31].

First, we have the classical distinction in signals and in signs. Signals are positioned at the physical/chemical level of description and their modus operandi is causal. In this respect signals do not fall into the definition of "something standing for something else." Part of the firing of a neuron is the chemical substances that are emitted: signals. A signal is part of the functioning of a cell, an organelle or a neuron as elements of the material world. Signs, however, are semantic in their functioning. For something to be a sign implies an interpretation mechanism. Smoke is part of a fire and therefore can be called a signal, but as soon as an interpreting mechanism, an animal, a human or an electronic sensor, takes action, the signal is a sign. It stands for something and it is interpreted. It is an open question whether the firing of a neuron or synapse activity is a signal or a sign. The choice has consequences for the kinds of research questions: mainly cognitive in the case of signs and merely physiological in the case of signals (see also [2], who accepts the functional level, but abandons the notion of central processors).

Second, a distinction can be made in various kinds of signs: index, icon or symbol [25]. An index is a sign that is not arbitrarily, but directly connected to what it represents. It resembles very much the signal, but a

signal is not interpreted, an index is. In case of an icon, the sign resembles, mimics or imitates what it stands for, without incorporating all characteristics. An image of a nerve with MRI resembles the nerve, without consisting of proteins or potassium (K). A symbol is a sign that has an arbitrary or conventional relationship with what it stands for. The word "apple" has an arbitrary relationship with apple (at least in English) and words of the language or codes have to be learned.

Third, [13,14] distinguishes various kinds of sign sets (Goodman speaks of symbol sets) in order to define notational systems. A notional system, such as mathematics, logic or musical scores, fulfills syntactic and semantic requirements and realizes communication without ambiguity. If the elements of a sign set met none of the requirements it is just a collection of markers, strokes or noises. If the elements fulfill the syntactic requirements of disjointness and finite differentiation it is a notational scheme, such as language or the Arabic number system. If the elements also fulfill the semantic requirements, that is to say they are unambiguous, semantically disjoint and semantically finitely differentiated, the sign set is a notational system.

In the above categorizations neurons and synapses can be seen as signals, and if one accepts that firing of neurons involves information transmission it is a sign, that is to say an index and not an icon or a symbol, and finally in terms of Goodman's distinction it is a set of markers, without syntactic and semantic characteristics.

The distinctive element in the question whether we are dealing with signals or signs and the comprehensive effect of neurosemiotics is the place and role of an interpretation mechanism, a signal interpreter, which activity some would call semiosis (sign understanding). An interpretation mechanism implies that meaning, sense or signification is attached to signals. If that takes place we have a sign, in whatever variety. From a neurosemiotic point of view the question is whether we can demarcate such a mechanism at the physiological or neuronal level. If the answer to this question is no, the question moves to the next functional level and it is generally agreed that cognition - in a better defined sense - does the work here, in the form of processing units [19]. Here we speak of information processing resulting in knowledge. However, if the answer to the question at the physiological level is affirmative, it is the assignment of neuroscience and neuropsychology to describe and explain an "interpreter" at this physiological level without jumping to the next higher level. Despite the vast research in this area this has not been accomplished yet.

## The role of Neurosemiotics

Neurosemiotics is definitely not the first domain where neuroscientists seek their primary inspiration. Nevertheless, looking at neuroscience from a semiotic perspective has three advantages. It raises questions of data or information transmission in unconventional terms, in unusual conceptualizations. Because of its higher level and multi-disciplinary perspective it brings to neuroscience results from domains such as logic, systems engineering or aesthetics, where issues of sign exchange and understanding are omni-present. Third, it brings modesty to the field of neuroscience, where - with exaggeration - the dominant view at the moment is that it should and can replace psychology, physiology, cognitive science and information science. Semiotics had that dream in the past.

## Neurosis

### Definition

Large group of non-psychotic disorders. As defined by S. Freud, a disease that has psychological causes, due to conflicts and traumata in early life history. The symptoms are direct consequence and symbolic expression of an unconscious psychical conflict. This conflict has its origin in the early childhood. The symptoms are a compromise between an instinctual desire and its psychical defense.

►Personality Disorder

## Neurosphere Culture

### Definition

Neurosphere culture enables the selective expansion of NSCs in floating culture within a serum-defined medium containing growth factors, such as EGF and/or FGF2. A neurosphere derived from a single cell has been shown by the differentiation assay to be capable of generating all the major three cell lineages of the CNS, i.e., neurons, astrocytes and oligodendrocytes, indicating the multi-potency of the neurosphere-initiating cell.

When a neurosphere is dissociated into single cells, each cell starts to form secondary neurospheres at a high frequency. For human NSCs, however, some different protocols are being used.

# Neurotransmitter

Kazuhide Inoue
Department of Molecular and System Pharmacology, Graduate School of Pharmaceutical Sciences, Kyushu University, Japan

## Synonyms

Chemical transmitter

## Definition

Neurotransmitter is a chemical that achieves chemically mediated transmission, a major mode of interneuronal and neuron-effector communication. The chemical should meet several criteria to be recognized as a neurotransmitter. The criteria are: (i) A neurotransmitter must be synthesized in a neuron and released from a presynaptic terminal, (ii) A neurotransmitter should reproduce the specific responses that are evoked by the stimulation of presynaptic neurons at the postsynaptic neuron or effector cells, (iii) The effect of the chemical should be blocked by antagonists in a dose-dependent manner, and (iv) A neurotransmitter must be reabsorbed into the presynaptic neuron or glia, or metabolized into an inactive form by enzymes to terminate the stimulation.

## Characteristics

### Function

Neurotransmitters transmit information from presynaptic neurons to postsynaptic neurons or peripheral effector cells through the activation of a receptor/channel. The function of a neurotransmitter depends on the receptor/channel. A neurotransmitter that stimulates an ionotropic receptor/channel causes an excitatory or inhibitory current in a target cell resulting in depolarization or hyperpolarization, respectively. A neurotransmitter that stimulates GTP binding of a protein-coupled metabotropic receptor causes second messenger signal transduction in a target cell, resulting in cell response.

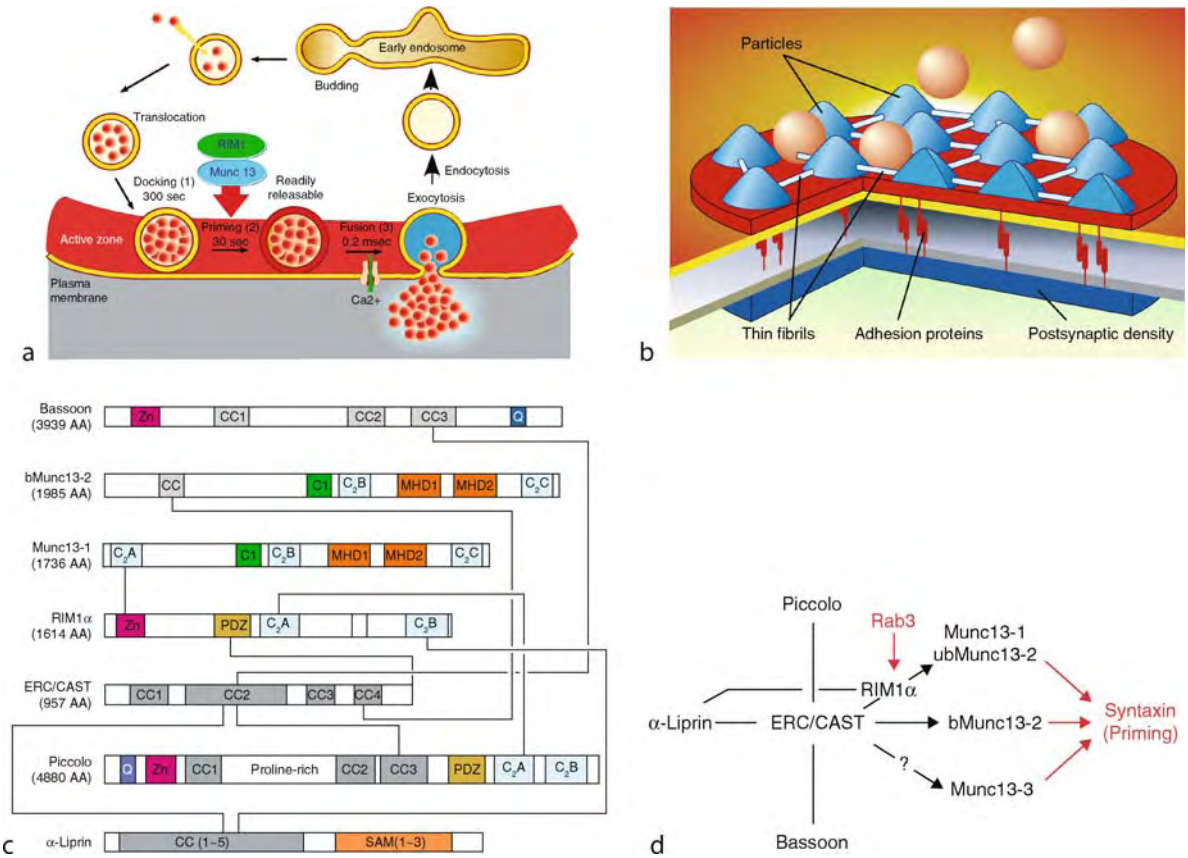
## Definition

### The Vesicle Priming Step in the Neurotransmitter Release Process

$Ca^{2+}$-triggered fusion of ►synaptic vesicles is the key step in neurotransmitter release and synaptic signalling. Before vesicles can fuse with the plasma membrane in response to an arriving action potential and concomitant $Ca^{2+}$ influx, they have to be translocated and tethered/docked to the plasma membrane. A subset of these tethered vesicles are then primed to fusion competence. Only these docked and primed vesicles, also referred to as readily releasable vesicles, can fuse with the plasma membrane in a $Ca^{2+}$-dependent manner. In the absence of vesicle priming, transmitter release is completely blocked.

In synapses, vesicle docking and priming are spatially restricted to and temporally coordinated at active zones, which represent a highly specialized presynaptic subcompartment (Figs. 1a and b) [1].

Vesicle translocation, tethering (►Translocation and tethering of synaptic vesicles), and priming are rather slow processes. However, the fact that these processes are spatially restricted to and temporally coordinated at active zones, leading to the generation of a readily releasable vesicle pool at synaptic release sites, guarantees that synaptic transmitter release is spatially accurate and very fast. In fact, excitation–secretion coupling at many synapses occurs in a sub-ms time frame. This, in turn, allows neuronal networks to propagate information at very high density and with very high reliability.



**Neurotransmitter Release: Priming at Presynaptic Active Zones. Figure 1** (a) Schematic representation of neurotransmitter release at the presynaptic active zone. Shown is a segment of a presynaptic terminal, and the trafficking and maturation steps that synaptic vesicles pass through. Synaptic vesicles filled with neurotransmitters translocate from the presynaptic cytoplasmic pool to the plasma membrane, where they dock (1) and undergo a priming step (2) to become fusion competent. Fusion competent vesicle exocytose in response to an arriving action potential and concomitant $Ca^{2+}$ influx (3) Note that all these steps are spatially restricted at the active zone. (b) The structure of an active zone. Pyramid-like particles are connected to each other with thin fibrils forming a particle web. Synaptic vesicles can access the presynaptic plasma membrane through a grid surrounded by fibrils. Figure adapted from the review by Dr. Hugo Bellen. (c) Structures of active zone components. Any given active zone specific protein has a multi-domain structure and interacts with several other active zone proteins. Direct binding between proteins is indicated by black lines. (d) Regulation of Munc13 proteins by ERC/CAST. ERC/CAST can bind to Munc13 proteins either directly or indirectly through RIM1. This interaction likely controls the Munc13 priming efficiency. In addition, ERC/CAST can directly interact with all other active zone components, and it is possible that this protein is at the core of an active zone protein network that forms “particles” of the active zone.

N

## Characteristics

### Quantitative Description

Active zones are defined morphologically on the basis of three criteria: (i) They constitute an electron dense area at the presynaptic plasma membrane that is located opposite of the ►postsynaptic density, (ii) they harbour morphologically docked synaptic vesicles, and (iii) they provide the tethering site for synaptic vesicles on electron-dense protrusions, which emanate from the active zone and form a presynaptic proteinaceous cytomatrix (Fig. 1b). The electron dense structures of active zones contain a network of at least six types of active zone specific proteins, whose functional characteristics and interactions constitute the molecular basis of active zone morphology and function (Figs. 1c and d).

The number of active zones at each synaptic terminal can vary between synapse types and can range from one to several hundred. In cultured primary hippocampal neurons, for example, 70% of presynaptic boutons contain only a single active zone [2]. On the other hand, at the calyx of Held in the medial nucleus of the trapezoid body, one synaptic terminal contains some 550 active zones [3].

At most active zones in the central nervous system, synaptic vesicles are recruited and docked at the

presynaptic plasma membrane within about 300 s, and docked vesicles are then primed within 30s or even faster. After arrival of an action potential and the subsequent influx of $Ca^{2+}$ through voltage-gated $Ca^{2+}$ channels, the local $Ca^{2+}$ concentration rises beyond 10–20 μM and fusion events occur within 0.1–1 ms (Fig. 1a). Priming appears to involve multiple reversible maturation steps of synaptic vesicles, and primed vesicles are stabilized before the influx of $Ca^{2+}$ [1].

## Higher Level Structures

Chemical synapses are asymmetric intercellular junctions that typically form between the axon of a presynaptic neuron and the dendrite, cell body, or, in some cases, the axon of a postsynaptic neuron. These junctions are maintained by adhesion and scaffolding proteins (Fig. 1b). At chemical synapses, signal propagation is achieved by transducing the axonal electric signal into the exocytosis of neurotransmitters at the presynaptic active zone. Released transmitter diffuses to the postsynaptic neuron where it binds to surface receptors. Their activation, in turn, changes the physiological state of the receiving neuron.

## Lower Level Components

Active zones vary in appearance from one synapse to another, especially in size and shape of electron dense particles [4]. The three-dimensional structure of the cytoskeletal matrix of the active zone (CAZ) at the frog neuromuscular junction has been studied in detail. It is 1–2 μm long, 75 nm wide and extends 50–75 nm from the presynaptic membrane into the cytoplasm. It consists of three structures: beams, ribs, and pegs. The presynaptic membrane underneath the CAZ curves outwards forming a ridge and the beams run parallel to the ridge's long axis, whereas the pegs connect the CAZ and the presynaptic membrane. Most interestingly, the ribs extend orthogonally to the ridge's long axis and form 7–12 connections to docked vesicles located on each flank of the ridge. The actual protein constituents of these beams, ribs and pegs are unknown.

In view of these and other data, proteins forming the active zone should not only be restricted in their localization to the CAZ, but they should also be of large molecular size and contain multiple protein interaction sites. In the mammalian central nervous system, active zones form "particle web" structures (Fig. 1b), in which ~50 nm pyramid-like "particles" are spaced uniformly and connected to each other with thin fibrils forming a "web" structure. This particle web likely contains all of the known active zone components: Munc13s, Bassoon, Piccolo, RIM1, α-Liprin, and ERC/CAST (Fig. 1c). Each one of these proteins binds to several others, thus forming a large multimolecular complex (Fig. 1c and d). While it is not known if these CAZ proteins depend on each other for localization, mutual functional regulation has been demonstrated for some combinations (e.g. RIM1 and Munc13-1).

## Structural Regulation

### *Synaptogenesis and Active Zone Formation*

Functional synapses are formed in two steps [5]: (i) Initial contact formation between immature axons and dendrites – in this step, several classes of cell adhesion molecules, including ►Cadherins and Protocadherins, Neurexins and Neuroligins, and ►SynCAMs/Nectins, are implicated; and (ii) recruitment of pre- and postsynaptic transmembrane and cytoplasmic proteins to the sites of initial contacts.

Trans-synaptic interactions of cell adhesion molecules are thought to trigger the recruitment of presynaptic active zone components, and postsynaptic scaffolding molecules and receptors to the forming synapse. Interestingly, many postsynaptic components are recruited to the initial synaptic contact in a gradual manner, while presynaptic active zone components are recruited in a stepwise manner. A fascinating hypothesis has emerged recently to explain this difference. According to this hypothesis, active zones are formed by the delivery of precursor active zones in the form of transport vesicles. These contain active zone specific proteins such as Piccolo and Bassoon, and are thus named Piccolo/Bassoon transport vesicles or PTVs, in addition to RIMs, Munc13s, Syntaxins, and SNAP-25. Upon fusion of such vesicles with the plasma membrane of a nascent synapse, active zone proteins are deposited and localized. In cultured hippocampal neurons, one functional release site appears to be composed of 2–3 PTVs. In mature neurons, after the establishment of functional synapses, PTVs are extremely rare. Thus, it is possible that mature neurons employ alternative transport mechanisms for active zone components, and alternative mechanisms to form active zones and synapses.

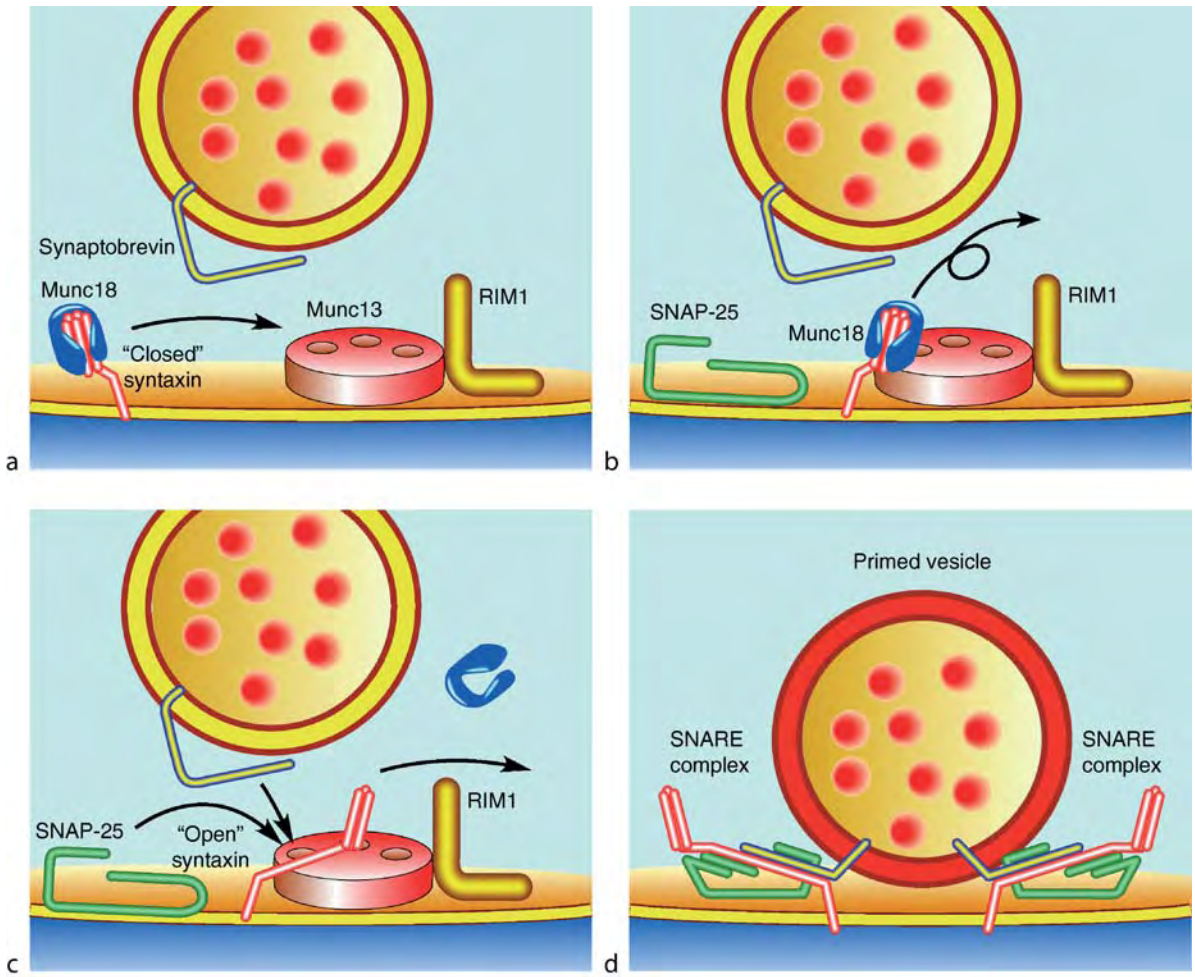
## Lower Level Processes

### *The SNARE Complex and Munc13 Proteins*

The synaptic SNARE (soluble NSF attachment protein receptors) complex is a trimeric complex composed of one synaptic vesicle protein, Synaptobrevin 2, and two synaptic plasma membrane proteins, Syntaxin and SNAP-25 (Fig. 2).

This complex catalyzes synaptic vesicle fusion by bringing the fusing vesicle and plasma membranes into close proximity, thus facilitating lipid bilayer mixing and subsequent membrane fusion.

Structural studies on Syntaxins showed that members of this protein family contain an autonomously folded N-terminal domain in addition to the C-terminal SNARE domain. These two domains can interact in an intramolecular fashion to form a "closed" conformation, which is unable to form a SNARE complex with



**Neurotransmitter Release: Priming at Presynaptic Active Zones. Figure 2** Hypothetical regulation of SNARE complex formation during the priming step. Syntaxin in its "closed" conformation forms a stable complex with Munc18 (a). Munc13 displaces Munc18 from the Syntaxin-Munc18 complex and facilitates the structural switch of Syntaxin from the "closed" to the "open" conformation (b and c), thus promoting the assembly of the SNARE complex (d). Figure adapted from images by Dr. Erik Jorgensen.

Synaptobrevin 2 and SNAP-25. Only "open" Syntaxins are thought to be able to enter SNARE complexes.

SNARE complex formation is controlled by several types of regulatory proteins. Two of these, Munc18-1 and Munc13s, are absolutely essential for synaptic vesicle fusion. The molecular mechanism of Munc18-1 function is still poorly understood. Based on the structure of the Syntaxin 1/Munc18-1 complex, it was postulated that Munc18-1 binds to the "closed" Syntaxin conformation and blocks its SNARE motif from participating in SNARE complex formation [6]. Thus, Munc18-1 has to dissociate from Syntaxins in order to allow SNARE complex formation.

Interestingly, Munc18-1, Syntaxin 1/2, and SNAP-25 are localized to the presynaptic terminal, but their distribution is not restricted to active zones. Specific proteins localized to the active zone plasma membrane or cytomatrix are likely to coordinate the active zone processes of vesicle tethering, priming, $Ca^{2+}$-influx, and vesicle fusion, and to spatially restrict the synaptic vesicle exocytosis process to active zones. Indeed, neurons appear to employ a very simple molecular mechanism to limit transmitter release to active zones: They restrict the localization of essential components of the release machinery, Munc13s, to this subcellular compartment. Munc13-1, the best characterized Munc13 protein, binds to the N-terminal domain of Syntaxin, and likely promotes the conformational switch in Syntaxin from the "closed" to the "open" form, thus permitting the assembly of the synaptic SNARE complex (Fig. 2).

Rodents and humans express five Munc13 genes, Munc13-1, -2, -3, and -4, and Bap3. Two splice variants of Munc13-2 are known, the ubiquitously-expressed Munc13-2 (ubMunc13-2) and the brain-specifically

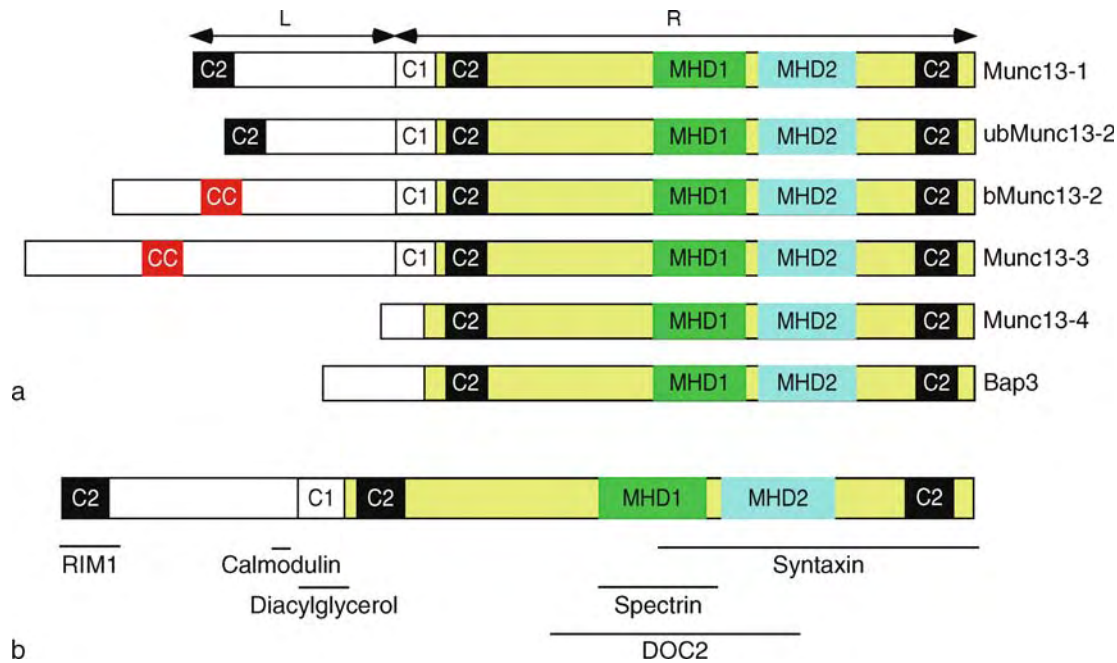
expressed Munc13-2 (bMunc13-2). Munc13 proteins contain two or three $C_2$ domains, one $C_1$ domain, and two Munc13-homology domains (Fig. 3a). At least one of the four Munc13 isoforms, Munc13-1, is enriched at active zones. Studies on Munc13-1 and Munc13-2 deletion mutant mice showed that Munc13 proteins are absolutely required for the priming process in central nervous system synapses. In their absence, both spontaneous and evoked transmitter release are completely blocked.

### *Regulation of Readily Releasable Vesicle Pools by SNARE Proteins*

Several perturbations that interfere with SNARE complex assembly or stability (e.g. antibodies to SNAP-25, deletion of SNARE regulators, or Clostridial toxins that cleave SNAP-25) also interfere with vesicle priming and the maintenance of a readily releasable pool of vesicles. This indicates that the molecular process of SNARE complex formation resembles the functionally defined step of vesicle priming. Indeed, a recent study employing over-expression of SNAP-25 variants in chromaffin cells demonstrated a role of this SNARE protein in the priming step. Two SNAP-25 splice variants are known, SNAP-25a and -b. Over-expression of SNAP-25b increases the readily releasable vesicle pool size but leaves the kinetics of vesicle fusion or docking unchanged, indicating a role of SNAP-25b in blocking depriming.

## Process Regulation

Functionally, the synaptic vesicle priming rate defines the size of the readily releasable vesicle pool, which is a key determinant of presynaptic release probability and synaptic efficacy. During periods of high frequency stimulation, the basal priming rate and its dynamic regulation determine the speed of recovery of the presynaptic release machinery, and thus regulate short-term plasticity characteristics of synapses.



**Neurotransmitter Release: Priming at Presynaptic Active Zones. Figure 3** (a) Domain structures of Munc13 proteins. The Munc13 protein family contains five isoforms, Munc13-1, -2, -3, and -4, and Bap3. Two Munc13-2 splice variants are known, ubMunc13-2 (ubiquitously expressed), and bMunc13-2 (brain-specific). All Munc13 proteins share a common, highly homologous C-terminal region (R region) with $C_1$, $C_2$, and Munc13 homology domains, but have unrelated N-termini (L region). This modular structure and differential evolution indicate that the conserved R-regions play essential roles, and unrelated L-regions play regulatory roles in Munc13 function. (b) Binding partners of Munc13-1. The N-terminus of Munc13-1 binds to another component of the active zone, RIM1, and to second messengers, $Ca^{2+}$/Calmodulin and diacylglycerol. These interactions are not essential for priming of synaptic vesicles, but modify the efficacy of priming and thus regulate short-term plasticity. The C-terminus of Munc13-1, -2, and -3 binds to the SNARE protein Syntaxin. This interaction is thought to be essential for the actual priming step and to involve the regulation of the Syntaxin conformation. In addition, the C-terminus of Munc13-1 binds to DOC2 (Double C2 protein), β-Spectrin, and Msec7, but the physiological significance of these interactions is not known.

Munc13 proteins are regulated by multiple proteins and second messengers. As a consequence, synaptic vesicle priming is a highly dynamic and tightly regulated presynaptic process (Fig. 3b) [5]. Synapses driven by Munc13-1 exhibit ►synaptic depression during high frequency stimulation, whereas synapses using ub-Munc13-2 as the main priming protein show ►synaptic facilitation during, and ►augmentation following periods of high frequency stimulation. Munc13 mediated synaptic depression, facilitation, and augmentation are regulated by two second messenger dependent processes: (i) Diacylglycerol activates Munc13s by binding to their $C_1$ domain, resulting in Munc13 activation and frequency facilitation/augmentation (in the case of Munc13-2) or at least compensation of synaptic depression (in the case of Munc13-1); (ii) $Ca^{2+}$-dependent binding of Calmodulin to Munc13 proteins resulting in an increase of the priming activity and functional changes in short-term plasticity that are similar to the effects of diacylglycerol.

In addition to second messengers, several proteins bind to and regulate Munc13 proteins (Fig. 3b). The most striking example is RIM1. RIM1 is a component of the active zone and was originally identified as a target of Rab3 small GTPases. RIM1 binds to the N-terminal $C_2$ domain of Munc13-1 and ubMunc13-2. Several lines of evidence support the notion that RIM1 is a functional regulator of Munc13 proteins but not an actual mediator of the priming step: (i) Over-expression of Munc13-1 mutants lacking RIM1 binding activity leads to a 50% reduction in priming activity as compared to the over-expression of wild type Munc13-1; (ii) in the absence of RIM1α, the dominant RIM isoform, the readily releasable vesicle pool size of hippocampal neurons is reduced by only 50%, while deletion of Munc13s eliminates primed vesicles entirely; (iii) RIM1 deficient mice show a 50% reduction in Munc13-1 expression levels; (iv) application of diacylglycerol to RIM1α deficient neurons can still increase Munc13 mediated priming and transmitter release.

## Pathology

### *Vesicle Priming and Memory Formation*

Abolishing RIM1-expression in mice results in compromised ►long-term potentiation in hippocampal and cerebellar mossy fibre terminals [7,8], and dramatic deficits in associative learning and locomotor responses to novelty [9]. As one main function of RIM1 is the regulation of Munc13 priming activity, it is likely that the dynamic regulation of synaptic vesicle priming is a key process in mossy fibre long-term potentiation. These considerations, and the finding that Munc13 mRNAs are affected in fragile-X type mental retardation, indicate that the priming step regulated by the Munc13-RIM1 complex might be important for the pathology of learning disorders and mental retardation.

### *Cytotoxic Granule Exocytosis Deficiency in Patients With Mutant Munc13-4 Expression*

An immunoproliferative syndrome, familial hemophagocytic lymphohistiocytosis or FHL, is an often fatal childhood disorder characterized by infiltration of multiple organs by activated T cells and macrophages. One of three forms of FHL, FHL3, is caused by mutations of the gene encoding Munc13-4, a ubiquitously expressed distantly related Munc13 isoform [10]. In Munc13-4 deficient cytotoxic T cells, lytic granules are associated with the plasma membrane, indicating that Munc13-4 is dispensable for vesicle trafficking and docking in these cells, but is necessary for a step subsequent to docking. Although it is not clear whether a priming step exists in the exocytosis of lytic granules, Munc13-4 appears to play a similar role in a post-docking step of this type of exocytosis as other Munc13 proteins do in synapses.

# Neurotransmitter Transporter

Kohichi Tanaka
Laboratory of Molecular Neuroscience, School of Biomedical Science and Medical Research Institute, Tokyo Medical and Dental University, Bunkyo-Ku, Tokyo

## Synonyms

Uptake carrier

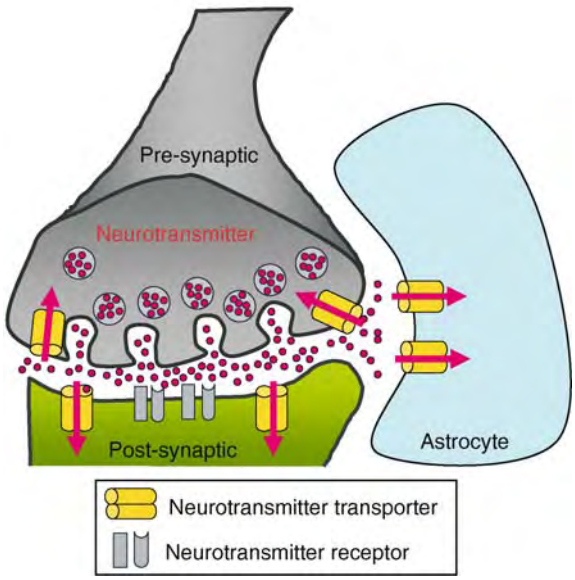
## Definition

►Neurotransmitter transporters are uptake carriers in the plasma membrane of neurons and glial cells, which pump neurotransmitters from the extracellular space into the cell (Fig. 1) [1].

## Characteristics

### Quantitative Description

The size of neurotransmitter transporters ranges between 523 and 798 amino acids (Table 1).



**Neurotransmitter Transporter. Figure 1** Schematic Representation of the Main Neurotransmission Steps at a Synapse. The neurotransmitter is synthesized in the presynaptic neuron, stored in synaptic vesicles and released into the synaptic cleft by exocytosis to act on neurotransmitter receptors. To terminate the neurotransmission, the released neurotransmitter has to be removed promptly from the synaptic cleft. High-affinity neurotransmitter transporters present at pre-synaptic or post-synaptic neurons and/or astrocytes are responsible for rapid removal of neurotransmitter [1].

Chemical and stereological quantification shows that the number of glial glutamate transporter GLAST (EAAT1) is 2,300 $\mu m^{-2}$ of membrane in the hippocampus [2].

### Higher Level Structures

Since the physiological action of neurotransmitter is terminated by its ►removal by high-affinity neurotransmitter transporters, they are concentrated in the plasma membrane of neurons and glial cells surrounding the synaptic clefts [1].

### Higher Level Processes

Synaptic transmission is a fundamental process in neuronal communication in the brain (Fig. 1). Neurotransmitter transporters influence many aspects of synaptic transmission, including the timecourse of the postsynaptic response and the peak postsynaptic receptor occupancy, by modulating the duration and the intensity of neurotransmitters action at the synapse. Therefore, they are involved in the fine tuning of information processing in the brain. They are also responsible for the replenishment of neurotransmitter pools within nerve endings [3,4].

### Lower Level Processes

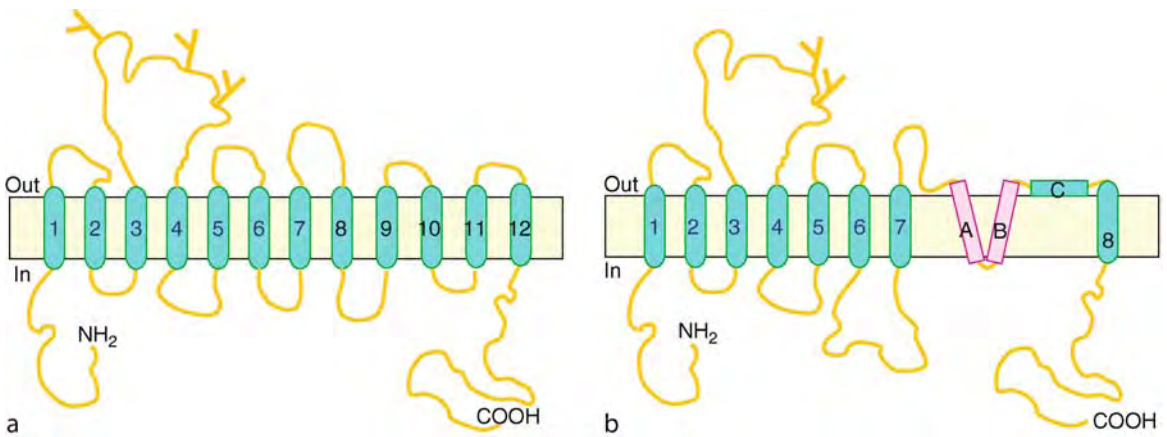
The neuronal neurotransmitter transporters shuttle transmitters from the extracellular fluid and concentrate them up to 10,000 times higher within the cytosol of the presynaptic terminal. They use the transmembrane ion gradients of $Na^+$, which are ultimately set up by $Na^+/K^+$ pump, as an energy source for moving transmitter molecules up to steep concentration gradients. They also display absolute requirements for other ions and can be divided into two families depending on their ionic dependence: (i) the $Na^+/Cl^-$-dependent transporters, and (ii) the $Na^+/K^+$-dependent transporters (Fig. 2). [1]. Glutamate transporters co-transport 3 $Na^+$ and 1 $H^+$ ions, and countertransport 1 $K^+$ ion along with one glutamate molecule [5]. In contrast, the other family of transporters for most of the amino acid (except glutamate) and amine neurotransmitters, co-transport 2–3 $Na^+$ ions and $Cl^-$ ion [1].

### Process Regulation

Activation of kinases can modulate the activity of neurotransmitter transporters. Protein kinase C (PKC) activation inhibits the activity of gamma-amino butyric acid (GABA), serotonin, and glycine transporters. Glutamate transporters are also modulated by phosphorylation by PKC. Furthermore, several proteins have been shown to interact with neurotransmitter transporters and have effects on their activity. The most commonly observed way of dynamically regulating transport activity is thought to be the removal and recycling of the protein from the cell surface [6–8].

**Neurotransmitter Transporter. Table 1** Plasma membrane neurotransmitter transporters

| Name | Substrate | Coupling ions | Size (amino acids) |
|---|---|---|---|
| GLAST | L-Glutamate | $Na^+$, $H^+$ and $K^+$ | 543 |
| GLT1 | L-Glutamate | $Na^+$, $H^+$ and $K^+$ | 572 |
| EAAC1 | L-Glutamate | $Na^+$, $H^+$ and $K^+$ | 523 |
| EAAT4 | L-Glutamate | $Na^+$, $H^+$ and $K^+$ | 561 |
| EAAT5 | L-Glutamate | $Na^+$, $H^+$ and $K^+$ | 559 |
| GAT1 | GABA | $Na^+$ and $Cl^-$ | 598 |
| GAT2 | GABA | $Na^+$ and $Cl^-$ | 614 |
| GAT3 | GABA | $Na^+$ and $Cl^-$ | 602 |
| GAT4 | GABA | $Na^+$ and $Cl^-$ | 627 |
| GLYT1a | Glycine | $Na^+$ and $Cl^-$ | 633 |
| GLYT1b | Glycine | $Na^+$ and $Cl^-$ | 637 |
| GLYT2 | Glycine | $Na^+$ and $Cl^-$ | 798 |
| DAT | Dopamine | $Na^+$ and $Cl^-$ | 619 |
| SERT | Serotonin | $Na^+$ and $Cl^-$ | 630 |
| NET | Norepinephrine | $Na^+$ and $Cl^-$ | 617 |



**Neurotransmitter Transporter. Figure 2** Schematic Structural Organization of Neurotransmitter Transporters. (a) Schematic topology of $Na^+/Cl^-$-dependent transporters depicting 12 transmembrane domains connected by intracellular (*in*) and extracellular (*out*) loops. Y, potentially *N*-glycosylated asparagines residue. (b) Schematic topology of $Na^+/K^+$-dependent glutamate transporters showing the transmembrane domains (1–8), the "re-entrant hairpin loops" (A and B) similar to the ion-permeating pore of ion channels, and a "loop" that is predicted to extend partially into the "translocation pore" between transmembrane domains 7 and 8.

## Function

### *Glutamate Transporters [2,5,9]*

Glutamate transporters are well positioned to regulate extracellular glutamate concentrations, but their contributions to shaping excitation at glutamatergic synapses vary between different types of synapses. Glutamate transporters do not determine the decay rate of the synaptic currents in the hippocampus, whereas glutamate transporters (GLAST and EAAT4) are the dominant factors that determine the kinetics of excitatory postsynaptic currents (EPSCs) at the synapses from cerebellar parallel fibers and climbing fibers to Purkinje cells. Glutamate transporters clear glutamate not only inside the synaptic cleft, but also from the extracellular space outside the synapse. Thus, glutamate transporters play a critical role in the specificity of synaptic communication in the brain by determining the amount of glutamate efflux from the synaptic cleft and the distance it diffuses. Furthermore, glutamate transport by glial transporters triggers astrocytic glycolysis and release of lactate, which in turn nourish neurons and sustains neuronal activity.

### GABA Transporters [7]

GABA transporters regulate the extracellular levels of GABA, the main inhibitory neurotransmitter in the mammalian brain. Four distinct genes encoding GABA transporters have been identified (Table 1). A fraction of GABA transporters is located in the vicinity of symmetric synapses and are responsible for GABA uptake at inhibitory synapses, thus contributing to terminating GABA's action and to shaping inhibitory postsynaptic responses. A study of GABAergic synaptic transmission in the hippocampus of GAT-1 knockout mice supports this view, and suggests that GAT-1 deficiency results in elevated GABA levels, thus inducing post- and presynaptic changes in GABAergic synapses.

### Glycine Transporters [6,7]

Glycine exerts multiple functions in the central nervous system (CNS), as one of the major inhibitory neurotransmitters and as a positive modulator on glutamatergic neurotransmission through *N*-methyl-D-aspartate receptors. The synaptic action of glycine ends by active recapture through specific high-affinity glycine transporters located in neuronal and glial plasma membranes. Two genes encoding glycine transporters, GLYT1 and GLYT2, have been cloned (Table 1). GLYT1 is widely expressed in astroglial cells throughout the mammalian CNS, whereas GLTT2 is localized in the axon terminals of glycinergic neurons. Knockout mice deficient in glycine transporters revealed distinct roles of GLYT1 and GLYT2 in glycine-mediated synaptic transmission. GLYT1 is essential for regulating glycine concentrations at glycine receptors, whereas GLYT2 plays a critical role in replenishing the cytoplasmic pool of glycine that is needed for transmitter loading of synaptic vesicles in glycinergic nerve terminals.

### Dopamine Transporter [4,8]

Dopamine is a mediator of many functions, such as movement, emotion and cognition. The dopamine transporter (DAT) is present exclusively in neurons and is the primary mechanism for clearance of dopamine from the extracellular space. Deletion of DA in mice results in disrupted clearance of dopamine, an elevated extracellular concentration of dopamine and dramatically decreased intraneuronal storage of dopamine.

### Serotonin Transporter [4,8]

The serotonin transporter (SERT) plays a critical role in the maintenance of normal neurotransmission by serotonin, and is the primary target for several antidepressants and psychostimulants. SERT can be used as a marker of serotoninergic neurons because it is present exclusively on dendrites, perikarya, axons, and nerve endings of the serotoninergic neurons. The SERT knockout mice showed a six-fold elevation in the extracellular concentration of serotonin and a marked reduction (60–80%) in intracellular concentration.

### Norepinephrine Transporter [4,8]

Norepinephrine is an important neurotransmitter in the CNS. It regulates affective states, learning and memory, endocrime and autonomic functions. The norepinephrine transporter (NET) in the plasma membrane acts to terminate noradrenergic transmission by uptaking released norepinephrine back into the cell for cyclic use, and is a direct target of various antidepressants and psychostimulants. NET is a specific marker of noradrenergic neurons in the CNS. Similar to the findings obtained with DAT knockout mice and SERT knockout mice, the prolonged synaptic lifetime of noradrenaline in NET knockout mice results in elevation of the extracellular level of noradrenaline and depletion of intraneuronal stores.

The profound neurochemical alternations that were observed in mice lacking DAT, NET or SERT show that the plasma membrane monoamine transporters are crucial not only in terminating neurotransmission, but also in replenishing transmitter stores.

## Pathology

### Glutamate Transporters [2,5,9]

L-glutamate is the major excitatory neurotransmitter in the brain, and its interactions with specific receptors are responsible for most aspects of normal brain function including cognition, memory, movement, and sensation. However, high glutamate exposure triggers neuronal death, a process known as excitotoxicity. Excitotoxicity has been implicated as the mechanism of neuronal injury resulting from acute insults such as ischemia, epilepsy and trauma as well as chronic neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), Alzheimer's disease (AD), multiple sclerosis (MS) and HIV-1-associated dementia. The linkage between impaired glutamate transporter function and a rise in extracellular levels of neurotoxic glutamate suggests that transporter malfunction is a plausible mechanism of these neurologic diseases.

Increased extracellular glutamate during ischemia triggers the death of neurons. During ischemia, the reversal of glutamate transporter (particularly GLT1), due to the depletion of energy and the rundown of ionic gradients, leads to the release of glutamate into the extracellular space, exacerbating excitotoxicity in the ischemic region.

In ALS, a decrease in the glutamate transporter activity due to the reduction of the GLT1 in affected areas of the CNS, or the expression of aberrantly spliced transcripts from the GLT1 gene, are associated with impaired glutamate uptake and increased extracellular

levels of glutamate, resulting in excitotoxic damage to motor neurons.

### GABA Transporters [7,10]

Electrophysiological studies of human temporal-lobe epilepsy suggest that a loss of hippocampal GABA-mediated inhibition may underlie the neuronal hyperexcitability. Temporal-lobe epilepsy is characterized in part by a loss of reversal of GABA transport that is secondary to a reduction in the number of GABA transporters [10].

### Glycine Transporters [3,6]

GLTY1 knockout mice show severe motor deficits accompanied by lethargy, hypotonia and hyporesponsivity. This overall reduction of motorsensory functions is similar to the symptoms associated with glycine encephalopathy. GLYT2 knockout mice display a severe neuromotor disorder characterized by spasticity, muscular rigidity, tremor and impaired righting response. These symptoms are similar to those associated with human hyperekplexia. Although neither of the human GLTY genes has been linked to either disease, mutations in glycine receptors and enzymes responsible for degrading glycine have been implicated.

### Dopamine Transporter [4,8]

DAT is the major target for psychostimulants such as cocaine methylphenidate and amphetamine. The large increase in extracellular dopamine levels that are produced by these drugs result in continuous stimulation of target neurons, a key event leading to the rewarding action of cocaine and thus to addiction.

Mice lacking DAT display symptoms found in attention-deficit/hyperactive disorder (ADHD), and their increased locomotor activity is inhibited by the psychostimulants that are commonly used to treat ADHD. Furthermore, genetic studies indicate that the polymorphisms in the DAT gene is associated with ADHD.

DAT densities are affected in several brain disorders, including Parkinson's disease, Wilson's disease, Lesh-Nyhan disease, Tourette's syndrome, and major depression.

### Serotonin Transporter [4,8]

SERT is implicated in the etiology of various neurological or psychiatric syndromes. Previous studies have shown that midbrain SERT levels were reduced in patients with impulsive aggressive behavior, alcoholism or depression. Multiple polymorphisms are found in the 5′-flanking promoter region and in the second intron of the SERT gene. The two variants in the 5′ region are associated with different rates of SERT expression, and the one leading to the lower transcriptional efficacy seems to be more frequent in subjects with anxiety-related personality traits and in alcoholics with suicidal behavior. Moreover, the polymorphisms at the second intron seem to be associated with bipolar and unipolar disorders.

### Norepinephrine Transporter [4,8]

NET is a major target of tricyclic antidepressants and several psychostimulants. NET levels are reduced in the locus coeruleus in people with major depression. A single mutation in the coding sequence of NET has been linked to Orthostatic Intolerance.

# Neurotransmitters and Pattern Generation

Patrick J. Whelan
Hotchkiss Brain Institute, University of Calgary, Calgary, AB, Canada

## Synonyms

Neuromodulation of central pattern generators

## Definition

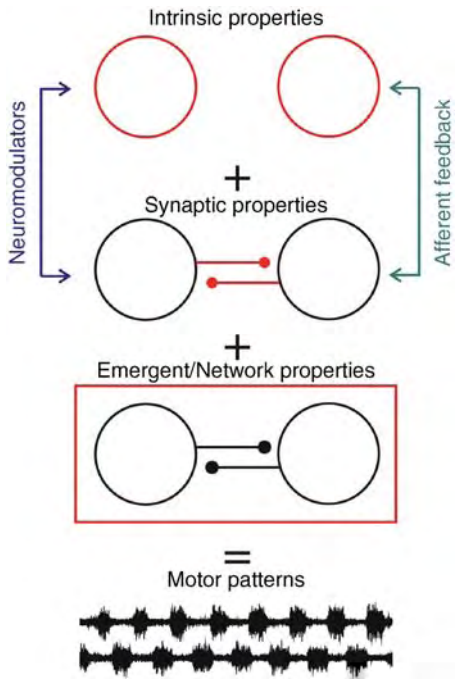
Many motor behaviors fundamental to life such as chewing, breathing, and stepping are produced by networks of interconnected neurons termed Central Pattern Generators (CPGs). CPGs are defined as networks of neurons that can generate rhythmic behaviors in the absence of phasic input. The motor outputs of CPGs are determined by a complex interaction between synaptic, cellular and network properties. This system ensures that CPGs can produce a rich ensemble of behaviors. The purpose of this essay is to describe the components of CPGs and briefly highlight how new technology is providing tools to unravel network architecture.

## Characteristics

### Introduction to CPGs

Perhaps the first experiments suggesting the existence of an intrinsic network of neurons that could produce rhythmic patterns were published in 1911 by Thomas Graham Brown [1]. These seminal experiments demonstrated that rhythmic activity of the hindlimbs of cats could be evoked for a short period after the spinal cord was fully transected. Since that time his observations have been confirmed in a number of species and for different behaviors. An important advance in the field was the development of ►in vitro techniques where tissue containing CPGs could be removed and maintained outside the body. Mainly as a result of these types of experiments it was found that CPGs are formed from interconnected groups of neurons whose output is a result of a complex interaction between cellular, synaptic and network properties [2]. The rhythmic behaviors they produce must be robust and yet be capable of being modified to meet the needs of the animal. Within motor control there have been a number of classic preparations used to examine motor rhythms such as the digestive centers of crustaceans, the lamprey and xenopus swimming centers, the heart beat system of the leech and the rodent locomotor network. Here we will discuss how synaptic, intrinsic and cellular properties contribute to network function (Fig. 1).

1. *Motor rhythms are often generated by neurons that have rhythmogenic capabilities (so called endogenous and ►conditional bursters*). Pacemaker cells have voltage-dependent ion channels that when expressed allow a neuron to oscillate and produce bursts of action potentials. Pacemaker cells come in two flavors; ►endogenous bursters can produce oscillations in the absence of synaptic input, while conditional bursters require synaptic input to produce oscillations. For example, the mollusk *Clione* moves through the water by alternating movements of its dorsal and ventral fins. Pacemaker interneurons critical to this behavior can generate a rhythmic membrane oscillation without external inputs. Ablation of these interneurons has established that these pacemaker neurons are necessary to produce fictive swimming. More commonly, pacemaker cells found in CPGs are conditional bursters. For example, in protovertebrates such as the lamprey, excitatory interneurons have been identified that are part of the swim CPG [3]. These excitatory neurons show oscillatory membrane properties that are N-methyl-D-Aspartate (NMDA) receptor dependent. The voltage-dependent conductances that produce endogenous and conditional oscillations can be controlled by external neuromodulators. In this way, the oscillation frequency, burst duration, and burst spike rate can all be modulated. More dramatically, cells with pacemaker properties can become non-oscillatory in a state-dependent manner. In invertebrate networks, the consequence of changes in these state-dependent properties can often be correlated with the output of the network. However, in mammalian networks that contain many thousands of cells it is difficult to ascribe a function to pacemaker cells. This is because of the redundancy that is inherent in complex interconnected networks. However, with the advent of genetic tools (see Future Directions) it may be possible to circumvent this issue by selectively silencing candidate interneuronal populations.



**Neurotransmitters and Pattern Generation.**
**Figure 1** Schematic illustrating the components of Central Pattern Generators that interact to produce rhythmic motor output.

2. *Intrinsic cellular properties can promote and stabilize motor rhythms.* Neurons are endowed with a rich set of voltage-dependent conductances that can sculpt the firing characteristics of a neuron to a given synaptic input [4]. Therefore, two cells with similar synaptic inputs can produce very different outputs. ►Intrinsic properties can have profound effects on the behavior of networks. For example, in many CPGs, alternating activity between populations of cells are mediated by mutual inhibitory connections. When one centre is active the other is inhibited. After inhibition is removed, the inhibited side "rebounds" with a burst of activity, which then inhibits the other population of cells, leading to rhythmic bursting behavior. Cellular properties can promote oscillatory behavior. One of these properties is spike frequency adaptation [3]. Progressive increases in ►intracellular $Ca^{2+}$ during a burst can lead to a longer after hyperpolarization thereby increasing the interval between spikes. This slowing in the spike rate over time reduces the inhibition of the mutually inhibited population of cells. Another intrinsic property that promotes oscillatory behavior is postinhibitory rebound. When cells that exhibit this property are inhibited, a long-lasting voltage-dependent mixed cationic conductance is often activated ($I_h$ current). When inhibition is removed this excitatory conductance is still active and pushes the membrane potential above rest making the cell more excitable. At a network level this boost in cellular excitability promotes activity on the formally inhibited side.
3. *Synaptic connectivity (inhibition/excitation) within the CPG is central for establishing patterns of output, such as alternation or synchronicity.* ►Synaptic properties are important for establishing the strength of connections between neurons in the network. For example, in many vertebrates, inhibitory commissural neurons couple together populations of cells that are rhythmically active and promote alternating activity between the two active populations. Interestingly, early in development intracellular chloride concentrations are high and as a result ►GABA and glycinergic (►glycine) effects are functionally excitatory. Therefore although the inhibitory commissural neurons still couple the two populations together, the bursting pattern is synchronized across the populations [5]. Thus changes in the sign of synaptic properties can fundamentally alter the motor pattern produced by CPGs. While chemical transmission is obviously critical, electrical synapses also contribute to network function. For example, in the pyloric rhythm of crustaceans, mixed synapses consisting of both chemical and electrical synapses can result in an activity-dependent reversal of sign. In vertebrate networks electrical synapses are common early in development, where they can lead to synchronization of cellular firing. One possible function of electrical synapses is to enhance network connectivity when the level of chemical transmission is low during embryonic stages of development [5]. It is now recognized that electrical synapses are also present in mammalian networks of adults, but their role is not well understood.
4. *CPGs are not static hard-wired networks.* A general principle of CPGs is that they can be reorganized to function in more than one motor task [6]. For example, the pyloric rhythm network in the stomatogastric ganglia of crustaceans consists of a network of 14 neurons connected by electrical and chemical connections. The pyloric rhythm activates striated muscles in the stomach, which helps push food through the digestive system, and is one of four networks within the stomatogastric ganglia. Neurons are able to switch from one network to another within the stomatogastric ganglia following administration of neuromodulators. Likely of importance to vertebrate systems, neuromodulators cause separate CPGs to blend together and even form entirely new networks. An intriguing possibility is that neuromodulators reconfigure vertebrate CPG circuits, similar to what occurs in invertebrate systems. Work on a variety of vertebrate preparations has demonstrated that 5-HT, noradrenaline and ►dopamine can modulate CPGs leading to the production of distinct patterns [5]. For example application of dopamine to the spinal cord can evoke a locomotor pattern that resembles walking whereas application of ►serotonin evokes a pattern closer to that of swimming. Of interest is how neuromodulators alter intrinsic and synaptic properties of interneurons that are components of the CPG. The lamprey system is arguably the best-described vertebrate system where 5-HT and dopamine's effects have been correlated to changes in cellular properties at the network level [3]. Both 5-HT and dopamine increase the duration of burst discharge thereby slowing the rhythm. The increase in burst discharge is due to actions on excitatory interneurons. Both neuromodulators act to decrease N, P/Q $Ca^{2+}$ conductances, thereby indirectly reducing the amplitude of apamin sensitive $K_{Ca}$ conductances. This leads to an increase in spike frequency and also results in longer lasting bursts of spikes. The cycle period increases because the increase in the population burst duration on one side ensures that inhibitory commissural interneurons inhibit activity on the opposite side. As a result of a longer period of inhibitory commissural activity it takes a longer time for the other side to "rebound" and the overall cycle period of the rhythm increases.
5. ►*Afferent feedback can affect the timing and pattern of CPG output.* Once networks are activated,

multiple changes in reflex sign and gain occur to allow afferent feedback to influence ongoing behavior. As a consequence, afferent feedback can stabilize the operation of CPGs and affect the timing and patterning of their output [7,9,10]. These types of observations have been made in many species performing diverse behaviors such as cockroach and cat walking, chewing in crustacea, feeding in the snail, scratching in the turtle and breathing in mammals. For example, under quiescent conditions, input from Golgi tendon organs that encode contractile force in extensor muscles has an inhibitory effect on motoneurons. However, when spinal CPGs are activated, input from extensor GTOs results in excitation of extensor motoneurons which delays the onset of the next flexor burst. Once CPGs are activated these effects are thought to occur by inhibition of the normal inhibitory pathway and an opening of a long-latency excitatory pathway. Afferent feedback can also select different patterns of CPG output. For example different scratch patterns in the turtle can be selected by afferent input from different regions. Similar types of results have been obtained when afferent input onto the gastric mill (crustacean chewing rhythm centre) is manipulated.

6. *Many of the patterns produced by CPGs are non-intuitive based on anatomical connectivity.* At first blush it would seem that once you understand what connects to what in a network you would be close to understanding its output. However, the output of a network also depends on the weighting of the connections, and the intrinsic properties of the neurons themselves. Importantly, these network, synaptic or intrinsic properties are interdependent and it is because of this interaction that many networks display ►emergent properties. An important tool for examining the dynamic performance of networks is to construct computational models [7]. For many reasons it is not realistic to model every parameter present in biological networks and all models make assumptions. Nevertheless, modeling a network offers several advantages for probing the operation of networks. For example, the effect of altering specific voltage-dependent conductances in a population of cells can be easily accomplished using a model, but is currently difficult to do experimentally. Modeling allows the exploration of parameter space that would be impossible to do experimentally which can lead to important insights into network function. Having said that, models should be able to offer predictions regarding network dynamics that can be tested experimentally. This process is important in order to validate the model as well as suggesting new avenues for exploration. An elegant example of the power of modeling is a study that took advantage of the stomatogastric ganglia system and demonstrated that multiple combinations of synaptic weights and intrinsic properties could produce similar network outputs in the pyloric network [7]. This type of insight would have been impossible to gain using conventional experimental techniques.

## Future Directions

One of the attractive features of some invertebrate networks is that the number of cells in the CPG is often manageable and the cells can be identified. This allows experiments to be performed where the output of these identified cells can be manipulated by injecting hyperpolarizing or depolarizing current. On the other hand vertebrate CPGs present several challenges for experimentalists. The underlying networks are large compared to invertebrates and furthermore different classes of inhibitory and excitatory cells are often not clustered into discrete regions. Examination of mammalian spinal networks provides a perspective on these issues. The interneurons involved in spinal CPGs are not localized to specific nuclei and thus have eluded ready identification [8]. Recently, genetic approaches have provided new tools that allow classes of interneurons within the spinal cord to be identified. These interneurons can be silenced chronically or acutely allowing experimentalists to test whether the output of the network is disrupted. For example, the excitability of a class of inhibitory interneurons was recently manipulated using an allatostatin based system to silence the cells acutely [9]. Allatostatin receptors are found in insects but are not normally expressed in mammalian systems. Allatostatin receptors activate GIRK channels which hyperpolarize cells. This means that when allatostatin is applied to the spinal cord only the classes of neurons in which allatostatin receptors were artificially introduced are hyperpolarized. At the moment these are among the best tools we have for determining whether certain classes of interneurons are important for regulating network function in mammals. Having said that, approaches that examine connectivity between oscillators will be easier to interpret compared to deletion of classes that are putatively part of the oscillator itself. One of the major issues here is addressing necessity and sufficiency. If deletion of a class of interneurons blocks activity, it is difficult to conclude that they are essential components of the network. This is because deletion of the ceus may transiently reduce the excitability of the network. However homeostatic mechanisms could compensate for this reduction in excitability. Likewise, if the perturbation produces no effect we cannot easily conclude that these cells are not part of the network. Therefore, we will need to develop techniques that rigorously examine the effectiveness of manipulation techniques at a population rather than a cell-by-cell

level. To do this we will need new tools to understand network function. Critically, we need to target candidate CPG interneurons and examine their connectivity within the network. It is clear that sampling the output of each neuron using intracellular recording techniques will not be sufficient to make conclusions regarding connectivity within the population of interneurons in mammalian networks. What is needed is perhaps the use of voltage sensitive dyes combined with genetic approaches that would double label populations of interest. In the future we will likely see the merging of these two approaches to examine network connectivity. Another critical test will be the ability to quickly activate and inactivate discrete populations of cells during network activity, like those performed in other preparations such as the STG network of crustacea. Once classes of interneurons that contribute to CPG function are identified, it will be necessary to test their ►in vivo functionality. The zebrafish embryo provides an example of what is possible. The zebrafish embryo is transparent and cells in the escape network can be visualized in the behaving animal [10]. This has allowed experimenters to ablate cells in the circuit and examine changes in behavior. While similar experiments in mammals will obviously be much more difficult, the use of multiphoton approaches in combination with genetic silencing approaches should allow new insights into the operation of mammalian CPG circuits.

# Neurotransmitters in the Auditory System

Ronald S. Petralia, Robert J. Wenthold
NIDCD/NIH, Bethesda, MD, USA

## Synonyms

Excitatory and inhibitory neurotransmission at synapses in the central auditory system and cochlea

## Definition

In the auditory (hearing) system, as in other parts of the nervous system, neurotransmitters are chemicals that cross a synapse and mediate nerve impulse transmission from one neuron to the next neuron, or from sensory cells (hair cells in the cochlea of the inner ear) to neurons, or from neurons to effector cells (in this case, the same sensory hair cells of the cochlea). Neurotransmitters typically excite or inhibit the neuron to enhance or reduce nerve impulse transmission, but they can also mediate long-term changes in the neuron, including maturation and learning. All of these functions involve interplay of different neurotransmitters, with some kinds modulating the effects of other kinds, to shape the response. For the auditory system, this results in accurate sound identification and localization, and the integration of audition with other sensory modalities and with locomotor responses.

## Characteristics

The auditory system is a complex system of interconnected neural centers extending from the sensory hair cells of the cochlea to the auditory cortex, and employs a wide variety of neurotransmitters and their receptors. As in other neural systems in the brain, neurotransmission in the auditory system largely involves a balanced release of excitatory and inhibitory neurotransmitters. The ascending excitatory neurotransmission from the cochlea to the cortex relays the transduced auditory information; along the way, the information is filtered and refined utilizing inhibitory neurotransmission. Excitatory neurotransmission is mediated primarily by glutamate, while GABA and glycine mediate inhibitory neurotransmission. In general, discussion here of excitatory connections within the brain will refer to glutamatergic-type connections, although the glutamatergic nature of the connection may not have been established definitively in all cases. In addition, a number of other neurotransmitter compounds (described below) can modulate neural responses in a variety of ways.

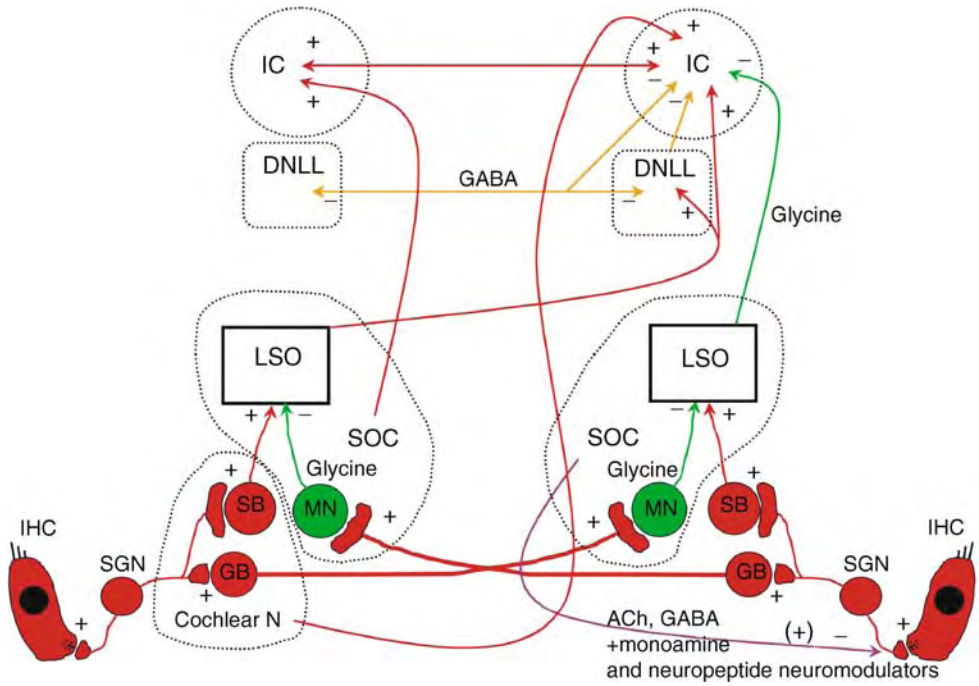
The auditory system serves to identify both the nature of a sound and its localization in space and time. In particular, sound localization requires unusually rapid

neurotransmission. Thus, several components of the auditory system are designed for this very fast transmission and include specialized ►glutamate receptors (GluRs) for fast excitatory connections, and a preference for glycinergic inhibitory neurotransmission over the somewhat slower GABAergic neurotransmission, as discussed below.

## Basic Patterns of Excitatory and Inhibitory Innervation in the Auditory System

The component structures making up the auditory system are numerous and their interconnections are complex [1–3]. They are discussed in detail in other essays in this encyclopedia and can only be summarized here (Fig. 1).

Sound elicits vibrations in the cochlea; these vibrations are increased and sharpened by outer hair cells (OHCs), which act as a cochlear amplifier. These vibrations are then transduced into nerve impulses by the inner hair cells (IHCs), which have a glutamatergic connection with afferent dendritic nerve endings from spiral ganglion cells. The latter send axons into the brain (auditory nerve) and these axons form glutamatergic connections with the ventral (VCN) and dorsal (DCN) cochlear nuclei. In addition to these IHC connections, OHCs form synapses with a small number of ganglion cells and these also send input to the cochlear nuclei, but their function is not well known. Axons from various neuron types in the cochlear nuclei form excitatory connections with the nuclei of the superior olivary complex (SOC) and lateral lemniscus (LL) and the inferior colliculus (IC). In the SOC, the best-studied nuclei include the lateral and medial superior olive (LSO, MSO) and the medial nucleus of the trapezoid



**Neurotransmitters in the Auditory System. Figure 1** *Simplified diagram of a sample of neurotransmission in the Auditory System.* Only a few of the main cell types, nuclei, and connections are shown. In the cochlea, sounds induce vibrations, which are amplified by OHCs (not shown), and these vibrations are transduced into nerve impulses by IHCs (IHCs). The first few connections are mainly rapid relays. IHCs form excitatory synapses (*red color*; +) with spiral ganglion neurons (SGN), and these form excitatory synapses with neurons in the cochlear nuclei. Within the cochlear nuclei, spherical bushy cells (SB) send excitatory input to LSO in the SOC. Beginning at this level, some more complicated connections allow neurons to compare sound input from both ears (i.e., for sound localization). LSO neurons receive ipsilateral excitatory input from SB and contralateral input from globular bushy cells (GB) via an excitatory synapse with neurons of the MNTB (MN). MNTB neurons make glycinergic inhibitory (*green color*; –) synapses with LSO neurons. In turn, cochlear nuclei and LSO and other SOC nuclei make excitatory and inhibitory connections with higher centers. Combination of excitatory (probably mainly glutamatergic) and inhibitory (GABA {*orange color*} or glycine {*green color*}) connections allows binaural integration of sound information at these higher centers (DNLL; IC). The latter brain regions then send connections to MGB, which connects to auditory cortex (not shown). In addition, sound transduction in the cochlea is modulated by the olivocochlear efferent input from the SOC to both IHCs and OHCs.

body (MNTB). The major excitatory connections from the cochlear nuclei are with the ipsilateral LSO, bilateral MSO, and contralateral MNTB. This contralateral MNTB then makes a glycinergic inhibitory connection with its ipsilateral LSO. Thus, the SOC is the lowest level where the ascending auditory inputs from the two ears converge. Next, the three nuclei of the LL (NLL) receive contralateral (i.e., monaural only) excitatory input from the cochlear nucleus. Convergence of auditory input is seen again in the IC, which receives contralateral excitatory input from the cochlear nuclei, LSO and other IC, ipsilateral excitatory input from the MSO, and ipsilateral glycinergic inhibitory input from the LSO. The IC also receives ipsilateral GABA, glycine and excitatory input from the three NLL, as well as GABA inhibitory input from the contralateral dorsal nucleus of the NLL (DNLL; i.e., 1 of the 3 NLL) and IC. The IC then sends glutamatergic excitatory and GABA inhibitory connections to the ipsilateral medial geniculate body (MGB) in the thalamus, and the MGB sends excitatory connections to the auditory cortex.

## Major Examples of Excitatory Inhibitory Control of Auditory Signal Processing

Many of the complex ipsilateral and contralateral excitatory and inhibitory connections discussed in the previous paragraph serve to localize sounds based on interaural intensity disparities (i.e., between the two ears). This is for high frequency sounds; for low frequency sounds, sound localization depends on interaural timing/phase differences. Basically, neurons that measure interaural intensity differences are excited by stimulation of one ear and are progressively inhibited by increasing stimulus intensity at the other ear, and are called EI neurons [1]. Neurons that act in this way are found in the LSO, DNLL and IC (Fig. 1). Although the combined roles of these three structures is not fully understood, the LSO may be responsible for the basic sound localization; it has an ipsilateral excitatory input, and an ipsilateral glycinergic MNTB input from neurons that receive a contralateral excitatory (cochlear nuclear) input. In contrast, the IC combines inputs from the LSO (excitatory contralateral and glycinergic ipsilateral) and DNLL (GABAergic bilateral) with other direct inputs, including those from the cochlear nuclei; the IC may utilize this input to distinguish the first sound from the typically abundant echoes that follow it.

While the previous examples look at the convergence of excitatory and inhibitory connections between different brain regions, most parts of the brain have local inhibitory interneurons within the brain structure, and these impinge on the principal excitatory (usually glutamatergic) neurons of that structure. This local inhibitory circuitry helps to refine the output of the excitatory principal neurons, making the response more specific. The best example of this is the auditory cortex [2], which has pyramidal neurons that send glutamatergic, descending efferent fibers to lower auditory structures. These excitatory neurons receive their major excitatory input from the MGB, and receive GABA-mediated inhibition from a variety of neuron types within the cortex. Another good example is the DCN [2]. Its (pyramidal) neurons project excitatory fibers to the contralateral IC (and MGB) and receive glutamatergic input from the auditory nerve onto their basal dendrites; the auditory nerve also provides glutamatergic input to small GABA and glycinergic inhibitory neurons that then form synapses on these basal dendrites. In contrast, the apical dendrites of these fusiform cells receive glutamatergic input from small, local ▶granule cells. Granule cells also form glutamatergic synapses on local glycinergic (+GABA) cartwheel cells and GABAergic stellate cells; both of these inhibitory neurons form synapses on the apical dendrites of the fusiform cells [4]. The major input to granule cells appears to come from somatosensory inputs from the external ear (pinna). Thus, basal dendrites receive auditory nerve input and associated inhibition and apical dendrites receive mainly somatosensory input and associated inhibition. This arrangement may allow the DCN to coordinate pinna orientation and sound localization [5].

Two notable exceptions to this pattern of principal excitatory neurons modified by local inhibitory neurons are found in the rat auditory system – almost all DNLL neurons are GABAergic and almost all MGB neurons are excitatory. The MGB may show an evolutionary trend, with almost no GABAergic neurons in rats and bats, while about 25% of the neurons in the MGB in monkeys and cats are GABAergic; this may reflect more complex auditory communication in the latter animals [2,6]. For rats and bats, refinement of the MGB output via inhibitory input depends on GABAergic fibers from the IC and the thalamic reticular nucleus; the latter inhibitory input may affect synchronization of MGB processing with general arousal.

## Specific Neurotransmitters of the Auditory System

Ideally, identification of a specific type of neurotransmission will include studies of neurotransmitters and their receptors, transporters and vesicular transporters using biochemistry, in situ hybridization and light and electron microscope immunocytochemical localization [7].

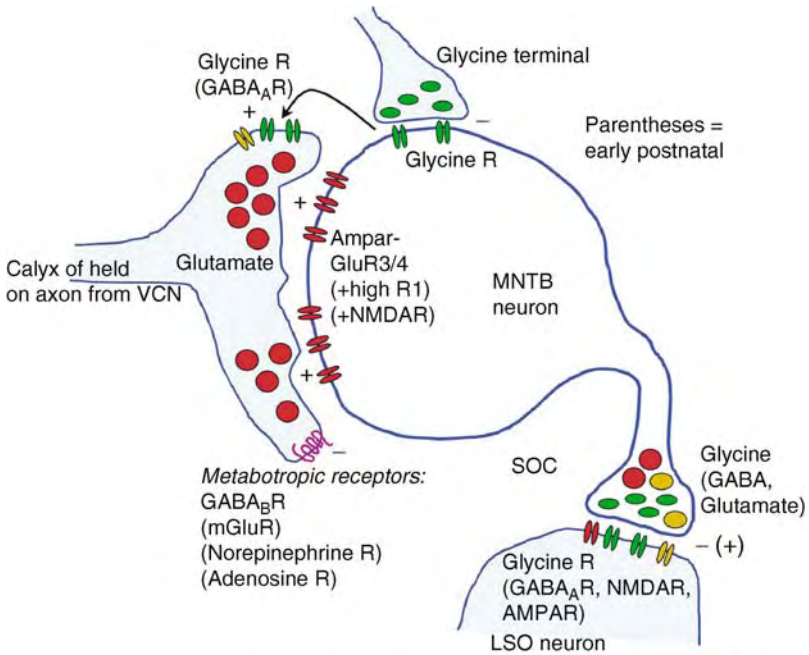
### *Excitatory Neurotransmitters*

As noted above, most excitatory neurotransmission in the auditory system is mediated by glutamate or related compounds; we also consider acetylcholine (ACh) neurotransmission in this section, because they classically are considered excitatory.

As noted above, glutamate or a related compound probably acts as the excitatory neurotransmitter for the IHCs, spiral ganglion neurons (auditory nerve), and

principal projection neurons in most auditory brain structures. However, for many of these excitatory projections, the glutamatergic nature of the neurotransmitter has not been determined definitively. GluRs are common at auditory nerve terminals, granule cell terminals, and other kinds of terminals in neurons throughout the cochlear nuclei [8]. Both ipsilateral and contralateral glutamatergic input was confirmed for the LSO, MSO, and another SOC nucleus [9]. Cochlear nuclear input that forms giant terminals, the calyces of Held, on neurons of the MNTB is also probably glutamatergic (Fig. 2). Other studies have supported the glutamatergic nature of inputs to the DNLL, various inputs to the IC, IC commissural connections, inputs from the central nucleus of the IC to the MGB, input from the IC and auditory cortex to the ventral division of the MGB, and in general the output of the auditory cortex, including that from the layer V pyramidal cells to the IC [2].

GluRs include ionotropic receptors, which form a sodium or calcium channel made up of four or five subunits, and metabotropic receptors, which link to G proteins to elicit long-term changes in neurons [7,8,10]. The major ionotropic GluRs that handle fast neurotransmission are AMPA receptors. AMPA receptors vary in function and properties depending on their subunit makeup (GluR1–4); the most common type contains GluR2 and passes sodium but is impermeable to calcium. While the latter type is common in many parts of the auditory system, some auditory synapses use a special kind of ▶AMPA receptor that contains primarily GluR3



**Neurotransmitters in the Auditory System. Figure 2** Example of how various neurotransmitters and their receptors are integrated in part of the auditory system, and how this changes during postnatal development. *Red, green, and orange colors* represent excitatory, glycinergic, and GABAergic neurotransmission, respectively, as in Fig. 1. During early postnatal development, some neurotransmitters and their receptors are present transiently (shown in parentheses in the diagram) and mediate synaptic plasticity, e.g., establishment of final synaptic connections and maturation of their physiological properties. The basic adult circuit shown here includes a thick axon from a VCN-globular bushy cell that forms a calyx of Held-glutamatergic synapse on a neuron of the MNTB. The postsynaptic AMPA receptors contain the GluR3 and GluR4 subunits; these mediate a fast relay of the signal. In addition, presynaptic receptors (mainly glycine and GABA) help to modulate the signal. The MNTB neuron then relays the signal via a glycinergic inhibitory connection with neurons in LSO in the SOC. However, during early postnatal development, neurotransmission is slower, being mediated through postsynaptic AMPA receptors that are high in GluR1 subunit, and through NMDA receptors, as well as being modulated by several neurotransmitters impinging on presynaptic receptors. These include $GABA_A$ ionotropic receptors (later replaced by glycine receptors) and $GABA_B$, mGluR (glutamatergic), norepinephrine, and adenosine metabotropic receptors (only $GABA_B$ remains common in adult). This early arrangement is required for maturation of this synapse. An even more radical change is seen during development of MNTB neuron synapses with LSO neurons. During early postnatal ages, these terminals secrete both excitatory and inhibitory neurotransmitters, although the adult synapse is just inhibitory. The early presence of glutamate and its associated receptors at an inhibitory synapse indicates the fundamental role that GluRs play in maturation of synapses.

and GluR4 (especially the "flop" subtype of GluR4), is calcium permeable, and is unusually fast – this facilitates the very rapid neurotransmission needed to effect the rapid relay of auditory information, such as needed for sound localization. For example, this type is found in the giant specialized endbulb-type glutamatergic synapses between the auditory nerve and the spherical ►bushy cells of the VCN, and in the ►calyx of Held between axons from globular bushy cells of the VCN and neurons of the MNTB (Fig. 2). Interestingly, neurotransmission at this synapse is relatively slow in early postnatal development, probably due to the prevalence of GluR1 in the AMPA receptors; neurotransmission becomes faster coincident with an increase in the prevalence of GluR3/4-containing AMPA receptors [11]. A similar reduction in GluR1 with development may occur in some kinds of neurons of the cochlear nuclei [7].

Another important ionotropic GluR is the ►NMDA receptor, which passes calcium and is implicated in neuronal plasticity during development and learning; it is most famous for its role in the establishment of long-term potentiation of synaptic current. Typical NMDA receptors contain the main subunit, NR1, combined with one or more NR2 subunits. NMDA receptor levels vary widely in the auditory system [2,8]) and they probably participate in modification of synaptic responses where they are prevalent; this may be particularly important for the development of many synapses (Fig. 2). In addition to typical NMDA receptors, there may be other, less studied forms containing subunits of NR3. NR3A is found in a number of auditory brain regions [12] and may form a special kind of excitatory glycine receptor when combined with the most common subunit, NR1.

Delta (δ) ionotropic GluRs are poorly understood and do not normally form a functional channel. Interestingly, the δ1 subunit is highly expressed in IHCs and ganglion cells of the cochlea [13]. Expression of δs is generally low in the adult brain, except in the cerebellum (δ2) and outer DCN [8]. In the DCN, δ labeling is high in granule cell-parallel fiber synapses of cartwheel cell neurons and those of apical dendrites of fusiform cells; δ is relatively uncommon in basal dendrites of fusiform cells. In contrast, in these fusiform cells, the AMPA receptor subunit, GluR4, and the metabotropic GluR, mGluR1α, are found only in synapses of basal dendrites. This differential distribution of GluRs is related to co-processing of functionally different sensory inputs on fusiform cells, as discussed above. Thus, fast auditory nerve transmission to basal dendrites probably requires high GluR4, while granule cell input to apical dendrites is a type that is not modulated by metabotropic GluRs. The need for high δ in synapses between granule cells and outer DCN neurons is not understood; probably the function of these synapses corresponds to that of similar δ2-containing, granule cell-parallel fiber synapses in the cerebellum and as in the latter, δ probably plays a modulatory role.

Cholinergic neurotransmission has been studied best in the olivocochlear system. This consists of special medial and lateral groups of neurons in the SOC that send efferent axons to outer and inner cochlear hair cells, respectively [2]. Those going to OHCs probably modify OHC function to enhance transduction or signal detection, while those associated with IHCs mainly form synapses on the afferent fibers beneath the IHCs and probably have a modulatory role. Interestingly, cholinergic neurotransmission that is mediated through α9/α10 nicotinic ACh receptors has an indirect hyperpolarizing effect on hair cells, and thus inhibits hair cell neurotransmitter release [14]. In addition to this efferent system to the cochlea, some cholinergic connections are seen throughout the auditory system. Both groups of olivocochlear efferents provide some collateral input to the VCN. There is also evidence for a substantial number of cholinergic neurons in the external cortex of the IC. Cholinergic input probably exerts regulatory influences on basic neural circuitry. ACh receptors in the auditory system include both nicotinic ionotropic and muscarinic metabotropic types. In particular, α7 nicotinic ACh receptors may be important during postnatal development throughout the brain auditory system [15,16]. Presynaptic α7 nicotinic ACh receptors at immature glutamatergic synapses, activated via diffusion of ACh from nearby cholinergic terminals, may facilitate glutamate release at these terminals and consequently help mediate maturation of these synapses [16]. The auditory system is also involved with the cholinergic system of the brain in an indirect way. Auditory stimuli activate cholinergic neurons in the reticular activating system in the brainstem; these neurons project ascending and descending tracts extending from the cortex to the spinal cord and provide an arousal mechanism that precedes locomotor response [17].

### *Inhibitory Neurotransmitters*

As noted above, both GABAergic and glycinergic inhibitory neurotransmission are prevalent throughout the auditory system [2,3,7]. Generally, inhibitory synapses may be distinguished from excitatory synapses by the shape of the vesicles (oval to flat in inhibitory and round in excitatory) and the proportion of pre/postsynaptic densities (thicker postsynaptic density in excitatory synapses). ►GABA receptors include both ionotropic ($GABA_A$) and metabotropic ($GABA_B$) types. A portion of the lateral group of neurons of the olivocochlear system, associated with IHCs, is GABAergic. In fact, in the mouse, GABA may co-localize with ACh in olivocochlear efferent terminals going to both IHCs and OHCs [18]. Auditory brain regions typically have mixtures of GABAergic and glycinergic neurons in different proportions. In the cochlear nuclei, inhibitory neurons and both GABA and ►glycine receptors are more common in

DCN than VCN. Other auditory brain regions send out particularly important groups of inhibitory fibers (as noted above) – GABAergic especially for those fibers from DNLL to IC and from IC to MGB, and glycinergic especially for those from MNTB to LSO, LSO to IC, and VNLL to IC. GABA and glycine can also occur in the same neuron populations. Glycinergic inputs tend to mediate faster neurotransmission than GABAergic. Not surprisingly, glycinergic neurotransmission may replace GABAergic neurotransmission in some neurons during postnatal development, as some auditory connections speed up (Fig. 2; as described above for a similar developmental change in AMPA-type GluRs). Thus, in the calyx of Held (glutamatergic) synapses on MNTB neurons, presynaptic glycine receptors replace $GABA_A$ receptors during postnatal development, coincident with development of inhibitory glycinergic input on postsynaptic MNTB neurons [19,20]. The presynaptic glycine receptors probably respond to spillover of glycine released from the nearby glycinergic synapses; activation of these presynaptic receptors enhances glutamate release from the calyx terminals. Another interesting association between excitatory and inhibitory neurotransmission at the same synapse is found in MNTB-neuron terminals in LSO (Fig. 2). During early postnatal development, these terminals release GABA, glycine and glutamate, and the postsynaptic membrane bears receptors for all three neurotransmitters [21]. Glutamate activation of NMDA receptors at these synapses probably mediates activity-dependent refinement of this inhibitory circuit. Finally, as this synapse matures, it becomes predominantly glycinergic.

### Monoamine Neurotransmitters/Neuromodulators

The monoamines (biogenic amines) include the catecholamines (dopamine, norepinephrine, and epinephrine), serotonin (=5HT), and histamine. They act as neuromodulators (►Monoamine Neurotransmitters/Neuromodulators) that activate second messenger systems in the affected neuron, thus modifying synaptic responses or having other broad effects on neurons. The auditory regions of the brain are widely innervated by different monoamines, especially norepinephrine (=noradrenaline; from locus coeruleus and other brainstem cell groups) and serotonin (from midline raphe nuclei of the brainstem reticular formation), although their function in the auditory system remains mainly speculative (e.g., [22–24]). Norepinephrine helps regulate glutamate release from the calyx of Held synapses on MNTB neurons, via inhibition mediated by presynaptic norepinephrine receptors (Fig. 2; [25]).

Both norepinephrine and serotonin are involved in arousal mechanisms, so they probably affect selective attention in the auditory system [17,22]. In the cochlear nuclei, norepinephrine may have effects on detection of sounds in noise and on timing mechanisms [23]. The cochlea contains norepinephrine, dopamine, and serotonin; changes in turnover of the former two occur in response to white noise [26]. Serotonergic fibers are closely associated with olivocochlear efferent fibers near the bases of IHCs and OHCs.

### Neuropeptides and Other Substances as Auditory Neuromodulators

A wide variety of ►neuropeptides are found throughout the auditory system and they modulate neuron excitability and other functions, usually via metabotropic receptors [27–29]. In the cochlea, opioid peptides and calcitonin gene-related peptide (CGRP) are found in the olivocochlear efferents; these innervate hair cells and afferents to IHCs (Fig. 2). Two opioid peptides, endomorphin-1 and dynorphin B, inhibit α 9/α10 nicotinic ACh receptor-mediated inhibition of hair cells (see above; [14]. Opioids are probably released from cholinergic efferent terminals when the firing frequency passes a certain threshold (e.g., after noise exposure), which is sufficient to induce exocytosis of opioid-containing large dense-core vesicles. Opioid secretion has been implicated in hyperacusis and peripheral tinnitus [14,28]. In auditory brain regions, neuropeptide input includes that from other auditory regions. For example, somatostatin is found in some neuron somata in VCN, some cells near LSO, and some cells of LL and IC [27]. The greatest convergence of neuropeptide innervation may be in the ventral nucleus of the trapezoid body (VNTB) and the small cell cap plus granule cell regions of the cochlear nuclei; these include substance P, CGRP, enkephalins, dynorphins, cholecystokinin, and somatostatin [28]. These peptides exert different effects  substance P strongly excites VNTB neurons, leu-enkephalin strongly inhibits VNTB neurons, and cholecystokinin can show either excitatory or inhibitory effects on VNTB neurons, while somatostatin modulates the release of other neurotransmitters.

There are probably numerous other substances that can act as neurotransmitters or neuromodulators. Nitric oxide (NO) can act as a neuromodulator in the brain and may be involved in NMDA GluR-mediated synaptic plasticity; NO has been described in IC [2] and cochlear spiral ganglion neurons [30]. The purine ATP can act as a neuromodulator in the cochlea in the spiral ganglion neurons, and specifically at their afferent synapses with hair cells. ATP activates ionotropic ►purine receptors (P2X) on spiral ganglion neuron membranes. This initiates a calcium influx that induces NO production in the neuron. Purines can also act on metabotropic receptors, including ATP-sensitive P2Y and adenosine-sensitive P1 receptors. Adenosine, converted from ATP that is probably secreted with glutamate from immature calyx of Held synapses, binds to presynaptic adenosine receptors (Fig. 2; see above), inhibiting glutamate release to help regulate high frequency neurotransmission at this synapse [31].

# Neurotransmitters in the Gut

## Definition

Enteric neurons synaptically communicate with each other using neurotransmitters. Acetylcholine (ACh) is the main transmitter mediating fast excitatory postsynatptic potentials (fast EPSPs, nicotinic in nature).

Many other neuroactive substances have also been identified as putative neurotransmitters for fast EPSPs

(ATP, glutamate) and slow EPSPs (serotonin (5-HT), substance P, vasoactive intestinal peptide (VIP), and other peptides) and inhibitory PSPs (noradrenalin, GABA, somatostatin) within the enteric nervous system. Furthermore, neurotransmitters released from enteric efferent neurons to intestinal effectors include: motor excitatory (substance P); motor inhibitory (ATP, nitric oxide, VIP, PACAP); and secretary (VIP). Many substances, including amines, amino acids and peptides may act as neuromodulators in the gut. So called braingut peptides are a group of peptides present both in the enteric and central nervous systems.

# Neurotrophic Factors

## Definition

Neurotrophic factors are a family of proteins responsible for the growth and survival of neurons during development and for the maintenance of adult neurons.

They are also capable of promoting damaged axons to regenerate after various peripheral and central nervous system injuries.

►Neural Development
►Neurotrophic Factors in Nerve Regeneration
►Regeneration
►Growth Factors

# Neurotrophic Factors in Nerve Regeneration

Matt S. Ramer, Lowell T. McPhail
International Collaboration on Repair Discoveries, the University of British Columbia, Vancouver, BC, Canada

## Definition

Neurotrophic factors (NTFs) are naturally-occurring multifunctional secreted proteins, expressed throughout development and into adulthood, and in part serve to promote neuronal survival, to support axonal outgrowth and target innervation, and in some cases to modulate synaptic transmission. This essay covers only their involvement in axonal regeneration. Three families of NTFs (the neurotrophins, the glial cell line-derived NTF family, and the ►interleukin-6 (IL-6) family), and their effects on regeneration of two classes of peripheral nerve axons (primary sensory axons, and the axons of lower motoneurons) are used to illustrate the principle that regeneration is often, but not always, accelerated or otherwise improved by endogenous or exogenous NTFs. Where known, mechanisms of action are also described.

## Characteristics

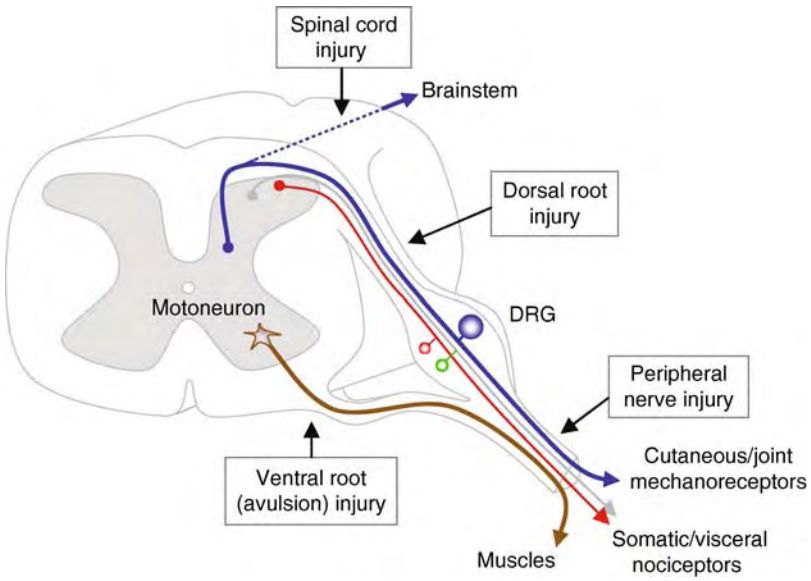
### Quantitative Description

#### *The Model Systems*

Vertebrate primary sensory neurons are pseudounipolar and clustered in bilaterally-symmetrical ganglia (dorsal root ganglia, DRG) adjacent to the spinal cord (Fig. 1).

Their single axon bifurcates within the DRG: one branch travels to the periphery where it innervates sense organs in skin, muscles or viscera; the other projects via the dorsal root to the spinal cord where it innervates spinal and/or supraspinal neurons. Most (~70%) DRG neurons detect temperature or noxious (painful) stimuli. These are small-to-medium in diameter, with thin, unmyelinated and slowly-conducting axons which innervate superficial spinal laminae centrally. Large diameter DRG neurons subserve proprioception and mechanoreception and terminate in deeper spinal laminae. Many of these axons also bifurcate central to their entry point within the cord and send a long projection via the dorsal columns to nuclei in the brainstem (Fig. 1). While injury to sensory axons can occur in any of these regions (peripheral nerve, dorsal roots and spinal cord), the differing environments in which the axons are injured dictate vastly differing outcomes: peripheral nerve injury can be followed by successful regeneration and target reinnervation; axons injured within dorsal roots regenerate up to the PNS: CNS interface, but do not penetrate the spinal cord; axons injured within dorsal columns do not regenerate at all, and may retract from the injury site for several hundred microns.

Lower motoneurons are situated in the ventral spinal cord and brainstem. Their axons exit the CNS via ventral roots or cranial motor nerves. Spinal motor axons join mixed spinal nerves just distal to the DRG, and innervate intra- and extrafusal muscle fibers in the periphery (Fig. 1). Motor axons can be injured anywhere along their length, but as with sensory axons, regenerative success depends on the site of injury: if axons are severed between their exit point in the spinal cord and their peripheral targets, they may regenerate and



**Neurotrophic Factors in Nerve Regeneration. Figure 1** The axons of sensory neurons located in the ►dorsal root ganglia (DRG) bifurcate, one branch travels to peripheral sensory organs; the other projects via dorsal roots to the spinal cord where it innervates spinal and/or supraspinal neurons. Small DRG neurons detect temperature or noxious (painful) stimuli. These are small-to-medium in diameter, with unmyelinated, slowly-conducting axons that innervate superficial laminae in the spinal cord. Large DRG neurons subserve proprioception and mechanoreception and terminate in deeper laminae. Many of the DRG axons also bifurcate central to their entry point within the cord and send a long projection via the dorsal columns to nuclei in the brainstem. Lower motoneurons are situated in the ventral spinal cord and brainstem. Their axons exit the CNS via ventral roots or cranial motor nerves. Spinal motor axons join mixed spinal nerves just distal to the DRG, and innervate muscle fibres in the periphery.

restore function; if they are avulsed (torn from the cord such that the injury site lies deep to the pial surface), regeneration fails.

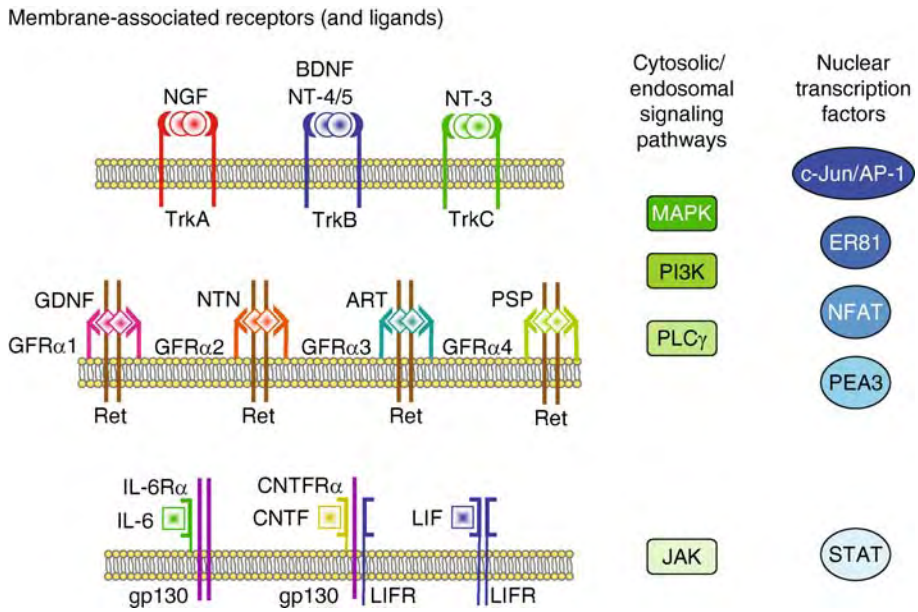
### *Neurotrophic Factors*

The first NTF to be discovered, based on its ability to promote neuronal survival and neurite outgrowth, was nerve growth factor (NGF). NGF is the prototypical member of a family which includes brain-derived NTF (BDNF), neurotrophin 4/5 (NT-4/5) and neurotrophin-3 (NT-3) (Fig. 2).

These molecules act through specific receptors: NGF binds to tropomyosin related kinase A (TrkA), BDNF and NT-4/5 bind to TrkB, and NT-3 binds to TrkC. All of these receptors are expressed in dorsal root ganglia, and (with the exception of TrkA) motoneurons. All neurotrophins also bind a receptor, ►$p75^{NTR}$, which is co-expressed with the Trks but whose role in regeneration remains enigmatic. The neurotrophin sensitivity of DRG neurons is subtype-specific and has been repeatedly demonstrated *in vitro* and *in vivo*: half of all nociceptors/thermoreceptors express TrkA (the other half do not express any Trk but do express GDNF receptor components), whereas the majority of mechano/proprioceptors express TrkC, and a minority express TrkB. Motoneurons express both TrkB and TrkC.

The glial cell line-derived NTF (GDNF) family includes GDNF, neurturin, ►artemin and ►persephin (Fig. 2). GDNF was isolated based on its ability to promote survival of midbrain dopaminergic neurons, and the rest were identified based on sequence homology. All GDNF family members have been shown to augment neurite outgrowth *in vitro*, but only GDNF and neurturin have proved to enhance regeneration *in vivo*. GDNF family members signal through receptor complexes which involve a common signaling component (►Ret) and ligand-specific binding components (GFRα1–4). GFRα1–3 are expressed in DRG neurons, mainly among thermo/nociceptors, while GFRα1, 2 and 4 are expressed by motoneurons.

Three members of the interleukin-6 (IL-6) family of neurotrophic ►cytokines will be considered here: ciliary NTF (CNTF), leukemia inhibitory factor (LIF) and IL-6 (Fig. 2). Peripheral nerve injury increases the exposure of severed axons to all three factors, which are synthesized in nonneuronal cells. IL-6 upregulation also occurs following axotomy in large-diameter DRG neurons and in motoneurons. These molecules share a common receptor component, gp130, but activate it through receptor complexes: IL-6 and CNTF first bind non-signaling receptor components [IL-6Rα and ►CNTFRα (Cilary Neurotrophic Factor Receptor)] and then to a gp130 homodimer (in the case of IL-6) or a



**Neurotrophic Factors in Nerve Regeneration. Figure 2** The neurotrophin family of NTFs consists of nerve growth factor (NGF), brain-derived NTF (BDNF), neurotrophin 4/5 (NT-4/5) and neurotrophin-3 (NT-3). NGF binds tropomyosin related kinase A (TrkA), BDNF and NT-4/5 bind to TrkB, and NT-3 binds to TrkC. The glial cell line-derived NTF (GDNF) family includes GDNF, ►neurturin (NTN), ►artemin (ART) and persephin (PSP). GDNF members signal through receptor complexes involving (Ret) and specific ligand binding components ►Glial cell line – Derived neurotrophic factor receptors (GFRα1–4). Three examples of the interleukin-6 (IL-6) family of neurotrophic ►cytokines are, ciliary NTF (CNTF), ►leukemia inhibitory factor (LIF) and IL-6. IL-6 members share the receptor component, ►gp130, but activate it through specific receptors: IL-6 with ►Interleukin-6 Receptor IL-6Rα, CNTF with ►CNTFRα and LIF with ►LIFR. Cytosolic/endosomal signaling pathways following NTF ligand receptor binding include; Phosphatidyl inositol-3-kinase (PI3K), mitogen-activated protein kinase (MAPK), Phospholipase C (►PLC γ) and Janus kinase (JAK). Transcription factors induced by NTF activated pathways include; ►c-Jun (AP-1), ►ER81, ►NFAT, PEAT and STAT.

heterodimer consisting of gp130 and ►leukemia inhibitory factor receptor (LIFR, in the case of CNTF). LIF signals through LIFR: gp130 heterodimers. All DRG neurons express gp130, IL-6Rα, and CNTFRα, while thermoceptors and nociceptors express LIFR. While LIFR, CNTFRα and gp130 are also found in motoneurons, data on motoneuronal IL-6R are lacking.

## Higher Level Processes

### *Positive and Negative Signaling Associated With Axotomy*

Peripheral nerve injury results in a switch in the neurons from a transmissive to a regenerative state. The change of state of the neuron is accomplished predominately by an alteration in activation and/or expression of transcription factors, resulting in a decrease in molecules involved synaptic transmission and a concomitant increase in regeneration-associated structural and cytoskeletal proteins. Injury-induced changes are mediated by three broad classes of signals. The first is the immediate entry of ions such as sodium and calcium into the open end of the proximal axon stump, resulting in depolarization. The two other signals are those related to the retrograde transport of molecules in the axon. There are those signals which appear as a result of injury (positive signals): factors released from cells at the injury site which have direct actions on the severed axons or are retrogradely transported to the cell body. There are also signals that disappear (negative signals) as a result of the interruption of retrogradely transported molecules from axonal targets. Positive signals include NTFs derived from Schwann cells and other non-neuronal cells at the site of injury. The loss of target-derived NTFs contributes to negative signaling. It has been proposed (although in many cases evidence is still lacking) that NTFs involved in both types of signaling promote regeneration: positive signals at the injury site may help begin the regenerative process, while target-derived signals may consolidate functional reinnervation. This reasoning has underpinned the application of exogenous NTFs following nerve injury *in vivo*.

### *Effects of NTFs at the Axonal Growth Cone*

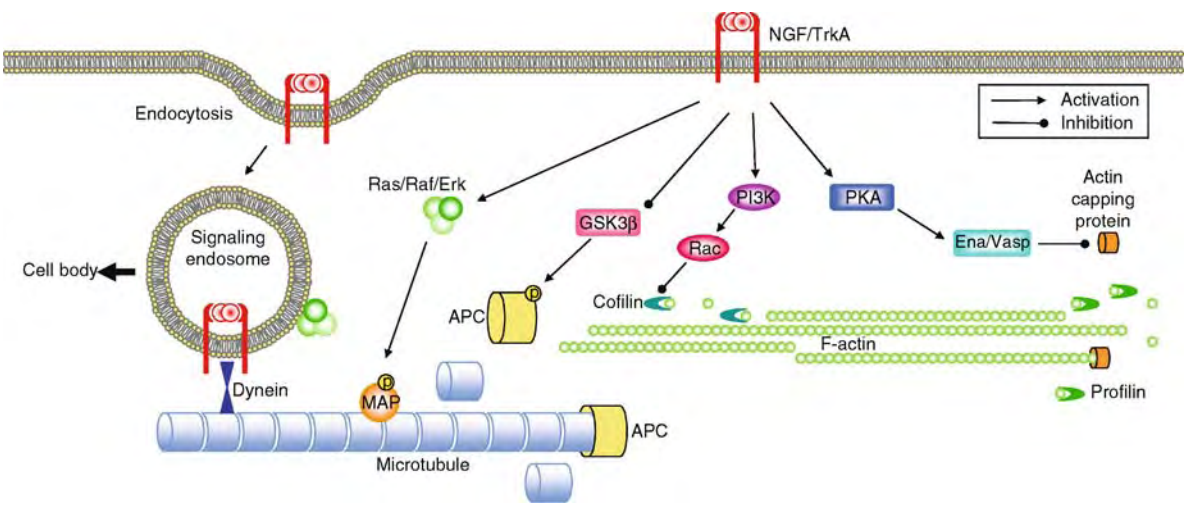
NTFs can promote regeneration through local signaling at the growth cone, where they act to increase the motility of filopodial actin and microtubules, the principal cytoskeletal elements governing growth cone

dynamics. This has been most clearly demonstrated for the Trk receptors, and for TrkA in particular [1] (Fig. 3).

tidyl inositol-3-kinase (PI3K) which leads to filopodial elongation via its effectors Rac and ►Cdc42, Rho family ►GTPases whose activation is generally associated with increased axonal outgrowth. Trk activation also leads, via increases in intracellular cyclic adenosine monophosphate (cAMP), to protein kinase A (PKA) activation, which has a number of positive effects on filopodial extension including activation of an actin anti-capping protein, ►Ena/VASP, the effect of which is to allow for profilin-mediated increases in filopodial length. Microtubule stability is another prerequisite for regenerative growth that is positively regulated by Trk signaling. Trk-mediated activation of a pathway including the kinases Ras, ►Raf and ►Erk2 (a mitogen-activated protein kinase, MAPK) results in phosphorylation of microtubule associated proteins (MAPs) leading to increased stability. More recently it has been shown that TrkA activation allows microtubule plus-end capping by adenomatous polyposis coli (APC), through inhibition of glycogen synthase kinase 3β (GSK-3β). In the absence of NGF signaling, GSK-3β phosphorylates APC, preventing microtubule plus-end capping, reducing stability and decreasing motility [2] (Fig. 3). GDNF family members also activate MAPK and PI3K pathways, and have similar effects on growth cone motility. IL-6-related NTFs are not known to have direct effects on cytoskeletal dynamics at the growth cone.

### *Effects of NTFs at the Neuronal Cell Body*

Receptor-bound NTFs, including NGF, BDNF, NT-3, and NT-4/5, CNTF and LIF, are transported from the growth cone and axon to the cell body where they can effect transcription of ►regeneration-associated genes (RAGs) (see essay in this Encyclopedia by H. Aldskogius). Such transport may be mediated by dynein-microtubule interactions, and is thought to involve a "signaling endosome", which includes, in addition to the neurotrophin receptor and its ligand, MAPK, PI3K and ►PLCγ pathway-associated signaling molecules [3] (Fig. 3). Therefore, the retrograde transport of the internalized neurotrophins and their receptor complex as well as the retrograde propagation of signaling pathways may work in concert to support survival and growth of the injured axon. Once at the cell body, retrogradely transported NTFs effect regeneration via both activation and *de novo* synthesis of appropriate transcription factors (TFs) (Fig. 2): the TFs CREB and ►NFAT (Nuclear factor of activated T cells) are both activated by retrogradely transported neurotrophins; NT-3 signaling results in the upregulation of ER81 while GDNF upregulates ►PEA3 – both are required for



**Neurotrophic Factors in Nerve Regeneration. Figure 3** NTFs promote regeneration through signaling at the growth cone or via signaling endosomes directed towards the cell body. TrkA binding results in the activation of phosphatidyl inositol-3-kinase (PI3K) and filopodial elongation/axonal growth via the ►GTPase Rac. Trk binding activates protein kinase A (PKA) producing filopodial extension and activation of an actin anti-capping protein, ►Ena/VASP allowing a profilin-mediated increased filopodial length. Trk-mediated activation of the kinases Ras, ►Raf and ►Erk2 (►Extracellular stress regulated kinase) results in phosphorylation of ►microtubule associated proteins (►MAPs) and increased microtubule stability. TrkA activation also allows microtubule plus-end capping by ►adenomatous polyposis coli (APC), through inhibition of ►glycogen synthase kinase 3β (GSK-3β). GDNF NTFs activate MAPK and PI3K pathways, and have similar effects on growth cone motility. IL-6-related NTFs have no known direct effects on growth cone motility. Following endocytosis, the ligand-receptor complex forms a signaling endosome and is retrogradely transported to the cell body via the microtubule associated motor dynein.

NTF-mediated outgrowth. The immediate-early gene product ►c-Jun, which associates with the AP-1 TF complex, is perhaps the best characterized downstream effector of NTF signaling. Not only is c-Jun upregulated following peripheral nerve injury in sensory and motoneurons, but also it is activated by ►Jun kinases (►JNK), recently shown to be downstream effectors of neurotrophin-dependent MAPK signaling [4]. Finally, retrograde signaling by IL-6 family members results in the activation of Janus kinases (JAKs) and the subsequent nuclear translocation of activated ►signal transducers and activator of transcription 3 (STAT3), effecting RAG expression (Fig. 2).

## Regulation of the Process

### NTFs and Regeneration of Sensory Axons

The majority of sensory neurons respond to either NGF, NT-3 or GDNF. Surprisingly little is known about the efficacy of these factors in enhancing regeneration of sensory axons following peripheral nerve injury, possibly because peripheral nerve regeneration is often successful. However, there appears to be little requirement for endogenous NTFs in naturally-occurring regeneration: axotomized TrkA- and TrkC- expressing nociceptive and mechanosensitive axons, for example, reinnervate their peripheral targets normally in the presence of antibodies which block NGF and NT-3 [5]. The effects of exogenous NTFs have been more clearly demonstrated following dorsal root lesions [6]: while sensory axons normally fail to regenerate beyond the PNS:CNS interface, NGF, NT-3 and GDNF treatment resulted in the regrowth of appropriate populations of axons into the spinal cord. Furthermore, regrowth was accompanied by functional recovery, which was demonstrated both electrophysiologically and behaviorally. Mechano/proprioceptive axons injured within dorsal columns are also able to regenerate when treated with NT-3, but not with BDNF or GDNF [7].

The neurotrophic cytokines LIF and IL-6 do not induce neurite outgrowth form ►DRG neurons directly, but collaborate with other growth-promoting factors or manipulations: LIF enhances DRG neurite elongation in NGF-treated cultures, and IL-6 has a similar effect in cultures treated with either NGF or NT-3 [8]. *In vivo*, peripheral nerve regeneration is impaired in LIF knockout mice [8]. Additionally, the growth-enhancing effect on axotomized dorsal column sensory axons of a prior peripheral nerve "conditioning" injury was abolished in the absence of IL-6 [8]. No data are available on the effect of CNTF on sensory axon regeneration.

### NTFs and Regeneration of Motor Axons

While direct actions of NTFs on sensory axons are evident from their differential effects on distinct subpopulations of adult DRG neurons, the same cannot be said for adult motoneurons, which are more homogenous and, by virtue of their poor survival in isolation, difficult to study *in vitro*. Like DRG neurons, motoneurons do not appear to require endogenous NTFs for successful axonal elongation, since function-blocking antibodies against BDNF, CNTF and GDNF (the most potent motoneuronal NTFs) do not prevent axonal elongation following injury to the facial nerve (a purely motor nerve) [9]. On the other hand, exogenous NTFs, including BDNF, NT-3, GDNF, CNTF and IL-6, have been shown to improve functional recovery, and in several cases increase muscle innervation, following peripheral nerve injury or ventral root avulsion. Despite these findings, it is as yet unclear how exogenous NTFs promote functional recovery. Motoneuron survival following axotomy (particularly following ventral root avulsion injury), collateral sprouting of spared axons, and even trophic or migration-enhancing effects on nonneuronal cells are all able to explain increased target reinnervation and improved motor performance [10]. While all of these factors have well-described survival promoting effects on motoneurons, there is as yet little evidence supporting direct effects of NTFs on the regeneration of motor axons *in vivo*.

## Neurotrophin 4/5 (NT-4/5)

### Definition

Neurotrophin 4/5 is a neurotrophic factor that has been shown to have a protective effect on the survival of retinal ganglion cells.

►Regeneration of Optic Nerve
►Retinal Ganglion Cells

## Neurotrophins

### Definition

Neurotrophins are molecules important for the health and maintenance of neurons. They are structurally and functionally related to nerve growth factor, the first identified neurotrophin, and signal through high affinity tyrosine kinase receptors (Trk A-C) and a low affinity p75 neurotrophin receptor. Neurotrophins can stimulate neurite outgrowth and act as a long-range diffusible guidance cue. In addition, neurotrophins can stimulate gene expression and promote neuron survival.

►Neural Development
►Regeneration

## Neuroturin

### Definition

A member of the glial cell line-derived neurotrophic factor (GDNF) family of neurotrophic factors that also includes artemin and persephin. GDNF family members use a receptor complex that consists of the common receptor tyrosine kinase signaling component Ret and one of the GPI-linked receptors (GFRα1 to 4) that regulate ligand binding specificity. GFRα2 is the preferred receptor for neuroturin.

►Glia Cell Line-derived Neurotrophic Factor

## Synonyms

Cell signaling; Molecular pharmacology; Signal transduction

## Definition

Approximately 1% of the genome of higher organisms encodes the family of G protein-coupled receptors (GPCRs). These receptors are characterized by containing seven transmembrane domains, being linked to guanine nucleotide-binding proteins (GTP-binding proteins) and ubiquitously distributed on the plasma membrane of all cell types. The first wave of research into these molecules identified family members, assigned coupling to individual GTP-binding proteins, characterized signaling pathways and elucidated the molecular apparatus by which GPCRs are switched off and recycled back to the membrane. A new wave of GPCR research is underway, looking at the more complex relationship that these molecules have with a variety of processes both cellular and pharmacologic.

## Characteristics

### Dimerization/Oligomerization

Although protein-protein interactions have been shown to be instrumental in the organizational structure and function of many cell signaling processes, it has been the belief that G protein-coupled receptors occur and function as monomeric, non-interacting species. However, it has become clear that a number of GPCR species can form dimers (both ►GPCR homodimers and ►GPCR heterodimers) and/or larger oligomeric (►GPCR oligomer) complexes. Although the precise cellular function of GPCR homodimerization is unclear, a number of roles have been proposed for this process. These revolve around the participation of dimerization at the level of synthesis or during protein maturation in the Golgi apparatus and result in the successful delivery of the protein to the cell surface. Crucial to the process is the involvement of specific dimerization motifs that occur in various structural domains within the protein. Disruption of such a motif in TMD VI (transmembrane domain VI) of the β2 adrenoceptor resulted in loss of homodimerization and subsequent insertion of this receptor into the plasma membrane. With over 400 genes encoding non-sensory GPCRs now having been identified, it is no surprise that co-expression and subsequent dimerization between different receptor species has been observed. Heterodimerization has been proposed to promote the formation of receptors with unique pharmacological properties, contributing to the pharmacological diversity of GPCRs. Jordan and Devi [1] first provided biochemical and pharmacological evidence for a fully functional heterodimer comprising kappa and delta opioid receptors. This new formation resulted in a novel receptor that exhibited ligand binding and functional properties distinct from those of either receptor. Furthermore, the kappa-delta heterodimer synergistically binds highly selective agonists and potentiates signal transduction. More recently, other heterodimer receptor pairs including the orexin-1 receptor (►Orexin receptor) and cannabinoid CB1 receptor dimer and the angiotensin AT1 receptor and bradykinin B2 receptor dimer have been identified. These have been demonstrated to display changes in GTP-binding protein-coupling specificity as well as altered receptor-mediated endocytosis.

### GPCR – Protein Complexes in Living Cells

In addition to binding to protein and peptide ligands, GTP-binding proteins and forming complexes amongst themselves, GPCRs also appear to interact with a large and diverse group of proteins that have a role in a number of receptor functions including trafficking, signal transduction, desensitization (►Receptor desensitization) and down-regulation and receptor recycling. Candidate molecules for interaction include ►GPCR kinases (GRKs), arrestins, protein kinase A, protein kinase C, molecular chaperones and receptor activity-modifying proteins (RAMPs). The use of novel biophysical techniques such as fluorescence resonance energy transfer (FRET) and ►bioluminescence resonance energy transfer (BRET), which utilize energy transferred from a fluorescent donor to an acceptor molecule, has allowed observation of protein-protein interactions to be analyzed in real time in living cells.

The receptor-activity-modifying proteins (RAMPs) are single transmembrane proteins that heterodimerize with GPCRs. To date 3 RAMPs (RAMP1,2,3) have been molecularly identified. Calcitonin-gene-related peptide (CGRP) and adrenomedullin are related peptides with distinct pharmacological profiles and signaling pathways. Each of these ligands function through the calcitonin-receptor-like receptor (CRLR). It is association with the various RAMPs that determines ligand specificity. RAMP1 presents the receptor at the cell surface as a mature glycoprotein and a CGRP receptor whilst RAMP2-transported receptors are core-glycosylated and are adrenomedullin receptors. Adrenomedullin and CGRP receptors are potential therapeutic targets for several diseases including

migraine, hypertension, pulmonary hypertension and sepsis. Thus, understanding how ligand binding to the receptor complex is regulated by RAMPs is crucial for the development of pharmaceutical agents. Recent studies showing association of RAMPs with other GPCR families has broadened the importance of this class of accessory proteins [2].

## Inverse Agonists/Constitutive Activation

GPCRs are able to achieve and maintain a spontaneously active conformation that results in a constitutively active receptor, a process termed ►negative efficacy.

Certain ligands (termed inverse agonists) have been demonstrated to decrease this ►constitutive activation. Indeed, many drugs that were originally classified as neutral antagonists, including prazosin, pirenzipine, trihexylphenidyl and losartan, can now be reclassified as inverse agonists (►Inverse agonism). In 1996, five GPCR subtypes (δ opioid receptor, β2 adrenoceptor, 5-$HT_{2C}$ receptor, bradykinin B2 receptor, M1 muscarinic acetylcholine receptor) were noted to display negative efficacy. At present several dozen constitutively active GPCR subtypes have been identified [3]. Although original studies used systems that overexpressed GPCRs, native GPCRs expressed at normal levels demonstrate constitutive activity. In addition, this activity has a physiological role. For example, in rat brain synaptosomes, inverse agonists, but not competitive antagonists, acting at the $H_3$ histamine receptor suppress $K^+$-induced release of histamine. Thus a degree of constitutive $H_3$ receptor activity in presynaptic terminals *in vivo* limits histamine release [4].

Furthermore, the existence of this phenomenon has allowed for the consideration of inverse agonists to be used as pharmacotherapeutic agents. In diseases where mutation in receptors results in increased constitutive signaling via the receptor (such as male precocious puberty where there is a mutation in the LH receptor in the testes that results in early onset of puberty), use of an appropriate inverse agonist could eliminate the constitutive activity of the receptor [3]. A number of pharmacological agents originally determined to be neutral antagonists but now reclassified as inverse agonists, are in use within a clinical setting. Included in this category are a series of dopamine D2 receptor ligands including haloperidol, clozapine and olanzapine, that are currently used in the treatment of schizophrenia [5]. Similar results were obtained demonstrating that the putative antipsychotic agents L-745,870 and U-101958, thought to be dopamine D4-specific antagonists, display inverse agonist effects at this receptor [6].

## Free Fatty Acids as GPCR Ligands

Although originally thought primarily as direct energy sources, free fatty acids also play key roles in regulating a variety of physiological effects. Although these responses were thought to occur as a consequence of their metabolism, it is now clear that free fatty acids including α-linolenic acid and docosahexanoic acid, function directly as agonists at GPCRs. The breakthrough came when a series of orphan GPCRs (►Orphan receptors) were identified from a variety of human tissues. Although most were involved with glucose metabolism in pancreatic β-cells, one, ►GPR40, was highly expressed in brain. This receptor couples to the Gq/G11 group of GTP-binding proteins and when activated by the FFA palmitate, results in substantial elevation in intracellular calcium. Although the physiological role of these receptors in brain is unclear, it has been speculated that they may play a fundamental role in the neurological disorders of aging, Alzheimer's disease, Parkinson's disease, and stroke [7].

## Addiction, GPCR Desensitization and Tolerance to Drugs

It has been well characterized that desensitization of agonist-occupied GPCR occurs first through phosphorylation of the receptor by GPCR kinases (GRKs) then subsequent binding of the phosphorylated receptor to arrestins that uncouple it from GTP-binding proteins. This in turn targets the receptors for internalization via clathrin-coated vesicles.

The frequent administration of certain drugs leads to the development of tolerance to the effects of the drug. This is best characterized by opiates such as the alkaloid morphine where the analgesic, rewarding and respiratory effects of the drug are diminished upon repeated administration, limiting its clinical usefulness (see Chapter on ►Tolerance and Dependence). Morphine causes its behavioral effects by activating μ opioid receptors, an effect verified by the loss of drug effects in μ opioid receptor knockout mice [8]. This receptor subtype couples to Gi/Go activating inwardly rectifying potassium channels, inhibiting voltage-activated calcium channels and decreasing intracellular cAMP levels through inhibition of adenylyl cyclase. As with other GPCRs, the μ opioid receptor is rapidly desensitized upon activation with agonist. However, the route of signal attenuation is dependent on the type of agonist activating the μ opioid receptor. DAMGO, a high-affinity peptide agonist, induces desensitization through GRK whereas morphine, which is a partial agonist at these receptors, desensitizes the GPCR through activation of protein kinase C. Although tolerance to morphine is a multi-faceted process, it is recognized that adaptive changes at the level of the μ opioid receptor is an important factor in tolerance in the intact animal. Indeed, there are numerous reports that implicate protein kinase C in both acute and chronic tolerance to the analgesic properties of opioids. Such studies employ the use of protein kinase C inhibitors such as H7 and bisindolylmaleimide to reverse tolerance in animals even when they are administered some

days after morphine infusion [9]. Thus the development of inhibitor drugs, to be used in negating tolerance to morphine, increasing the clinical efficiency of opiate drugs and reducing the social problems that accompany recreational opioid abuse, is of prime importance.

The 5-$HT_{2C}$ receptor is used as a target for drug addiction. Agonists at this receptor have been demonstrated to moderate addiction-related behaviors such as hyperactivity, place preference and compulsive behavior connected with common recreational drugs including cocaine, alcohol, nicotine and cannabinoids. However the use of such agonists is associated with a series of unwanted adverse effects including anxiety, hypophagia, hypolocomotion and disturbances of motor function. Activation of these receptors with agonists results in receptor phosphorylation then dephosphorylation, anevent demonstrated to mediate many of the adverse effects associated with addiction. One new strategy in the treatment of addiction has been to prevent the dephosphorylation of the receptor by inhibiting ►PTEN, the phosphatase responsible, with specific peptides that blocks its interaction with the receptor. This mimics the agonist activation process but suppresses the adverse effects associated with dephosphorylation [10]. This approach could lead to a more effective strategy for the treatment of drug addiction.

# Newtonian Mechanics

## Definition

A formulation of the laws of mechanics based on Newton's approach, whereby forces are primary quantities to be related to the motion of the system by certain vectorial laws. In the case of particle mechanics, these laws are essentially those formulated by Newton himself. In continuum mechanics, this approach is generalized by (i) the introduction of appropriate balance laws in terms of densities, (ii) the independent postulation of the balance of angular momentum and (iii) the inclusion of the first and second laws of thermodynamics for continuous systems.

## Definition

### Neural Stem Cells

Stem cells are defined as undifferentiated cells with the ability to (i) proliferate, (ii) exhibit self-maintenance, (iii) generate a large number of progeny, including the principal phenotypes of the tissue, (iv) retain their multilineage potential over time, and (v) generate new cells in response to injury or disease.

Neural stem cells can be found within their complex niche in the mammalian brain. Neural stem cells could be maintained in culture via propagation of floating cell clusters called "neurospheres." Neurospheres contain committed progenitors, differentiated astrocytes, neurons and neural stem cells. A progenitor is defined as mitotic cell with a fast cell-devision cycle that retains the ability to proliferate and give rise to terminally differentiated cells but that is not capable of indefinite self-renewal.

### Nuclear Factor-κB

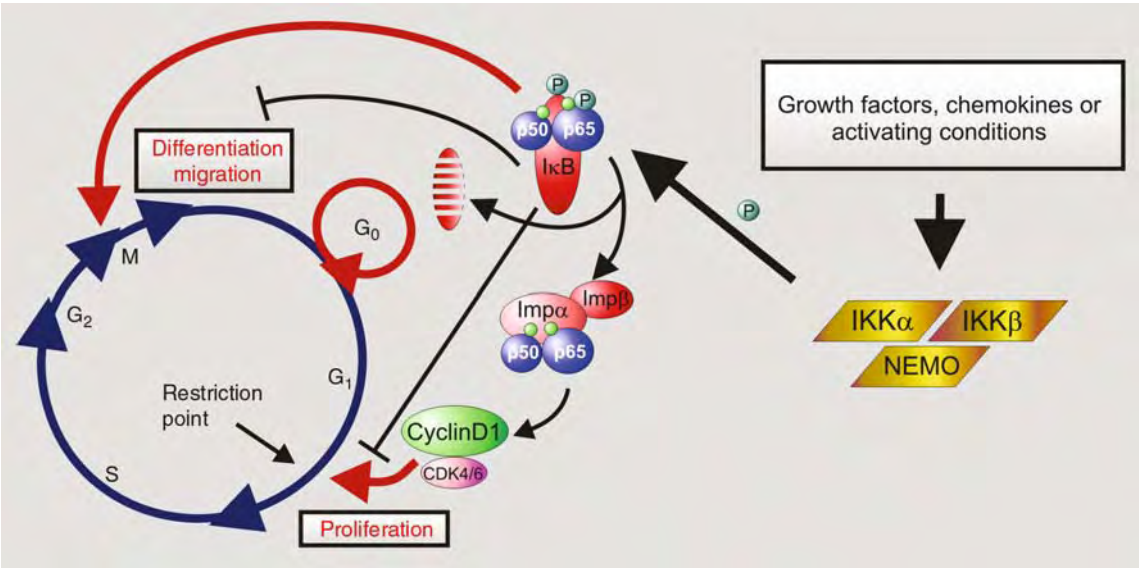
Nuclear factor kappa B (NF-κB) is a ►transcription factor (TF) composed of homo- or heterodimeric DNA-binding subunits (e.g., p50 and p65). Inducible forms of NF-κB reside in the cytoplasm due to an interaction with one inhibitory subunit (e.g., IκB-α). Upon activation by growth factors, etc. (see Fig. 1), the IκB Kinase complex (IKK) catalyzes phosphorylation of the inhibitory subunit IκB, which leads to proteasomal degradation. This exposes the nuclear localization signals (see green dots in Fig. 1). Nuclear import of NF-κB via importins activates transcriptional target genes driving ►proliferation, such as Cyclin D1 (see Fig. 1). NF-κB is involved in many biological processes, such as inflammation and innate immunity, development, apoptosis and anti-apoptosis [1]. In the nervous system NF-κB plays a crucial role in neuronal plasticity, learning, neuroprotection and neurodegeneration. In addition, recent data suggest a crucial role of NF-κB on proliferation, migration and ►differentiation of neural stem cells.

In the $G_1$ phase, NF-κB activates cyclin D1 expression by direct binding to multiple sites in the cyclin D1 promotor. This promotes $G_1$-to-S progression. In contrast, NF-κB action in the M-phase leads to differentiation or migration induction.

In this essay we suggest a model explaining the multiple action of NF-κB within neural stem cells.

### CNS

The Central Nervous System (CNS, systema nervosum centrale), consisting of the brain and spinal cord is one of the two major parts of the nervous system. CNS integrates all nervous activities. The second part is the peripheral nervous system (PNS) which is outside the brain and spinal cord and regulates e.g., the heart muscle, the muscles in blood vessel walls or glands.



**NF-κB – Potential Role in Adult Neural Stem Cells. Figure 1** Model for the involvement of NF-κB in the molecular machinery of the cell cycle essential for proliferation, differentiation and migration of neural stem cells. Activation of IKK complex and subsequent NF-κB activation via growth factors, chemokines or activating conditions leads to ubiquitination and proteasomal degradation of IκB. After nuclear translocation NF-κB binds to specific promoter regions of the target genes and activates their transcription. Depending on the cell cycle point these targets are genes regulating proliferation or migration and differentiation.

On the cellular level, CNS consists of a network of nerve cells, glial cells (e.g., astrocytes and microglia) and neural stem cells. Neurons, the primary cells of the CNS, are responsible for information processing and storage. Glial tissue surrounds and supports neurons and is important for response against infection and tissue repair (e.g., microglia). Novel data define astrocytes and radial glia as a potential stem cell pools.

## Characteristics

### Adult Neural Stem Cells

Until recently, the dogma existed that stem cells are not present in the adult CNS. Currently, there are many reports clearly demonstrating neurogenesis in different regions of the adult brain [2,3]. Stem cells within the adult brain were found within the subgranular zone of the hippocampus and in the subventricular zone (SVZ). The immunocytochemical markers expressed by NSCs include inter alia the intermediate filament Nestin, the transcription factors Sox1 and Sox2, the RNA binding protein Musashi and the transmembrane protein prominin-1(CD133) (see Table 1).

Isolated and cultured NSCs may have the ability to replace lost cells within the central nervous system, - an important issue for future therapy of neurodegenerative diseases as Parkinson's and Alzheimer's disease. Moreover NSCs also offer hope for fighting against cancer by the delivery of chemotherapy agents directly to tumor cells.

### NF-κB in the Nervous System

In the nervous system, the most frequent form of NF-κB is a heterodimer composed of p50 and p65. Activating stimuli like ▶Tumor Necrosis Factor (TNF) (see Fig. 2) or Erythropoietin (EPO) activate a kinase complex composed of two IκB-specific kinases (IKKα and IKKβ) and a modulatory subunit (IKKγ/NEMO). The IKK-α/β complex phosphorylates the inhibitory IκB, which is then ubiquitinilated and degraded via the proteasome. This degradation triggers the translocation of NF-κB into the nucleus followed by initiation of transcription. For a detailed discussion on the action of NF-κB in the CNS see also [4,5 and 6].

Apart from the inducible NF-κB activity, there are reports on constitutively active NF-κB in several cell types, such as hippocampal neurons, or numerous brain-related cancer types such as gliobastomas.

### NF-κB and Neural Stem Cell Proliferation

Most of the culture protocols for NSCs use bFGF (FGF-2) and EGF for keeping the cells in undifferentiated and proliferating state [2–3]. Over the years many additional molecules and cultivation conditions were identified to influence the NSC proliferation (see Table 2).

Here we summarize several evidences for a crucial involvement of NF-κB in proliferation control.

An enhanced proliferation of NSCs in vitro and in vivo after Erythropietin (EPO) treatment has been reported. Demonstrably, the authors provide evidence

**NF-κB – Potential Role in Adult Neural Stem Cells. Figure 2** TNF-induced nuclear localization of the transactivating NF-κB subunit p65 in neural stem cells. NSCs were fixed and stained with an antibody against the p65 subunit of NF-κB. Nuclei (DNA) were stained with SYTOX (*green*). The activation of the NF-κB pathway is shown as nuclear translocation of NF-κB visualised using an antibody against the p65 subunit. The nuclear translocation of NF-κB is followed by the transcription of target genes responsible for proliferation, migration and differentiation of neural stem cells.

that EPO is a homeostatic autocrine-paracrine signaling molecule with actions mainly mediated by NF-κB [7].

EPO and EPO receptors are upregulated in the CNS after hypoxia. Similarly, hypoxia activates NF-κB in neonatal rat hippocampus and cortex. Under hypoxic conditions, hypoxia-inducible-factor1α (HIF-1α), an important transcription factor for regulation of the oxygen response, translocates into the nucleus and binds to promoter region of the *epo* gene leading to upregulated expression (for review see [8]). Induction of proliferation is also conceivable for culture density. The level of reactive oxygen species (ROS) is significantly elevated under low density conditions, leading to increased proliferation. Bonello et al. recently reported that ROS activates HIF-1α itself via a functional NF-κB binding site in pulmonary artery smooth muscle cells.

We and others demonstrated that TNF-α triggers the proliferation of NSCs. NF-κB has been identified as the main driving force of TNF-mediated proliferation [9].

In the nervous system glutamate is described as a potent activator of NF-κB. In respect of the influence on NSCs, also glutamate enhances survival and triggers the proliferation of SVZ derived NSC.

As another molecule which increases the proliferation of NSCs, Sphingosine-1-phosphate (S1P) was described. Studies investigating endothelial cells showed that S1P induces the activation of NF-κB-mediated transcriptional activity.

Amyloid beta-peptide (Aβ), a self aggregating peptide and responsible for Alzheimer's disease, significantly decreases the proliferation of neural stem cells in vitro and in vivo. This result correlates with the fact that high amounts of Aβ acts as repressor of NF-κB. In contrast – the soluble secreted form of amyloid precursor protein, a well known NF-κB target gene, increases the proliferation of neural stem cells. In this context it is of importance that secreted beta-amyloid precursor protein counteracts the proapoptotic action of mutant presenilin-1 by activation of NF-κB.

Neurofibromin is able to increase the proliferation of NSCs. Neurofibromin, a product of the neurofibromatosis 1 (*nf1*) gene is one of the key regulators of the RAS oncogene. Noteworthy, expression of activated RAS stimulates NF-κB.

Cyclin dependent kinase 4 and 6 (CDK4/6) signaling is essential in ►cell cycle regulation in NSCs. In addition, the formation of the complex of CDKs 4 and 6 with Cyclin D1 is necessary for the cell cycle progression. Demonstrably, NF-κB controls growth and differentiation through transcriptional regulation of Cyclin D1 (see Fig. 1).

NO is a physiological inhibitor of neurogenesis. In addition, nitric oxide synthesis inhibition increases proliferation of neural precursors. It is noteworthy that NO is a well known repressor of NF-κB in neurons providing a link between NO dependent increase of progenitor proliferation and decreased NF-κB activity.

TGF-β1 is one of the well known inhibitors of NF-κB. According with our theory of proliferation control by NF-κB, TGF-β1 has been identified as a potent inhibitor of neurogenesis inducing a cell cycle arrest in the $G_0/G_1$ phase.

Taken together there are numerous evidences for a crucial role of NF-κB in control of neural stem cell proliferation.

## NF-κB and Migration of Neural Stem Cells

In spite of many important proceedings on the field of neural stem cell biology, the factors that orchestrate homing of NSCs are largely unknown. There are only few reports identifying factors inducing migration of NSCs (see Table 2).

The expression of several chemokine receptors by NSCs such as CCR2, CXCR4 and c-kit (Stem Cell Factor Receptor) is well described.

MCP-1 is a very potent chemotactic factor for neural precursors [10]. Interestingly, MCP-1 expression can be strongly induced by TNF. In addition, the *mcp-1* gene contains a functional NF-κB binding site in its promoter region which is necessary for response to TNF. In the hematopoietic system, binding of MCP-1 to its receptor strongly activates NF-κB, providing a further hint for NF-κB regulation of migration.

In another approach Sun et al. demonstrated potent induction of migration by neuronally expressed stem cell factor (c-kit Ligand, SCF) in vitro and in vivo. Analogous to *mcp-1*, also the *scf* gene contains a NF-κB binding site. Stromal derived factor 1α (SDF-1α), a well known ligand of the CXCR4, is described as a further chemokine, inducing migration of NSCs. Here, directed migration of neural stem cells induced by the SDF-1α secreted by astrocytes and endothelium was demonstrated. Furthermore, the over-expression of IκB results in loss of SDF-1α mediated migration of breast cancer cells in vivo.

All those results let us hypothesize that NF-κB is not only crucially involved in NSC proliferation, but also in control of migration.

## NF-κB and Neural Stem Cell Differentiation

The IL-6 family of cytokines, including the leukemia inhibitory factor (LIF) and ciliary neurotrophic factor (CNTF) promote astrocytic differentiation by activating transcription factors, such as STAT 3, AP-1 and NF-κB. Both CNTF and LIF triggers the recruitment of glycoprotein 130 (gp 130) to their specific receptors leading to activation of the RAS-MAP kinase pathway. Downstream of RAS MAP kinases and PKC transduce the signals to their substrates activating nuclear transcription factors (NF-κB, AP-1 and NF-IL6). This cross-talk of those transcription factors and co-activators induce astrocytic fate specification in NSCs.

Recent reports demonstrated that NF-κB is required for neuronal differentiation of neuroblastoma cells. Cells induced to differentiate with retinoic acid, show nuclear NF-κB localization. In contrast, over-expression of NF-κB super-repressor suppressed neuronal differentiation.

NF-κB activity, induced via activation of the Rho family of small GTPases, regulates neurite outgrowth and dendritic spine formation in neuroblastoma cells.

Some studies demonstrated that bone morphogenetic proteins (BMPs) promote astroglial lineage commitment by mammalian subventricular zone progenitor cells. In contrast other approaches suggest that BMPs promote neuronal differentiation of NSCs in SVZ. These controversial findings can be explained by dose-dependent action and complex signaling via several cooperating transcription factors. Interestingly, it has been suggested, that NF-κB may positively regulate BMP-2 gene transcription and that overexpression of a NF-κB superrepressor may lead to changes in downstream signals including BMP-4.

All these results suggest a very complex control mechanism and clearly indicate an involvement of NF-κB in differentiation regulation. Further studies should investigate the involved mechanisms in detail.

## Definition

NF-κB is a ubiquitous nuclear ►transcription factor (TF) found in the cytoplasm that regulates a number of physiological processes, such as inflammation, apoptosis, and cellular growth (reviewed in [1]). NF-κB is upregulated after injury in the central nervous system (CNS), and there have been suggestions that neurons, microglia and astrocytes upregulate NF-κB in response to injury. In this essay, we present data that NF-κB is upregulated in neurons, but not microglia or astrocytes, following peripheral nerve transection, and likely plays a role in the immediate survival of these neurons.

## Characteristics

### Description of the Structure/Process

NF-κB is a family of proteins that includes p50, p52, p65/RelA, RelB, and c-Rel which form homo- and heterodimers. The inactive form of NF-κB consists of dimers that are complexed with an inhibitory factor, IκB, in the cytoplasm. Diverse extracellular signals such as TNF, IL-1, and multiple growth factors activate alternate transduction pathways that converge to activate this transcription factor, which regulates more genes than any other DNA regulatory protein. Phosphorylation of IκB by protein kinases, such as inhibitory factor kappa B kinase alpha (IKKα), leads to its ubiquination and ultimate degradation. Once IκB is degraded, NF-κB is released and translocated to the nucleus, where it interacts with a specific DNA sequence in the promoter region stimulating the transcription of a wide array of genes. In the CNS, neurons contain constitutively active NF-κB, which is upregulated after injury [2–3]. Both microglia and astrocytes have been shown to induce NF-κB activity in response to injury [4].

NF-κB activity has been implicated in opposing apoptosis [5] and enhancing neuronal survival following CNS injury [7]. For example, activated NF-κB increases the expression of genes that block the activation of caspase-8 and caspase-3 apoptotic factors. NF-κB enhances the transcription of cytokines, such as IL-6, which are reported to be neuroprotective. The activation of NF-κB in response to noxious stimuli may indicate a survival mechanism that blocks apoptosis. The increased activity of NF-κB in response to Bcl-2, which is also an NF-κB target gene and a known anti-apoptotic factor, supports its role in the inhibition of apoptosis and neuronal rescue. However, some evidence has been presented suggesting that NF-κB may enhance apoptosis in cerebral ischemia [8]. The role of NF-κB in neuronal survival has recently generated a great deal of interest as a possible site of future therapeutic intervention following brain or spinal cord injury.

### Role of NF-κB in Spinal Cord Injury

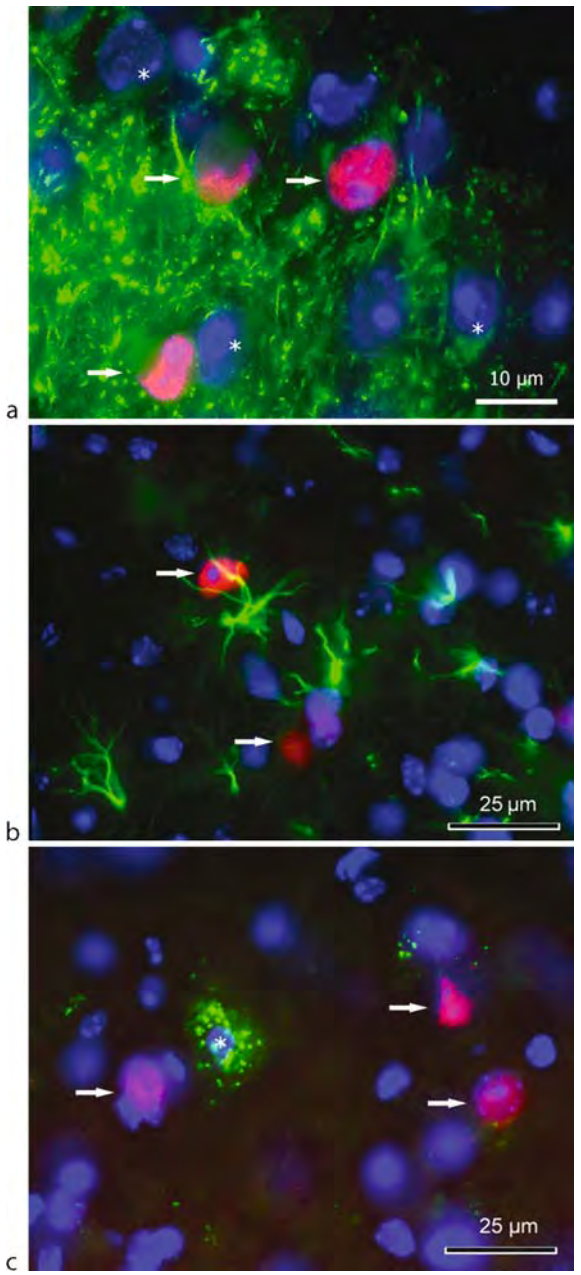
Studies have supported the hypothesis that NF-κB plays a role in the survival of neurons within the hippocampus [6]. NF-κB activation enhances neurosurvival by increasing the expression of genes that block apoptotic signaling [5].

Complete sciatic nerve transection leads to increased NF-κB activation in neurons on the side of the spinal cord ipsilateral to the side of axotomy in transgenic mice [9]. This increased activation is statistically significant at 3 and 5 d, and returns to baseline 10 d after transection. The number of neurons containing NF-κB activation was greater in the dorsal horn than the ventral horn at all time points. Neurons that activated NF-κB were located bilaterally in the dorsal horn of the spinal cord in un-operated animals as well as in the experimental animals, which is consistent with previous reports of constitutive NF-κB expression in the spinal cord [2].

Based on the results of immunofluorescent double-labeling, we have shown that the constitutive and induced activation of NF-κB, which was reported by production of β-galactosidase, occurs in neurons and not in astrocytes or microglia/macrophages (Fig. 1). Previous studies that measured p65 (RelA) levels in the spinal cord of rats that had undergone spinal cord injury (SCI) by contusion showed an increase in NF-κB activity in microglia and endothelial cells as well as neurons following crush SCI. However, crush SCI violates the blood–brain barrier and subjects the spinal cord to the presence and effects of blood borne cells and their inflammatory mediators. Pollock et al. also reported a more rapid increase in NF-κB activity, which was increased at 24 h and remained elevated for at least 72 h, than the time course in the present study. This earlier activation is most likely the result of the direct influence of immune cells releasing inflammatory cytokines.

NFκB activity is also increased in experimental autoimmune encephalomyelitis primarily in microglia, macrophages and T lymphocytes. In this study, myelin basic protein specific T lymphocytes were injected into the experimental animals causing an increase in NF-κB activity that peaked at 6 d and returned to normal by day 14. This follows a similar timeline of NF-κB activation to the present study, though Kaltschmidt and colleagues [10] did not examine NF-κB in neurons. Their results dealt primarily with the immune cell activation and the presence of perivascular infiltrates.

The time course of NF-κB activity is consistent with a study that evaluated dorsal root ganglion cells following sciatic nerve injury. This study demonstrated no increase in NF-κB activity 14 d after complete sciatic nerve transection, but increased activity after partial sciatic nerve ligation and chronic constriction injury at this time point. Our results suggest that the upregulation of NF-κB activity would have returned to baseline in the dorsal horn by this time point following complete sciatic nerve transection. This time course does not correspond to degenerative changes that occur within the spinal cord following axotomy. For example, degeneration of neurons in the dorsal horn in adult rats after sciatic nerve transection does not occur until 30 d post-axotomy. Reports have appeared of positive



**NF-κB: Activation in the Mouse Spinal Cord Following Sciatic Nerve Transection.**
**Figure 1** Fluorescent photomicrographs of β-gal-positive cells (*red*) in the spinal dorsal horn double labeled with a green fluorescent chromagen for (a) MAP-2 (neurons), (b) GFAP (astrocytes) and (c) cd11b (microglia). β-gal-positive cells double label with MAP-2 (*arrows*), but not GFAP or cd11b, suggesting that they are neurons, rather than astrocytes or microglia.

TUNEL staining in the dorsal horn 14 d following a constricting sciatic nerve injury but not after complete transection, which showed no TUNEL positive cells at 14 d post-axotomy. Motor neurons in adult rats undergo atrophy, but not apoptosis, following sciatic nerve transection, unlike neonatal rats which show apoptosis in both the dorsal and ventral horns. Pollock and coworkers [9] showed very little NF-κB activity in the ventral horns and none in the alpha motor neurons at any time examined following complete sciatic nerve transection. These previous studies demonstrate a difference between sciatic nerve transection in neonatal rodents and adult rodents with significant changes in the ventral horn of young animals but minimal changes in the ventral horns of the adult animals. Our results are consistent with these findings as there is very little NF-κB activity in the ventral horn of any of the experimental animals.

Many studies have shown that sciatic nerve transection in the neonatal mouse or rat leads to a marked cell loss in the ventral horn. There is ample evidence that in neonatal rodents, axotomy leads to motor neuron loss via apoptosis that is usually evident by 21 d and continues to increase out to 30 and 60 d. However, there is a significant difference between adult and neonatal animals in this response. Pollin and coworkers [6] showed that age is a major determinant of the response of motor neurons to axotomy in the mouse. While neonatal mice show massive apoptosis in the ventral horn in response to axotomy, adult mice show very little apoptosis of motor neurons in response to peripheral nerve transection. These data are consistent with the lack of changes seen during this time period in the ventral horn of the adult mice used in this experiment. While actual cell loss is seen at later time periods, the changes in transcription factor activity and apoptotic pathways are seen during the first few weeks following neuronal injury.

A trend in the total number of NF-κB-positive cells appears to show a decrease below baseline for the animals sacrificed at the 1 d time period and then a rise above baseline for the 3 and 5 d time periods, followed by a return to baseline at the 10 d time period. An initial decrease in NF-κB activation could be consistent with a decrease in p65 levels which occur as a result of a decrease in the retrograde transport of trophic factors, however, the decrease in NF-κB activation was not statistically significant at the 1 d time point.

## Function of NF-κB in Glial Cells and Neurons in Spinal Cord Injury

Glial cells have been shown to proliferate in response to sciatic nerve transection in both neonatal and adult rats. There was no evidence of NF-κB activity in any cells other than neurons in the work by Pollock et al. [9]. It has been shown that glial cells interact with neurons to regulate NF-κB activity in the CNS [2]. The sciatic nerve transection model does not violate the blood–brain barrier in the spinal cord and this may account for the lack of NF-κB activity seen in cells other than neurons. This may have important implications as to the NF-κB activity response to different types of spinal cord insults as the response appears to be only in neurons in this model but is also evident in microglia and endothelial cells in the contusion model. This may present an opportunity to target different cells in peripheral nerve injury versus direct spinal cord injury.

NF-κB plays a central role in promoting neuronal survival within the injured spinal cord and thus is an important target for research and future interventions. The extensive variety and availability of transgenic and knockout strains of mice provide an advantage over the rat for investigative opportunities in spinal cord injury.

## Niemann-Pick Disease

### Definition
Niemann-Pick disease is subdivided into two classes. In types A and B, the genes for acid sphingomyelinase are deficient; in types C and D, the genes for the NPC-1 protein are deficient. Niemann-Pick disease type C (NPC) is a fatal autosomal-recessive, neuro-visceral lipid storage disorder resulting from mutations in either the NPC1 (95% of families) or NPC2 gene and presenting with a plethora of symptoms related to hepatic and pulmonary diseases, and various neuro-psychiatric disorders. The clinical spectrum ranges from a neonatal rapidly fatal disorder to an adult-onset chronic neurodegenerative disease. In the latter, symptoms include ►cerebellar ataxia, movement disorders, vertical supranuclear ►ophthalmoplegia, ►dysarthria, ►dysphagia, psychiatric and cognitive impairments as well as, less frequently, ►epilepsy and ►cataplexy.

## Night Terrors

### Definition
Night terrors, also known as Sleep Terrors or Pavor Nocturnus, consist of sudden arousals from slow-wave

(delta) Non-REM sleep accompanied by a cry or piercing scream and behavioral manifestations of intense fear. There is pronounced autonomic discharge, with tachycardia, tachypnea, flushing of the skin, diaphoresis, mydriasis, and increased muscle tone.

Amnesia for the episode generally occurs, but some adults recall vivid dreaming that accompanied their sleep terrors.

## Nissl Stain

### Definition

A method of staining brain tissue due to interactions between a basic stain (e.g. cresyl violet) and acidic groups, e.g. in DNA, RNA ("Nissl substance"). Since most negatively charged groups (DNA, RNA) are in the soma, this technique stains somata of neurons, but not their distal dendrites and axons. The technique is named after its discoverer Franz Nissl (1860–1919).

## Nissl Technique

### Definition

The Nissl (turn of nineteenth century German Neurologist) technique is a neuron staining method that uses basic dyes to stain the chromatin material (ribose nucleic acid) in the cell body.

## Nitric Oxide

### Definition

Nitric Oxide (NO) has been proposed to play a role in intercellular communication and is considered to be an unconventional transmitter. Unlike classical neurotransmitters it is not stored in vesicles, does not bind to specific target receptors on the membrane surface, and does not have an active process to terminate its action. The gas nitric oxide is synthesized from arginine a reaction that depends on the enzyme nitric oxide synthase (NOS).

## NMDA

### Definition

N-methyl-D-aspartatic acid is an amino acid derivative that binds to the NMDA-type glutamate receptor.

## NMDA Receptors

### Definition

A variety of ionotropic receptors for the common excitatory neurotransmitter glutamate. They are ligand-gated ion channels that are gated open when glutamate binds to them but only when the membrane potential is relatively depolarized; thus they have voltage-dependent properties. Voltage dependence is conferred on these channels by the binding of $Mg^{2+}$ ions in the channel pore at relatively hyperpolarized membrane potentials. NMDA (N-methyl-D-aspartate) is a specific agonist for these receptors, i.e., it is a drug that selectively activates NMDA receptors and not other glutamate receptor types.

Receptor activation induces the influx of sodium and calcium ions, and the efflux of potassium ions. The movement of ions causes depolarization of the neuronal membrane and increases the probability that an action potential will be generated. NMDA receptors consist of NR1 (GluRζ1) and some of NR2A (GluRε1), NR2B (GluRε2), NR2C (GluRε3) and NR2D (GluRε4) subunits and are localized at the postsynaptic site on the dendritic spine.

The NR1 subunit is an essential component of NMDA receptors and the composition of the NR2 subunits determines the properties of NMDA receptor channels.

## Nociceptive Neurons

### Definition

According to the International Association for the Study of Pain, a nociceptor is a receptor that is

preferentially sensitive to a noxious stimulus or to a stimulus which would become noxious if prolonged.

Nociceptors respond selectively to damaging stimuli and transmit information via Aδ and C afferent neurons. They are broadly classified as mechanical nociceptors that respond to strong mechanical stimulation, heat nociceptors that respond to temperatures above 45°C, and polymodal receptors that respond more generally to noxious stimuli (including mechanical, heat, and chemical). Although the primary nociceptive responses are generated by nociceptors in the periphery, neurons throughout the central nervous system that respond to noxious stimuli are also nociceptive, including those in the midline and intralaminar thalamus and parts of cingulate cortex.

# Nociceptors: Adequate Stimulus

H. Richard Koerber
Department of Neurobiology, University of Pittsburgh, Pittsburgh, PA, USA

### Definition

The ►adequate stimulus for a given sensory neuron is a sensory event that is of sufficient magnitude to elicit action potentials, typically resulting in a sensory experience. A ►nociceptor is defined by the International Association for the Study of Pain (IASP) as a receptor preferentially sensitive to a noxious stimulus (one which is damaging to normal tissues [see ►Visceral pain for exception re. visceral nociceptors]), or to a stimulus which would become noxious if prolonged. Thus the adequate stimulus for a nociceptor would be one that has the capability to cause pain or discomfort. While most sensory neurons respond best to stimuli of a single ►sensory modality (e.g., mechanical or thermal), nociceptors can often be activated by stimuli of different modalities (i.e., are polymodal).

### Characteristics

#### Historical Perspective

The concept of nociception was first introduced by Sherrington [1] at the turn of the twentieth century. He proposed that the sensation of pain was mediated by specific sensory organs that were responsive to painful or noxious stimuli. However, it was several decades before the existence of specific pain sensing fibers or nociceptors was firmly established [2]. During the intervening period of time, many different theories about how peripheral sensory neurons could code for the sensation of pain were hypothesized. A recent eloquent historical review of the subject by E. R. Perl [3] provides a detailed timeline of these events. In brief, the differing theories on the roles of peripheral receptors can be generalized as specificity versus intensity. In the specificity theory of pain, only those sensory neurons that respond to stimulus intensities in the noxious range would be responsible for signaling pain, whereas in the intensity theory most, if not all, sensory neurons would be responsive to innocuous stimuli, but would be more responsive (generate more action potentials over time) to stimuli of noxious intensity. This increased number of inputs would signal the fact that the intensity of the stimulus had reached a noxious level. Here, I will briefly describe what has been reported about primary sensory neurons in general, and more specifically putative nociceptors over the past several decades and then discuss how these findings fit with these two contrasting theories.

## Primary Sensory Neurons

Primary sensory neurons provide constant feedback on the external environment as well as the internal state of the body. These neurons are located in sensory ganglia that lie outside of the central nervous system. While some of these ganglia are associated with cranial nerves such as the trigeminal ganglion, the majority of these neurons are to be found in dorsal root ganglia associated with each spinal nerve (see ►Visceral pain for role of sensory neurons in the nodose ganglion). Their axons bifurcate within the ganglion and give rise to a peripheral branch that innervates various tissue types in the trunk, limbs and viscera and a central branch that travels through the appropriate dorsal root to enter the spinal cord, where it forms synapses with second-order neurons.

There are several different ways of classifying primary sensory neurons. The most common means of classification is based on the conduction velocity of their peripheral axons, which is directly related to the axon diameter and to whether the axon is myelinated. Based on the distribution of these peripheral nerve conduction velocities, primary sensory neurons are routinely divided into different groups: Aα/β, Aδ, and C. While the actual conduction velocity of these groupings varies across different mammalian species, the Aα/β group consists of large myelinated axons that have the fastest peripheral conduction velocities and approach 100 m/s in some species. The Aδ group contains smaller caliber fibers that are thinly myelinated and conduct at an intermediate velocity, and the C-fiber group is comprised of the smallest, unmyelinated and most slowly conducting fibers, usually <2 m/s. Another convenient means of classification of primary sensory neurons is the peripheral tissue they innervate. Fibers innervating skin are described as cutaneous sensory neurons. Similarly, afferent fibers innervating thoracic, abdominal or pelvic viscera are termed visceral afferents.

Primary sensory fibers are responsive to a variety of sensory modalities, including mechanical, thermal and chemical stimuli. Fibers responsive to a specific sensory modality are further classified according to the intensity of the adequate stimulus. Those primary sensory fibers that respond to gentle mechanical forces or innocuous thermal stimuli, and fail to encode a broad range of stimulus intensities, are classified as low threshold mechanoreceptors or innocuous cooling or warming fibers, respectively. As defined above, sensory fibers that respond only to stimulus intensities that would be considered tissue threatening or have the potential to be damaging are termed nociceptors. The majority of these nociceptive fibers is responsive to two or more stimulus modalities, and for that reason are referred to as polymodal nociceptors.

Sensory neurons responding to different intensities of peripheral stimuli are distributed across the different conduction velocity groups. Most sensory neurons with fibers conducting in the Aα/β range respond to innocuous mechanical stimuli, and are classified as low threshold mechanoreceptors. A subset of these fibers can respond to relatively innocuous mechanical stimuli, but also encode stimulus intensities into the noxious range and in some cases respond to noxious heating of the skin. This trend reverses with decreasing conduction velocity as a majority of Aδ-fibers and most C-fibers are classified as nociceptors. The relative numbers of functional types in specific conduction velocity groups varies between species and the areas of the body the fibers innervate. However, it is important to point out that both nociceptors and non-nociceptors exist in all three conduction velocity groups.

Primary sensory neurons also exhibit diversity in many other properties, including cell membrane properties, laminar location of central projections and neurochemical content [4]. Myelinated fibers that respond to innocuous mechanical stimulation of the skin have narrow somal action potentials without breaks in the rising or falling phase of the spike. Unmyelinated and myelinated nociceptive fibers have broader action potentials that most often have a distinct inflection on the falling phase of the spike [4]. While this relationship is quite constant for myelinated fibers, all unmyelinated fibers have broad inflected somal action potentials regardless of their peripheral response properties.

## Spinal Projections

The central branches of myelinated low threshold mechanoreceptive fibers enter the spinal cord and bifurcate into main ascending and descending branches that travel in the dorsal columns. Additional collateral branches turn ventrally and pass through the dorsal horn before terminating in lamina III-V. These laminae are largely involved in processing inputs elicited by innocuous mechanical stimuli. The central projections of myelinated nociceptors were first described by Light and Perl [5], who focused on fibers conducting in the intermediate Aδ range. They found that upon entry into the spinal cord, the main branches were laterally located in the dorsal column often in or near ►Lissauer's tract. Terminal arbors from these afferents were centered primarily on laminae I and IIo, spinal laminae largely involved in the processing of inputs elicited by noxious peripheral stimuli, with some passing ventrally to terminate in lamina V. More recently, Woodbury and Koerber [6] have demonstrated an additional central projection pattern for myelinated nociceptive fibers. These fibers have projections very similar to those of low threshold mechanoreceptors in laminae III-V, however, their projections also extend dorsally through laminae I and II.

Unmyelinated C-fibers, most of which are considered to be nociceptors, enter the spinal cord and usually

bifurcate and run rostrally and caudally along the surface of the dorsal horn in Lissauer's tract. The primary collaterals send off several additional branches that penetrate ventrally into the superficial dorsal horn laminae I and II where they end in dense terminal fields. While individual C-fibers have projections that are focused more or less in different parts of the superficial dorsal horn, most are found in both laminae I and II with the primary focus usually in lamina II [7,8].

In summary, the sensory neurons that have peripheral response characteristics of nociceptors (i.e., code stimulus intensity in the noxious range), consistently have direct projections to the superficial dorsal horn laminae known to be involved in nociceptive processing. However, it is also important to note that not all sensory neurons projecting to these spinal laminae are nociceptors.

## Neurochemical Properties

As a group, nociceptors have been the main target of neurochemical analysis in recent years, and they have been shown to exhibit the most pronounced phenotypic diversity among sensory neurons. Unmyelinated nociceptive sensory neurons contain a large number of neuroactive compounds and express receptors and have been divided into two major groups based on the combination of neurochemical phenotype and sensitivity for different ►neurotrophins. The first group of nociceptive neurons is sensitive to nerve growth factor and expresses its high-affinity receptor tyrosine kinase receptor A (trkA); they also usually contain ►neuropeptides such as calcitonin gene-related peptide (CGRP), substance P and galanin. The second group is responsive to members of the glial cell line-derived neurotrophic factor family, and expresses the cognate ►receptor tyrosine kinase. This group usually does not contain peptides, have binding sites for the isolectin IB4 (obtained from *Bandeiraea simplicifolia*), and contains the ►purinergic receptor $P2X_3$, suggesting sensitivity to ATP [7].

Less is known about the different neurochemical phenotypes of myelinated nociceptive fibers. However, they can be divided into two groups based on whether they express the trkA receptor and contain peptides such as (CGRP), or as, it has recently been shown, contain the neurtrophic factor 3 receptor trkC and lack peptides [9].

## Nociceptors: Intensity vs. Specificity

As discussed above, it has been shown that there is a population of sensory neurons that only respond to stimulus intensities in the noxious range, corresponding to the classical definition of a nociceptor. In addition, most individual nociceptors can respond to several stimulus modalities. These sensory fibers are distinctly different from those that are responsive to innocuous stimuli and do not encode stimulus intensity.

However, not all sensory neurons fit neatly into these two different categories. It has long been known from animal studies that some fiber types are not easily classified as associated with nociceptors or non-nociceptors. For example, Burgess and Perl [2] reported a group of myelinated fibers that were distinct from low threshold or innocuous myelinated fibers, but had thresholds below those considered to be nociceptors. They referred to these as moderate pressure units. In addition, more recent experiments in humans have demonstrated that many putative nociceptive fibers, including polymodal fibers, have mechanical and/or thermal thresholds at intensities that are well below those necessary to evoke pain. However, it was also shown that there was a clear and significant relationship between the numbers of action potentials elicited by suprathreshold stimuli in these fibers and the perception and intensity of pain in these subjects [10]. Taken together, these findings suggest that while it is clear that some sensory neurons clearly fit the original concept of nociceptors put forth by Sherrington, others that have ►absolute response thresholds that would suggest a non-nociceptive function may also function as nociceptors (i.e., they contribute to the sensation of pain). These two groups of fibers share many other properties, including broad somal action potentials, neurochemical content and central projections in the superficial laminae of the spinal dorsal horn.

In summary, nociceptors, the necessary substrate for the specificity theory, are clearly present. However, it is also clear that sensory neurons that do not fit the Sherringtonian definition of a nociceptor do code for the intensity of a stimulus into the noxious range and thus have the potential to contribute to the sensation of pain.

# Nociceptors and Characteristics

Herrmann O. Handwerker
Institut für Physiologie und Pathophysiologie, Erlangen, Germany

## Synonyms

Nociceptors (human)

## Definition

The term "nociceptor" has been derived from the Latin "nocere," which means to harm or to damage. Nociceptors are characterized by two distinctive features: (i) they are responsive preferentially to tissue threatening stimuli and encode their intensity, (ii) they mediate nocifensive motor and vegetative reactions by their central connections.

## Characteristics

### General

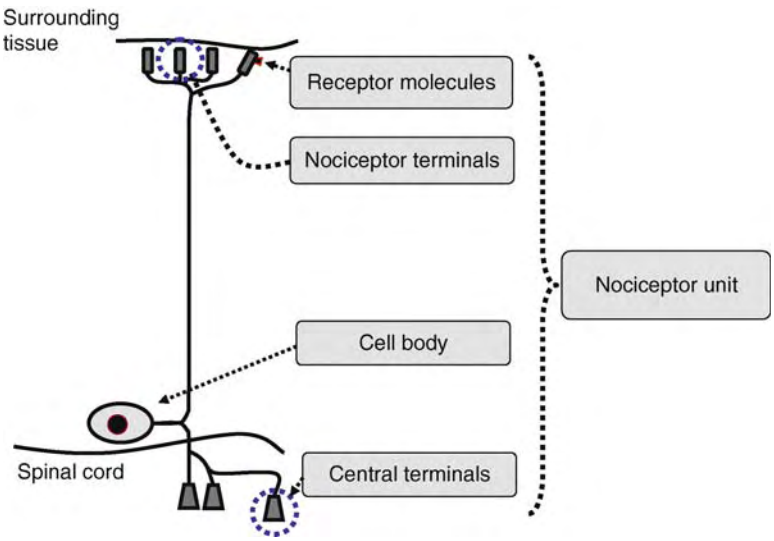
The nociceptor concept was introduced by the famous physiologist Sir Charles Sherrington in a monograph published in 1906. Sherrington used it to describe primary afferent neurons which were processing information on tissue-threatening stimuli in animal experiments. He observed that noxious stimuli induced withdrawal reflexes and defined nociceptors as a type of afferent nerve inducing withdrawal (nocifensive) reflexes, which became the surrogate of human pain experiences in animal experiments. In addition, nocifensive motor reflexes and the respective reactions of the autonomic nervous system (i.e., rise in blood pressure, increase in heart rate, etc.) can also be observed in human subjects, even in states of unconsciousness, when pain experiences are precluded.

For obvious reasons, a proof of nociceptor functions cannot be based solely on responses to damaging stimuli as the Latin word stem would suggest. Many neurons may be excited by damaging stimuli at least temporarily in the process of their decay. Therefore, the concept of the nociceptor requires at least one additional element: central nervous system connections.

One may note that nociceptors are not just "pain receptors." Pain is related to functions of the conscious central nervous system. Excitation of nociceptors is neither a necessary nor a sufficient condition for pain experiences. Nevertheless, it is true that in conscious healthy human beings a more or less linear relationship has been found (e.g., between the activation of heat sensitive nociceptors in the skin and the intensity of burning pain). In addition, the ►hyperalgesia of inflamed tissue is reflected in the increased activity of nociceptors [1], provided that no other factors interfere, such as placebo suggestions, analgesic medications, etc.

On the other hand, the term nociceptor can not be restricted to the receptor and channel molecules in the nerve terminals that are activated by noxious physical or chemical stimuli. One such a membrane receptor, which is often erroneously labeled as "the nociceptor," is the TRPV1 (transient receptor potential vanilloid) receptor channel which is opened by binding of the pungent substance capsaicin, by heating, and by application of acids. This molecule is also expressed in non-sensory cells and in neurons with arguable nociceptive functions.

Figure 1 shows a systematic diagram of a nociceptor neuron. The cell bodies of these neurons are in the dorsal root ganglia and in the trigeminal ganglia, respectively. The peripheral terminals may be found in most tissues of the body. The central terminals form synapses with secondary neurons in the superficial dorsal horn of the spinal cord and in the nucleus caudalis of the trigeminal complex. An "ideal" nociceptor should provide the central nervous system exclusively with nociceptive information, and hence encode only stimulus intensities in or near the noxious range. In the CNS, nociceptor input must contribute to the information processing within the central nociceptive neuronal network and hence to the subjective experience of pain. Visceral afferents provide a particular challenge for the nociceptor concept. For example, in the wall of the urinary bladder and of intestines, numerous slowly conducting afferent nerve fibers have been found which may serve two purposes (see ►Visceral Pain). In the case of the urinary bladder, they control micturition and mediate sensations of increasing urgency with filling of the bladder. At higher tension of the bladder wall, these sensations become painful while the same neuronal population is more vigorously excited. Thus it seems as if these afferent nerves contribute to two functions: nociceptive and non-nociceptive. The complex issue of peripheral coding of visceral pain has been controversially discussed [3].



**Nociceptors and Characteristics. Figure 1** Schematic diagram of the relevant parts of a nociceptive neuron. The cell bodies (pericaria) are situated in the dorsal root ganglia and in the ganglia trigemini, respectively. Peripheral terminals can be found in most tissues of the body, central terminal make synapses with secondary nociceptive neurons in the CNS. (Reprinted from [2], by courtesy of Elsevier Pb).

## The Trp (Transient Receptor Potential) Receptor Family and Other Molecules in Nociceptor Terminals

The fast progress of the molecular analysis of receptor and channel structures in nerve terminals has lead to a deeper understanding of the molecular mechanisms of stimulus transduction in nociceptor terminals [4]. This topic can only marginally be covered by this essay. A large group of nociceptor neurons express the ►trk-A receptor, the high affinity receptor for nerve growth factor (NGF). This applies also to humans, since a genetic defect of the trk-A receptor leads to congenital insensitivity to pain (CIPA-syndrome) [5]. Recently it has been discovered that a genetic defect of the voltage dependent NaV1.7 channel also leads to congenital pain intensity. This finding points to a major role of this molecule in safeguarding spike conduction in nociceptive nerve endings [6]. Most of the peripheral neurons expressing trk-A receptors are also peptidergic (their cell bodies synthesize the ►neuropeptides CGRP [calcitonin gene related peptide] and to a minor extent also substance P). These neuropeptides may be released from central nerve terminals as ►neuromodulators of synaptic transmission in the dorsal horn of the spinal cord. They can also be released from peripheral nerve terminals, leading to ►neurogenic vasodilatation and plasma-extravasation (see ►Inflammatory Pain). This is the basis of the axon reflex reaction following noxious stimulation of the skin (neurogenic flare reaction). However, from animal experiments it can be extrapolated that another group of nociceptors exists which are not dependent on NGF, but on other nerve growth factors, in particular BDNF (brain-derived neurotrophic factor). Immuno-cytochemically, many of these neurons are characterized by staining with a plant isolectin, IB4.

Many human nociceptors are equipped with receptor channels of the trp family [7]. Most important is the above mentioned TRPV1. This molecule forms an nonspecific cation channel which is operated by binding of the plant derived molecule capsaicin. TRPV1 receptors are common in trkA expressing peptidergic primary afferent units, but it is not expressed in all nociceptors. As mentioned above, the TRPV1 receptor is also operated by noxious heating and acids. From experiments with genetically modified knockout mice, it is known that this receptor is partly, but not exclusively responsible for the nocifensive responses to acids and noxious heat. There are other ►trp receptor molecules such as TRPA1 which may also explain part of the sensitivity of nociceptor terminals to algogenic chemical substances (e.g., mustard oil). Another group of receptor molecules important for the functioning of nociceptors are G-protein coupled receptors for bradykinin (B1, B2) and for prostaglandins of the E-group (EP1,2,3). Activation of these G-protein coupled receptors by endogenous algogenic substances released in the course of inflammatory tissue reactions leads to sensitization of nociceptors to mechanical, heat and chemical stimuli. Intracellularly, this process is mediated by second messenger cascades involving protein kinases, which leads to a characteristic lowering of thresholds

and greater magnitude of suprathreshold responses to mechanical and thermal stimuli, and forms the basis of hyperalgesia due to inflammation.

## Microneurography of Human Nociceptors

The functional properties of nociceptors in man are mainly studied with the methods of ►microneurography, which is the extracellular recording of spike potentials from individual afferent nerve fibers in peripheral nerves of awake healthy volunteers and patients [8]. These studies have been performed by about a dozen laboratories worldwide during the last 30 years. Studies on muscle nociceptors are difficult and rare [9] and even in cutaneous nerves, with a few exceptions, only unmyelinted C-fibers have been studied because it is difficult to obtain stable recordings from small myelinated nociceptive nerve fibers [10]. For this fiber class, one has to resort to data from monkeys which have a similar afferent nerve fiber spectrum. Apparently, myelinated nociceptors (A-δ) are heterogeneous. Some are high threshold mechanosensors with little chemical or thermal responsiveness. These units may, however, play a role in motor withdrawal reflexes. Another group of small myelinated nociceptors are similarly equipped with molecular receptor molecules in their terminals, as is the case with C-fiber nociceptors.

As indicated above, the nociceptor nerve terminal expresses a mosaic of receptor molecules. However, this mosaic is differentially distributed in different nociceptor populations. Cutaneous nociceptors have been sorted into subclasses according to their thresholds for certain types of stimuli and the coding of suprathreshold noxious stimuli. The most common group of C-nociceptors respond to mechanical stimulation with von Frey bristles (thresholds in most cases 30–150 mN) and to heating (thresholds in most cases 40–44°C). These units have been named C-MH units because they are responsive to *m*echanical stimulation and to *h*eating. They are comparable to the "polymodal nociceptors" originally described in the hairy skin of the cat. Many of those units are also responsive to capsaicin and to vasoneuroactive endogenous agents such as bradykinin. However, on intracutaneous injection of capsaicin, responses are usually short lived and followed by desensitization of nociceptor terminals. Another group of C-units in human skin are insensitive to noxious mechanical stimulation, including pricking the skin with a hypoderminc needle. Due to their insensitivity to mechanical stimuli, they have often been called "►silent nociceptors." However, they gain mechanical sensitivity comparable to that of C-MH units in the course of inflammation; therefore, they have also been poetically named "sleeping nociceptors." These units are sensitive to capsaicin and indeed show a greater response to capsaicin than C-MH units. Because capsaicin treatment leads to sensitization to mechanical stimuli, the mechano-insensitive nociceptors are the source of primary mechanical and heat hyperalgesia following intracutaneous capsaicin injection. We have named this nociceptor class C-$M_i$H or C-H units because in intact skin they are also sensitive to heating, having slightly higher thresholds than C-MH units (around 46°C). In addition, nociceptor terminals that express G-protein coupled receptor molecules seem to be different in the C-MH and C-$M_i$H classes. A subgroup of C-$M_i$H units is particularly sensitive to histamine and express the histamine $H_1$ receptor, and it has been shown that responses of this group of nociceptors parallels closely the itch sensation induced by intracutaneous application of histamine [9]. Discovery of histamine sensitive "itch-nociceptors" does not solve the puzzle of the peripheral mechanism of itching entirely, however. There are forms of itching which are not mediated by this group of primary afferents.

In human skin, $CM_iH$ units and not the more common C-MH units mediate sustained flare responses by releasing CGRP upon noxious stimulation [8]. All these features indicate that the class of mechano-insensitive C-nociceptors (i.e., C-$M_i$H nociceptors) is more important for inflammatory pain and probably also for other types of pathological pain than the more common C-MH units.

# Nocturnal Myoclonus

## Definition

Periodic stereotyped leg twitches during sleep.

# Nocturnal/Diurnal

Laura Smale, Antonio A. Nunez
Psychology Department, Michigan State University, East Lansing, MI, USA

## Definition

A diurnal animal is one that is most active during the day, and a nocturnal animal is one that is most active at night.

## Characteristics

### General Considerations

Virtually all organisms undergo rhythms associated with the day-night cycle, but the patterns of these rhythms can vary considerably from one species to the next. The most striking differences have to do with the coupling between the rhythms and the day-night cycle. Specifically, in some animals activity is elevated during the day, while in others activity is highest during the night. The former are referred to as "diurnal" organisms and the latter as "nocturnal" ones. In both cases, an internal "circadian" ►clock generates endogenous rhythms that have a period of approximately 24 h and that are synchronized, or "►entrained," to a 24 h day by environmental cues such as the ►light-dark cycle.

One of the key adaptations that made the evolution of mammals possible was a change in this circadian timekeeping system from one that promoted a diurnal pattern in reptiles to one that supported a nocturnal pattern of adaptation in mammals. Although nocturnality remains most common, diurnality resurfaced in a variety of independent mammalian lineages, including our own. At each of these transitions changes occurred in the biological timekeeping mechanisms that coordinate a wide range of behavioral and physiological processes. More is known about how circadian systems operate in nocturnal than diurnal species because the animals traditionally used in biomedical research are nocturnal (e.g., mice, rats and hamsters). However, research on diurnal mammals has accelerated in recent years. Below, some of the ways in which rhythms in diurnal and nocturnal mammals are similar and different are first described briefly, and then the neural mechanisms that might cause the differences are outlined.

### Patterns of Rhythmicity in Diurnal and Nocturnal Mammals

Day- and night-active animals differ with respect not only to their patterns of general activity, but also their rhythms in virtually every aspect of behavior and physiology [1]. Peaks in rhythms in secretion of most hormones, body temperature, digestive function, heart rate, mating behavior and feeding all occur approximately 180° out of phase in diurnal and nocturnal mammals. Some examples are highlighted below.

The circadian timekeeping system produces rhythms in secretion of many hormones, almost all of which are quite different in nocturnal and diurnal species [2]. The major period of prolactin secretion occurs at night in humans, while in rats this hormone does not rise until the second half of the day. The rhythms in adrenal secretion of corticosteroids are also inverted in nocturnal and diurnal species, with the rise always occurring in this case at the beginning of the active period of the day. Pituitary hormones regulating the gonads undergo rhythms that can differ between the sexes and can change across development and with reproductive states such as pregnancy and lactation.

However, in each case these patterns are not the same in diurnal and nocturnal species. For example, as young men go through puberty, their plasma levels of gonadotropins change from being arrhythmic to rhythmic, with the highest levels during the night, and then they revert back to an essentially arrhythmic state when adulthood is reached. Such changes are not apparent in nocturnal species. Just before ovulation, the pituitary gland produces a surge in luteinizing hormone release that is precisely timed in many rodents to precede the onset of the daily active period by three to four hours. This surge thus occurs 180° out of phase in day- and night-active animals. The rhythm in secretion of the hormone ►melatonin is notable in that it is actually the same across species, regardless of an animals' activity pattern. The ►pineal gland releases this hormone into the blood stream at night, when diurnal

animals sleep and nocturnal animals are active. The duration of the period during which melatonin is secreted varies with daylength and can consequently serve as a signal of the changing seasons, regardless of an animal's activity pattern. There is some evidence that melatonin has a soporiphic effect in humans, and that its administration to people whose endogenous release is low, such as the elderly, can help in the consolidation of sleep at night. As one might expect, nocturnal mammals do not exhibit this response.

Body temperature (Tb) is influenced by a variety of factors that govern its pattern of change across the day. While ►homeostatic mechanisms can elevate Tb when ambient temperatures drop in both diurnal and nocturnal animals, circadian systems have opposite effects on them, promoting a rise during the day in diurnal animals and at night in nocturnal ones. Although rhythms in Tb persist when we are completely inactive, their amplitude is ordinarily increased by activity. This consequently increases the magnitude of the difference between nocturnal and diurnal animals. Many other factors, such as pregnancy and lactation, can alter the pattern of daily rhythms in Tb, but the circadian drive behind the rhythms is always quite different in diurnal and nocturnal species.

Rhythms in feeding behavior also are typically inverted in day- and night-active animals, but they are quite unusual with respect to their plasticity [3]. As one might expect, when food is freely available, diurnal animals eat most during the day, and nocturnal ones at night. However, restricting the period of food availability to short intervals during daylight hours eventually causes activity of nocturnal rats to begin prior to the presentation of the food, effectively entraining the animals' circadian rhythms in activity and feeding. The result is that nocturnal rats become considerably more diurnal. Such studies have established the existence of two interacting oscillators that together shape the degree to which an animal is more, or less, active during the day than night. One of these is referred to as a "light entrainable oscillator" and the other as a "►food entrainable oscillator." Although their interactions are poorly understood in diurnal species, they may provide some insight into mechanisms that govern when the active phase of an animal will be.

## The Circadian Oscillator and its Synchronization to Environmental Cycles

At the simplest level, one way in which the nervous system might generate different circadian patterns in nocturnal and diurnal animals is that the central clock and mechanisms responsible for its synchronization with a light-dark cycle could differ, while the coupling of that clock to the physiological and behavioral functions that it regulates could be the same. However, a sizeable body of data has accumulated to support the idea that mechanisms coupling the clock to the environment are actually the same.

This issue has been examined via behavioral studies in a variety of mammals, including humans. One line of such work has involved studies looking directly at mechanisms that synchronize the clock with a light-dark cycle. This entrainment process involves a rhythm in how the clock itself can be shifted by light. In both nocturnal and diurnal animals, light has relatively little effect during the day, but causes delays early in the night and advances late at night. As this rhythm is responsible for the pattern of entrainment of the clock itself to light, it suggests that the coupling between the clock and photic inputs to it are the same in nocturnal and diurnal species. This model is further supported by more direct studies of the brain mechanisms involved in the process.

At the center of this system is a small collection of neurons within the ►hypothalamus referred to as the ►suprachiasmatic nucleus ►(SCN) [4]. Cells within it receive input from the retina that is responsible for the entrainment of that clock to the light-dark cycle, and that emit signals that broadcast temporal information directly and indirectly to a variety of other regions of the brain [4]. Several indices of overall SCN activity fluctuate on a daily basis and have patterns that are very similar from one species to another, regardless of whether they are nocturnal or diurnal [5]. For example, rhythms in metabolism within the SCN, as measured by glucose uptake, peak during the day in representatives of widely varying taxa exhibiting a range of activity patterns (e.g., lab rats, Turkish hamsters, golden hamsters, mice, opossums, squirrel monkeys, sheep, house sparrows and cats). Another indication that the SCN functions similarly in species with different behavioral rhythms is that firing rates of neurons peak during the day in diurnal chipmunks as well as in several nocturnal rodents. The most direct evidence that the key differences between nocturnal and diurnal species lie downstream of the primary circadian ►oscillator has been obtained recently through direct examination of molecular elements intrinsic to it. *Per1* and *Per2* are ►clock genes representing important components of that clock and their expression patterns have now been examined in several diurnal and nocturnal species. In all of these, rhythms in messenger RNA (mRNA) for *Per1* and *Per2* peak during the day. Taken together, the considerations above suggest that entrainment of the circadian oscillator to the light-dark cycle are the same in nocturnal and diurnal mammals and that the coupling of the clock to the functions that it controls are therefore likely to differ.

## Clock-Driven Output Signals

Differences in the coupling of the circadian oscillator to the systems that it controls could theoretically reside in

the SCN or in tissues that receive direct or indirect signals from it. In nocturnal mammals the SCN uses a combination of classical axonal outputs and an as yet unidentified factor that is released into, and diffuses through, the ►ventricular system. This diffusible factor has not been identified in any species, and there are no data bearing on whether one exists in diurnal animals or not. The discussion here therefore focuses on axonal output systems. The SCN projects to a relatively restricted set of targets located primarily within the hypothalamus in nocturnal rodents. Information on this issue is more limited in diurnal mammals, but recent studies have revealed that the SCN projects to the same regions in a diurnal rodent, *Arvicanthis niloticus*, (also referred to as a grass rat), as in nocturnal ones [6].

Another feature of SCN outflow that has been examined is the nature of the molecules the SCN uses to transmit temporal information to other regions of the brain. Three such molecules have been identified in both nocturnal and diurnal species: vasopressin (VP), vasoactive intestinal polypeptide (VIP) and ►prokineticin 2 (PK2). VP has been seen in cells within the SCN of almost every species that has been examined and the projections of these cells represent a major output of the SCN. Evidence that VP release is the same in diurnal and nocturnal species was obtained originally through its measurement in ►cerebral spinal fluid in many mammals and these rhythms peaked during the day in all of them. *VP* mRNA in the SCN fluctuates on a daily basis in two diurnal species, (*Arvicanthis ansorgei* and *Arvicanthis niloticus*), in a pattern that is the same as in several nocturnal rodents. Thus, both transcription of its gene and the daily rhythm in its secretion suggest that the VP signal is the same in nocturnal and diurnal species.

This is likely to be the case for the VIP output as well. Neurons containing VIP exist in the SCN of all species examined to date, and their axons form a major output system. Rhythms in *Vip* mRNA are very different in male and female lab rats, with the rise occurring approximately ten hours earlier in females than in males. The same patterns are seen in the SCN of female and male *A. niloticus*, respectively.

Recent evidence has implicated prokineticin 2 (PK2) as a third output signal, contributing in this case to rhythms in locomotor activity. The gene for PK2 in *A. niloticus* is expressed according to the same rhythmic patterns as in mice.

Although there are likely to be other molecular outputs of the SCN, and these might vary across species, all of those that have now been examined are the same in the nocturnal and diurnal animals that have been looked at. The current data thus support the conclusion that the primary differences between nocturnal and diurnal species emerge from differences in responsiveness of SCN targets to SCN signals, or downstream of these targets, rather than from temporal or spatial characteristics of output systems within the SCN. Studies of SCN targets in diurnal mammals, discussed next, are more scarce and have focused primarily on the diurnal grass rat, *A. niloticus*.

## The Lower Subparaventricular Zone (sPVZ)

It has been suggested that one source of the differences between diurnal and nocturnal mammals may be a group of cells located just dorsal to the SCN [6]. The primary projection of the SCN extends dorsally into a region known as the ►subparaventricular zone (sPVZ). The ventral portion of the sPVZ, referred to as the lower sub-paraventricular zone (LSPV) shows significant functional differences when diurnal grass rats are compared to nocturnal lab rats. This was first seen is studies of what is referred to as an ►immediate early gene called cFos which regulates the expression of a host of other genes. Rhythms in cFos are apparent in the LSPV of both lab rats and grass rats, but in grass rats the rising phase of the rhythm begins four to five hours after lights go off in a light-dark cycle with 12 h of light and 12 h of darkness, whereas in lab rats this rise does not occur until eight to nine hours later, when the lights come on. Another important difference is that, whereas in grass rats the cFos rhythm in this cell population persists in constant darkness, it goes away in lab rats held in the same conditions. This region also exhibits a rhythm in a calcium-binding protein, calbindin, in grass rats but not lab rats.

Further support for a role of the LSPV in the circadian regulation of diurnality has come from work on activity rhythms of grass rats with axon-sparing lesions in this region [6]. Animals with damage to the LSPV exhibited severe disturbances in both free-running and entrained activity rhythms. Furthermore, an increase in the proportion of activity that occurs at night was positively correlated with the extent of damage produced by these lesions. It therefore seems likely that although the LSPV is not essential for the maintenance of diurnality, it contributes to the organization of the normal stable diurnal activity rhythms in these animals.

In grass rats and lab rats the SCN and LSPV project to virtually all of the same target regions. Taken together, the data suggest that cells in the LSPV could function as oscillators that modulate the ways in which target cells respond to other signals originating in the SCN. Given the species differences in the rhythms in the LSPV, its influence on rhythms in other SCN targets is likely to differ considerably in lab rats and grass rats. It has been proposed that the LSPV could thus contribute to the maintenance diurnality through effects on rhythms within a host of other cells that receive direct input from the SCN [6]. These include cells with highly specialized functions as well as ones with more widespread projections and more general functions.

## Reproductive Rhythms

Several specialized groups of neuroendocrine cells receive direct input from the SCN, including those associated with estrus-related events. As noted above, many behavioral and neuroendocrine events associated with reproduction undergo rhythms that peak at very different times of day in diurnal and nocturnal animals [7]. This is the case for sexual behavior and for the secretion of hormones associated with it. Neuroendocrine functions are particularly amenable to analysis of SCN target systems because direct projections from the SCN to at least some neuroendocrine cells have been identified. This is the case for some neurons that contain estrogen receptors (ERs) and others containing gonadotropin-releasing hormone (GnRH). Below, the roles of the latter population of cells in regulation of the timing of the ovulatory surge in luteinizing hormone (LH), and how it differs in nocturnal and diurnal animals, are discussed.

Ovulation is triggered by a surge in LH that occurs at the end of the follicular phase of the female reproductive cycle. In female lab rats and hamsters it occurs three to four hours prior to the onset of estrus behavior, which begins at the time of lights-off. In these species, both the behavior and the LH surge are promoted by rising levels of ovarian hormones in conjunction with a signal originating in the SCN. The SCN signal reaches both GnRH neurons and estrogen receptor-containing cells in the ►preoptic area (POA), a region critical for the surge. The system is therefore one in which the circadian regulation of specific behavioral and physiological events depends upon well-defined populations of cells to which the SCN projects directly in nocturnal rodents. These pathways have now been examined in diurnal grass rats in efforts to identify where and how the system might differ in nocturnal and diurnal species.

The LH surge associated with estrus occurs 12 h apart in grass rats and lab rats, as does a rise in cFos within GnRH neurons associated with it [7]. Activation of these cells occurs 12 h apart in ►ovariectomized grass rats and lab rats that are kept in constant darkness, providing evidence that endogenous circadian mechanisms regulate the timing of GnRH neuron responses to steroid hormones. This could occur via direct projections from the SCN to these cells [6].

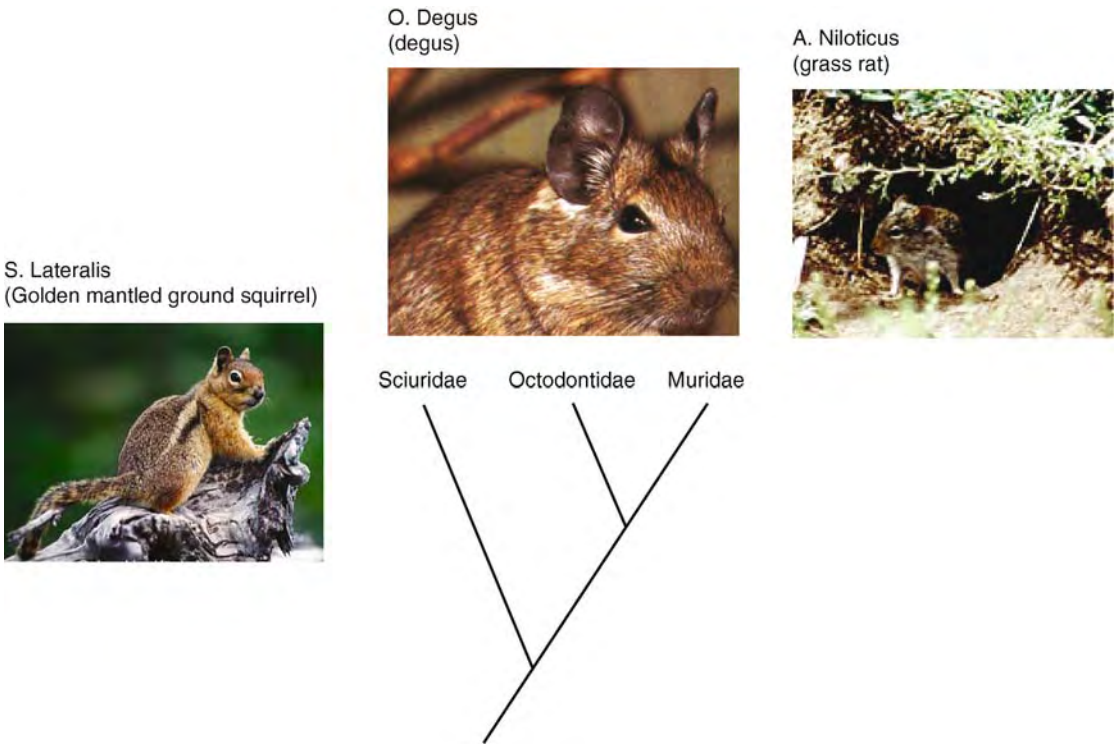
One important signal released by SCN cells projecting to GnRH neurons in rats is VIP. Evidence for such a projection comes from the demonstration of VIP fibers forming synapses, most of which are eliminated by SCN lesions, on GnRH cells. A role for this projection in the timing of the surge in nocturnal rodents is further suggested by evidence that it is delayed and attenuated by interference with VIP. Another way in which the SCN appears to promote the surge is through the release of VP, which, when administered into the POA generates a surge in SCN-lesioned lab rats. In diurnal grass rats, appositions between fibers containing either VIP or VP and GnRH cells are numerous in regions critical for the generation of the LH surge [7]. As rhythms in mRNA for these two peptides are very similar in lab rats and grass rats, it is likely that VP and VIP rise and fall at the same times of day in these two species.

Taken together, the data from lab rats and grass rats suggest that the SCN releases the same rhythmic signals onto a population of cells that is very different with respect to their circadian pattern of function in diurnal and nocturnal rodents. The question of diurnality in this system is therefore a question of what might make GnRH neurons respond differently to VIP and VP in grass rats and lab rats (Fig. 1). Theoretically, the answer could be that GnRH neurons are intrinsically different with respect to the ways in which they respond to these two signals. Another possibility is that GnRH neurons are fundamentally the same in the two species, and that differences are produced by inputs to them from other regions. The LSPV could represent such an area.

## Sleep and Arousal

The neural control of the ►sleep-wake cycle involves numerous neuronal populations in the forebrain, midbrain and hindbrain [8]. Two mutually antagonistic components of this complex network are found in the in the hypothalamus-preoptic area. One of these is a small cluster of cells in the ►ventrolateral preoptic nucleus (VLPO) that contains ►galanin and provides inhibitory inputs to a series of ascending arousal systems originating in the hypothalamus and ►brainstem. In nocturnal animals these cells become active during the light phase of the cycle when levels of sleep are highest (Sherin et al., 1996). The primary ►hypothalamic system that antagonizes the sleep promoting influence of the VLPO is made up of ►orexin/hypocretin-positive cells located in the lateral hypothalamus. These neurons provide excitatory inputs to most of the arousal systems that are inhibited by the VLPO, and in lab rats these neurons are most active during the dark phase of the day-night cycle when these animals are active. The diurnal grass rat shows a very similar distribution of galanin-positive neurons in the VLPO and orexin-positive cells in the lateral hypothalamus, and rhythms in both of these cell groups are 180° out of phase in diurnal grass rats and nocturnal lab rats [5].

The question of what is responsible for this complete reversal in the rhythms in VLPO and orexin/hypocretin neurons is of considerable interest. In the case of the arousal system, fibers originating from both the LSPV and the SCN of grass rats appear to project to cells in the lateral hypothalamus that contain orexin/hypocretin. Thus, interactions between these two sources of circadian signals may influence the phase of the rhythm in activity of orexin/hypocretin cells and consequently the arousal systems to which they project. As rhythms in



**Nocturnal/Diurnal. Figure 1** Phylogenetic relationships of three diurnal rodents that are currently being studied. Neural mechanisms associated with circadian timkeeping systems are similar in some, but not all, ways in these species. This may reflect the fact that diurnality evolved independently in the three lineages.

the LSPV are very different in grass rats and lab rats, these interactions are likely to have very different effects.

The circadian influence on the sleep-promoting system originating in the VLPO may be achieved in a more indirect fashion, as projections to this region from the LSPV and the SCN are sparse in both grass rats and lab rats. One route through which circadian signals may reach the VLPO includes SCN cells that project to the ►dorsomedial nucleus of the hypothalamus, which, in turn, contains cells that project to the VLPO. It has been suggested that the integration of circadian signals that influence the phase of rhythms of neural activity in the VLPO may take place in the ►dorsomedial nucleus [9]. Differences within these regions of the hypothalamus could therefore contribute to differences in the daily organization of sleep of nocturnal and diurnal animals.

## Summary and Significance for Humans

The system through which the SCN regulates specific rhythms comprises multiple parallel but intersecting output pathways. Rhythms within the SCN appear to be the same in nocturnal and diurnal species, but direct and indirect components of this output system differ between them in a variety of ways. Some SCN targets have widespread projections and play regulatory roles in a variety of different functions, some of which are quite specialized (e.g., VLPO) and others that play more general roles (e.g., LSPV). Rhythms in these components of the system exhibit an array of patterns of rhythmicity with varying phase relationships in nocturnal and diurnal species. Other SCN targets, such as neuroendocrine GnRH cells, receive inputs that converge on them from a variety of regions but have very restricted output pathways, are more specialized and are linked more directly to the endpoints whose functions they regulate. In the case of GnRH cells, the rhythms are inverted by 180° in nocturnal laboratory rats and diurnal grass rats.

Taken together, the overall pattern of results emerging from recent studies on the issue suggests that there is not one simple all-or-none "switch" that determines whether an animal is diurnal or nocturnal. The ultimate differences between mammals expressing these different patterns are more likely to emerge through a variety of interrelated mechanisms operating at varying points between the SCN and the behavioral and physiological systems that it regulates. However, these data supporting this general model come from comparisons between only one nocturnal species, lab rats, and one diurnal one, grass rats. Although it seems likely that this general principle will apply to other diurnal species, including humans, the specifics of where the differences are, and the details of the rhythmic patterns in such cell populations, may vary.

# Node

## Definition

Primary organizer present in all chordates, called node in chick and mouse, Spemann's organizer in frog, and the shield in fish. It produces signals that are involved in neural induction.

►Evolution and Embryological Development of the Forebrain

# Node of Ranvier

## Definition

The node of Ranvier is a small stretch of bare axonal plasma membrane (axolemma) that separates myelin segments along individual myelinated nerve fibers.

In the peripheral nervous system, individual Schwann cells form each myelin sheath segment, while in the central nervous system, oligodendrocyte processes form myelin sheath segments. Easily identified in longitudinal sections, nodes separate the terminal paranodal loops of adjacent myelin internodes. Nodal length is related to the diameter of the axon and can vary from less than 1 μm in the small fibers of the optic nerve to more than 5 μm in the large fibers of the spinal cord.

The node is the site of $Na^+$ channels clusters to allow for saltatory conduction of action potentials, as well as the site for axonal sprout formation in peripheral nerve regeneration. (Louis Antoine Ranvier, 1835–1922).

# Nodes in Acoustics

## Definition

A point, line, or surface of a standing wave in which the net energy flux is zero at all points.

►Acoustics

# Nodulus

## Synonyms

Nodule

## Definition

The vermis segment nodulus and the hemisphere segment flocculus together form the flocculonodular lobe.

Phylogenetically it is very old and is thus called the archicerebellum. Since its afferents come mainly from the vestibular nuclei (vestibulocerebellar tract), the "vestibulocerebellum" is another synonym.

►Cerebellum

# Nogo

## Definition

Member of the reticulon protein family with potent inhibitory effects for neurite outgrowth. The membrane- bound Nogo is associated with CNS myelin and

exists as three splice variants (Nogo-A, Nogo-B and Nogo-C). Neutralization of Nogo in vivo results in enhanced regeneration of severed axons, increased plasticity of uninjured fibers, and functional recovery in animal models of CNS injury.

## Nogo-Neutralizing Antibody IN-1

### Definition

An antibody generated using the rat CNS myelin N1250 protein. It is raised in hybridoma cells and has been shown to promote axonal regeneration in the damaged central nervous system (CNS).

## Noise

### Definition

A signal, which is superimposed onto the signal of interest. Noise can be random or deterministic.

►Signals and Systems

## Noise, Colored

### Definition

A random noise whose spectrum is not flat, i.e., its amplitude at some frequencies is different from that at other frequencies.

►Signals and Systems

## Noise, White

### Definition

Random noise, whose spectrum is flat, i.e., its amplitude is the same at all frequencies. White noise at different time intervals is uncorrelated, unless the interval is zero.

►Signals and Systems

## Noise-induced Transport

### Definition

A phenomenon in which the fluctuations inherent in the system create or enhance directed motion.

►Brownian Ratchet

## Nominalism

### Definition

Nominalism is the doctrine that there are no universals, i.e. no abstract, general entities like e.g. Platonic forms.

Only particular things are thought to exist. The functions of universals are attributed to the signs of human language, i.e., as predicates or common nouns that can be applied to many particular things.

►Information
►Possible World
►Property

## NOMPC

### Definition

NOMPC forms a $Ca^{2+}$-permeable channel in Drosophila mediating sensory hair cell mechanotransduction.

►TRP Channels

## Non-associative Learning

### Definition

Non-associative learning can be defined as a change in the behavioral response that occurs over time in

response to a single type of stimulus. Habituation and sensitization are typical examples.

►Learning

## Non-conceptual Knowledge

### Definition

Non-conceptual knowledge is knowledge which cannot be communicated (fully and satisfactorily) by the use of concept words, for example pictorial knowledge or knowledge how to do something.

►Knowledge

## Nondeclarative (Implicit) Memory

### Definition

Nondeclarative memory refers to a heterogeneous collection of nonconscious memory abilities such as skills (e.g., riding a bicycle), conditioned responses, priming, skills, habits and other learnings, which are displayed through performance and not conscious recollection. These components are preserved in amnesic patients.

►Amnesia
►Long-Term Memory

## Non-dystrophic Myotonias

### Definition

Heterogenous group of rare hereditary diseases characterized by ►myotonia or electrical myotonia and resulting from mutations in several ►ion channel genes ($Cl^-$, $Na^+$, $Ca^{2+}$, $K^+$ channels). There are three main groups. Sodium channel dysfunctions underlie paramyotonia congenita (which is cold-sensitive), $K^+$-aggravated myotonia, and ►hyperkalemia periodic paralysis with myotonia. Chloride channel dysfunctions underlie the myotonia congenita disorders (ClC-1 mutations cause 'pure' myotonia congenitalis), which are not sensitive to temperature. Channel myotonia comes in a recessive (Becker type) form and a dominant (Thomsen type) form. In contrast to ►myotonic dystrophy, paramyotonia congenita is a non-dystrophic, rather benign disorder, in which the skeletal muscle is not dystrophic, but rather shows hypertrophy secondary to 'exercise' by prolonged contractions.

## Non-holonomic Constraint

### Definition

A non-integrable constraint involving the velocities of the particles of a system.

►Mechanics

## Non-invasive Imaging Techniques

### Definition

Non-invasive imaging techniques like electroencephalography (EEG), magnetoencephalography (MEG) and functional magnetic resonance imaging (fMRI) allow the study of the human brain in vivo during active processing. Whereas EEG and MEG measure the electrical neuronal activity directly with high temporal (ms) but less spatial resolution (cm), fMRI is based on the hemodynamic changes following electrical brain activity. Since the hemodynamic response is slow (several seconds), fMRI has a poor temporal resolution.

However, spatial resolution is in the range of millimeters.

## Nonlinear Control Systems

Nahum Shimkin
Department of Electrical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

### Definition

►Nonlinear control systems are those ►control systems where nonlinearity plays a significant role, either in the controlled process (plant) or in the controller itself.

Nonlinear plants arise naturally in numerous engineering and natural systems, including mechanical and biological systems, aerospace and automotive control, industrial process control, and many others.

Nonlinear control theory is concerned with the analysis and design of nonlinear control systems. It is closely related to nonlinear systems (►System – nonlinear) theory in general, which provides its basic analysis tools.

## Characteristics

Numerous methods and approaches exist for the analysis and design of nonlinear control systems. A brief and informal description of some prominent ones is given next. Full details may be found in the textbooks [1–6], and in the Control Handbook [7].

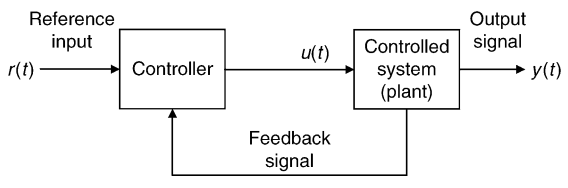
Most of the theory and practice focus on feedback control. A typical layout of a feedback control system is shown in Fig. 1.

A basic (finite dimensional, time invariant) nonlinear system in continuous time may be specified by the standard state-space model:

$$\begin{aligned} \tfrac{d}{dt}\, x(t) &= f(x(t), u(t));\ x(0) = x_0 \\ y(t) &= h(x(t), u(t)) \end{aligned} \qquad (1)$$

or, more succinctly, as $\dot{x} = f(x,u)$ (the state equations) and $y = h(x,u)$ (the output equation). Here $x(t) \in R^n$ is the state vector, $u(t) \in R^m$ is the vector of input signals, and $y(t) \in R^q$ is the output vector. This model may apply to the plant (see Fig. 1), as well as to the controller (with appropriately modified inputs and outputs). The state of the overall feedback system is then the combined state of the plant and the controller. A specific class of systems that has been studies in depth is linear-in-control systems, where $f(x,u) = f_0(x) + \sum_{i=1}^{m} f_i(x)u_i$. We limit the discussion here to continuous-time systems, although similar theory exists for the discrete-time case.

Nonlinear models may be classified into smooth and non-smooth ones. The latter are often associated with parasitic effects such as dry friction and actuator saturation. When significant, these effects may enter as constraints in the design, or even require specific compensation techniques. Our discussion below pertains mainly to smooth nonlinearities.



**Nonlinear Control Systems. Figure 1** Basic feedback control system.

## Basic Concepts from Systems Theory

The following notions from systems theory are of particular importance and relevance to nonlinear control, and are dealt with in depth in the cited texts.

a. *Equilibrium points:* For the nonlinear system $\dot{x} = f(x)$, a point $x_e$ in the state space is an equilibrium point if $f(x_e) = 0$. Similarly, for the controlled system $\dot{x} = f(x,u)$, the pair is an equilibrium point if $f(x_e, u_e) = 0$.

b. *Lyapunov stability:* This is the basic notion of stability that deals with the asymptotic behavior of trajectories that start off an equilibrium point. An equilibrium point $x_e$ of the system $\dot{x} = f(x)$ is (weakly) *stable* if all solutions *x(t)* that start near $x_e$ stay near it forever. It is *asymptotically stable* if, in addition, *x(t)* converges to $x_e$ whenever started near enough to it. If this convergence occurs for any initial state then $x_e$ is *globally* asymptotically stable. Exponential stability requires an exponential rate of convergence to the equilibrium. Note that a nonlinear system may have several ►equilibrium points, each with different stability properties. For input-driven state equations with unspecified input, namely $\dot{x} = f(x,u)$, these stability notions are generalized by the concept of *input-to-state stability*, which requires the state vector to be close to equilibrium whenever both the initial state and the control input *u(t)* are close to their equilibrium values.

c. *Lyapunov's direct method:* The most general approach to date for stability analysis of nonlinear systems is Lyapunov's method, which relies on the concept of a ►Lyapunov function or generalized energy function. Essentially, a Lyapunov function for an equilibrium point $x_e$ of the system $\dot{x} = f(x)$ is a differentiable function *V(x)* which has a strict minimum at $x_e$, and so that its derivative $\dot{V}(x) \stackrel{\Delta}{=} \frac{\partial V(x)}{\partial x} \cdot f(x)$ along the system trajectories is negative in some neighborhood of the equilibrium. Existence of such *V(x)* implies stability of $x_e$, and further implies a symptotic stability if *V(x)* is stricty negative for $x \neq x_e$. Many extensions and refinement of this result exist, covering various stability properties such as exponential stability, global stability, and estimates on the domain of attraction of the equilibrium.

We note that various converse theorems establish the existence of a Lyapunov function whenever the equilibrium point is stable (in the appropriate sense); however no general procedure exists for finding such a function.

d. *Linearization:* The small-signal behavior of the nonlinear system (1) around an equilibrium point $(x_e, u_e)$ may be captured through a linear state equation of the form: $\dot{\tilde{x}} = A\tilde{x} + B\tilde{u}$, where $\tilde{x}(t) = x(t) - x_e, \tilde{u}(t) = u(t) - u_e$, and the matrices $(A,B)$ are computed as corresponding gradients of the system function $f(x,u)$ at $(x_e,u_e)$. A similar relation holds for the output equation. A basic stability result (also known as

N

Lyapunov's indirect method) is that the Hurwitz-stability of the matrix $A$ (namely, all eigenvalues have strictly negative real part) implies the asymptotic stability of the respective equilibrium point.

e. *Input-output stability and gain:* The dynamic system (1) is said to input-output stable with respect to a signal norm $||\cdot||$, if $||y(\cdot)|| \leq \gamma||u(\cdot)|| + \beta$ for some constants $\gamma \geq 0$ and $\beta$ (and every input $u(\cdot)$ in the input space). The name BIBO stable is also used when the norm is the max norm, namely $||y(\cdot)|| = \sup_t ||y(t)||$. The system gain is the smallest number $\gamma$ that satisfied the above bound. For state-space models, various results relate input-output stability to corresponding stability properties of the state.

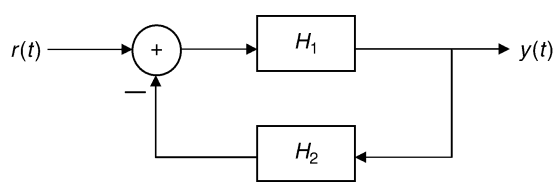
f. *Passivity:* The system-theoretic notion of passivity essentially captures the physical notion of a system that does not generate energy. As such, many mechanical and other systems satisfy this property. Passivity provides a useful analysis tool, and a basis for design methods. Notably, passivity implies stability, and the feedback connection of passive systems is passive.

g. *Controllability and Reachability:* These two closely-related concepts that apply to the state equation $\dot{x} = f(x, u)$ concern the possibility of reaching a given state from any other state (controllability) or reaching any other state from a given state (reachability) by choosing appropriate controls. Local versions focus on small neighborhoods of any given point. These properties have been studied in depth, especially for the class of linear-in-control systems, using tools from differential geometry.

h. *Observability:* Observability concerns the ability to distinguish between two (initial) states based on proper choice of input and observation of the system output. This concept, roughly, indicates whether a feedback controller that uses only the output $y$ can fully control the state dynamics.

## Analysis of Feedback Systems

Alongside general tools and methods from system theory, a number of results and analysis methods apply specifically to feedback systems, and some of these are described next. The basic feedback connection of two subsystems is shown in Fig. 2.



**Nonlinear Control Systems. Figure 2** Negative feedback connection.

*a. Limit Cycles and* ▶*Describing Function Analysis:* Limit cycles, or sustained oscillations, are common in nonlinear feedback systems, and are usually not desired in control systems. The describing function method checks for the possibility of oscillations by (i) approximating the response of nonlinear elements to sinusoidal inputs of given amplitude and frequency by their first harmonics only (ii) checking for the possibility of a loop gain of 1 with phase shift of 180° (the so called harmonic balance equation, for a negative feedback system). In case of a positive answer the analysis yields estimates for the frequency and amplitude of oscillations. While the method is essentially heuristic it is often useful for initial analysis.

*b. Small Gain Theorem:* The small gain theorem allows to establish the input-output stability of a feedback system from properties of its subsystems. Assume that $H_1$ and $H_2$ are both input-output stable, with respective upper-bounds $\gamma_1$ and $\gamma_2$ on their gains. If $\gamma_1\gamma_2 < 1$, then the feedback system in Fig. 2 is input-output stable, and its gain is bounded by $\gamma_1/(1 - \gamma_1$ that $\gamma_2)$.

*c. Circle Criterion:* Consider the special case $H_1$ is a linear time-invariant system, and $H_2$ is a static nonlinearity $h_2(\cdot)$ that satisfies a $[k_1, k_2]$ sector condition; in the scalar case this means that $h_2(x)/x \in [k_1, k_2]$. The circle criterion (and the related Popov criterion) provides frequency-domain conditions on the transfer function of $H_1$ that imply the stability of the feedback system.

## Design Methods

Control system design in general aims to satisfy certain performance objectives, such as stability, accurate input tracking, disturbance rejection, and robustness or insensitivity to parameter uncertainty (see the Control section for further details). The diverse nature of nonlinear systems necessarily calls for a variety of design approaches of different nature, and some of the more notable ones are briefly described below.

One design viewpoint is to consider the controlled system as an approximately linear one, or linearize the system by appropriate transformation, to which well-established linear control techniques may be applied.

*a. PID Control:* The PID (Proportional-Integral-Derivative) regulator is a simple linear controller, which is often cited as the most prevalent feedback controller. In particular, it finds use in many non-linear applications, from industrial process control to robotic manipulators. On-site tuning of the ▶PID controller parameters is often used, especially in the process control industry, and numerous manual and auto-tuning procedures exist based on direct measurement of some characteristics of the system response. Analytical

(model-based) design is of course also used, often building on one of the ►linearization methods below.

*b. Local linearization and Gain Scheduling:* The simplest analytical approach to controller design for a nonlinear system relies on fitting an approximate linear model to the controlled system, usually through local linearization around a typical working point (see above), and then designing a linear controller for this model. Evidently this method may fail when non-linear effects are significant. ►Gain Scheduling takes this approach a step further: Linear controllers are designed for a range of possible operating points and conditions, and the appropriate controller is put into play according to the current system state.

*c. Feedback Linearization:* ►Feedback linearization or ►global linearization uses input and state variable transformations to arrive to an equivalent linear system. As a simple example, the scalar system $\dot{x} = u^3 + f(x)$ is readily transformed to $\dot{x} = v$ by defining an auxiliary input $v = u^3 + f(x)$. A control law to determine $v$ can now be designed for the linear system, and the actual control $u$ may then be computed using the inverse relation $u = (v - f(y))^{1/3}$. The latter equation, which is in the form of state feedback, gives the method its name. One can distinguish between full state linearization, where the state equation is fully linearized, and input-output linearization, where the input-output map is linearized. In either case, measurement of the entire state vector is required to implement the transformation. The theory provides conditions under which feedback linearization is possible, and procedures to compute the required transformations.

The following methods approach the design problem directly using non-linear tools, notably ►Lyapunov stability and Lyapunov functions, and are notable examples of *robust* nonlinear control.

d. ►*Lyapunov Design and Redesign:* In Lyapunov-based design, a stable system is synthesized by first choosing a candidate Lyapunov function $V$, and then selecting a state-feedback control law that renders the derivative of $V$ negative. The Lyapunov redesign method provides the system with robustness to (bounded) uncertainly in the system dynamics. It starts with a stabilizing control law and Lyapunov function for the nominal system, and adds certain (non-smooth) terms to the control that ensure stability in the face of all admissible uncertainties. While Lyapunov redesign is restricted to systems that satisfy a matching condition, so that the uncertainty terms enter the state equations at the same point as the control input, the basic approach has been extended to more general situations using recursive or *backstepping* methods.

e. ►*Sliding Mode Control:* In this robust design approach, also known as Variable Structure Control, an appropriate manifold (often a linear surface) in the state space is first located on which the system dynamics takes a simple and stable form. This manifold is called the sliding surface or the switching surface. The control law is designed to force trajectories to reach that manifold in finite time, and stay there thereafter. As the basic control law is discontinuous by design around the switching surface, unwanted chattering around that may result and often require some smoothing of the control law.

Many other techniques from control engineering are applicable to the design of nonlinear systems. Among these we mention:

- Optimal Control: Here the control objective is to minimize a pre-determined cost function. The basic solution tools are Dynamic Programming and variational methods (Calculus of Variations and Pontryagin's maximum principle). The available solutions for nonlinear problems are mostly numeric.
- Model Predictive Control: An approximation approach to optimal control, where the control objective is optimized on-line for a finite time horizon. Due to computational feasibility this method has recently found wide applicability, mainly in industrial process control.
- Adaptive Control: A general approach to handle uncertainty and possible time variation of the controlled system model. Here the controller parameters are tuned on-line as part of the controller operation, using various estimation and learning techniques.
- Neural Network Control: A particular class of adaptive control systems, where the controller is in the form of an Artificial Neural Network.
- Fuzzy Logic Control: Here the controller implements an (often heuristic) set of logical (or discrete) rules for synthesizing the control signal based on the observed outputs. Defuzzification and fuzzification procedures are used to obtain a smooth control law from discrete rules.

A detailed description of these are related approaches, which are often considered as separate fields of control engineering, may be found in [7].

## Nonlinear System

### Definition

A system whose output spectrum contains frequency components in addition to those in the input to the system.

## Nonmonotone Dynamics

### Definition

Equations specifying state transition of a recurrent neural network consisting of units with nonmonotonic output functions.

## Non-NMDA-LTP

### Definition

LTP that does not require activation of the NMDA receptor for its induction. In most cases, voltage-gated $Ca^{2+}$ channels at presynaptic terminals play a role in its induction. A typical example is LTP in the hippocampal mossy fiber-CA3 synapse and it is believed that activation of presynaptic protein kinase A is involved in its expression.

## Non-photic

### Definition

Circadian rhythm phase is primarily under the influence of light acting through photoreceptors connected directly or indirectly to the circadian clock. However, certain phase shifts are induced by non-photic stimuli that influence the clock via pathways not directly involving retinal projections. Such shifts can be as great in magnitude as light-induced phase shifts. The term, non-photic stimulus, has had a non-specific use in reference to any non-light input to the circadian clock, including such endogenous neurotransmitters as serotonin agonists that are internally administered to test animals. A more specific application of the term is in reference to externally applied stimuli that exert phase control over the circadian clock. These non-photic (Stimuli, Shifts, Resetting) stimuli have a phase response curve (PRC) similar to that obtained by infusing neuropeptide Y (NPY) directly into the suprachiasmatic nucleus (SCN). This "NPY-type PRC" differs from the "light-type PRC" in several respects: (i) maximum phase advances occur during the mid- to late subjective day; (ii) phase delays occur during the subjective night; and (iii) there is no dead zone. Such stimuli apparently require an intact geniculohypothalamic tract (GHT) and activation of NPY neurons in the intergeniculate leaflet (IGL) that results in NPY release in the SCN.

## Non-rectifying Gap Junctions

### Definition

Non-rectifying gap junctions conduct ionic current equally well in both directions. In contrast to electrical synapses comprised of rectifying gap junctions, electrical synapses comprised of non-rectifying gap junctions transmit electrical signals in a bidirectional fashion.

►Electrical Synapses

## Non-REM (NREM) Cells

### Definition

Also Called Sleep-Active Neurons; Neurons that exhibit increases in extracellularly recorded discharge rate during NREM sleep compared to waking and REM sleep. This type of cell is mostly located in the anterior

hypothalamus and preoptic area (POA) and some are also located in the basal forebrain area, solitary tract nucleus, and in the dorsal raphe nucleus. The neurotransmitter identity of these neurons is not definitive but they are most likely to contain the neurotransmitter GABA.

►Rapid Eye Movement (REM) Sleep

## Non-REM Sleep

### Definition

In mammals there are two types of sleep – rapid eye movement (REM) and non-REM (NREM). Normally, when we first enter the sleep state it is via quiet NREM sleep.We lie passively, breathing slowly. Our eyes drift slowly back and forth and every once in a while we shift our sleep position. During non-REM sleep there are decreases in blood pressure, heart rate, and respiratory rate. One could therefore characterize NREM sleep as an exceedingly dormant behavioral state. There are many important events that occur during this state, however, such as increases in pulsatile release of growth and sex hormones from the pituitary, antibody production, and elimination of unwanted and excess mental traces. REM and NREM stages are defined in terms of electro-physiological signs that are detected with a combination of electroencephalography (EEG), electrooculography (EOG) and electromyography (EMG), the measurement of which in humans is collectively termed polysomnography. In a human, NREM sleep is divided into four stages, each corresponding to an increasing depth of sleep. As the depth of sleep increases, the EEG recordings are progressively dominated by high-voltage, low-frequency wave activity. Stage I NREM sleep is characterized by relatively low voltage (<50 μV), mixed frequency activity (4–7 Hz: theta frequency range) and vertex sharp waves in the EEG. Stage II NREM sleep is characterized by slow (<1 Hz) oscillations with distinctive sleep spindles (waxing and waning of 12–14 Hz waves lasting between 0.5 and 1.0 s; peak amplitudes of 100 μV) and K-complex waveforms (a negative sharp wave followed immediately by a slower positive component). Stage III NREM sleep is demarcated by the addition to the spindling pattern of high voltage (>100 μV) slow waves (1–4 Hz; delta frequency waves), with no more than 50% of the record occupied by the latter. In Stage IV, the record is dominated by high-voltage (150–250 μV) slow waves (1–3 Hz). Collectively, stages III and IV NREM sleep are also called slow-wave sleep (SWS). Distinctions between stages of NREM sleep in animal models (mouse, rat, cat, and non-human primates) differ slightly from that of humans. In these animals, NREM sleep is normally divided into two stages (SWS I and II). SWS-I is identified by the presence of sleep spindles in the cortical EEG. SWS-II is considered deep sleep, also termed delta sleep, and is identified by the presence of high amplitude, low-frequency waves (0.1–4.0 Hz) in the cortical EEG. NREM sleep can also be confidently identified in most reptiles and birds but is not seen with convincing clarity in either fish or amphibians.

## Nonsense Mutation

### Definition

A nucleotide substitution that causes premature termination of protein translation, which invariably results in nonfunctional proteins.

## Non-spanning Muscle Fiber

### Definition

A muscle fiber that ends in the middle of the muscle belly and is attached with a tapering end to the stroma of the muscle. It does not span the distance between two aponeuroses (tendon plates) of a muscle, but is attached to one of them by a myotendinous junction.

►Intramuscular Myofascial Force Transmission

## Nonspecific Control Parameter

### Definition

A nonspecific control parameter does not prescribe or contain the code for an emerging pattern. Rather, the nonspecific control parameter leads a dynamical system through a variety of patterns or states. When the control

parameter passes through a critical point, a qualitative change (bifurcation) occurs in the dynamical system (e.g., coupled oscillators) leading to a new output pattern.

# Non-steroidal Anti-inflammatory Drugs (NSAID)

## Definition

Non-steroidal anti-inflammatory drugs reduce pain, fever, and inflammation. The term "nonsteroidal" is used to distinguish these drugs from steroids, which have a similar anti-inflammatory action.

## Synonyms

Exocytosis; Vesicle fusion

## Definition

Vesicular release of neurotransmitters, hormones or mediators for cellular communications at sites other than the synaptic cleft.

## Characteristics

### Diversity of the Molecular Machinery for Exocytosis

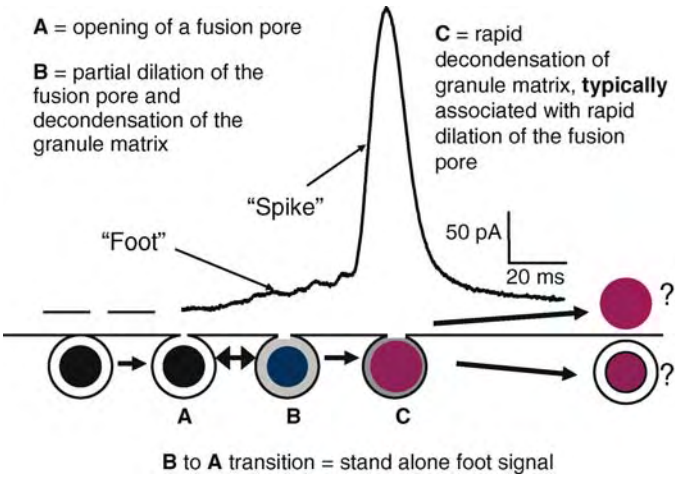
The process of exocytosis mediates the cellular secretion of chemicals (including neurotransmitters, hormones and mediators) that are stored in intracellular vesicles or granules. In addition, exocytosis also regulates the delivery of transmembrane proteins to the plasma membrane. In the last 10 years, over a dozen proteins (each typically with multiple isoforms [1]) in the molecular machinery that mediate, or regulate, exocytosis have been identified. It is increasingly clear that this machinery is not identical in different cell types, or even among different types of granules in the same cell. Here, we shall discuss how changes in the molecular machinery of exocytosis may contribute to some of the variability in the quantal release and $Ca^{2+}$-sensitivity among the different types of granules.

### Detection of Quantal Release from Different Types of Granules

In most neurons, neurotransmitters (e.g. dopamine) are stored in small synaptic vesicles (SVs; average diameter of ~50 nm) and peptides (e.g. arginine vasopressin) are stored in large dense core granules (LDCGs; average diameter of ~200 nm). In electron micrographs, the lumen of a SV is electron lucent but that of a LDCG is electron opaque. The electron dense material (dense core) in the LDCG is largely contributed by the presence of either a gel-like matrix, or the dense packaging of crystalline cargo. In the neuroendocrine system, secretory cells such as adrenal chromaffin cells store catecholamine hormones (e.g. adrenaline) in LDCGs. In some interneurons (e.g. in sympathetic ganglia) and chemosensory cells (e.g. carotid glomus cells), neurotransmitters are stored in small dense core granules (SDCGs; average diameter of ~100 nm).

The development of carbon fiber ►amperometry has enabled researchers to study in detail the release kinetics of easily oxidizable transmitters (e.g. catecholamines) from a single granule. Each molecule of catecholamine released from the cell is oxidized by the carbon fiber electrode (placed on the cell surface) and the resultant electrical signal is measured as an amperometric current. Figure 1 shows an example of a large amperometric signal recorded from a rat chromaffin cell during the exocytosis of a LDCG. Upon the fusion of a LDCG with the plasma membrane, the lumen of the granule forms a transient connection (a ►fusion pore) with the exterior of the cell.

The fusion pore first opens to a semi-stable state that lasts for up to tens of milliseconds, and results in a leakage of catecholamines (detected as the "foot" signal; Fig. 1). Occasionally some fusion pores flicker and close at this stage and give rise to the "stand-alone" foot signals. For the vast majority of LDCGs, the semi-stable fusion pore suddenly starts to dilate very rapidly and the rapid release of catecholamine gives rise to the "spike" phase of the amperometric signal. The rapid dilation of the fusion pore is significantly driven by the rapid decondensation (and probably rapid expansion) of the gel matrix. The decondensation of the gel matrix is in turn regulated by the change in vesicular pH and the concentrations of other ions (e.g. $Ca^{2+}$). The amount of catecholamines released from a single granule (i.e. quantal size, Q) can be estimated from the time integral of the amperometric signal. The



**Non-Synaptic Release. Figure 1** An amperometric signal showing the complex kinetics of catecholamine release from a large dense core granule (of a rat chromaffin cell). The overall release kinetics was determined by the complex interactions between the fusion pore and the gel matrix.

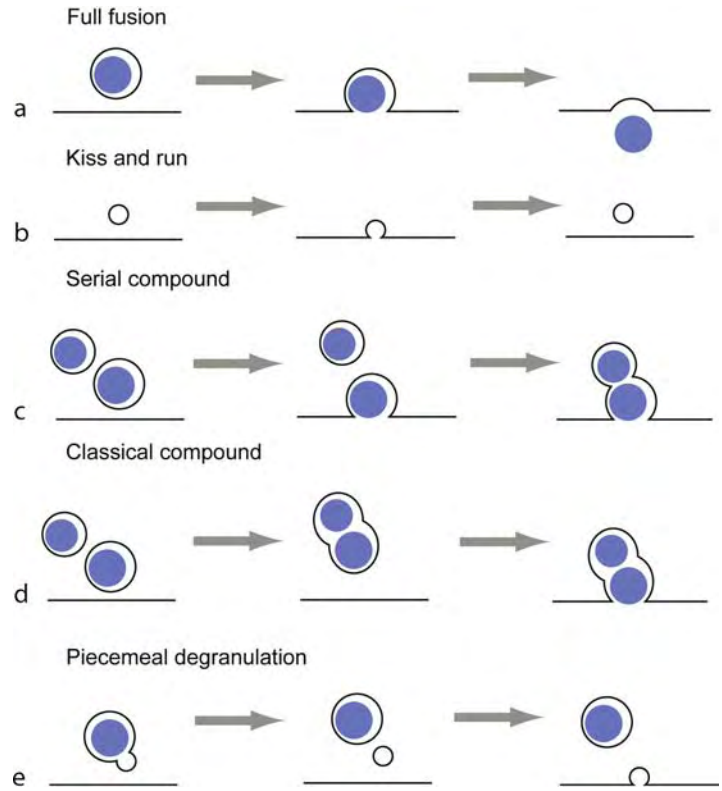
kinetics of main spike provides information on the rapid phase of release from a single granule, and the kinetics of the semi-stable fusion pore can be inferred from the foot signal.

In general, granules with larger vesicular diameters have been associated with larger values of Q as well as slower quantal release kinetics. For example, in leech Retzius cells, the LDCGs have larger Q values and the main spike of the amperometric signal from LDCGs also exhibits slower kinetics than those from SVs [2]. However, the slowing in the kinetics of quantal release does not increase monotonically with granule size. Our recent study in chromaffin cells [3] shows that in some LDCGs with very large Qs, their most rapid phase of release is comparable or even faster than LDCGs with smaller Qs. While the semi-stable fusion pore of a LDCG with a larger Q tends to persist for a longer duration, it also tends to reach a larger size before the onset of rapid dilation. Moreover, once the fusion pore of a LDCG with very large Q starts to dilate, the spike portion of the amperometic signal typically has very rapid kinetics [3]. Thus, other than the differences that are directly caused by the vesicular size, differences in fusion pore structures can also contribute to the variability in release kinetics among the different types of granules.

## Different Forms of Exocytosis

The fusion of a chromaffin LDCG shown in Fig. 1 reflects the "►full fusion" type of exocytosis in which a single granule fuses with the plasma membrane and releases its entire content (Fig. 2a). However, other forms of exocytosis have also been reported (Fig. 2).

Amperometric studies have shown that SVs in midbrain dopamine neurons [4] as well as chromaffin LDCGs [5] can undergo "►kiss and run" exocytosis (Fig. 2b). During this mode of release, the fusion pore can either close before the complete discharge of if its vesicular content, or undergo rapid flickering such that only a fraction of the vesicular content is released during each flicker [4]. This mode of release allows a vesicle to be reused with minimal reorganization of the molecular machinery that is involved in exocytosis. A recent study with two photon fluorescent microscopy [6] has shown that chromaffin LDCGs can also undergo "►serial compound" exocytosis (Fig. 2c). During this mode of exocytosis, a granule that is deeper in the cytoplasm fuses with another granule which has already fused the plasma membrane. Because of the increased distance for the diffusion of transmitters to the cell's surface, the release kinetics of granules deeper in the cytoplasm is expected to be slower. This mode of exocytosis is found to occur predominantly in the intercellular space in a cluster of chromaffin cells and only during high intensity stimulation [6]. Other forms of exocytosis, which have been described in white blood cells, include "►classical compound exocytosis" and "►piecemeal degranulation." "Classical compound exocytosis" involves the pre-fusion of granules before they finally fuse with the plasma membrane (Fig. 2d) and "piecemeal degranulation" involves the exocytosis of small vesicles that are probably formed by a fission process from certain type of LDCGs (Fig. 2e). What determines the prevalent form of exocytosis in each type of granule in a certain cell type is unclear, but both the selective expression of specific molecular machinery of exocytosis in different types of granules (see next section), as well as their selective regulation by specific intracellular messengers such as $Ca^{2+}$ (for example, see [5] have been implicated.



**Non-Synaptic Release. Figure 2** Different forms of exocytosis. The dense core in individual dense core granules is depicted in *blue*.

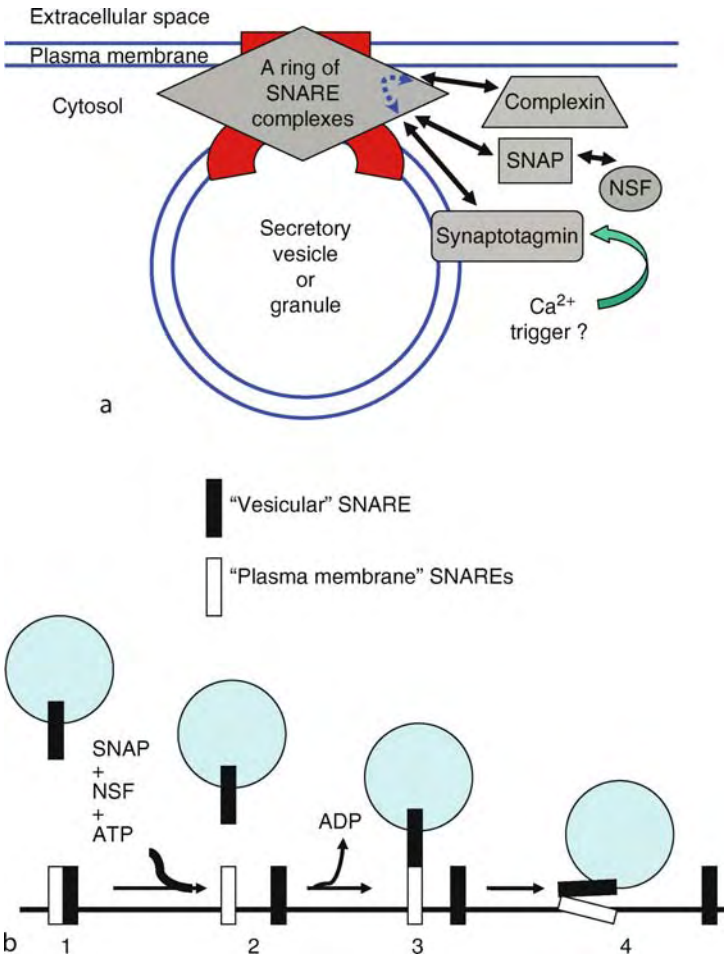
## Difference in the Molecular Machinery of Fusion may Contribute to the Variability in Release Kinetics and $Ca^{2+}$-Sensitivity Among Granule Subtypes

As described earlier, one factor which may contribute to the differences in the release kinetics between SVs and LDCGs is the structure of the fusion pore. This raises the question whether the molecular machinery for fusion is different among the various types of granules. It is generally accepted that a protein complex, called the soluble ►N-ethylmaleimide-sensitive factor (NSF) attachment protein receptor (SNARE, typically concentrated at lipid rafts), can act as a physical link between a "docked" vesicle (or granule) and the plasma membrane (Fig. 3a), and is part of the essential machinery for regulating exocytosis of SVs and LDCGs.

In the presynaptic terminal, the ►soluble NSF attachment protein receptor (SNARE) complex comprises three proteins, syntaxin, ►synaptosome-associated protein of 25 kDa (SNAP-25) and synaptobrevin (also called *v*esicle *a*ssociated *m*embrane *p*rotein, abbreviated as VAMP). In the trans-configuration of the SNARE (Fig. 3b), syntaxin and SNAP-25 are predominantly on the plasma membrane, and synaptobrevin is on the vesicular membrane. Each of the three proteins in the SNARE complex has multiple isoforms, and different cell types express different isoforms [1].

It turns out that cell types which undergo the more unusual forms of exocytosis (such as piecemeal degranulation in some white blood cells, see Fig. 2), indeed have some unusual isoforms of SNAREs expressed on their granules. Moreover, the proportion or molecular conformation of the dominant isoform(s) in an individual cell type can also be differentially regulated (e.g. by cAMP, diacylglycerol or protein kinase C). In view of these complexities, it is likely that variations in the molecular structure of the SNARE complex contribute to the diversity among the fusion pore structure and kinetics in different types of granules.

In addition to the more rapid kinetics for quantal release, the exocytosis of SVs has been suggested to have a higher $Ca^{2+}$ requirement than LDCGs. Moreover, even among the SVs, both synchronous (i.e. those triggered with a minimal delay after a rise in the concentrations of intracellular $Ca^{2+}$ ($[Ca^{2+}]_i$) and asynchronous (i.e. those triggered with an obviously longer delay) releases in synapses appear to have different $Ca^{2+}$ requirements. However, a recent study suggests that the same $Ca^{2+}$-sensing mechanism (involving five $Ca^{2+}$-binding sites interacting allosterically) may mediate both synchronous, as well as asynchronous release, and interference with the SNARE-complex may affect the $Ca^{2+}$-sensitivity of SVs [7]. Multiple proteins



**Non-Synaptic Release. Figure 3** (a) Multiple proteins interact with the SNARE complex. The lipid raft is depicted in *red*. The *arrow in blue* represents the interactions among complexin, SNAP and synaptotagmin at the SNARE complex. (b) Cis- and trans-SNARE complexes. (1) A cis-SNARE complex (from a previous cycle of exocytosis) on the plasma membrane. (2) The cis-SNARE complex is dissociated by the recruitment of NSF (ATPase) to the complex in the presence of SNAP. (3) The formation of a trans-SNARE complex in a "loose" conformation. (4) The transformation of a trans-SNARE complex into a "tight" conformation.

are known to interact with the SNARE complex (Fig. 3a). Among these proteins is synaptotagmin, which is a key $Ca^{2+}$ sensor for triggering exocytosis. Synaptotagmin has at least a dozen isoforms, some with vastly different $Ca^{2+}$-sensitivities, and the dominant expression of specific isoform(s) varies even among different types of synapses. Therefore, the absence of synaptotagmin, or the presence of specific synaptotagmin isoform(s) in different types of granules, may already contribute significantly to the variations in their $Ca^{2+}$-sensitivity for exocytosis.

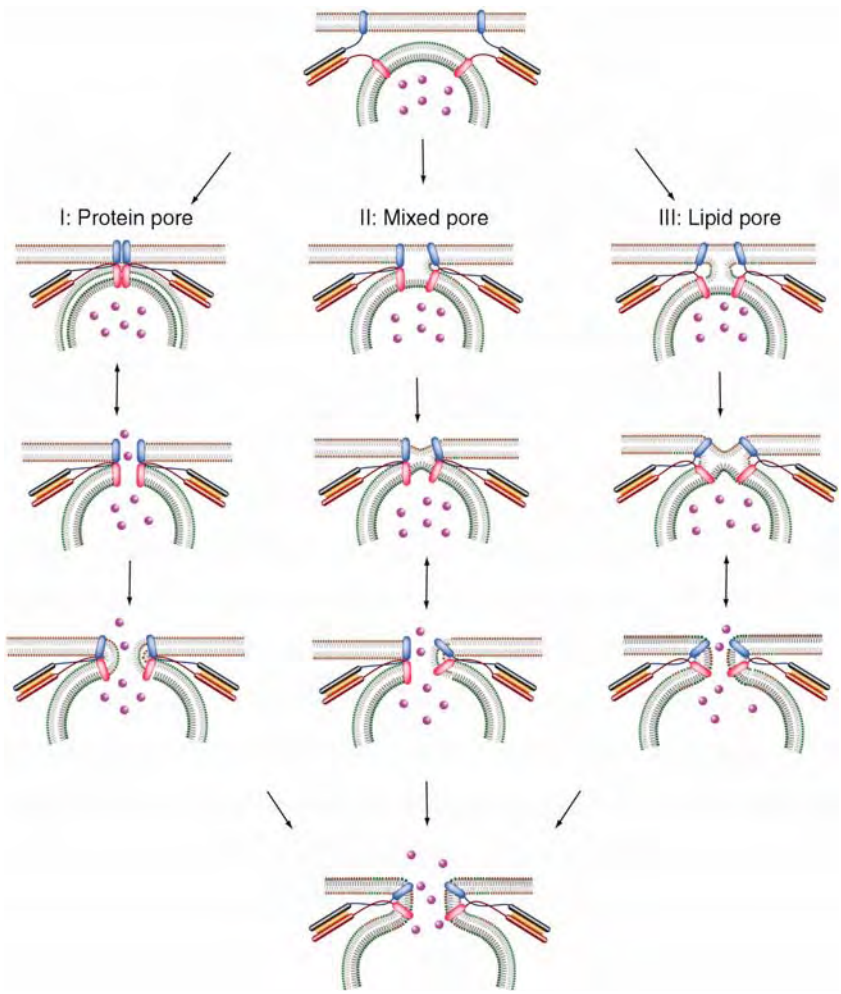
The site on the SNARE complex that interacts with synaptotagmin also interacts with at least two other proteins: (►soluble NSF attachment protein (SNAP), not related to SNAP-25) and complexin (Fig. 3a). The three main known isoforms of SNAP (α-, β-, γ-) all recruit the ATPase, ►N-ethylmaleimide-sensitive factor (NSF), to the SNARE complex. The ATPase activity of NSF is essential for breaking the cis-SNARE complex (in which all SNARE components are topologically on the same membrane, see Fig. 3b) which allows the subsequent formation of the trans-SNARE complex (the one depicted in Fig. 3a). Other than this important function of priming granules for fusion, α-SNAP may also affect the $Ca^{2+}$ sensitivity in some LDCGs. In chromaffin cells, an oversupply of exogenous α-SNAP selectively enhances a component of exocytosis that is only prominent at submicromolar $[Ca^{2+}]_i$ [8]. Since α-SNAP can displace synaptotagmin from the SNARE complex, one possible interpretation is that oversupply of α-SNAP allows the formation of a larger proportion of trans-SNARE complex on some LDCGs either with no synaptotagmin, or with a certain isoform of synaptotagmin that has a higher-sensitivity for $Ca^{2+}$. On the other

hand, binding of complexin to SNARE is suggested to activate SVs into a "superprimed metastable state." Subsequently, the binding of $Ca^{2+}$ to synaptotagmin 1 results in the displacement of complexin from the SNARE complex, which triggers fast synchronous synaptic release [9]. Thus, the $Ca^{2+}$-requirement for exocytosis in the different types of granules may be dependent on the complex interactions among synaptotagmin, SNAP and complexin at the SNARE complex, and a major challenge in the study of exocytosis is to understand how these complex sequential interactions are regulated *in vivo*.

## Do All Fusion Pores for Exocytosis have the Same Macroscopic Structure?

Currently there are two main models of the initial fusion pore for exocytosis [10]. The first model postulates that the initial fusion pore is similar to a gap junction, which is a ring of protein complexes that connects the vesicular lumen to the extracellular space via an opening whose wall is entirely proteinaceous (Fig. 4I).

The second model postulates that a ring of protein complexes first causes hemi-fusion of the lipid monolayer of cytosolic leaflets; then when the other monolayer (on the extracellular leaflet of the plasma membrane and the luminal monolayer of the granule) also fuse to open the fusion pore, the wall of the initial fusion pore is essentially lined by lipid molecules (Fig. 4III). For both models, the existence of an initial ring of protein complexes arises mainly from the assumption that a fusion pore has radial symmetry, and each protein complex is probably a SNARE complex with some of its associated proteins. Published



**Non-Synaptic Release. Figure 4** Three models for the macroscopic structure of a fusion pore. Note that in (I) and (III), all subunits in the ring of proteins that initially surrounded the fusion pore underwent identical conformational changes simultaneously. In contrast, the subunits in (II) underwent similar changes, but not synchronously. The opening of the semi-stable fusion pore in each model is depicted as reversible.

versions of both models typically depict that every complex in the ring simultaneously undergoes the same macroscopic structural changes to open the fusion pore. Moreover for both models, if the fusion pore indeed proceeds to further rapid dilation, there must be significant influx of lipids between at least some pairs of adjacent protein complexes.

Building on the scenario that the specific isoforms of individual SNAREs, as well as the SNARE-interacting proteins, may not be identical in every SNARE complex that form the initial ring around the fusion pore, we propose a third model in which the initial fusion pore for exocytosis can be lined with both lipids and proteins (Fig. 4II). If we consider that some SNARE complexes in the ring are more sensitive to the trigger $Ca^{2+}$, then with an intermediate elevation of $[Ca^{2+}]_i$, it is unlikely that all complexes in the ring respond synchronously. If a certain protein complex (e.g. the one on the right hand side of the fusion pore shown in Fig. 4II) can be triggered more readily to fuse the vesicular and plasma membranes near it, the resultant fusion pore can be initially lined by lipid on the right side, but lined by proteins in the left side. According to this model, the initial fusion pore can also dilate or close in ways that are very similar to the two other models (depicted in Fig. 4I & Fig. 4III). Also similar to the other two models, our model suggests that the initial size of the fusion pore is determined by the number of SNARE complexes that surrounds it. However, in our model, the influx of lipid adjacent to each triggerd SNARE complex and the total number of triggered SNARE complex in each fusion pore can increase over a period of time with an intermediate elevation of $[Ca^{2+}]_i$ (that does not trigger essentially all SNARE complexes in each fusion pore synchronously). Therefore the initial dilation of individual fusion pores up to the triggering of all SNARE complexes can vary considerably even if fusion pores with the same number of SNARE complexes are compared. Furthermore, the influx of lipid adjacent to each activated SNARE complex also predicts that the size of the dilating fusion pore is unlikely to increase in precisely "quantized" steps as each additional SNARE complex is triggered.

### Summary

The diversities among the proteins in, and associated with, the SNARE complex can contribute significantly to the variability in kinetics of release as well as the $Ca^{2+}$-sensitivity of exocytosis among the different types of secretory vesicles and granules. These diversities may be part of the molecular adaptation to allow different patterns of exocytosis to regulate diverse physiological functions in time scales that range from submillisecond (e.g. in synapses), to seconds (e.g. in endocrine cells) to days (e.g. in cell growth).

## Non-verbal Communication

### Definition

Communication without words. General form of communication in the animal kingdom.

## Nootropic Drugs

Paul F. Smith
University of Otago Medical School, School of Medical Sciences, Department of Pharmacology and Toxicology, Dunedin, New Zealand

### Synonyms

Cognitive-enhancing drugs; "Smart" drugs

## Definition

The word "►nootropic" is derived from the Greek word for "mind", which is "noos." ►Nootropic drugs are intended to enhance cognitive function, either in individuals with neurological and psychiatric disorders that include symptoms such as memory loss, or in healthy individuals who seek to increase their cognitive function beyond the normal level. Nootropic drugs comprise a heterogeneous, often controversial, collection of drugs that work with varying degrees of success.

## Characteristics

### Cognitive Enhancement: What does it mean?

The term "cognitive enhancement" is often used to refer to an increase in memory, but it can also refer to an increase in other aspects of cognitive processing, such as attention and even elements of a behavioral response that are not easily distinguished from memory itself. There is a basic distinction between enhancing cognition in a patient who has a neurological deficit of some sort, for example, a brain lesion, and enhancing cognition in someone with normal cognitive function. In the former case, the drug therapy is intended to replace a brain chemical that is missing or reverse a pathological change; in the latter case, the drug is intended to enhance normal neurochemical function in some way. While drug treatment for memory deficits in diseases such as ►Alzheimer's disease have had limited success, it is debatable whether any nootropic drug has clearly been shown to enhance normal cognition in humans. In the case of drug treatment to restore memory in a neurological disorder, there is a clear objective, which is to improve a patient's performance on a memory test to within normal limits. In the case of drug treatment to enhance normal cognition, the objective is less clear. The major obstacle for the development of all nootropic drugs is that the precise mechanisms of cognition, including memory, have not yet been identified. Consequently, it is difficult to design drugs to manipulate a neural system that is not fully understood. However, progress is being made in understanding the neural basis of memory, using models of memory such as ►long-term potentiation (LTP), and this is gradually leading to the development of novel nootropic drugs [1,2].

### Types of Nootropic Drugs

Most nootropic drugs that are currently used to treat cognitive deficits in neurological disorders manipulate the brain neurotransmitter, ►acetylcholine. Acetylcholine is diminished in Alzheimer's disease [3]; therefore, these drugs are intended to replace the missing neurotransmitter. Nootropic drugs in this category include inhibitors of the cholinesterase enzymes, which metabolize acetylcholine in the synaptic cleft, in addition to drugs that activate the acetylcholine receptors (►acetylcholine receptor agonists). ►Cholinesterase inhibitors prolong the action of acetylcholine in the synapse. Acetylcholine receptor agonists increase the level of activation of acetylcholine receptors. ►Tacrine was the first cholinesterase inhibitor used to treat Alzheimer's disease; however, ►donepezil, ►rivastigmine and ►galantamine are now the first line treatments [4–8]. All three drugs inhibit acetylcholinesterase, but rivastigmine also inhibits butyrylcholinestase, and galantamine acts as an agonist at nicotinic acetylcholine receptors [4]. Unfortunately, their beneficial effects are limited, they work more effectively in some patients than others [5], and they can cause adverse side effects such as nausea, vomiting and liver toxicity [4].

Many other drugs have been investigated for possible efficacy in the treatment of cognitive deficits, including ►memantine, selegiline, modafanil, vitamin E, *Ginkgo biloba* extracts and a variety of other herbal extracts, and ►α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor potentiators. Of these, only memantine and AMPA receptor potentiators have been shown to have any clinical effect [4]. Memantine blocks the calcium ion channel associated with the ►N-methyl-D-aspartate (NMDA) subtype of glutamate receptor (an uncompetitive NMDA antagonist). Since the NMDA receptor is involved in increases in synaptic efficacy associated with LTP, it may at first seem paradoxical that memantine could benefit cognition. However, over-stimulation of the NMDA receptor causes neurotoxicity and therefore memantine may improve cognition in diseases such as Alzheimer's disease by limiting this form of neural damage [3,4,6,7]. ►Piracetam is one of a number of AMPA receptor potentiators that has been actively researched but is not yet prescribed for Alzheimer's disease. Along with aniracetam, it is a pyrrolidone that increases the response of the AMPA subtype of glutamate receptor [9]. Other AMPA receptor potentiators, sometimes referred to as "►ampakines," include benzylpiperidines such as CX-516 and CX-546, which are in clinical trials [1,9].

Most of the drugs that are used clinically in the treatment of cognitive disorders do not enhance cognition in people without a neurological deficit. However, many drugs that were first investigated for their general nootropic effects, were then tested in patients with Alzheimer's disease and other neurological disorders to determine whether they would have any beneficial clinical effect. Some herbal drugs such as *Ginkgo biloba* extracts have been claimed to improve memory in both Alzheimer's disease patients and in neurologically intact individuals; however, there is no convincing evidence for a consistent effect in either case [4,10].

### Summary of Nootropic Sites of Action

Where in the brain do nootropic drugs act to produce their effects? Many areas of the brain are involved in the

encoding, consolidation and retrieval of memories. Areas such as the hippocampus and other areas of the medial temporal lobe are believed to be important for encoding new memories; the neocortex is thought to be important for long-term storage of memories [1,2].

### *Molecular Mechanisms of Action of Nootropic Drugs*

The precise mechanisms of the formation and retrieval of memories are not understood and therefore the precise mechanisms of action of nootropic drugs are not known. However, it is well established that acetylcholine is important for the formation new memories. Activation of acetylcholine receptors causes intracellular changes in neurons that result in the activation of proteins such as the cyclic adenosine monophospshate (cAMP) response element binding protein (►CREB), which many researchers regard as a form of "molecular switch" that converts short-term memories into long-term ones [2]. The neural model of memory, LTP, has been used to better understand the increases in synaptic efficacy that are likely to underlie the formation of memories. In LTP, the activation of post-synaptic NMDA receptors is thought to be a critical step in producing the biochemical changes that lead to enhanced synaptic efficacy. While excessive activation of NMDA receptors results in excessive calcium influx and neurotoxicity, a smaller elevation of NMDA receptor activation may enhance memory. For example, the ampakines have been developed so that they elevate NMDA receptor activation indirectly, by potentiating AMPA receptor activity, which then leads to increased depolarization, thus lowering the threshold for NMDA receptor activation [1,9]. The downstream effects of AMPA receptor modulation include an increase in growth factors such as brain-derived neurotrophic factor (BDNF), which is known to be important in synaptic plasticity [9]. While still in clinical trials, these drugs may be one class of nootropic drug that is used to treat Alzheimer's disease and other related neurological disorders in the future. Other possibilities include drugs that modulate dopaminergic and serotonergic function. Many researchers believe that no one drug with a single mechanism of action is likely to provide successful therapy for cognitive disorders.

Will the same nootropic drugs that are used to treat cognitive disorders be useful for enhancing cognition in healthy individuals? It is possible but more likely that there are natural limits to the extent that the normal neurochemical machinery of memory can be enhanced before adverse side effects develop.

# Noradrenaline or Norepinephrine

## Definition

Noradrenaline (also called norepinephrine) is a biogenic amine neurotransmitter that is widely distributed throughout the brain and is also present in sympathetic adrenergic neurones and adrenal gland. Central noradrenergic cells are involved in the ascending arousal system and attention. Noradrenaline released from sympathetic nerve endings can cause increased heart rate and blood pressure.

# Noradrenergic Neuron/Cell

## Definition

A noradrenergic neuron uses noradrenaline (norepinephrine) as its neurotransmitter. Groups A1-A7 are examples of noradrenergic neurons located in the medulla.

►A1-A7 cell groups Cellulae noradrenergicae/A1 – A7)

## Norepinepherine

►Noradrenaline

## Normosmia/Hyposmia/Anosmia

### Definition

Normosmia is the subjectively perceived normal olfactory function, usually defined as the ability to detect the great majority of tested odors in a given olfactory test. Hyposmia means the decrease of this olfactory function and anosmia the total loss of any olfactory function. Beside total anosmia, specific anosmias have been described, where only certain odors are not perceived and most odors are smelt normally.

►Smell Disorders

## Northern Blot

### Definition

A molecular assay that identifies specific messenger RNA components by using a radioactively complementary probe. mRNA from a cell is isolated and separated based on size by polyacrylamide gel electrophoresis.

The antisense probe is then used to identify the mRNA species in the gel.

## Notochord

### Definition

Axial mesoderm that lies beneath (ventral to) the neural palte/tube and extends from head to tail in chordates. It produces signals that are involved in the specification of ventral parts of the neural tube.

►Evolution and Embryological Development of the Forebrain

## Noxious (Algogenic) Chemical Stimulation of the Heart

### Definition

Cardiac afferent fibers are activated by injecting noxious chemicals via a catheter that is placed inside the pericardial sac of an anesthetized animal. The noxious chemicals are substances such as bradykinin, capsaicin or an algogenic cocktail composed of serotonin, bradykinin, prostaglandin E2, histamine and adenosine. An algogen is a chemical mediator that is usually generated within diseased or damaged tissue and produces pain behavior.

►Viscero-Somatic Reflex

## Noxious Stimuli

### Definition

Stimuli that are intense enough to potentially or actually damage body tissue. For example, thermal stimulation of the skin up to 46°C evokes a sense of warmth, while that over 48°C is noxious.

## Noxious Stimulus-evoked Vocalizations

### Definition

These are animal vocalizations that occur during noxious stimulation. These vocalizations are mediated by brainstem mechanisms and exhibit different spectrographic characteristics than vocalizations that occur after a noxious stimulus (vocalization afterdischarges, VADs). VADs are considered to be a direct index of the unpleasantness associated with the sensations evoked by noxious stimulation. VADs are mediated by brain structures involved in mediating pain unpleasantness in humans (medial thalamus, anterior cingulate cortex, amygdala) and suppressed by drug treatments that reduce pain unpleasantness in humans.

►Emotional/Affective Aspects of Pain

## NRSF

### Definition
Neuron-restrictive silencing factor (NRSF), also known as repressor element-1 silencing transcription factor (REST), silences neuronal gene expression in neural progenitors as well as non-neuronal cell types.

►NF-κB: Potential Role in Adult Neural Stem Cells

## Nuclear Factor of Activated T Cells (NFAT)

### Definition
A transcription factor that is activated as a result of axonal injury. Following binding of a neurotrophin to its receptor, both serine/threonine phosphotase and nuclear GSK3β regulate NFAT transcriptional activity and its translocation to the nucleus. NFAT interacts with members of the AP-1 complex, Fos and Jun.

►Neurotrophic Factors in Nerve Regeneration

## Nuclear Magnetic Resonance

### Definition
Nuclear Magnetic Resonance is used to describe the phenomenon where an atomic nucleus positioned in a strong magnetic field absorbs energy in the form of electromagnetic radiation at a specific frequency (Lamor frequency). A NMR signal is thereafter recorded as an induced current in a receiver coil near the sample as the atomic nuclei return to their thermal equilibrium state. The NMR technique is used to study molecular structure.

►Magnetic Resonance Imaging

## Nuclear Matrix

### Definition
The nuclear matrix is defined as the non-chromatin structure resistant to detergent extraction and nuclease digestion followed by high salt treatment.

# Nuclei of Posterior Column

## Synonyms

Nuclei columnaepost.

## Definition

In the cuneate nucleus and gracile nucleus terminate the epicritic afferents of the posterior column – funiculus dorsalis – (cuneate fasciculus and gracile fasciculus), which is the reason why they are also called posterior column nuclei.

- Gracile nucleus: afferents from the trunk and lower extremities.
- Cuneate nucleus: afferents from the upper extremities and neck (medial cuneate nucleus) and vestibular organ (lateral cuneate nucleus). The efferents of both nuclei cross to the contralateral side in the medulla as the internal arcuate fibers and join the trigeminal efferents (epicritic sensibility of the face) to form the medial lemniscus, before passing to the thalamus (ventral posterolateral thalamic nucleus), from where they project into the somatosensory cortex (postcentral gyrus).

# Nuclei, Telencephalic, Deep

## Definition

Nuclei that form within the basal parts of the walls of the paired telencephalic vesicles, including the amygdaloid and septal nuclei, caudate nucleus, putamen, accumbens, globus pallidus, ventral pallidum, bed nuclei of the stria terminalis and nuclei of the diagonal band.

►Striatopallidum

# Nuclei, Ventral Tier, Thalamic

## Definition

Principal or "relay" nuclei comprising anterior motor and posterior sensory groups. Anteriorly, cerebellar inputs spread widely in the ventrolateral nucleus, whereas basal ganglia inputs are more restricted in the ventromedial nucleus and anterior, medial parts of the ventrolateral (ventral anterior nucleus, in primates). The ventral posterolateral and posteromedial nuclei relay sensory information from the dorsal column system of the spinal cord and trigeminal nerve, respectively.

►Striatopallidum

# Nuclei of the Lateral Lemniscus

Ellen Covey
Department of Psychology, University of Washington, Seattle, WA, USA

## Synonyms

Cell groups of the lateral lemniscus; Lateral lemniscal nuclei; NLL

## Definition

The nuclei of the lateral lemniscus (NLL) comprise several groups of neuron cell bodies in the mammalian brainstem embedded within or lying near the fiber tract known as the lateral lemniscus. Neurons in the nuclei of the lateral lemniscus constitute a major component of the ascending auditory pathway and include both monaural and binaural cell groups. They are a major source of input to the inferior colliculus.

## Characteristics

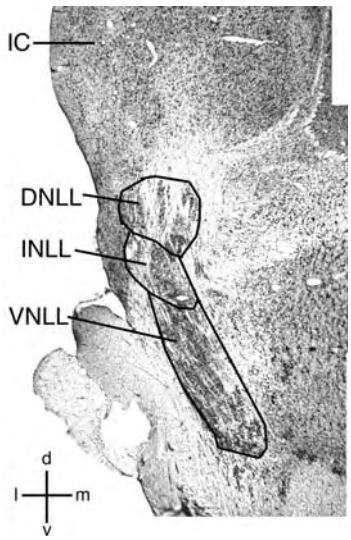
### Quantitative Description

Figure 1 shows a schematic drawing of the nuclei of the ►lateral lemniscus (LL) as seen in a frontal section through the lower brainstem of a cat and an echolocating bat.

The NLL of the cat is typical of most mammals. In the bat, the nuclei of the lateral lemniscus are hypertrophied and much more clearly differentiated than they are in other mammals. For this reason, the bat has proven to be an ideal species in which to study the properties of specific cell types in the NLL. In all mammals the NLL can be divided into two major subdivisions, the dorsal nucleus of the lateral lemniscus (DNLL) which receives input from ►binaural structures, and a ventral complex of nuclei comprising the intermediate nucleus of the lateral lemniscus (INLL) and the ventral nucleus of the lateral lemniscus (VNLL). The INLL and VNLL receive their primary input from one ear only and collectively make up the ►monaural pathway (for review, see [1]).

#### *Monaural Pathways*

The INLL and VNLL receive projections from the contralateral ear, mainly via the ventral ►cochlear



**Nuclei of the Lateral Lemniscus. Figure 1** Frontal section through the brainstem of a cat showing the nuclei of the lateral lemniscus. DNLL, dorsal nucleus of the lateral lemniscus; IC, inferior colliculus; INLL, intermediate nucleus of the lateral lemniscus; VNLL, ventral nucleus of the lateral lemniscus; d, dorsal; l, lateral; m, medial; v ventral.

nucleus, medial nucleus of the trapezoid body, and ►periolivary nuclei. Because their input originates mainly from one side, they are sometimes referred to as the monaural nuclei of the lateral lemniscus. Both INLL and VNLL project to the central nucleus of the ►inferior colliculus and constitute the largest single source of projections to the auditory midbrain.

Figure 2 summarizes the principal cell types that are found in the INLL and VNLL. In all species, the INLL contains predominantly elongate cells whose dendrites are oriented orthogonal to the ascending fibers of the lateral lemniscus.

The VNLL contains a population of small round neurons with a single highly branched dendrite. These neurons resemble ►spherical bushy cells in the cochlear nucleus, and receive ►calyx-like terminals on their cell body. The calyces originate from cells in the ventral cochlear nucleus. In most mammals the bushy cells are intermingled with other cell types throughout the VNLL, but in echolocating bats they are segregated into a highly organized and homogeneous structure termed the ►columnar nucleus of VNLL (VNLLc) [2,3]. Neurons in the VNLLc are ►glycinergic, so are thought to provide inhibitory input to their target cells. The other main cell type in VNLL is mutipolar neurons, which in bats are segregated into a subdivision referred to as the ►multipolar cell region of VNLL (VNLLm). Figure 2a is a block diagram summarizing the ascending monaural pathways via the nuclei of the lateral lemniscus.

### *Binaural Pathways*

The DNLL receives most of its input from the binaural structures of the superior olivary complex, including projections from the ipsilateral ►medial superior olive (MSO) and projections from the ►lateral superior olive (LSO) of both sides. The right and left DNLLs are reciprocally connected with one another via a fiber tract, the ►commissure of Probst. The DNLL provides bilateral projections to the inferior colliculus. Most neurons in the DNLL are ►GABAergic and are therefore thought to be inhibitory to their postsynaptic neurons. Figure 2b is a block diagram summarizing the binaural components of the ascending pathway via the DNLL.

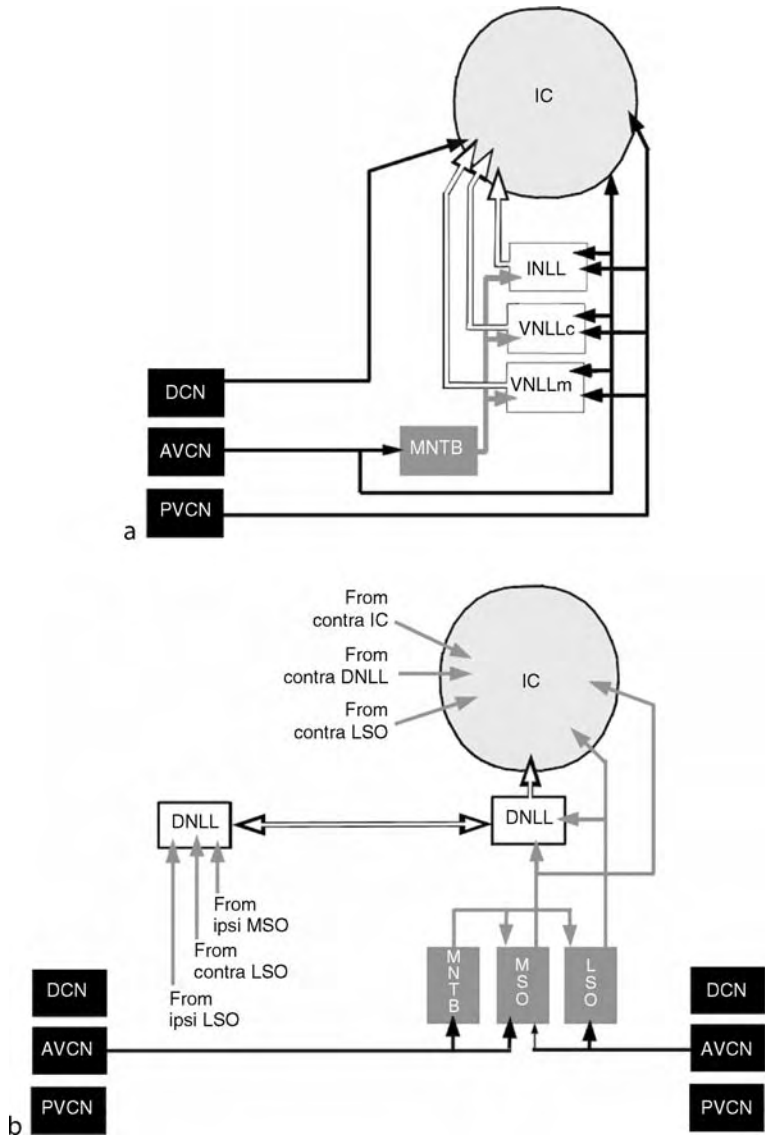
## Function

The nuclei of the lateral lemniscus are a major component of the complex system of parallel pathways in the mammalian auditory brainstem. However, their role in the neural processing underlying sound perception is not well understood. What we do know is that most neurons in the INLL and VNLL respond to sounds at the contralateral ear and are unaffected by sounds at the ipsilateral ear while most neurons in the DNLL are sensitive to differences in the intensity or timing of sounds at the two ears. Thus, it has been suggested that the DNLL plays a role in localizing sound sources while the monaural nuclei play a role analyzing temporal patterns of sound (for review, see [1,4]).

### *Monaural Pathways: INLL and VNLL*

Based on the limited evidence available, the structure, connectivity, and functional properties of INLL and VNLL seem to be similar in all mammals. However, because these structures are unusually large, clearly organized, and accessible in echolocating bats, much of what we know about their physiology comes from these animals. It is thought that the different neuron types of INLL and VNLL transform inputs from the cochlear nucleus in various ways depending on their ►intrinsic properties, and integrate inputs from multiple sources to provide a system of ►delay lines that are important for creating temporal ►feature detector neurons in the inferior colliculus. Response latencies of neurons in the ventral cochlear nucleus range from about 1–6 ms, but in the INLL and VNLL, this range lengthens to include latencies from about 2–20 ms [5]. Delayed input from some neurons converging with rapid input from others provides a mechanism through which it is possible to compare sound events that occur at different times (see [6], for review).

Neurons in the INLL and VNLL respond to sounds with a variety of discharge patterns, which are probably shaped through each neuron's intrinsic properties and integration of multiple synaptic inputs. Sustained responses provide a real-time representation of a sound's duration, since the neuron fires for as long as the sound is



**Nuclei of the Lateral Lemniscus. Figure 2** Block diagram of monaural and binaural pathways to the midbrain via the nuclei of the lateral lemniscus. (a) Monaural pathways via INLL and VNLL. (b) Binaural pathways via DNLL. Abbreviations same as in Fig. 1; AVCN, anteroventral cochlear nucleus; DCN, dorsal cochlear nucleus; LSO, lateral superior olive; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; PVCN, posteroventral cochlear nucleus; VNLLc, columnar nucleus of VNLL; VNLLm, multipolar nucleus of VNLL.

present. Onset responses provide a precise marker for the time when a sound begins, or when a changing sound enters the neuron's area of sensitivity. Echolocating bats have a specialized group of cells in VNLL, the columnar nucleus, which are extraordinary in having timing precision on the order of several tens of microseconds, across a wide range of conditions. It is possible that these neurons have evolved to provide precise timing markers for when the bat emits an echolocation call and when the echo of that call returns, allowing the bat's neural circuitry to calculate the distance to the object from which the echo was reflected. Although this cell type is segregated in bats, it is present in other mammals as well, intermingled among other cell types. This suggests that the precise timing information about sound onset provided by the VNLL is important for all animals that hear, albeit on a different level of time resolution (for reviews see [1,4]).

### The Binaural Pathway: DNLL

The DNLL represents an intermediate binaural processing stage between the superior olivary complex (SOC) and inferior colliculus. It receives inhibitory and excitatory input from the SOC on the same side, excitatory input from the SOC on the opposite side, and

inhibitory input from the opposite DNLL (see Fig. 2b). As a result, responses of DNLL neurons are influenced by sound at both ears, in complex ways, being binaurally facilitated under some conditions and inhibited in under other conditions. It has been suggested that DNLL may play a role in perception of sounds originating from multiple sources [7], but at present its function is not well understood.

## Nucleus, Bed, of the Stria Terminalis

### Definition

The bed nucleus of the stria terminalis is a deep telencephalic nucleus comprising a number of variably distinct subnuclei, of which all resemble, in terms of intrinsic composition and extrinsic connections, the centromedial part of the amygdaloid complex.

The bed nucleus of the stria terminalis and the centromedial part of the amygdala are densely interconnected by long associational connections of which one part traverses the stria terminalis and another part traverses the sublenticular part of the basal forebrain. Hence, the bed nucleus is regarded as an integral part of the extended amygdala.

►Striatopallidum

## Nucleus, Caudate

### Definition

The caudate nucleus is one of the deep telencephalic nuclei consisting of a large globular head that occupies the rostral part of the hemispheric wall, an elongated body that arches upward and backward over the internal capsule and a long slender tail that arches downward and forward into the temporal lobe in relation to the hippocampus and amygdaloid complex. The caudate nucleus receives massive cortical inputs largely from the frontal lobe and a number of subcortical inputs, particularly from intralaminar thalamic nuclei and dopaminergic neurons in the substantia nigra pars compacta. It projects strongly to the globus pallidus and substantia nigra.

►Basal Ganglia
►Striatopallidum

## Nucleus, Lentiform (Lenticular)

### Definition

The lentiform nucleus is a large cone-shaped gray mass forming the central core of the hemisphere with a convex lateralward-facing base, comprising the putamen, and medial-ward pointing apex, comprising the globus pallidus. Grouping of the globus pallidus and putamen as the lentiform nucleus reflects an artificial association, in so far as the globus pallidus is structurally and functionally dissimilar to the putamen, receiving dense projections from the striatum (caudate nucleus and putamen) and projecting to the subthalamic nucleus, substantia nigra, brainstem reticular formation, and via a relay in the thalamus, to motor staging areas of the cortex.

►Basal Ganglia
►Striatopallidum

## Nucleus, Mediodorsal, Thalamic

### Definition

The mediodorsal (MD) thalamic nucleus is situated within the internal medullary lamina at the dorsomedial extremity of the thalamus and surrounded by nuclei of the midline-intralaminar group.

The mediodorsal nucleus (MD) is always included with the thalamic association nuclei, sometimes as a subcategory of the principal or "relay" nuclei. Comprising medial, central and lateral segments involved with, respectively, emotional expression, olfaction and visual attention, the MD is reciprocally connected with frontal lobe association cortex including the orbitomedial and agranular insular (medial and central segments) and the frontal eye field (lateral segment). In addition, the MD receives projections from basal ganglia structures including ventral striatopallidum (medial and central segments) and the substantia nigra reticulata (lateral segment). The cortical projection field of the MD has been said to define the extent of the "prefrontal" cortex.

►Thalamus
►Striatopallidum

## Nucleus Accumbens

### Definition

A large gray mass located in the medial part of the basal forebrain that, over the years, has been variably associated with the septal nuclei and striatum. Previously called the "nucleus accumbens septi", it is interposed without clear boundaries between the ventral parts of the caudate nucleus and putamen and the olfactory tubercle or its homologue. Contemporarily regarded as an integral part of the striatal complex, it is no longer considered to be a nucleus in its own right. It receives cortical inputs from the basal amygdala, hippocampus and medial prefrontal cortex and projects to the ventral pallidum, lateral hypothalamus and ventral mesencephalon. Experimental histochemical and connectional studies have revealed that the accumbens comprises sub-territories, including a core, shell and arguably a rostral pole.

►Striatopallidum

## Nucleus Ambiguus

### Definition

Like the dorsal nucleus of the vagus nerve and the nucleus of the hypoglossal nerve, the ambiguus features a cellular column of at least 2 cm in length and also runs parallel to these nuclei. This is no surprise as it is the origin of somatomotor (actually special visceromotor) fibers of glossopharyngeal nerve (IX) and vagus nerve (X), which are responsible for innervation of the pharynx and larynx muscles.

►Myelencephalon

## Nucleus Basalis Magnocellularis

### Definition

Group of cholinergic cells in the basal forebrain, term used in nonprimates to refer to the area equivalent to the nucleus basalis of Meynert in primates

►Evolution of Subpallial Cholinergic Cell Groups

## Nucleus Basalis (NB) of Meynert

### Definition

The NB is a group of neurons in the basal forebrain that receive inputs from limbic and paralimbic regions and send cholinergic excitatory projections to the entire brain, particularly the neocortex. Projections to the sensory cortical areas are strictly topographically ordered. The NB seems to play a key role in the control of selective attention.

►Basal Forebrain

## Nucleus Intermediolateralis (IML)

### Definition

The IML is present in the thoraco-lumbar (upper lumbar) and sacral spinal cord and contains the highest

density of spinal preganglionic neurons. It is part of the intermediate zone.

►Autonomic Reflexes

## Nucleus Isthmi

### Definition

It is found at the dorsocaudal end of the dorsal tegmentum; and is homologous to the mammalian parabigeminal nucleus. Indirect visual input to the nucleus isthmi originates from the ipsilateral tectum.

An ipsilateral isthmotectal projection to several retinorecipient layers and a contralateral isthmotectal projection to only the superficial layer of retinal afferents is found in amphibians and all other vertebrate taxa. The isthmotectal projection is topographically organized and in register with the retinal maps. Recordings from isthmic neurons and lesion experiments of the nucleusisthmi reveal that the representation of the visual space differs from that of the tectal representation of the visual space. The isthmic nucleus is essentially involved in object localization and selection.

►Evolution of the Visual System: Amphibians

## Nucleus of the Optic Tract

### Definition

As the optic tract curves around the brain stem toward the lateral geniculate nucleus there are a number of terminations in a nucleus within the pretectal area, just dorsal to the superior colliculus. The subcortical neuronal substrate of the optokinetic reflex has been investigated in many mammals. In all of these animals, the pretectal nucleus of the optic tract and the dorsal terminal nucleus of the accessory optic tract (NOTDTN), with its strongly direction-selective neurons, links the visual information from the retina and visual cortex, via projections to the inferior olive, the nucleus praepositus hypoglossi, the nucleus reticularis tegmenti pontis and the dorsolateral pontine nucleus, with the cerebellum and the oculomotor structures. In most mammals, the direct retinal input to the NOT-DTN comes almost exclusively from the contralateral eye, whereas in the monkey the retinal input is strongly bilateral. Data show that the motion-sensitive areas in the superior temporal sulcus (STS) provide the main input to the NOT-DTN.

►The Central Mesencephalic Reticular Formation – Role in Eye Movements

## Nucleus of the Solitary Tract

►Nucleus Tractus Solitarii

## Nucleus Prepositus Hypoglossi

### Definition

The nucleus prepositus hypoglossi is located on the surface of the fourth ventricle between the abducens and the hypoglossal motor nuclei. Main oculomotor-related inputs to prepositus neurons arrive from the ipsilateral paramedian pontine reticular formation, from both vestibular nuclei, and from the contralateral prepositus nucleus. Prepositus neurons project to the abducens nucleus, superior colliculus, cerebellum, and other brainstem centers related to eye movements.

►Neural Integrator – Horizontal
►Vestibular Secondary Afferent Pathways

## Nucleus Proprius

### Synonyms

Nucl proprius

### Definition

Nucleus in the middle of the posterior horn of the spinal cord. Present in all spinal cord segments, it is a synaptic center for proprioceptive afferents from the locomotor apparatus. The impulses pass on to the cerebellum via the anterior spinocerebellar tract where they are compared with setpoint values.

►Medulla Spinalis

# Nucleus Reticularis Gigantocellularis (NRG)

## Definition

The rostral and medial portion of the medullary reticular formation named for the giant cells that it contains. It is a major source of reticulospinal neurons.

►Reticulospinal Long-Lead Burst Neurons

# Nucleus Reticularis Pontis Caudalis (NRPc)

## Definition

Roughly the caudal half of the pontine reticular formation. Its borders are based on cytoarchitecture but are poorly delineated. NRPc gives way to nucleus reticularis gigantocellularis roughly at the caudal border of the abducens nucleus.

# Nucleus Reticularis Tegmenti Pontis (NRTP)

## Definition

A large reticular nucleus at the bottom of the pontine reticular formation overlying the pontine nuclei. NRTP receives input from cortical and higher-level subcortical structures and conveys (presumably integrated) information to the cerebellum. NRTP also receives substantial feedback from the cerebellum by way of efferents from the deep cerebellar nuclei.

# Nucleus Tractus Solitarii (NTS)

## Definition

►Nucleus of the Solitary Tract

# Nucleus Tractus Solitarii

R. Alberto Travagli
Neuroscience, Pennington Biomedical Research Center-LSU System, Baton Rouge, LA, USA

## Synonyms

Nucleus of the tractus solitarius; NTS; Nucleus of the solitary tract; NST

## Definition

The nucleus tractus solitarius (NTS) is the principal visceral sensory nucleus in the brain and comprises neurochemically and biophysically distinct neurons located in the dorsomedial medulla oblongata. The NTS conveys information from the gustatory, cardiorespiratory, esophageal and the subdiaphragmatic gastrointestinal viscera that is subsequently assimilated with homeostatic signals arriving from other integrative centers of the pons, diencephalon and forebrain.

An exceptionally large diversity of neurochemical phenotypes and receptor proteins coupled with an impressive network of connections to and from the NTS and a loose blood brain barrier characterizes this brainstem nucleus as a vital controller of homeostatic functions.

The old concept of the NTS (and the closely related dorsal motor nucleus of the vagus and area postrema) as a simple relay center is overcome by an increasingly large body of work showing that the NTS has segregated lines of specificity in controlling sensory and pre-motor visceral information.

## Characteristics

### Anatomical and Neurochemical Description

The NTS is a Y shaped nucleus whose caudal pole is at the level of the pyramidal decussation and rostral pole is at the lower limit of the facial nucleus (VII cranial nerve). The lateral limits of the NTS are adjacent to the substantia reticulata, its medial portions are fused caudally to form the subnucleus commissuralis. Moving rostrally, the NTS abuts the ►area postrema (AP) medially and, rostral to AP, the walls of the fourth ventricle. The ►dorsal motor nucleus of the vagus (DMV) is located ventral to the NTS while the nucleus of the hypoglossus (XII cranial nerve) is located medially to NTS but only in regions rostral to the AP. Dorsally the NTS is separated from the nucleus gracilis and, rostral to AP, from the nucleus cuneatus by their respective fasciculi.

Separate subnuclei can be distinguished within the NTS of several animal species, but these subnuclei are more useful in defining the general regions of the NTS rather than its neuronal subclasses, neurochemical

characteristics, visceral representations or projection targets. In general, the visceral projections sites within the NTS reveal a rostro-caudal pattern reflecting the head-to-toe location of the viscera; the gustatory (i.e., tongue) NTS, for example, is uppermost, while the pharyngeal, cardiorespiratory and esophageal areas are somewhat overlapping at levels spanning both rostrally and caudally to the AP. The subdiaphragmatic viscera are represented in the more caudal portions of the NTS, where the distal gastrointestinal projections are denser. A loose viscerotopic organization is also recognizable along the medio-lateral extent of the NTS; moving from lateral toward medial NTS, the afferent receptive fields of the tongue, soft palate and pharynx, lungs, esophagus, baro- and chemoreceptor nerves, stomach and distal intestines, respectively, are located. Reviewed in [1–3].

The NTS integrates the inputs received from viscera with the inputs it receives from the spinal cord, the spinal trigeminal nucleus (V cranial nerve), ventrolateral medulla, raphe nuclei, several components of the reticular formation, A5 and A6 areas, parabrachial and Kolliker Fuse nuclei, dorsal tegmental regions including the periaqueductal gray, and bed nucleus of the stria terminalis. From the forebrain, the NTS receives descending input from a large and interconnected complex of neurons in the paraventricular and lateral hypothalamic areas and the central nucleus of the amygdala. Significant cortical projections also come from the medial prefrontal and insular regions. These regions projecting to the NTS are richly interconnected and the NTS itself maintains reciprocal connections with practically all of the abovementioned areas.

Neurons in the NTS are of medium size (10–15 μm diameter) and can be distinguished morphologically into multipolar (or stellate) neurons with 3-four dendrites exiting the soma or bipolar neurons with two dendrites only exiting the soma at opposite poles. These neuronal dendrites can extend outside the boundaries of the NTS itself to make contact with adjacent nuclei or the ependymal layer of the fourth ventricle. No apparent morphological or biophysical characteristic can be correlated with certainty to a specific physiological role of any given neuron, although recent works by MC Andresen and RA Travagli's groups has started to investigate this possibility.

The NTS contains a large array of membrane receptors and an even larger variety of neurochemical phenotypes, from "classical" neurotransmitters such as glutamate, GABA, glycine, serotonin, nitric oxide and catecholamines to an assorted content of neuropeptides or neuromodulators such as neuropeptide Y, enkephalins, cholecystokinin, somatostatin, glucagon-like peptide-1, etc. Peculiar to NTS, compared to other brain regions, is the apparently fundamental role in the modulation of neuronal NTS activity played by co-transmitters, in particular peptides such as substance P and CGRP, released from vagal afferent fibers. Similar to previous description, no specific physiologic role can be attributed to any given cell containing a particular neurochemical phenotype, although the localization of neuronal groups with a similar phenotype is, in some instances, very localized. Catecholaminergic neurons, for example, are confined to the A2 area whereas cholecystokinin-containing neurons are located in the caudal portions of the NTS.

## Physiological Description

Fibers from the trigeminal (V cranial nerve), facial (VII cranial nerve), glossopharyngeal (IX cranial nerve) and vagus (X cranial nerve) form the solitary tract (or tractus solitarius) and their terminals overlap along the rostro-caudal extent of the NTS. Afferent fibers belong to the myelinated A- and unmyelinated C-groups. Regardless of their origin or type, though, afferent fibers enter the brainstem in the tractus solitarius and activate NTS neurons via the release of excitatory neurotransmitters, mainly glutamate.

The majority of NTS neurons do not possess pacemaker activity, i.e., they do not have spontaneously occurring action potentials; thus, to convey the sensory information to other areas, NTS neuronal projections must be driven and are modulated by synaptic activity, either from the afferent fibers of the tractus solitarius, from other neuronal areas, or via circulating hormones. In fact, we have to consider that the NTS is a circumventricular organ with a leaky blood brain barrier, fenestrated capillaries and enlarged perivascular space that allows the passage of large molecules, including circulating hormones and neurotransmitters. Additionally, the adjacent area postrema, which lies entirely outside the blood brain barrier, has a series of short, communicating vessels that potentially send postremal venous drainage to the NTS. These morphological characteristics allow NTS neuronal activity to be open to modulation by a wide variety of transmitter and hormonal peptides, including, among many others, glutamate itself, cholecystokinin, leptin, and ATP.

By being subject to a vast array of modulatory activity, the synaptic connections between NTS and the motor neurons controlling cardiorespiratory, pharyngo-esophageal and gastrointestinal functions, by implication, play a major role in shaping the efferent output. Further, recent studies suggested a potential role of NTS neurons in the integration of nociceptive signals and cardiorespiratory afferent fibers.

## Role of NTS in

►Swallowing: NTS neurons behave as pattern generators in the initiation and organization of the sequential or rhythmic motor pattern of swallowing.

N

Application of excitatory aminoacids (glutamate) or antagonism of inhibitory amino acids (GABA) in NTS induces sequential and rhythmic motor pattern of swallowing. Swallowing can also be evoked by cortical stimulation, however, this is abolished by lesions of the NTS indicating that the NTS is the main central system responsible for swallowing. Since batches of NTS neurons are activated sequentially during swallowing, it is likely that distinct neuronal subgroups control different regions of the swallowing canal. Integrated swallowing information from the NTS is transmitted mainly to the nucleus ambiguus, whose motoneurons innervate the esophagus, pharynx, and intrinsic laryngeal muscles [4].

►Gustatory: fibers from the facial (VII cranial nerve) and glossopharyngeal (IX cranial nerve) carry gustatory afferent fibers to the rostral portions of the NTS. Although morphologically distinct, the gustatory-related NTS neuronal subtypes all receive synaptic inputs that use excitatory (glutamate) or inhibitory (GABA) amino acids as the main neurotransmitters. Gustatory-related NTS neurons project rostrally to the pontine gustatory relay area, to the reticular formation and to motoneurons of cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), X (vagus) and XII (hypoglossus) [5].

►Cardiorespiratory: most cardiovascular afferent fibers and practically all fibers from the aortic depressor nerve and the carotid sinus nerve converge on the dorsomedial portion of the NTS. Electrical or pharmacological excitation of NTS neurons mimics baroreceptor activation and induces a decrease in heart rate, blood pressure and sympathetic nerve activity. Baroreflexes are blocked by pressure application of glutamate antagonists in the NTS, while GABA antagonists increase blood pressure, indicating glutamate and GABA as major players in the reflexive cardiovascular control from the NTS. Cardiovascular-related neurons of the NTS provide the premotor integration to neurons of the caudal ventrolateral medulla and neurons of the nucleus ambiguus, which control sympathetic and parasympathetic output, respectively [6].

Fibers innervating the slowly- and rapidly-adapting stretch receptors and bronchopulmonary C-fibers innervating the lungs and airways terminate in the caudal lateral NTS where they target different neuronal subtypes, suggesting that each afferent fiber may contribute to several different components of the respiratory phases. Excitatory (glutamate) and inhibitory (GABA and glycine) amino acids are the main neurotransmitters used by fiber terminals onto NTS neurons. Respiratory-related NTS neurons project to areas involved in rhythm- and pattern-generating neurons of the pre-Botzinger and Botzinger regions, to cranial and bulbo-spinal premotor neurons involved in respiratory pattern formation and to other neuronal areas devoted to a further integration with ingestive, cardiovascular, orofacial, airway protective and pain pathways [7].

►Gastrointestinal: mechanical or chemical manipulations of the proximal gastrointestinal tract activates NTS neurons, mainly via a vagal-mediated release of excitatory aminoacids such as glutamate. Localized pressure applications of glutamate directly into the medial NTS can evoke rapid, large, and vagally mediated gastric relaxations similar to those evoked by stimulation of vagal afferent fibers. The inhibition of gastric motor function occurs probably via activation of GABAergic or catecholaminergic NTS neurons projecting to the efferent motoneurons of the DMV. Antagonism of inhibitory amino acids (GABA) in NTS induces a dramatic increase in gastric motor functions indicating the presence of a robust GABAergic tone that dampens vagal gastrointestinal motor output [3].

►Feeding: signals that relate to ingestive behavior are generated by the interaction of food with chemo- and mechano-sensors in the alimentary canal before and during absorption. Signals related to satiation (i.e., short term feedback signals) and meal size are detected by sensory afferent neurons terminating in the NTS, which orchestrates the basic features of reflexive ingestion and gastrointestinal needs. Since afferent fiber terminals use excitatory amino acids (glutamate) as their main neurotransmitter, blockade of ionotropic glutamate receptors delays satiation and increases meal size. Circulating hormones and robust hypothalamic projections contribute to the NTS control of the integration of food intake [8].

In summary, neurons of the NTS provide the framework for the hardware responsible for coordinating vital homeostatic responses; emerging evidence shows that NTS neurons are functionally distinct and comprise an important station in segregated lines of specificity controlling sensory and pre-motor visceral information. In its static form, one may presume that activation of any given neuronal circuit within the NTS elicits the same hard-wired efferent response. Recent studies have, however, revealed a high degree of plasticity in available responses, such as, for example, in the control over the stomach or airway circuits [9,10]. One agonist signal may "gate" another, and the tonic effects of afferent input may "gate" agonist responses that are related to the "►state of activation" of a particular NTS circuit.

## Null Mutation

### Definition

Mutation to induce no expression of a certain gene. Equivalent to knockout of gene.

## Nyquist Sampling Theorem

### Definition

The sampling rate needed in order to be able to reconstruct a sampled signal back to its original (continuous) form, without loss of information, should be sampled at least twice as fast as the highest frequency component in the signal.

►Signals and Systems

## Nystagmus

### Definition

The rhythmic, alternating movement of the eyes, usually consisting of a rapid or saccadic movement in one direction followed by a slower, smooth movement of the eyes in the opposite direction. Nystagmus is designated based on the direction of the rapid eye movement.

►Cerebellar Functions
►Saccade

## Nystagmus – Optokinetic (OKN)

### Definition

Nystagmus produced by movement of the visual surround relative to a subject. In primates, the slow phase velocity rises sharply and maintains a steady state value throughout the rotation.

►Velocity Storage

## Nystagmus – Pathological

### Definition

Pathological nystagmus occurs at rest and can be caused by disorders in the brainstem, cerebellum or vestibular system, and is associated with vertigo and dizziness.

►Disorders of the Vestibular Periphery
►Ischemic Stroke

## Nystagmus – Per-Rotatory Vestibular

### Definition

Nystagmus produced during prolonged rotation of the head in space. For rapid initiation of rotation, the slow

phase velocity rises sharply at the start of rotation and declines to zero as the rotation continues at a constant velocity.

►Velocity Storage

## Nystagmus – Post-Rotatory Vestibular

### Definition

Nystagmus produced upon stopping after long term rotation (>10 s) of the head in space. Its characteristics are the same as those of per-rotatory vestibular nystagmus.

►Velocity Storage

## Nystagmus – Vestibular

### Definition

Vestibular nystagmus results from an asymmetry in the resting activity between the two labyrinths. The nystagmus that occurs in cases of unilateral vestibular hypofunction has fast and slow components. The slow components are directed toward the labyrinth that has diminished activity (hypofunction).

►Disorders of the Vestibular Periphery

## Obesity

### Definition
Increased body weight due to excessive amounts of fat; partly due to genetic disposition.

## Object Perception

### Definition
►Form Perception

## Object-based Attention

### Definition
Object-based attention refers to mechanisms by which an entire object is selected for further processing. Object-based attention will spread to all features of the selected object. For instance, if subjects perform a task on the shape of an object, the processing of the color of the object will also be enhanced. In addition, if subjects are attending to only a portion of the object, attention will spread over the entire spatial extent of the object (see Visual attention).

►Visual Attention

## OBPs

►Odorant Receptor

## Observability

### Definition
Observability represents the ability to detect (observe) physical system behavior by means of the sensors connected to it. In terms of system states, it is the ability to infer state values using sensor outputs.

►Control

## Observational Learning

### Definition
Learning that occurs as a function of observing, retaining and replicating behavior observed in others. Observation[al] learning is a looser concept than imitation learning. Social learning is a type of observation[al] learning. Motivation, attention and/or simple paring of novel stimuli may contribute to this process. Thus even invertebrates such as octopus can perform observation[al] learning (Florito and Scotto, 1992).

►Imitation Learning

## Obsessive-compulsive Disorder [OCD]

### Definition
A neurotical disease (in DSM-IV: anxiety disorder) in which the mind is flooded with persistent and uncontrollable thoughts or the individual is compelled to repeat certain acts again and again, causing significant distress and interference with everyday functioning.

►Personality Disorder

# Obstructive Sleep Apnea

Sigrid C. Veasey
Center for Sleep & Respiratory Neurobiology, Department of Medicine, School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

## Synonyms

Sleep apnea; Obstructive sleep apnea hypopnea syndrome; Obstructive sleep-disordered breathing

## Definition

►Apnea: a cessation in ventilatory airflow lasting for 10 s or longer.

►Sleep apnea: A diverse group of disorders with a common feature of repeated sleep-dependent cessations in airflow.

►Obstructive sleep apnea: A syndrome in which repeated cessations in airflow occur as a direct consequence of sleep-dependent collapse of the upper airway. The syndrome is characterized by sleepiness, fatigue and snoring.

## Characteristics

### Overview

Obstructive sleep apnea is a rapidly evolving syndrome. For decades, snoring was believed to be more of an inconvenience for the bed partner than a sign of significant disease. Recent studies, however, have clearly established that snoring in association with unrefreshed sleep is a warning sign of obstructive sleep apnea, and obstructive sleep apnea is now widely recognized as an independent risk factor for significant cardiovascular and neurological morbidities. Therefore, obstructive sleep apnea is a disorder for which high clinical suspicion, early diagnosis, and effective intervention are of utmost importance.

### Pathogenesis

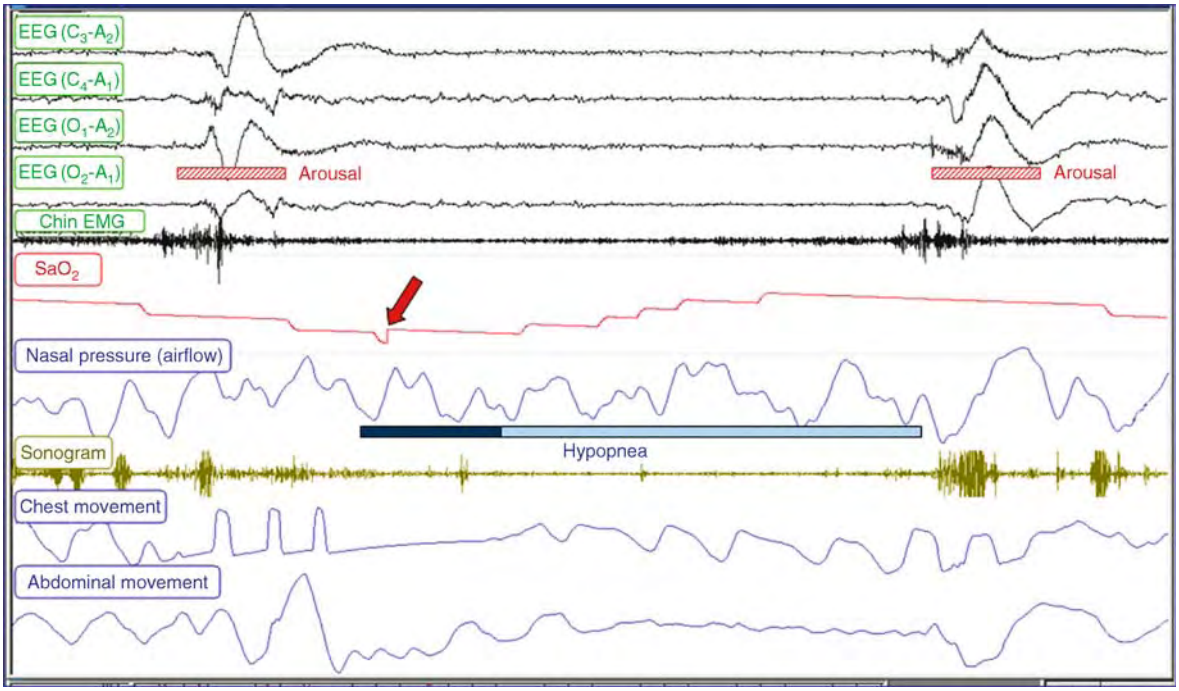
A unique feature of disorders of sleep apnea is that the brief cessations in ventilation occur exclusively in sleep. In wakefulness, neural mechanisms ensure continued respiration. In sleep, both ►non-rapid-eye-movement (NREM) and/or ►rapid-eye-movement (REM) sleep, ventilatory drive may fall sufficiently to allow apneas to develop. The obstructive nature of events occurs in part because ►NREM and ►REM sleep are associated with reductions in muscle activity, with a greater decline in ►pharyngeal muscle activity than reduction in pump muscle activity [1]. This occurs as a normal physiological response to sleep in all individuals. However, individuals with obstructive sleep apnea rely upon specific muscles surrounding the pharynx to stent open the airway for ventilation. Because the ►oropharynx is a highly collapsible tube, and one that may be collapsed from any direction, a number of pharyngeal muscles must act in concert to stent open the pharynx. These pharyngeal muscles include the tongue (►genioglossus), ►soft palate muscles, and muscles that stiffen the posterior wall or extend the lateral walls of the pharynx. In sleep, reductions in upper airway dilator muscle tone result in collapse of the upper airway [1]. Collapse of the upper airway is most likely to occur during inspiration, when negative pressures are generated in the lumen of the oropharynx [1]. Occlusion of the upper airway results in cessation of airflow, or apnea, that in turn results in ►hypercapnia, hypoxia and stimulation of upper airway afferents, resulting in arousal and resumption of the necessary upper airway muscle activity to reopen the upper airway. This process can be repeated up to 100 times/h of NREM and REM sleep. In many individuals, the slee p-dependent events involve a reduction in flow, rather than complete cessation of flow. A sleep-related reduction in flow, associated with a drop in oxygen saturation and an arousal, is termed a ►hypopnea. These events disrupt sleep and oxygenation and are considered as clinically significant as ►apneas. One of these events is illustrated in Fig. 1, showing a reduction in airflow just at sleep onset, result in a drop in oxygen saturation and arousal.

The intermittent hypoxia and frequent arousals from both apneas and hypopneas can increase sympathetic activity and induce inflammatory and smooth muscle changes in vessels, exacerbating hypertension and ►atherosclerosis. In addition, recent studies suggest the intermittent hypoxia can result in irreversible cognitive impairments and neural injury.

### Epidemiology

Symptomatic obstructive sleep apnea is present in 4–7% of adult males and 2–3% of adult females in North America, Europe and in select regions of Asia [2]. Despite the 2:1 male:female predominance in adults, there are no apparent gender differences in ►OSA prevalence in pre-pubertal children. Prevalence increases with age and is estimated to approach 40% in elderly individuals. While prevalence does not vary with race, the severity of OSA is greater in age-matched African American individuals than in Caucasians, and it appears that OSA develops at an earlier age in African Americans than in Caucasians. Familial aggregation has been established for OSA. Approximately 40% of the variance in the apnea hypopnea frequency may be explained by familial factors, and a positive family history increases the relative risk by 2- to 4-fold [2]. How much of this variance is simply ►obesity remains to be determined [2].

►Craniofacial anomalies that compromise upper airway space and stability provide additional risk



**Obstructive Sleep Apnea. Figure 1** Polysomnography for the diagnosis of obstructive sleep apnea. The electroencephalographic activity across the frontal, parietal and occipital cortices, is present in the top four channels. Channel 5 shows the chin elctromyogram. The arterial saturation ($SaO_2$) is presented in channel 6, and airflow measured with a nasal pressure transducer, the snore signal and chest and abdominal movements are shown below. An arousal from one hypopnea, underlined by the first red bar, is rapidly followed by sleep onset an another hypopnea. The hypopnea terminates with the second arousal, underlined by a red line. Notice the $SaO_2$ appears to fall just after the arousal. This is attributed to a delay in circulation time required for detection of the peripheral signal. Notice the snoring is quiet across the hypopnea when little airflow is exchanged. Polysomnography typically records four additional channels for leg movements, electrocardiogram and eye movements. These signals were removed to highlight the respiratory events.

factors for OSA. For example, ►micrognathia in ►Treacher-Collins syndrome and ►Pierre-Robin syndrome and ►maxillary insufficiency in ►Down and ►Apert syndromes predispose to collapsible upper airways. ►Hypothyroidism and ►acromegaly increase tongue soft tissue that impinges upon the oropharynx. The most common risk factor for OSA, however, is obesity, defined in adults as a body mass index >30 kg/$m^2$. In children, the major risk factor for OSA has been enlarged ►adenoid and ►tonsillar tissue. With the increasing prevalence of childhood obesity, obesity is becoming the major risk factor for OSA in children as well as in adults. A minority of patients diagnosed with OSA is non-obese. In these cases, chronic nasal obstruction from allergies, ►polyps or ►septal deviation, or craniofacial variances, e.g., ►retrognathia or ►macroglossia, may contribute to the increased collapsibility of the upper airway and OSA. In summary, the most important risk factor for OSA is obesity. Nonetheless, it is important to recognize that OSA occurs in diverse groups of patients, and in light of the significant neurobehavioral and cardiovascular morbidities, it is important to explore the possibility of OSA in all individuals presenting with snoring and unrefreshed sleep or poor sleep quality.

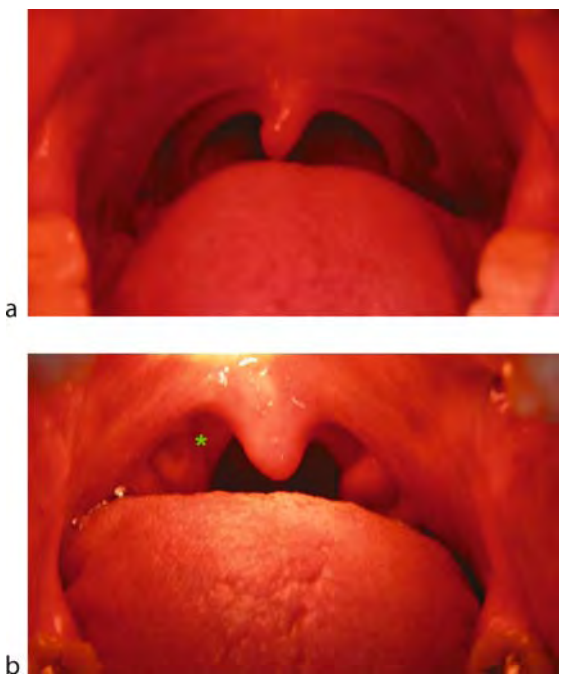
## Presentation and Diagnosis

The presence of snoring and excessive sleepiness or fatigue despite adequate time allowed for sleep (7–9 h) in adults should prompt evaluation for OSA. It is important to recognize that in females and in children the presentation may be less straightforward. In both women and children, the snoring may be subtle, and rather than sleepiness, adult females may complain of fatigue or insomnia. Children are far more likely to exhibit increased motor activity, poor performance in school, and/or impulsive behavior than to have daytime sleepiness. Snoring alone does not make a good screening tool. In the United States, habitual snoring is present in 40% of adult males, 20% of adult females and 10% of children. Thus, it is essential to identify associated neurobehavioral complaints in snorers, e.g., unrefreshed sleep, fatigue, insomnia, restless sleep or irritability before proceeding with diagnostic testing.

The physical exam in many individuals in which a clinical suspicion for OSA is raised will suggest upper airway compromise. A neck circumference (>17 in. in adult males or >15 in. in adult females, a low lying soft palate, a small space behind the soft palate, large tonsils, a small mandible, and thickened lateral walls of the oropharynx all suggest increased upper airway collapsibility. Figure 2 shows a typical oropharynx in a person with mild OSA. There is no obvious obstruction.

The tonsils and tonsillar pillars are somewhat medial and may result in lateral wall collapse in sleep, but it is entirely possible that the point of initial collapse is lower in the airway or caused by retrograde placement of the tongue in sleep. Because airway examination occurs with the patient awake, a clear obstruction is unlikely to be identified.

The gold standard diagnostic tool for OSA is ►polysomnography. Polysomnography refers to the recording of multiple physiological signals during sleep [3]. Electroencephalographic and electromyographic signals are used to score specific sleep stages, as described elsewhere in this text. Airflow is measured indirectly with use of a thermistor, or with a nasal pressure transducer, and chest and abdominal movements are measured using piezosensors or strain gauges. Arterial oxygenation is recorded with ►pulse oximetry. An example of 30 s polysomnographic recording is presented in Fig. 1.



**Obstructive Sleep Apnea. Figure 2** Upper airway physical findings. (a) top panel shows a normal wide oropharynx. (b) In this individual with mild OSA, the tonsils are only mildly enlarged and the soft palate (uvula) is readily visible with some lateral wall narrowing at the tonsillar pillars (*).

Complimentary channels include channels to detect leg movements or snoring and the electrocardiogram. The diagnosis of OSA in adults requires >5 apneas or hypopneas/h, on average, across sleep with symptoms, as above [3]. In children, neurobehavioral symptoms and an ►apnea index >1 is sufficient for the diagnosis. Presently, the majority of polysomnographies are performed in clinical sleep laboratories; however, because obesity is on the rise and the clinical suspicion for OSA is heightened, it is anticipated that there will be a shift in the near future towards the implementation of simpler, more cost-effective screening tools for OSA.

## Treatment

The primary goal of therapy for OSA is to prevent collapse of the upper airway. The mainstay therapy for OSA is a remarkably effective mechanical therapy; ►positive airway pressure (PAP) titrated to an optimal pressure in each individual can fully prevent collapse of the upper airway in all stages of sleep in almost all patients with OSA [4]. Each individual with OSA will require a unique pressure to stent open her upper airway across all of NREM and REM sleep. The pressure needed will vary with sleep stage (NREM sleep vs. REM sleep) and with position and with nasal obstruction and sleeping position [4]. All of these factors must be taken into consideration when identifying the optimal pressure to alleviate OSA. Thus, a properly performed titration must confirm that apneas and hypopneas are alleviated in all sleep stages, all sleeping positions and that sleep is less fragmented. The latter ensures that subtle events have also been prevented. Prescribed pressures typically vary between 5 and 15 cm $H_2O$. Although remarkably effective for OSA, PAP therapy is cumbersome, requiring a tightly fitted mask over the nose and/or mouth. Figure 3 shows one of the newer PAP interfaces that allows an individual improved visibility for reading prior to sleep onset.

Despite advancements in mask comfort and PAP delivery, less than half of the individuals prescribed PAP regularly use this therapy. Nonetheless, every effort should be made in individuals to encourage use of PAP regularly, as this is the only therapy for OSA shown to lessen cardiovascular and neurobehavioral morbidity. For patients with claustrophobia and other mask difficulties, behavioral therapy to adjust to mask use has been shown highly effective. Recent developments in PAP therapy include machines that can self-adjust the level of PAP based on airflow patterns, and these, too, may increase usage in select groups of patients [4].

Alternative therapies for OSA should be considered in individuals with mild sleep apnea and in individuals unable to acclimate to PAP use. These alternative

**Obstructive Sleep Apnea. Figure 3** Continuous positive airway pressure interface. This system is designed to deliver positive airway pressure to the nares and allow improved visibility. Flexible tubing connects the nasal mask to a small air pump to deliver positive pressure. Newer machines have the capability of detecting snoring, apneas and hypopneas, hours of usage and mask leaks.

therapies include surgical procedures to shorten the soft palate and reduce collapsibility of the pharynx (►uvulopalatoplasty), or to reduce the tongue volume (►genioglossectomy) or to advance the genioglossus forward (genioglossus advancement hyoid myotomy). These therapies in select groups of patients are expected to improve OSA in 50% of patients [5]. In patients with persistent symptomatic OSA, a second phase of surgery may be necessary to increase pharyngeal space (maxillary advancement or maxillary and ►mandibular osteotomy). Laser-assisted uvulopalatoplasty and temperature-controlled radio frequency are most effective for benign snoring. Some patients who do not tolerate PAP or in whom OSA is mild may benefit from oral appliances that advance the mandible. As with surgical therapies, the oral appliances are most likely to work in individuals with mild disease.

Weight loss should be recommended in all obese individuals with OSA. Dietary counseling should be the first step taken, and all patients should understand that reduced caloric intake is the critical factor for successful weight loss. Behavioral modification programs enhance sucess of weight loss. Exercise may help maintain weight, but in most non-athletic individuals, healthy caloric restriction should be the primary strategy for weight loss. ►Bariatric surgery should be reserved for individuals with morbid obesity who have failed dietary weight loss programs. The majority of individuals who have substantial weight loss after bariatric surgery will experience marked reductions in OSA, if not lasting reversal of the disease [6]. Treatment of OSA in persons with hypothyroidism or acromegaly should begin with PAP therapy, but across the treatment of the underlying endocrine disorder the PAP settings may need adjusting, as the soft tissues remodel. Several medical therapies for OSA may be considered as second line therapies for mild OSA. There may be subsets of individuals who respond to supplemental oxygen, positional therapy and rarely to pharmacotherapies such as selective serotonin reuptake drugs in individuals with mild ►REM sleep-predominant apnea [7]. Because these adjunctive therapies are rarely fully effective, treatment success should be determined with repeated polysomnography.

Stimulant therapy to reduce residual sleepiness in treated OSA has been recently examined [8]. The effect size for objective sleepiness is small, and it should be understood that individuals with residual sleepiness remain at high risk for motor vehicle accidents.

## Associated Morbidities

One of the most important advances in OSA has been the substantiation of OSA as an independent risk factor for cardiovascular, endocrine and neurological morbidities. OSA is now widely accepted as an independent risk factor for several cardiovascular diseases, including hypertension, congestive heart failure, and stroke [9]. Importantly, the relative risk for hypertension increases even at levels of mild OSA (5–15 events/h), and use of PAP therapy can reduce this risk. The rates of significant cardiovascular events across 10 years in a large prospective European trial were found to be fourfold larger in untreated vs. treated untreated OSA [10]. The risk of cardiovascular death is also reduced with PAP therapy in persons with severe OSA [10]. Children with OSA show left ventricular dysfunction and increased levels of circulating inflammatory markers associated with atherosclerosis [9]. The mechanisms are poorly understood, but contributing factors include increased sympathetic activity, endothelial inflammation and ►oxidative stress [9]. In light of the seriousness of morbidities and the disease interactions associated with OSA, even in children, every effort to treat OSA effectively should be made. There have been several recent reports suggesting that OSA is an independent risk factor for insulin resistance. This risk persists after controlling for obesity, and several

studies have demonstrated improvement in glucose control and insulin sensitivity with successful use of PAP therapy. Whether long-term PAP therapy reduces the occurrence of complications of diabetes remains to be studied. Several recent reports suggest that OSA may impair liver function and might contribute to non-alcoholic fatty liver disease, a major risk for liver failure in developed countries. OSA is an independent risk factor for motor vehicle crashes, raising the relative risk by 2.5-fold, and a direct link between OSA and motor vehicle accidents is supported by the reduction in car crash risk with successful treatment of sleep apnea.

### Future Directions

►Obstructive sleep apnea is now widely accepted as a serious disorder, associated with significant morbidity. The importance of recognition and treatment of obesity in children and young adults is critical for reducing the prevalence of this disorder. For the millions of individuals with undiagnosed OSA, there is a readily appreciable need to improve screening methodologies to dramatically increase availability. PAP is a remarkably effective therapy and efforts to improve its acceptance must continue, while we await the development of effective pharmacotherapies.

## Ocular Drift Movements

### Definition

Involuntary, smooth, and mostly slow, eye movements that do not correspond to a target movement. Some types of drift occur predictably in certain behavioral contexts such as: glissades in the aftermath of saccades, anticipatory drift in the direction of an imminent target movement, centripetal drift during the attempt to maintain an eccentric eye position in darkness. Others are predominantly random such as the miniature drifts during fixation with velocities of the order of 0.1°/ s which can cause deviations from the intended fixation point of up to 0.2°, or the slow wanderings of the eyes during drowsiness which result in considerably larger excursions.

►Oculomotor Control
►Saccade, Saccadic Eye Movements

## Ocular Following Responses (OFR)

### Definition

Smooth eye movement elicited by optic flow from relative motion between observer and visual scene (or parts thereof) in a highly automatic manner (unconscious reaction, no instruction required) and at short latency (70–80 ms). It often is initiated by a series of brief acceleration peaks creating a mean acceleration of up to 100°/s$^2$; considerably larger values are achieved in the aftermath of saccades, though. OFR is considered to be part of the early or direct component of the optokinetic reflex.

►Oculomotor Control

## Ocular Micromovements

### Definition

Involuntary movements occurring during fixation consisting of (i) tremor, (ii) slow drifts and (iii) microsaccades. Tremor and drifts are uncorrelated in the two eyes whereas microsaccades have the same direction and similar – though not identical -amplitudes in both eyes. As a result of these micromovements, the line of sight describes an erratic, two-dimensional path about the intended fixation point.

## Oculomotor Control (Theory)

Wolfgang Becker
Sektion Neurophysiologie, Universität Ulm, Albert-Einstein-Allee, Ulm, Germany

### Definition

The theory of oculomotor control aims at metaphorically understanding which types of innervation patterns are required to generate the various types of eye movements (►saccades, ►reflexive saccades, ►micro-saccades, ►express saccades, ►corrective saccades, ►pro-saccades, anti-saccades, ►catch-up saccades, smooth pursuit, vergence, fixation), and how afferent (mostly visual and vestibular) and efferent information is processed to shape these patterns (sensori-motor transformation). The metaphors it uses mostly draw on control systems theory and are referred to as models; typically, the modeling approach disregards the intricacies and variety of the neural substrates, lumping many of them into a small number of processing stages with either mathematically or empirically defined transfer characteristics between input and output. Processing stages interact by way of signals which can represent a flow of neural activity along axons or physical parameters such as position or velocity. Formerly, models had to be simple to be amenable to mathematical analysis, whereas nowadays the behavior of very complex structures can be rapidly determined by simulation software.

### Characteristics

#### Description of the Theory

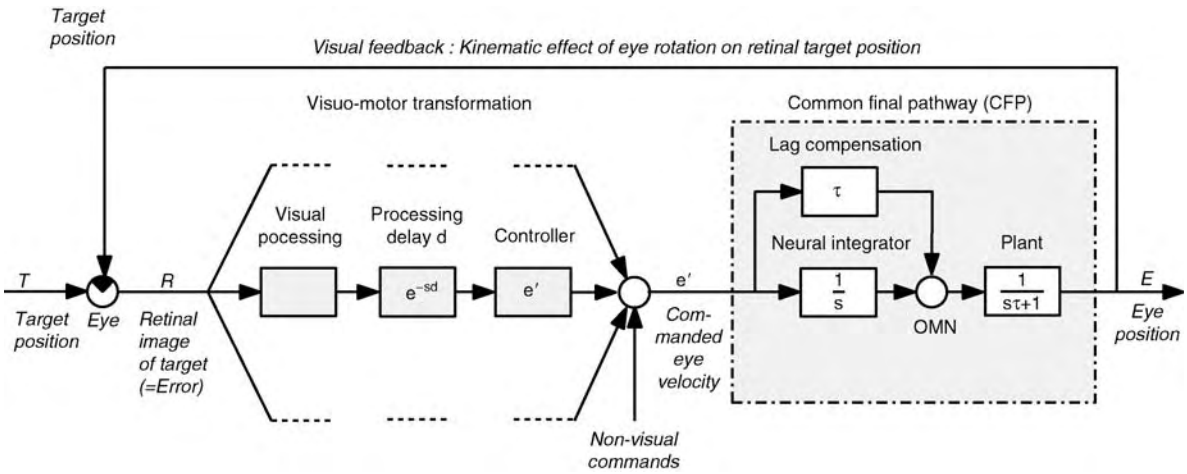
##### *Common Characteristics of Visual Eye Movement Control*

A prototypical scheme of visual eye movement control using a high level of abstraction is shown in Fig. 1. In particular, this and the following schemes do not explicitly show the bilateral symmetry of the oculomotor system and the elaborate push-pull interactions of its constituent elements; rather, they represent the net effect of these interactions.

Visually controlled eye movements aim at bringing the retinal image of visual target objects into the foveal area and at stabilizing them there. The basic information available to this end is *R,* the target's retinal eccentricity with respect to the fovea. *R* reflects the difference between target (*T*) and eye (*E*) position, and represents the current error in eye position; because of the "built-in" retroaction of *E* on *R*, that is, on the very signal it is reacting to, visual eye movement control constitutes a *negative feedback* system and is said to be *closed loop*. *R* is processed by a number of parallel, semi-independent pathways that perform the visuo-motor transformations required for the various types of visually controlled eye movements. In Fig. 1, these pathways are symbolized by dashed signal paths, while the typical structure of one of them is shown in more detail as a reference for the further description.

*R* first must be detected and processed by the visual system to obtain the information (e.g., error velocity) based on which the *controller* can generate an error-correcting motor command. Detection and processing of R, but also the operation of the controller and of other stages, require considerable time. These delays can be lumped into a single delay time (d) that represents the latency of the eye's response to a change of target position or velocity.

Interestingly, for all types of eye movements, including those controlled by non-visual signals (e.g., vestibular), the primordial motor commands issued by their respective controllers appear to specify *eye velocity* rather than eye position. In Fig. 1, these commands are shown to converge at a summing junction whose output represents a compound eye



**Oculomotor Control (Theory). Figure 1** Basic structure of visual eye movement control. Italicized text and symbols denote *signals*; symbols beginning with lower case denote neural activity; upper case refers to physical quantities. Normal print describes functions and identifies the various elements of the scheme; symbols inside boxes describe global transfer characteristics of these elements by Laplace transforms (s, complex frequency; τ, time constant of plant).

velocity command ($e'$). This signal is converted into an eye position command by a stage that calculates its time integral. The substrate of this so-called *neural integrator* (NI) has been located to the medial vestibular nucleus and the nucleus prepositus hypoglossi and their reciprocal connections with the vestibulo-cerebellum. NI is also being referred to as *hold integrator* because it is responsible for holding the eyes at whatever position they have been brought to by a preceding, but now gone, $e'$-signal. NI has been the target of interesting attempts to explain integration in terms of a network of neurones that excite themselves via reciprocal connections to neighboring neurones [1].

The output of NI reaches the oculomotor nuclei (OMN); in the case of horizontal eye movements the abducens nucleus (nVI) in the first place, from whence it is forwarded to the rectus medialis complex of the contralateral oculomotor nucleus (nIII). OMN, in turn, send the position command to the extraocular eye muscles. The mechanical compound consisting of these muscles, the eye ball, and its connective tissue is collectively referred to as *plant*. The dynamics of the plant is dominated by visco-elastic forces, while the mass of the globe plays a minor role. As a first order approximation it can be described by a first order lag system with time constant $\tau = 150–200$ ms. Thus, a step increase of OMN activity causes the eye to exponentially approach the position coded by this step, with fairly sluggish creeping in the final phase. To overcome this sluggishness, there is a direct projection of $e'$ to OMN, which adds a velocity component to the position command obtained from NI. This combination of position and velocity components becomes particularly clear during saccades, where a *pulse-step pattern* of innervation is observed in OMN.

Theoretically, if the gain of the direct projection assumes the numerical value of τ, the compound labeled "Common final pathway" in Fig. 1 behaves like an ideal integrator which accurately converts $e'$ into eye position $E$, and for many purposes such a simplification is an acceptable approximation. The term *common final pathway* (CFP) for the aggregate consisting of NI, lag compensation, OMN, and plant reflects the belief that all velocity commands – visual and non-visual, saccadic and smooth – are processed by the same integrator and that their direct projections all converge at the same pool of motoneurones. This notion is a useful approximation for many purposes but should not be overvalued. Already at the level of the extraocular eye muscles, the occurrence of different types of muscle fibres raises the suspicion of a functional division according to, for example, fast and slow eye movements. Also, as yet there is no agreement as to how far ►vergence movements share the integrator for ►conjugate eye movements or use separate pathways.

### Controllers

The oculomotor system's closed loop character combined with its considerable delay time ($d = 100–200$ ms) causes a major complication: If its response to a change of target position or velocity is to be accurate and fast (i.e., not much longer than d), the gain of its controller – essentially the ratio $E/R$ – must be large. On the other hand, long delays combined with a large gain cause instability (oscillations) in a closed loop system. Different strategies have been developed by the saccadic

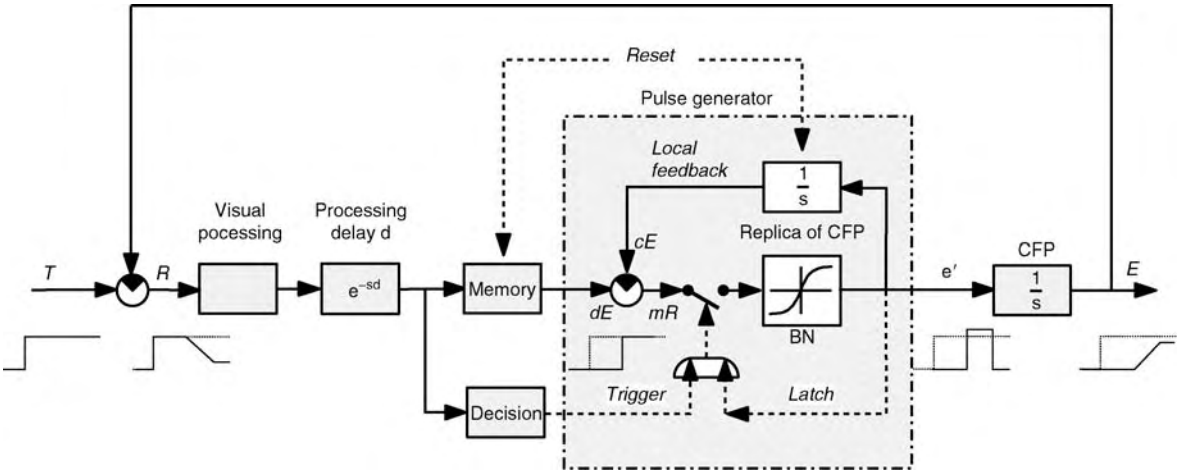
and smooth pursuit systems, to arrive at a viable compromise between response velocity and accuracy on the one side and stability on the other side.

### Saccades

Basically, the control of saccades [2,3] (Fig. 2) can be likened to the operation of a sample-and-hold system: The error $R(t_0)$ existing at time $t_0$ is measured by the visual system and transferred to a memory and a decision stage. After a processing delay (d), the decision stage triggers a neural *pulse generator* which emits a high-amplitude, short-duration pulse of neural activity, whose mathematical integral approximately equals the value of $R(t_0)$ held in memory. Fed into CFP, this pulse acts as the saccadic velocity command $e'$ and produces a fast, ramp-like movement of duration $d_S$ – the saccade. At the end of this saccade, the sequence of events repeats: the now existing error $R(t_0 + d + d_S)$ is again visually measured and, if non-zero, corrected by a further saccade. In this way the execution proper of saccades is not visually controlled, but *open-loop* with respect to visual feedback. It is, however, thought to be under *local feedback* control: a copy of the $e'$-command sent to CFP would be fed into a neural replica of CFP – basically an integrator – whose output therefore images current eye displacement (*cE*) without incurring visual delays. Subtraction of *cE* from the *desired eye displacement* held in memory (*dE*) yields the current *motor error* (*mR*) which indicates how far the eye still has to go. If switch OPN is closed, *mR* drives a pool of burst neurones (BN, located in the vicinity of nIV and in the mesencephalon) which emit the $e'$-pulse. The pulse, therefore, would last until $mR = 0$ (implying $\int e'dt = dE$, as desired). BN activity would vary linearly with small *mR* but level off with large *mR*, thus determining the well-known non-linear relationship between saccade velocity and amplitude. Switch OPN provides for the discrete nature of saccades; to close it, a trigger impulse representing an "explicit" decision for a saccade is required, and in order to remain closed BN activity must entertain a "latch" signal. Therefore, as mR approaches zero and silences BN, the switch opens making the loop refractory for new motor errors until a new decision is issued. In the mean time, both the replica of CFP and the memory would be reset to zero (the former is often referred to as "*resettable integrator*"). A likely substrate of switch OPN are the omnipause neurones in the pontine raphe, which inhibit BN during fixation and are silenced before BN activity starts.

Closer experimental analysis of the saccadic system has revealed important features that are not covered by the basic scheme in Fig. 2 (i) The decision for a saccade and the desired amplitude (*dE*) put into memory are not necessarily based on the same sample $R(t_0)$; rather, *dE* reflects some kind of average of $R(t)$ from the interval $t_0 < t <$ d-80 ms. (ii) Processing of successive saccades does not always occur in a strictly serial manner but can considerably overlap in time. (iii) Saccades are not completely open loop but can to some degree be modulated by concurrent visual events. (iv) A local (i.e., non-visual) feedback signal also reaches the visual processing stage, where it anticipates the visual consequences of ongoing (and perhaps even of as yet only decided-upon) saccades before the visual afferents can signal the resulting change of *R*.

Two other aspects not dealt with by the scheme in Fig. 2 are (i) The co-ordination between the eyes and the



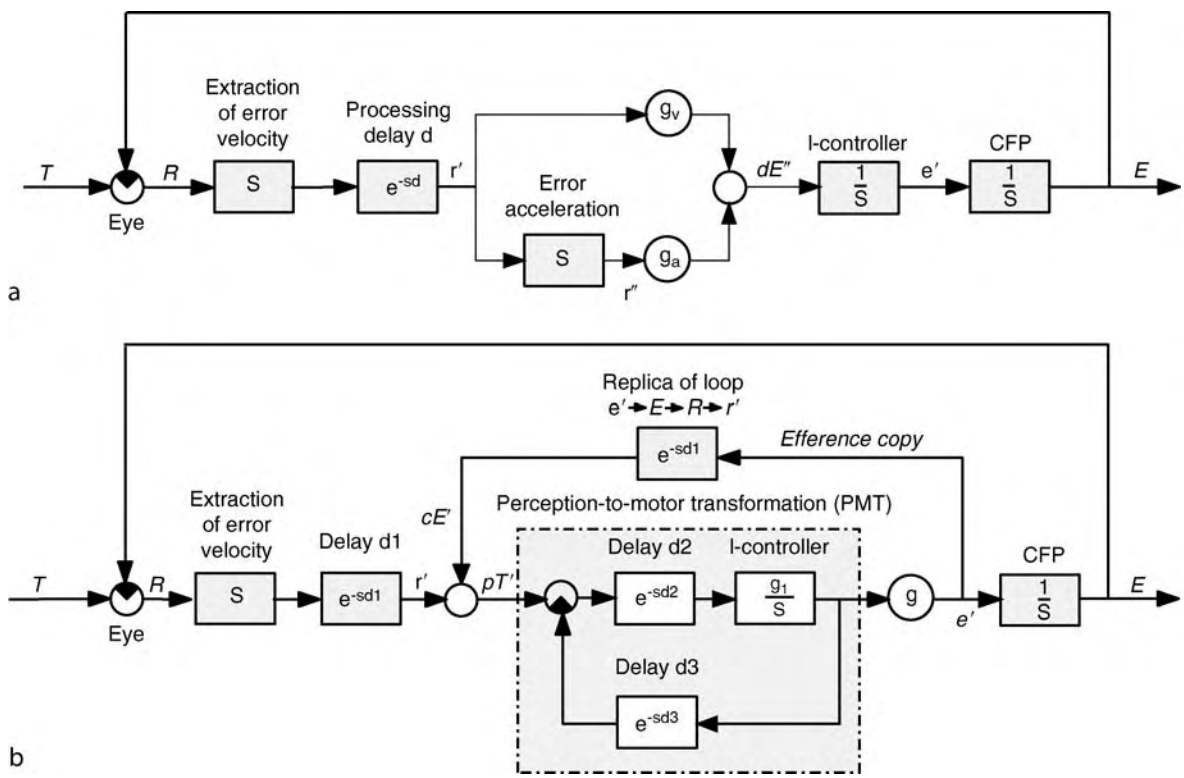
**Oculomotor Control (Theory). Figure 2** Structure of saccadic eye movement control. *dE*, desired eye displacement; *cE*, copy of current eye displacement; *mR*, motor error; BN, burst neurones (icon sketches non-linear relation between motor error and magnitude of *e'*); OPN, switch disabling burst neurones during fixation; other symbols and conventions as in Fig. 1. *Insets* show time course of signals *T, R, dE, e'* and *E* in relation to a step of *T* (*dashed*).

head during natural gaze shifts, which are generally executed with the head moving in support of the eyes; several expansions and variations of the basic structure have been proposed in which vestibular mechanisms play a crucial role for this co-ordination [4]. (ii) Whereas small displacements in 2D-space can be essentially accounted for by two orthogonal systems of the type sketched in Fig. 2, the laws of spherical geometry require that not only $R$ but also $E$ be taken into account when creating the $e'$-signal for large displacements between arbitrary positions.

### Smooth Pursuit Eye Movements (SPEM)

Basically, two alternative control structures are being discussed to account for the experimentally observed characteristics of SPEM [5] (Fig. 3). The *error-driven model* (also called *image motion model* or *closed-loop model*; Fig. 3a) posits that the motor output is driven exclusively by the current error in the way implied by Fig. 1. In accordance with SPEM's function of stabilizing the image of moving targets on the retina, first the current *error velocity* $r'$ (*retinal slip* of target image) is extracted from $R$. A second differentiating stage also calculates error acceleration $r''$. Signals $r'$ and $r''$ are then combined by weighted summation to obtain a signal representing the desired eye acceleration ($dE'' = g_v \cdot r' + g_a \cdot r''$) which in turn is converted, by integration in the controller proper, into the eye velocity command $e'$ sent to CFP. The lumped effect of this processing is that $E'(t + d) = g_a \cdot R'(t) + g_v \cdot \int R'(t)dt$; therefore, it can be likened to that of a PI-controller with delay time d. Dependent on the relative weights of the proportional and the integrating contributions, such a system can oscillate at frequencies from 0.5/d ($g_v = 0$) to 0.25/d ($g_a = 0$); given d = 0.1 s, this corresponds to the range 2.5–5 Hz. The SPEM responses of man to sudden target movements indeed exhibit damped oscillations of 3.8 Hz; yet, there is no combination of $g_v$ and $g_a$ that would account at the same time for this frequency and other essential features of SPEM responses (e.g., rise time, steady state accuracy, and dependence on target velocity). For a satisfactory explanation of all relevant SPEM characteristics, several non-linear gain elements (saturating with increasing input) have to be inserted into the pathways preceding the I-controller of Fig. 3a.

The alternative approach, the *perceived velocity* (or *open- loop*) model (Fig. 3b), tries to reconcile the various characteristics of SPEM by assuming that SPEM oscillations are caused by an "inner," local feedback loop rather than by the "outer," visual loop.



**Oculomotor Control (Theory). Figure 3** Smooth pursuit control: (a) error-driven model; (b), perceived velocity model. Conventions as in Fig. 1. $r'$ ($r''$) error velocity (acceleration); $dE''$, desired eye acceleration; $cE'$, delayed copy of eye velocity; $pT'$, perceived target velocity; $g$, gain coefficients. Other symbols as in Fig. 1.

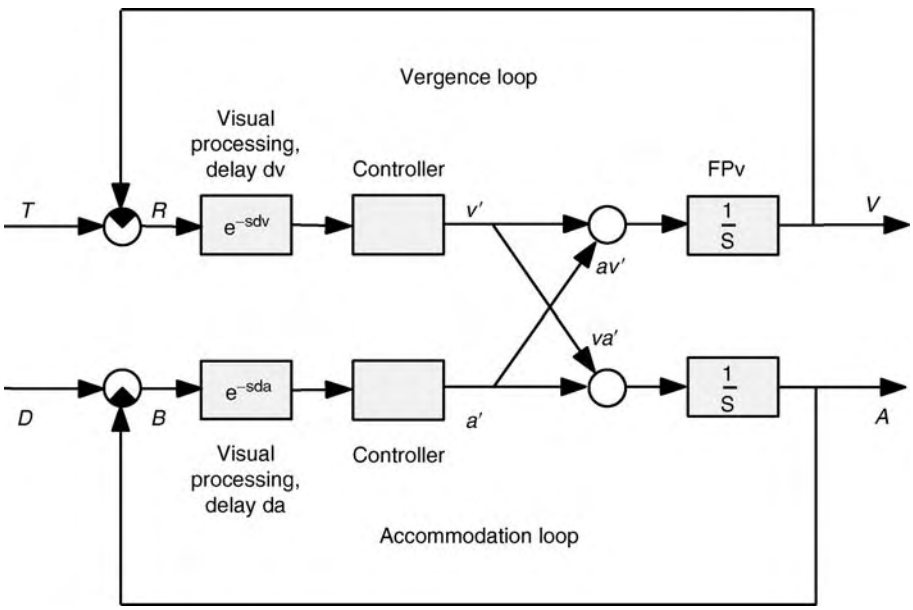
The model posits that the target's velocity, as it existed one visual delay time (d1) earlier, i.e., $T'$(t-d1), is *reconstructed* using delayed neural representations of (i) the retinal slip: $r' = R'$(t-d1), and of (ii) eye velocity: $cE' = E'$(t-d1); their sum, $pT' = T'$(t-d1), represents the "perception" of $T'$ by the SPEM-system and may also determine conscious perception of target velocity. $cE'$ would be obtained from an efference copy of the velocity command $e'$, passed through a neural replica of the pathway mediating the retroaction of $e'$ upon $r'$; with the simplifying assumptions of Fig. 3, this replica reduces to delay d1 (since $1/s \cdot s = 1$). If perceived target velocity $pT'$, is then translated one-to-one into the velocity command $e'$, SPEM velocity will faithfully follow $T'$ except for a delay. During steady state operation, the *perception-to-motor transformation* (PMT) stage, when envisioned as a local feedback loop with integrating controller, has indeed a gain of one. The fact that in most people tracking a target of constant speed SPEM is slightly slower than the target, can be accounted for by gain element g (e.g., $g \approx 0.9$); a value $g < 1$ also insures stable operation of the positive (or "regenerative") feedback loop through which the efference copy of $e'$ entertains the perception of $T'$.

By adding $cE'$ to $r'$ a positive, non-visual loop is created which offsets the subtraction of $E$ from $T$ and, hence, functionally neutralizes the negative visual feedback around the outer loop. Thus, SPEM becomes a virtually open-loop, feed-forward response to target movement. Therefore, oscillations cannot arise from the system architecture as a whole, but only in its constituents; specifically, it has been suggested that the experimentally observed damped oscillations arise in the inner (PMT-) loop, with frequency determined by delay times d2 and d3, and amplitude by integrator gain $g_I$. However, to render all relevant characteristics of SPEM, the perceived velocity model also requires the addition of non-linearities. Furthermore, proponents of the closed loop model point out that it has difficulties in rendering the effects observed during artificial prolongations of the delay time.

Both models apply only to the pursuit of targets moving at constant speed. With periodically moving targets, very effective predictive mechanisms dominate behavior which can virtually eliminate the delay between target and eye and, therefore, require more sophisticated models.

### Vergence Movements

The control of vergence movements (Fig. 4) differs from that of saccades and SPEM in several aspects: It must move the two eyes in opposite directions and it is not only driven by errors in eye position or velocity (here: by retinal disparity) but also by an input unrelated



**Oculomotor Control (Theory). Figure 4** Structure of vergence control. $T$, convergence called for by target; $R$, retinal disparity; $v'$, commanded velocity of vergence; $V$, vergence angle of eyes; $D$, target distance$^{-1}$ (diopters); $B$, error in accommodation (blur); $a'$, commanded rate of change of accommodation; $A$, accommodation; $av'$ and $va'A$, contributions of accommodation to vergence and vice versa (mostly denoted AC/A and CA/C in the literature); FPv, final pathway of vergence system (partially overlapping with CFP). Conventions as in Fig. 1. (For a broad synopsis of the use of models in oculomotor physiology see Carpenter RHS (1988) Movements of the eyes (2nd edition). Pion, London For examples of how models benefit the analysis of neuro-ophthalomological problems see Leigh RJ, Zee DS (1999) The Neurology of Eye Movements (3rd edition). Oxford University Press, New York, Oxford).

to eye position, namely the error in accommodation (retinal blur); the response to this input is known as *accommodative vergence*. As accommodation, in turn, is not only driven by blur but also by retinal disparity (*convergence accommodation*), two mutually coupled feedback circuits result with fairly similar constituent elements, except for a significantly larger delay (da) in the accommodative loop as compared to the vergence loop (dv). The situation is further complicated by the possibility that, much as with conjugate movements of the two eyes, there might be separate systems for pursuit vergence (tracking a target moving slowly in depth) and saccade-like vergence (called for by sudden changes of fusional demands) [6]; therefore, no details of the controller are specified in Fig. 4. As with other oculomotor subsystems, the controller signal reaches the plant both via a direct (velocity coding) and an integrating (position coding) pathway which, when lumped with the plant, could be roughly equated to an integrator (box FPv). Due to the disconjugate character of vergence, the integrating pathway cannot be identical to the neural integrator of the common final pathway (CFP) of conjugate movements, although it may partially overlap with it [7]; hence, the notion of a CFP is not applicable here in a strict sense. Finally, it is not clear whether the cross-coupling between vergence and accommodation occurs before the integration of the commanded vergence ($v'$) and accommodation ($a'$) velocities (as shown in Fig. 4), or thereafter [8].

# Oculomotor Dynamics

Charles Scudder
Portland, OR, USA

## Synonyms

Oculomotor plant; Orbital dynamics

## Definition

►Oculomotor dynamics are the properties of the oculomotor system that determine the time-course of the rotation of the eye in response to the discharges of ocular motoneurons. These properties are a product of the inertia of the eye, the viscoelastic properties of the tissue surrounding the eye, and the dynamic properties of the extraocular muscles that control its movements. These properties are usually described mathematically using differential equations or their equivalent (e.g. computer models).

## Characteristics

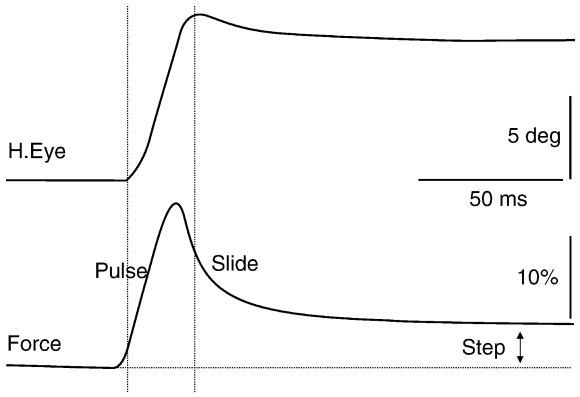
### Measurement of Oculomotor Dynamics

The time course of an eye movement is not a replica of the aggregate discharge rate of the ocular motoneurons, but is modified by oculomotor dynamics. The difference between the two can be quantified and used to describe oculomotor dynamics. This measurement is a composite of the three factors listed above. To interpret this measurement, it is also important to directly measure inertia, tissue viscoelasticity, or muscle properties in isolation using mechanical methods, as described below. Force transducers placed in series with the extraocular muscles have also helped to isolate the dynamics due to the muscles and the dynamics due to the eye and orbit [1,2].

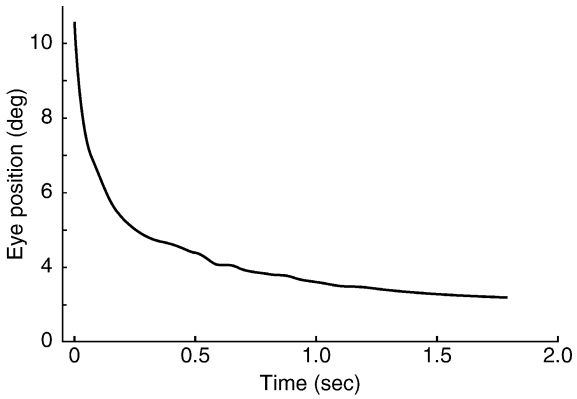
The force produced during the generation of a saccade is illustrated in Fig. 1. The time course is divided into three components; the "pulse" that occurs during the saccade, the "slide" (decay in force) occurring after the end of the saccade, and the "step" (long-term force) that keeps the eye in a static position until the next eye movement.

### Viscoelastic Properties of the Orbital Tissue

Rotation of the eye causes a displacement of the orbital tissue, such as the conjunctivum, Tenon's capsule, fat in the orbit, and the connective tissue of the extraocular muscles. These tissues resist rotation, their resistance displaying both an elastic and a viscous component. The elastic component provides a static restoring force that depends only on the angle of rotation away from straight ahead. This force increases with angular deviation nearly linearly over a range of angles, but



**Oculomotor Dynamics. Figure 1** Recording of the horizontal eye position (H. Eye) and muscle tension (Force) in the lateral rectus muscle recorded during an abducting horizontal saccade. Tension increases slightly before saccade onset and peaks somewhat before saccade termination. This phase is frequently called the "pulse" of force because of the waveshape of the associated motoneuron discharge, and is responsible for producing the rapid velocity of saccades. This is followed by an initially rapid and then slow decline in force commonly called the "slide." Normally the eye would be stationary during this time, but the force transducer has caused a minor abnormality. Force never declines to its initial value, but rather, there is a persistent force (the "step") that holds the eye in its final abducted position. Force is expressed as a percentage of the maximum force developed by the muscle during any saccade, probably 50–60 g-force. Dotted lines mark saccade onset and termination. Figure modified from Miller & Robins, Fig. 9 [2].



**Oculomotor Dynamics. Figure 2** The return of eye position towards straight-ahead gaze after being released from an abducted position. Movement is initially very rapid, then slows down, and finally creeps toward a final position over several seconds (not shown). Data is replotted from Sklavos et al. [4].

increases more rapidly after about halfway to the maximum of natural eye movements (see ►Orbital mechanics). The viscous component resists an ongoing rotation of the eye with a force that is proportional to the velocity of rotation.

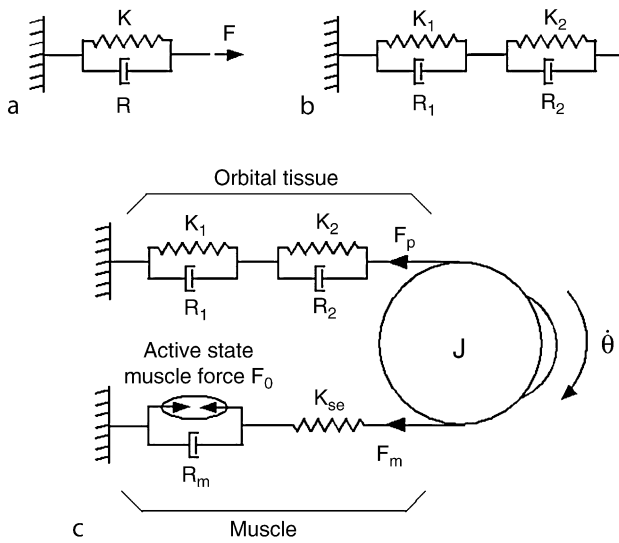
The mechanical method of measuring the viscoelastic forces is to pull on the eye with a constant tangential force, and measure the time course of the change in angular position. The eye rotates rapidly during the first few milliseconds, but progressively slows down and continues to move increasingly slowly over succeeding seconds. The process is characteristic of most tissue in the body and is known as "tissue creep" [3]. An equivalent experiment is illustrated in Fig. 2, where the eye is held in a static position and then released (isotonic force = 0). The eye rotates back towards straight ahead as described above. Technically, the change in position is described by the sum of an infinite number of exponentials with different ►time constants [3], but practically, a very good fit to the data can be obtained with a small number of exponentials. For the data in Fig. 1, one exponential accounts for 85% of the variance, two account for 98.5%, and four account for 99.9% [4].

For a quantitative description of the viscoelastic properties of the orbit, each exponential is modeled as the product of one "Voigt element," which is a spring (the elastic component with spring constant K) in parallel with a dashpot (the viscous element with viscosity R) as in Fig. 3a. Two exponentials are modeled as two Voigt elements in series, as in Fig. 3b.

Using a single Voigt element to describe oculomotor dynamics [5] has intuitive appeal because it requires a neural controller for eye movements having only two components. One is a velocity command, such as the burst of saccadic burst neurons (see ►MLBNs) or the discharge of vestibular afferents during the ►vestibuloocular reflex (►VOR) that is needed to overcome the viscosity of the orbital tissue. The second is a position command, thought to be obtained by integrating the velocity command (see ►Neural integrator), that is needed to overcome the elasticity of the tissue. However, this model cannot explain the presence of the slide (Fig. 1) or the frequency-dependent characteristics of motoneuron firing-rate modulation during sinusoidal ►smooth pursuit [6], and predicts an unrealistically high force to move the eye during a saccade [6]. Using two Voigt elements (Fig. 3b) greatly reduces all three problems, and is quite adequate for the didactic purposes of this article.

## Muscle Dynamics

Force in the extraocular muscles varies with the number of motoneurons recruited and the firing rate of each motoneuron. Three factors contribute to the dynamics of force buildup (or decline) in the muscles; the "twitch



**Oculomotor Dynamics. Figure 3** Components used in modeling oculomotor dynamics, including a nearly complete model. A single Voigt element (a) is composed of a spring with spring constant K (representing elastic restoring forces in the orbit) and a dashpot with viscosity R (representing the viscous, velocity dependent, properties of orbital tissue). A single Voigt element responds to a step change in force with a change in length fit by a single exponential having a time constant of R/K. The viscoelastic properties of the orbit are more accurately modeled by two (b) or more (not shown) Voigt elements in series. This model of the orbital tissue is shown attached to the eyeball (top of (c)), with a model of the muscle attached at the bottom. The parallel elastic component of the muscle has been lumped with the other orbital tissue. The active-state force generator (muscle crossbridges) is in parallel with a dashpot with viscosity $R_m$, which models the reduction in force $F_m$ according to the ►force-velocity relationship. The series elastic component (spring constant $K_{se}$) lengthens during the initial buildup of force at the onset of a saccade. For all practical purposes, the inertia of the eye (moment J) can be ignored, meaning that the magnitude of $F_p \approx F_m$.

time" of the muscle, the distributed recruitment of motoneurons over time, and the firing rate of the active motoneurons. These factors make little difference during slow eye movements (smooth pursuit, VOR), but a major one during rapid saccadic eye movements [6].

An action potential in a motoneuron and the muscle fibers it innervates produces a rapid buildup to a peak of force and then a gradual decline. The time to peak is called the "twitch time" [7], and is 5–7 ms in monkeys [8]. The finite twitch time is due to the fact that connective tissue and muscle proteins are springy (series elastic component [7]) in combination with the fact that rapidly shortening muscle develops less force (►Force velocity relationship [7]; see ►Muscle twitch).

During the repetitive firing of a motoneuron, the force of each twitch adds to the force that remains from the preceding twitches. At the start of repetitive firing, this superposition produces a cumulative force that builds up and saturates with a roughly exponential envelope whose ►time constant decreases as the firing rate increases [9]. During an actual saccade, there is a complex interplay between the ►extraocular motoneuron firing rates and the force-velocity and length-tension properties of the shortening muscle, which makes exact modeling difficult. In practice, it has proven satisfactory to approximate all these dynamics as a single spring and dashpot in series and parallel, respectively, with the active (force-producing) components of the muscle ($F_o$ in Fig. 3c).

The bursts of repetitive firing in extraocular motoneurons occurring just prior to saccades do not start simultaneously, but their onsets are spread over 6–8 ms in monkeys [5,9] and could be longer in humans, who have slower saccades. The effect of this distributed recruitment is to slow the initial acceleration of the eye during saccades.

## Inertia of the Eye

Calculations, modeling, and measurement all show that the force required to overcome the inertia of the eye is negligible during slow eye movements and is very small during saccades [6,10]. For all practical purposes, inertia can be ignored in models of oculomotor dynamics. However, the inclusion of an unrealistically high moment of inertia has been used in some modeling studies [11] to account for the discrepancy between the slow acceleration of the eye relative to the almost instant buildup of firing rate in single saccadic burst neurons (see ►Burst cells – medium lead). This discrepancy, however, is the product of finite twitch times in the extraocular

muscles and the spread of burst-neuron and motoneuron recruitment times in relation to saccade onset, with a minimal contribution from the inertia of the eye.

### Cumulative Orbital Dynamics

A model of oculomotor dynamics is illustrated in Fig. 3c. The viscoelastic properties of the orbital tissue are illustrated at the top of the eye, and the muscle is illustrated at the bottom. The agonist and antagonist muscles, which are reciprocally innervated and have mirror-image force profiles [2], have been lumped together into one muscle. The "parallel elastic component" of the muscle, which is sometimes modeled as a separate element, has been lumped into the orbital tissue. This is consistent with the fact that the passive muscle has viscous as well as elastic properties that are measured with the other orbital tissues in the release experiments described above [4,10]. The moment of inertia is denoted as J. Treating J as negligible, the differential equation describing eye acceleration as a function of muscle force ($F_m$), rate of change of force, and the viscoelastic impedance is below:

$$\ddot{\theta} = \frac{1}{\mu}\left(F_m + T_s\dot{F}_m - K_o\theta - R_o\dot{\theta}\right)$$

Ks, Rs, and Ts are composite spring, rate, and time constants [6,10]. Muscle force ($F_m$) is the active-state force ($F_o$) reduced by the rate of change of force and eye velocity:

$$F_m = F_o - T_m\dot{F}_m - R_m\dot{\theta}$$

Equations that include inertia can be found in Robinson [10]. Values for all parameters can be found in references [4,6,10].

The interaction of all the dynamic elements will be illustrated for a saccade. To begin the saccade, motoneurons begin their bursts over a range of times leading to a gradual buildup in active-state tension. The buildup of force delivered to the eyeball ($F_m$) is further slowed by the dynamic properties of the muscle, as discussed above. This buildup is illustrated in Fig. 1 during the so-called "pulse" phase. Shortly after the onset of force, the eye begins to rotate. As the inertia of the eye is small, $F_p$ is almost equal to $F_m$, reflecting that the primary impedance to motion is provided by the viscoelastic properties of the orbital tissue. At the end of the pulse, motoneuron firing rate drops rapidly at first, and then more gradually with a "slide" similar to that illustrated in the force trace of Fig. 1. In a normal eye (without a force transducer), the eye would stop moving at this point. The decline in muscle force compensates for the decline in the reactive force in the orbital tissues as they "creep" to a new steady state. In terms of the model in Fig. 3, the Voigt element with the faster time constant was initially stretched disproportionately, and relaxes during the slide as the Voigt element with the slower time constant stretches. At the end of the slide, which can take several seconds in the actual eye or a model with more than two Voigt elements, there is a residual force (the "step" in Fig. 1) that is needed to maintain the eye at its new position against the just stretched elastic components of the orbital tissue.

# Oculomotor Nerve (III)

### Synonyms

N. oculomotorius (N.III)

### Definition

The oculomotor nerve is a motor cranial nerve endowed with both somato- and visceromotor components, for which one complex is responsible in each case. Together with the trochlear nerve (IV) and abducens nerve (VI) it controls eye movements.

It is involved in the lateral and medial eyeball movements (lateral rectus muscle and superior oblique muscle), raising of the palpebra as well as accommodation (ciliary muscle) and adaptation (sphincter muscle of pupil). Skull: superior orbital fissure.

►Nerves

## Oculomotor Nucleus

### Definition

A nucleus which contains both motoneurons and interneurons. The motoneurons send direct projections to all extraocular muscles except for the superior oblique muscle and the lateral rectus muscle.

## Oculomotor Plant

►Eye Orbital Mechanics
►Oculomotor Dynamics

## Oculomotor Systems

►Evolution of Oculomotor System

## Oculomotor Vermis

### Definition

The circumscribed portion of the cerebellar vermis (lobules VIc and VII) that appears to be integral to the control of saccadic and smooth-pursuit eye movements. The time course of changes in eye position or the firing rate of neurons can sometimes be described mathematically by an exponential, $X = X_0e^{-(t/T)}$, where X is the position or firing rate, $X_0$ is the initial value of X, t is time, and T is the "time constant" of the exponential. The time constant is equivalent to the amount of time required for X to decay to 36% (1/e) of $X_0$.

## Odor

Martina Pyrski, Frank Zufall
Department of Physiology, University of Saarland School of Medicine, Homburg/Saar, Germany

### Synonyms

Odor; Odorant; Olfactory cue; Smell; Scent, Aroma

### Definition

"Odor" refers to an emanation composed of multiple different odor molecules termed odorants, whose individual chemical properties are perceived by the sense of smell. In humans, this term is frequently used to describe a sensation as a result of odor perception, for example the pleasure resulting from the floral smell of roses (good odor) or the disgust following the smell of spoiled food (bad odor).

### Characteristics

In contrast to the senses of vision, hearing and touch, the chemical senses - smell (and taste) - are challenged by an enormous number of molecularly distinct stimuli. Natural odors derived from food and plants and social stimuli, such as those present in urine, sweat and saliva, represent complex mixtures that contain a multitude of chemically diverse compounds. The information contained in these molecules is detected and processed by the sense of smell, a sensory modality that emerged very early in the evolution of living forms. Detection of olfactory cues is initiated by interaction of odor molecules with specific receptors located in the cellular membrane of olfactory sensory neurons in the nasal epithelium. The initial chemical odor information is then translated into neuronal activity patterns and subsequently converted into perceived odor quality and behavioral responses as a result of pattern recognition and evaluation by the brain.

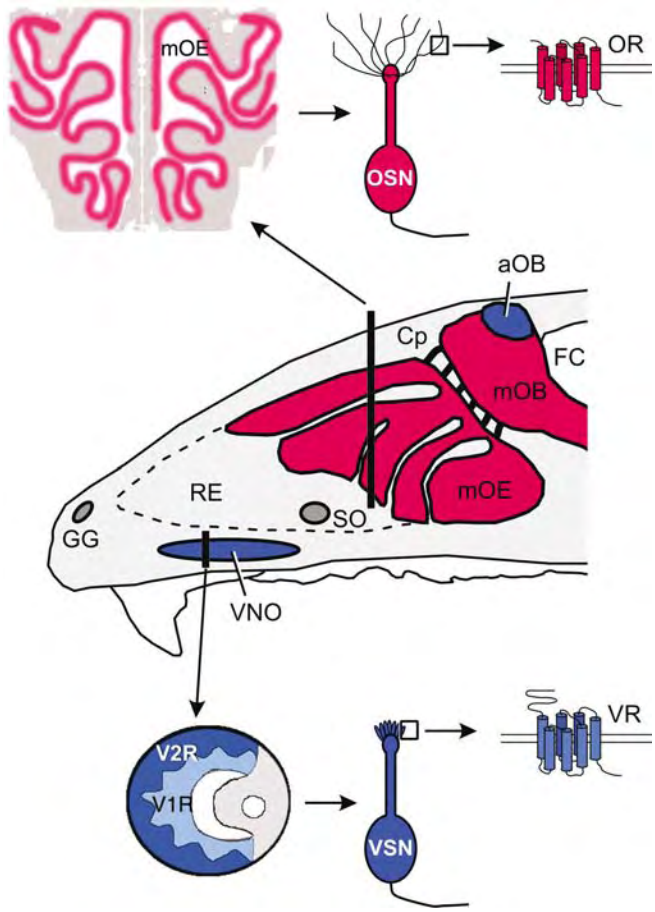
### Odor Detection in Mammals Occurs Through Multiple Olfactory Subsystems

In vertebrates, the cellular, molecular and genetic mechanisms underlying odor detection and the sense

of smell are probably best understood in the mouse olfactory system. Odor detection begins in the olfactory sensory neurons (OSNs) located in the main olfactory epithelium (mOE) of the nasal cavity. Volatile odor molecules enter the nasal cavity with each breath and dissolve in the mucus covering the epithelial surface, a process that may be facilitated by small carrier molecules or odor binding proteins. The next step is a direct contact of odor molecules with the olfactory cilia which emanate from the dendritic knob of each OSN (Fig. 1).

These cilia contain all the necessary components for odor detection and subsequent chemo-electrical signal transduction. The electrical output signal produced by each OSN travels along a single axonal projection toward the main olfactory bulb (mOB) in the forebrain, the first relay station of odor processing in the brain. The axons from several millions of OSNs coalesce to form the olfactory nerve, also known as 1st cranial nerve.

In addition to a main olfactory system, most mammals have evolved an accessory olfactory (or vomeronasal) system (Fig. 1), which is anatomically and functionally distinct from the main system. Odor detection in the accessory olfactory system begins in the paired vomeronasal organ (VNO), located ventrally at the base of the nasal septum and rostral to the mOE. Odor stimuli are actively transported into the lumen of the VNO by a vascular pumping mechanism. The sensory epithelium of the VNO covers the inner medial side of each tube and, in analogy to the mOE, contains vomeronasal sensory



**Odor. Figure 1** Schematic of a hemisected head of a mouse (sagittal view) illustrating the anatomical location of different olfactory subsystems and key structures. *Cp* cibriform plate; *FC* frontal cortex; *GG* Grüneberg ganglion; *mOB* main olfactory bulb; *RE* respiratory epithelium; *SO* septal organ of Masera; The black bar in the main olfactory epithelium (mOE, red) refers to the coronal section at the top left (arrow) that depicts the bilateral symmetry of the mOE. Olfactory sensory neurons (OSNs, red) contain numerous cilia that carry odor receptors (OR, red) of the GPCR type. The black bar in the vomeronasal organ (VNO, blue) refers to the coronal section shown at the bottom left with V1Rs and V2Rs expressed in the apical (light blue) and basal (dark blue) halves of the vomeronasal sensory epithelium, respectively. Vomeronasal neurons (VSN, blue) carry numerous microvilli that express vomeronasal receptors (VR, blue) of the GPCR type.

neurons (VSNs). These extend microvilli instead of cilia towards the lumen of the VNO. VSN axons project to the accessory olfactory bulb (aOB) located posterior and dorsal to the mOB (Fig. 1).

The traditional distinction that the mammalian main olfactory system recognizes general odor molecules and the vomeronasal system detects pheromones is no longer valid. The emerging picture is that both systems have considerable overlap in terms of the chemosignals they detect and the effects that they mediate [1]. Other, functionally less well characterized olfactory subsystems in rodents comprise of the septal organ of Masera and the Gruneberg ganglion (Fig. 1). Finally, some odor molecules such as menthol and phenylethyl alcohol can be detected by free nerve endings of the 5th cranial nerve which are part the somatosensory system. These nerves are often sensitive to pain as well as temperature stimuli and terminate in the nasal cavity.

## Odor Molecules

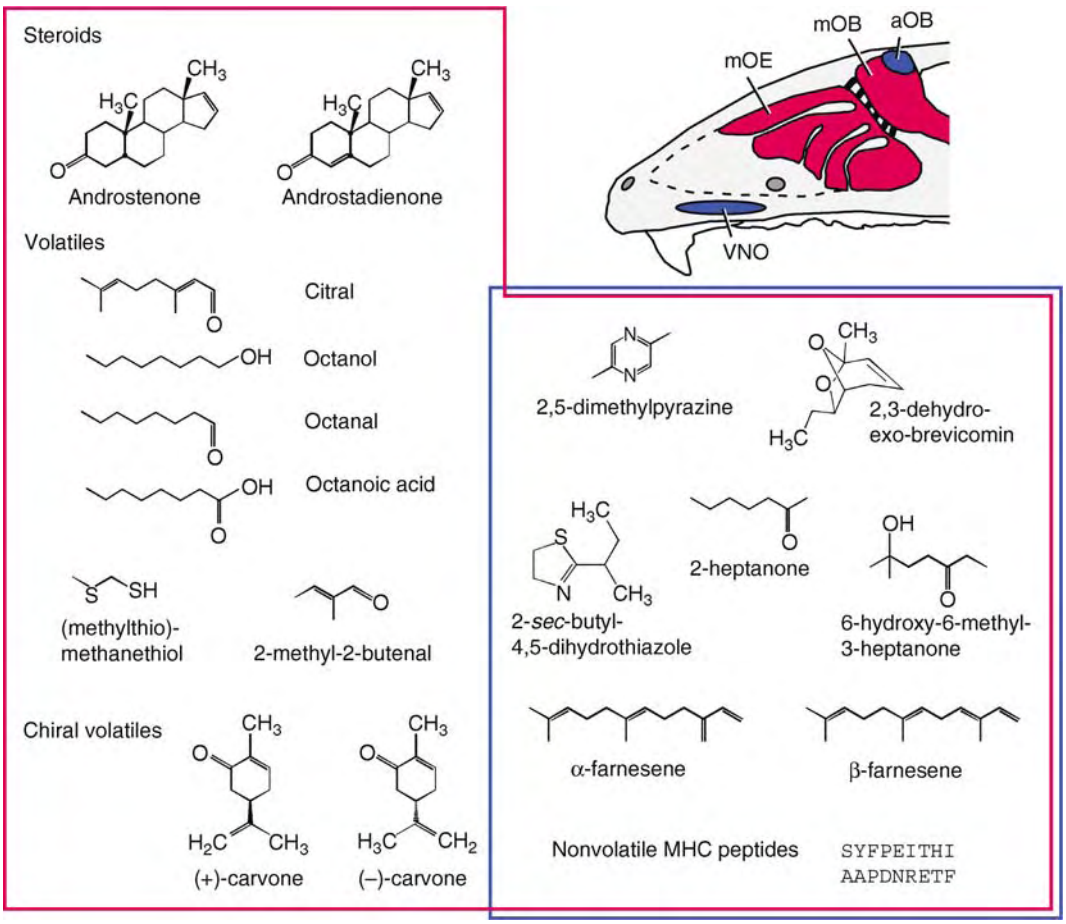
The olfactory environment is estimated to comprise hundreds of thousands of structurally distinct compounds that potentially can be detected and discriminated by the olfactory system. These odor molecules are classified by several means, most commonly by the presence of specific physical and chemical properties or encoded odor quality, but also by the characteristics of the corresponding receptors, resulting activity patterns in the brain, and function. Typical odor molecules of air-breathing species are small hydrophobic chemicals of organic origin with a molecular weight of less than 300 Da, i.e., they are volatile at ambient temperature. In aquatic animals, requirements for odor molecules are different, with non-volatile, hydrophilic compounds like amino acids being among the best odor ligands identified. Chemically, odor molecules differ by many parameters including size, functional groups, 3D-structure, and flexibility. They encompass the whole array of aliphatic acids, alcohols, aldehydes, ketones, and esters. To the human nose, changes of functional groups can cause pronounced differences in perceived odor quality, e.g., octanoic acid has the smell of sweat whereas the structurally related aldehyde octanal (Fig. 2) has the smell of oranges. The presence of functional groups is not always a prerequisite for odor. Alkenes such as 2,4,4-trimethylpentane and cyclooctane both have pronounced camphor quality as a consequence of molecular shape.

Further chemical features that are subject to olfactory discrimination include differences in carbon bond branching and saturation, as well as substitutions by aromatic, alicyclic, polycyclic, and heterocyclic ring structures or halogens in numerous possible positions. For some substances, substitutions can be exchanged without altering odor quality, e.g., exchanging the aldehyde group in benzaldehyde with other groups of similar size and charge does not affect its bitter almond quality. Most intriguingly, humans are capable to distinguish between the enantiomers of chiral odor molecules, such as (+)-carvone (caraway) and (−)-carvone (spearmint), which is likely mediated by stereo-selective receptors (Fig. 2). Enantio-selectivity is also exemplified by the pheromonal compound androstenone that induces mating stance in female pigs. (+)-Androstenone (Fig. 2) has an unpleasant (sweat, urine) odor quality to some humans and a pleasant (floral, sweet) odor quality to others, while (−)-androstenone is generally perceived as odorless. In contrast to mice, enantio-selectivity in humans is less pronounced and restricted to few odor molecules, while most enantiomers encode identical odor quality. Furthermore, carvone and androstenone are typical examples for which specific anosmias - the inability to detect particular odor molecules - have been identified in a certain percentage of humans.

## Odor Receptors

How is the neural recognition of this almost infinite number of structurally diverse odor molecules achieved? Early on it has been noted that for a molecule to have an odor it needs to possess a molecular configuration that is complementary to specific sites of its receptor system [2]. This stereospecific theory has been validated by the discovery of a multi-gene family encoding odor receptors (ORs) [3], a finding that has set a milestone in the molecular understanding of odor detection (http://nobelprize.org/medicine/laureates/2004/press.html). ORs belong to the superfamily of G-protein coupled seven-transmembrane domain receptors (GPCR) (Fig. 1), and are similar in structure to the rhodopsin and β-adrenergic receptors. The ability of the olfactory system to recognize thousands of different odor molecules derives from the large size and diversity of the OR family. Based on genome sequencing projects (http://www.ncbi.nlm.nih.gov/Genbank), more than 1,000 potentially functional OR genes have been identified in mouse, while humans are left with about 400 potentially functional OR genes. Phylogenetically, ORs are preserved from fish to mammals and divide into two major classes. Class-1 or fish-like ORs are encoded by aquatic animals detecting water-soluble molecules, but are also present in ~10% of the mouse gene repertoire. Class-2 ORs are unique to terrestrial vertebrates detecting volatile odors.

ORs are highly divergent, especially in transmembrane domains 3–5. As a result of multiple OR sequence alignments across species and the developing of computational prediction models, odor binding is envisioned to occur in a binding pocket formed by the OR. Specific amino acid residues in key positions, predominantly located in the highly variable transmembrane domains are thought to interact with different parts of the odor molecules. However, exactly which parts of



**Odor. Figure 2** Chemical structure of odor molecules detected by the main olfactory epithelium (mOE) and the vomeronasal organ (VNO, blue). Steroids, volatiles including chiral volatiles and nonvolatile MHC peptides are detected by the mOE (red box). Overlapping odor cues that are detected by the mOE and the VNO encompass volatiles as well as nonvolatile MHC peptides (overlayed red and blue boxes). The main olfactory bulb (mOB, red) receives odor information from the mOE and the accessory olfactory bulb (aOB, blue) from the VNO.

0

the odor molecules are recognized by the ORs is still subject to intense investigation.

In situ hybridization studies show that expression of ORs in the rodent mOE is organized in a zonal pattern and that each individual OSN expresses only one OR. OSNs that express the same OR are confined to one out of four rostro-caudal zones and axonal projections of homologous OSNs coalesce into two glomeruli (one lateral and one medial) in each mOB.

## Odor Coding: Molecular Level

Despite the large size and diversity of the OR family, the question arises how a limited number of ~1,000 different ORs is capable of detecting an exceedingly larger variety of environmental olfactory cues? Identification of the first functional OR–odor ligand pairs [4,5], a process known as the "deorphanizing" of an OR, has solved this apparent discrepancy. Functional recordings of physiological odor reponses and polymerase chain reaction analyses of single OSNs have revealed that the discriminatory power of the olfactory system depends on combinatorial receptor activation as a result of an unusually broad ligand-tuning of individual ORs. Given that single OSNs express only a single OR-type, different odor molecules activate specific, partially overlapping sets of OSNs with distinct sensitivities. In other words, a single OSN has a receptive field composed of different odor ligands that bind its OR with distinct affinity. The fact that ORs detecting the same ligands can be both highly homologous or extremly divergent suggests that these ORs recognize identical or different odotopes (i.e., functional groups of an odor molecule), respectively. The resulting neural activity patterns are thus concentration-dependent: OSNs expressing ORs with the lowest threshold for a given odor are activated first, and the less sensitive ones

are recruited at higher concentrations. This concentration dependence may explain the psychophysical phenomenon that some odor molecules are perceived differently at different concentrations. For example, with increasing concentration the perception of indole by humans ranges from "flowery" to "fecal."

## Chemical Properties of Odor Molecules

Despite the relatively small number of ORs that have been deorphanized thus far, several features underlying odor recognition have emerged. The receptive field of a given OR appears to be determined by the functional groups, structure, and flexibility of an odor ligand. Some ORs accept 2–3 functional groups such as aldehydes, alcohols, and aliphatic acids [5] in combination with 3–4 consecutive carbons, while other ORs appear to be restricted to single functional groups. For example, the rat I7 OR is activated by straight-chained aldehydes ranging from C7-C10, with octanal (Fig. 2) representing the best ligand identified thus far [4]. Unsaturated C-double bonds that confer molecular rigidity or carbon backbone branches are, depending on position, tolerated, but structurally related molecules with different functional groups, such as octanal and octanoic acid (Fig. 2), yield no receptor activation. Aldehydes are potent ligands with low detection thresholds, and more than 30 different octanal-responsive, yet unidentified rat ORs, have been estimated from octanal evoked activity patterns in the mOE. However, not all ORs exhibit such broad tuning and some receptors appear to be specialists for a single or very few odor molecules.

Ligand binding does not always induce receptor activation. Several studies show that odor molecules exhibit dual functions and are agonists for some ORs, but antagonists for others. Citral for example strongly reduces the response of OR-I7 to octanal (Fig. 2). Antagonistic effects of odor molecules add another level of complexity to olfactory coding and may coincide with the psychophysical observation that both perceived quality and intensity of odor is not necessarily the sum of its single components, and that single substances are perceived differently than the same substances in a mix. Thus, at the molecular level, odor coding is a function of OSN activity patterns emerging from the combinatorial activation (and inhibition) of subsets of ORs both of which depend on concentration and chemical features of the odor molecules.

## Odor Sensing by the Vomeronasal Organ

The VNO expresses a different set of chemosensory receptors, termed vomeronasal receptors (VRs), that also belong to the superfamily of GPCRs but are otherwise distinct from ORs [6]. VRs consist of two unrelated families, V1Rs and V2Rs, that are expressed in the apical and basal layers of the VNO sensory epithelium, respectively. Recent years have shown that vomeronasal sensory neurons detect a number of pheromones (see [7] for historic definition of the term pheromone) that mediate species-specific behavioral repertoires [1]. However, the VNO also detects some general odors without known pheromonal actions.

Compared to ORs, little is known about the chemical features or binding characteristics of VRs. From a chemical perspective, some of the molecules that stimulate the apical, V1R-expressing VSNs represent typical volatiles that for the human nose, would encode a specific odor quality. In some cases, the compounds are not specific for the VNO, but are detected by both mOE and VNO [1]. For example, 2, 5 dimethylpyrazine, a candidate key-food odorant for humans (with a smell of roasted beef), is also present in mouse urine and is known to delay puberty in mice (Fig. 2). The volatile 2-heptanone that has a fruity odor quality, is a male urinary compound that conveys pheromonal action by extending estrus in female mice (Fig. 2). For 2-heptanone two distinct mouse receptors have been identified, the vomeronasal receptor V1R2b and the olfactory receptor OR912–93 both of which are activated at nanomolar concentrations.

The basal, V2R-expressing layer of the VNO appears to be involved in the detection of nonvolatile ligand families, consisting of peptides and proteins, which requires direct physical with the stimulus source. One such family consists of antigenic peptides – the major hitocompatibility complex (MHC) class 1 peptides – that are crucial in the context of immune surveillance and carry information about the genetic make-up of an individual [1]. Interestingly, such MHC peptides are also detected in the mOE, which gives further support to a model involving parallel processing of the same social odor cues by the two olfactory subsystems (Fig. 2). Convergent information derived from the two olfactory systems is likely integrated by higher brain centers.

## Odor Processing by Higher Brain Centers

How is odor information represented in the brain? The olfactory glomeruli of the main olfactory bulb (mOB) form the first relay station in the brain where axonal projections of OSNs synapse onto second order neurons, the mitral and tufted cells. It is well-established that odor stimulation evokes spatially and temporally distinct glomerular activation patterns in the mOB that result from the differential activation of specific sets of ORs in the mOE [8] (e.g., see http://leonserver.bio.uci.edu). The brain then needs to extract the features of these bulbar activity patterns. These depend to some extent on chemical odor properties, mainly functional group and structure. For example, molecules with identical functional group, but different C-chain length activate in part overlapping glomeruli that are not activated by structurally related compounds with different functional

groups; single molecules with two different functional groups activate glomeruli that are distinct from those responding to binary mixtures.

Attempts to correlate molecular and functional results on odor coding in rodents with those derived from human psychophysics show that the relation between odor structure and perceived odor quality is still poorly understood. The fact that chemically closely related molecules can confer different odor qualities, whereas molecules that smell alike do not necessarily share chemical similarity suggests that molecular properties and their translation into neuronal activity patterns and spatial odor images in the mOB are not the only determinants in defining odor quality. Further processing of olfactory information by higher brain centers that eventually produce an olfactory percept is only beginning to be understood. Many olfactory-associated brain functions derive from psychophysical studies on humans with discrete brain lesions. Functional imaging of brain activity in humans provides a promising technique to decipher the neural basi of odor perception.

Mitral and tufted cells in the mOB transmit their output signals to the olfactory cortex (Fig. 3), a broadly defined area that consists of the anterior olfactory nucleus, the olfactory tubercle, the piriform cortex, the entorhinal cortex, and the cortical amygdaloid nuclei. The amygdala, which is part of the limbic system and associated with emotional state, participates in formation and storage of olfactory memory.

The entorhinal cortex that projects to the hippocampus plays a role in associative learning and olfactory memory. The orbitofrontal cortex receives afferents from parts of the olfactory cortex through the thalamus and is involved in the conscious perception and discrimination of odor. Recent studies connect the piriform cortex with mechanisms in odor identification as well as olfactory memory and learning. Its anterior region, the principal target of mOB output signals, has been suggested to synthetize information about odor structure into a quality percept.

Mitral cells of the aOB project to the medial amygdala, which regulates social behaviors such as mating and recognition of conspecifics. Odor information of the mOB and the aOB is possibly integrated by hypothalamic gonadotropin-releasing hormone (GnRH) neurons resulting in changes in endocrine status and social/sexual behavioral outputs [9]. Furthermore, odor information undergoes additional refinement by higher cortical centers that integrate olfactory input with previous odor experience, afferents from other sensory systems, and in the case of humans, information obtained through language.

## Odor Function

Odor cues play an important role in the perception of the environment and in the overall survival of a species. During breathing, air-composition is constantly and involuntarily evaluated. In addition to locating potential food sources, detection (and secretion) of odor has multiple functions in inter- and intraspecies chemical communication, i.e., in the identification of prey, predators, mates, and in the adjustment of social and reproductive behavior. Social behaviors are mediated by both the main and accessory olfactory systems. Common to many mammals is the marking of landscape by depositing individual odors. These complex odor messages carry information about gender, sexual and social status, territoriality, mood, and fitness. In chemical communication, scent marks often serve to deter rivals and attract potential mates. Across many species, scent marks elicited by predators are interpreted as warning signs causing escape behavior. Dogs and wolves produce scent marks through urination and defecation, whereas foxes have developed a specialized supracaudal gland that constantly secretes a mixture of volatile terpenes.

A particularly well-established, odor-induced social behavior is the suckling behavior of rabbit pubs. The milk of female rabbits contains 2-methyl-2-butenal (Fig. 2), a volatile pheromone that guides pups towards their mother's nipples and triggers immediate

suckling. Another well-known odor-mediated behavioral change depends on the steroid androstenone (Fig. 2), which induces mating stance in female pigs during heat.

In humans, the smell of androstenone is described as both unpleasant (sweat, urine) or pleasant (floral, sweet). Although present in human axillary sweat and urine, it is not yet clear whether androstenone represents a human pheromone. However, androstadienone (Fig. 2), a related compound in male human sweat, is known to affect endocrine status by maintaining high levels of the hormone cortisol in exposed women. Another example of odor-induced endocrine change in humans derives from odor stimulation of females with armpit or vagina secretions from donor females. Estrus cycles of acceptor females synchronize with that of the donor female ("McClintock" effect) by either advancing or retarding menstruation.

# Odor Memory

Peter Brennan
Department of Physiology, University of Bristol, Bristol, UK

## Synonyms

Memory-odor; Odor learning; Olfactory learning

## Definition

►Odor memory is the store of information about an odor that enables an animal to recognize an odor along with its associations and meaning and link it to an appropriate behavioral response. Olfactory learning is process by which the nervous system forms such odor memories.

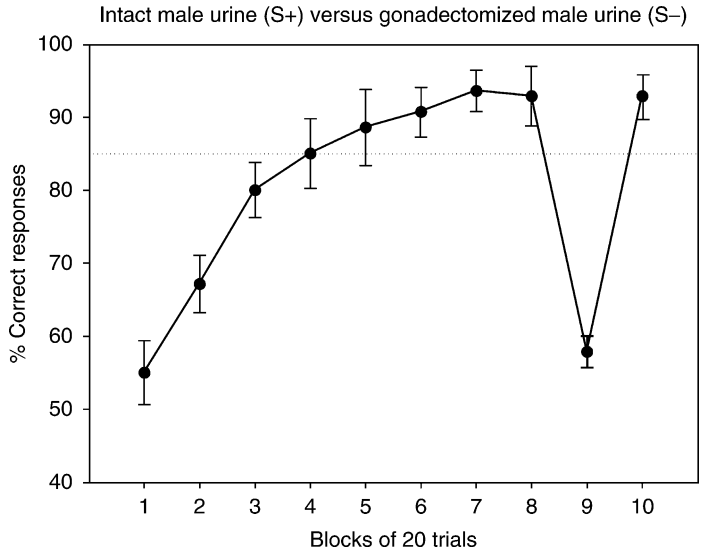
## Characteristics

The ability to learn to recognize a particular odor and associate it with a meaning or a predictive value can be demonstrated in a wide variety of vertebrates and invertebrates, and has been studied intensively in terrestrial mollusks, fruit flies, honeybees, rodents and primates. The odor stimuli used in such experiments can consist of individual ►odorants, odorant mixtures or complex, naturally occurring odors containing hundreds of constituents. Olfactometers can be used to carefully control the concentration of odorants and the composition of odor mixtures in the sampled air. Odorant mixtures are generally perceived and learnt as unitary sensory objects, rather than being analyzed in terms of their individual components [1].

One of the simplest form of olfactory learning is a "Go, No-Go" successive odor discrimination, in which an animal is rewarded for making a behavioral response to the rewarded odor (CS+), with no reward delivered in response to the unrewarded odor (CS−). This type of learning is comparatively rapid, occurring within tens of conditioning trails and the memory can last for months (Fig. 1).

Furthermore, the memory for the correct responses to a pair of odors is robust to subsequent learning of other odor pairs, and the learning of subsequent odor pairs is more rapid as the animal learns a win-stay, lose-shift strategy. This results in the ability of rats to learn the correct responses to a new pair of odors after only few trials, which is comparable to the ability of primates to learn visual discriminations. Rodents can also learn to discriminate odors presented simultaneously, either at separate odor ports or in air flowing down separate arms of a Y maze. These discriminations can be made extremely rapidly and it has been estimated that the time to make the discrimination is as small as 220 ms, less than the time taken for a single sniff [2].

Short-term memory (►memory, short-term) for odors can be tested using a delayed non-matching to sample procedure. In this procedure, subjects are presented with a sample odor, which is removed and then, after a variable delay, the subjects are presented with the simultaneous choice of the same odor and a different odor. Responses to the odor that is different from the sample odor are rewarded. Using this task, rats can be shown to have short-term memory for odors of at least 60 s. Moreover, rats can also be trained to learn odor sequences where the correct odor choice depends on the sequence of preceding



**Odor Memory. Figure 1** Typical learning curve for a "go, no-go" odor discrimination task for a group of seven inbred mice (Keller and Bakker unpublished data). The learning criterion of 85% correct responses was achieved by the fourth daily block of 20 trials. In block nine the same (S+) stimulus was used for S+ and S− trials. The drop in performance to chance levels demonstrates that the mice were using odor cues to perform the task rather than any extraneous sensory cues associated with the training procedure.

odors, which has been proposed as a test of episodic memory [3].

Rewarding and aversive training stimuli result in learning to approach or avoid the conditioned odor, respectively. However, animals can also learn about the familiarity of odors that have not been paired with any overt training stimulus. If an animal is presented with a novel odor it will initially spend time investigating it. Subsequent presentations of the same odor elicit reduced investigation, as the response habituates, whereas presentation of a novel odor elicits intense investigation. This forms the basis of the ►habituation/dishabituation test of olfactory discrimination, which in some ways is a more natural test of olfactory behavior, but requires the animal to be motivated to investigate the stimulus in the first place. Many innately attractive odors, such as urine odors in the case of rodents, may contain pheromonal components that can act as rewarding stimuli for the associative learning of non-pheromonal odors [4].

In many ways, odor learning has been most extensively studied in humans, who have the advantage of not requiring explicit reinforcement for learning to occur, as they can give verbal responses. However, the very fact that humans can name odors poses problems, in that it is often difficult to dissociate the odor memory from the memory for the verbal label. The association of a verbal label with an odor is a separate process from the recognition of an odor [1]. This is demonstrated by the "tip-of-the-nose" phenomenon in which a person reports that they recognize an odor, and its name is on the tip of the tongue, but they can't quite recall it.

## Neural Changes Underlying Odor Learning

A vast number of individual odorants are able to stimulate ►olfactory receptor proteins on olfactory sensory neurons (OSNs). If present at a sufficient concentration then the neural activity that is evoked by an odorant can lead to the perception an odor. However, most odors in nature are not the result of single odorants, but arise from complex mixtures of many odorants. The neural activity evoked by a mixture of odorants that come from a single source are associated to synthesize a unitary neural representation of the odor, known as an odor object. This allows the odor to be discriminated from similar odors and used to recognize and locate the source of the odor. The neural representation of the odor is also associated with neural representations of the object derived from other sensory systems, as well as the context in which it is perceived, and ultimately its meaning for the animal. The ability to subsequently recall these associations in terms of recognizing the odor and its meaning constitute the odor memory. This is not a trivial task. For instance, over 500 individual odorants contribute to the odor of fresh coffee. A few major components will be common between different varieties of coffee. These are the main contributors to coffee odor and will lead to different varieties being classified as coffee. It is the differences

in the numerous minor components that give rise to the fine distinctions between the different coffee varieties, and the ability to make such fine discriminations is enhanced by prior experience with the odors and the importance of making the discrimination [1].

In mammals, the process of associating odorant features into an odor object that can be readily discriminated from similar odors is primarily a function of the ►main olfactory bulb (MOB), anterior olfactory nucleus and anterior piriform cortex, at the initial stages of olfactory processing. OSNs in the main olfactory epithelium express a single odorant receptor type and respond to a small range of odorants with certain shared structural and functional attributes. ►Mitral cells in the MOB receive input from OSNs expressing a single receptor type. However, the responses of mitral cells in the MOB do not simply depend on the input that they get from the sensory neurons. They are also influenced by the arousal and motivational state of the animal, such as whether it is hungry, or the possible presence of a predator. In addition, mitral cell activity is likely to be influenced by a centrally generated expectation of an odor arising from reciprocal connections with higher-level olfactory processes, and activated in situations such as a predator searching for a particular type of prey.

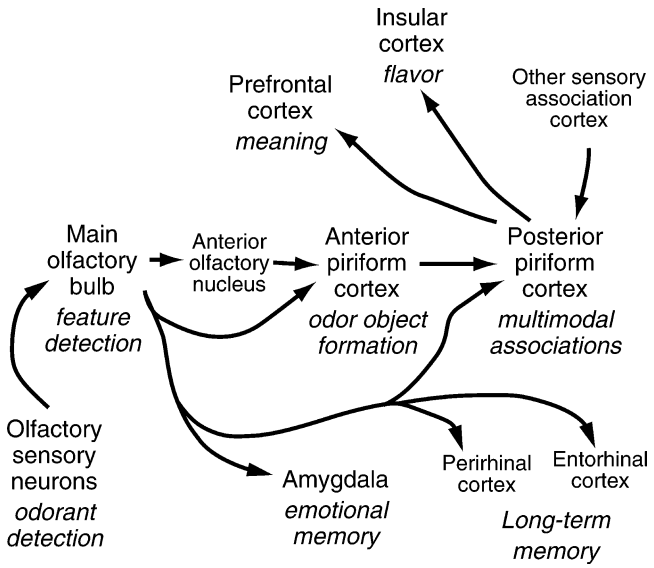
Significantly, there is accumulating evidence that the responses of mitral cells in the MOB depend not only on information provided by OSNs, but also on the meaning of the odor. Hence, the odor-evoked activity of mitral cells in the MOB has been found to change following learning a new reward association for an odor [5]. Such learning-dependent changes in the odor-evoked pattern of neural activity in the MOB are likely to be at least partially the result of changes in gain of lateral and recurrent inhibition from granule cell interneurons. The change in spatiotemporal pattern of mitral cell activity following learning has been hypothesized to "pull apart" the representation of the learned odor from those of similar odors generated by the MOB. This could increase the probability that they could be discriminated reliably and linked to different behavioral responses. There is evidence for this type of decorrelation of odor-evoked patterns of activity in the honeybee antennal lobe (the insect equivalent of the mammalian MOB) following appetitive odor conditioning [6].

Information from individual mitral cells in the MOB is distributed to a large number of pyramidal cells by virtue of their highly divergent projections to the anterior piriform cortex. Conversely, each anterior piriform cortex pyramidal neuron samples information from a large number of mitral cell neurons across a large extent of the MOB. It is thought that these pyramidal cells can therefore act as coincidence detectors. According to this hypothesis, when the pyramidal cells in the anterior piriform cortex receive synchronized input from a sufficient number of mitral cells, the strength of those inputs is enhanced, increasing the probability that the same combination of inputs will cause that pyramidal cell to fire in the future. This is supported by evidence arising from ►cross-adaptation to odorant mixtures. This suggests that whereas mitral cells at the level of the olfactory bulb respond to individual odorants, pyramidal cells in the anterior piriform cortex respond to specific combinations of odorants that form an odor object [1]. Moreover, the pattern of interconnectivity of the anterior olfactory nucleus and anterior piriform cortex is thought to confer pattern completion properties on the network, in which a degraded pattern of input is able to trigger activity in the complete network of pyramidal neurons that respond to the odor object [7]. This might underlie the ability of the olfactory system to cope with the naturally occurring variability in odorant mixtures that are generalized to a particular odor memory.

## Higher-Level Brain Areas Involved in Odor Learning

The network of cells in the anterior piriform cortex that represent an odor object communicate with cells in the posterior piriform cortex, which also receive direct input from the olfactory bulb and have widespread reciprocal connections with other brain regions. The interconnections of the posterior piriform cortex suggest that it is likely to function at a similar level to association cortex in other sensory systems and may be involved in forming multimodal representations of stimuli [7]. For instance, the posterior piriform cortex is likely to be involved in associating the sight, sound and smell of a predator into a single representation that can be recalled by input from any one ►modality. Perhaps the most important multimodal representations of odors are in relation to the taste, smell and texture of food, which combine to a representation of flavor, which appear to be stronger than those formed between odors and other sensory modalities. Neurons with multimodal responses to both taste and smell have been found in the orbitofrontal cortex and insular cortex of primates.

Finally these odor representations have to drive an appropriate response. This can be an innate response – especially in the case of ►pheromones. However for the majority of odors, the appropriate response is learned as a result of experience. The amygdala is particularly involved in eliciting learned emotional responses to odors, whereas neurons in the orbitofrontal cortex have been shown to respond to the meaning of an odor and the context in which it occurs. However, it should be remembered that there are extensive reciprocal connections among these areas, and the neural changes that underlie odor memory are distributed throughout all levels of the olfactory system (Fig. 2).



**Odor Memory. Figure 2** Major brain areas involved in distinct aspects of odor memory. Extensive reciprocal connections and interconnections between brain areas have been omitted for clarity.

## Importance of Odor Learning in Mammals

Odor memory is vital for the recognition of significant elements of the environment, such as food, predators and prey, as well as social cues that enable individual and kin recognition, and odor cues used for navigation. The sense of smell plays a particularly important part in mother-offspring interactions, which are vital for the reproductive success of most mammals. For example, ewes rapidly learn to recognize their own lamb by its odor, within a few hours of giving birth. This odor memory enables the ewe to discriminate between its own lamb, to which it shows acceptance behavior, and alien lambs, which it rejects. Formation of the memory for own lamb odors occurs during a period of a few hours, triggered by the vaginocervical stimulation of birth, and involves dramatic changes in the responsiveness of mitral cells in the MOB to lamb odors [8].

Odor learning is also important for neonatal mammals, especially those that are altricial, in which hearing and sight are poorly developed at birth. For instance, the rabbit mammary pheromone 2-methyl-but-2-enal not only acts as a pheromone to elicit nipple search behavior, but also acts as an unconditioned stimulus to induce memory formation to the maternal odors, or artificial odors that have been applied to the mother [4]. These conditioned odors are then able to elicit full nipple search behavior and therefore reinforce the innate response to the pheromone.

Adult rats can readily be trained to avoid an odor, which has previously been associated an aversive stimulus, such as a mild electric shock. This conditioned fear response is dependent on the amygdala, and is adaptive in helping the rat to avoid potentially dangerous environmental situations. However, if rat pups are exposed to an odor that has been paired with the aversive stimulus of a mild electric shock before postnatal day 10, they will learn to approach the odor [9]. Again this odor memory is adaptive, as at this age the rat pups are normally confined to the nest and are dependent on their mother for their survival. No matter how rough the nest environment or their mother is towards them, the pups remain attracted to the maternal odor. Therefore the function of odor memory can alter to adapt to the changing behavioral priorities of an animal during the course of postnatal and adult life. Moreover, the long-term memory (►memory, long-term) of neonates for odors learned in the nest environment, or even *in utero*, can have lasting effects on their behavior as adults, such as post-weaning food preferences or their choice of mate.

## Odor Cells in Hippocampus

### Definition

In a series of studies aimed at exploring the role of hippocampal function in memory using the model system of olfactory-hippocampal pathways and odor learning in rats, it has been demonstrated that hippocampus itself is not essential to memory for single odors, but is critical for forming the representations of relations among odor memories, and for the expression of odor memory representations in novel situations. The studies that exploit the exceptional qualities of olfactory learning are helping to clarify the nature of higher order memory processes in all mammals, and extending to declarative memory in humans.

### Definition

The processes by which essential features of odor molecules are translated into patterns of neural activity in the olfactory circuit.

### Characteristics

A code is a set of rules allowing the translation of information from one form or dimension into a different one, in such a way that essential features of the original message are preserved and made available for further unambiguous reading and information extraction. In the case of odors, the nervous system translates the information pertaining to chemical stimuli into patterns of neural activity at the first stages of processing in the brain. We focus here on odor encoding within the vertebrate olfactory bulb (OB) and the analogous circuit in insects, the antennal lobe (AL), excluding specialized pheromonal centers and higher-order centers of the olfactory circuit.

Odor molecule determinants such as chain length (number of carbon atoms), functional group (aldehyde, alcohol, ketone, etc.) and concentration, among others, seem to be the sensory primitives that are processed by the olfactory pathways. They are transduced from the chemical world into the neural domain by differential activation of olfactory receptor proteins on the surface of olfactory sensory neurons, on the insect antenna or in the nose of vertebrates.

The olfactory message is first processed at the level of the primary olfactory centers in the brain (the AL in the case of insects and the OB in the case of vertebrates). Both the AL and the OB are organized according to similar anatomical principles. They are constituted by glomeruli, which are the anatomical and functional units involved in the first steps of odor processing in the nervous system. Olfactory receptor neurons expressing the same receptor type converge to one or a few glomeruli [1] so that the response of a glomerulus is an amplified version of the responses of the receptor type under consideration. There are up to several hundred glomeruli in an insect antennal lobe and several thousand in a vertebrate olfactory bulb. Glomeruli are not simple convergence sites of olfactory receptor axons; they are interconnected by different sets of local

inhibitory neurons, which release the inhibitory neurotransmitter GABA (γ-aminobutyric acid), thus producing complex patterns of firing activity in response to an odor. In insects, local inhibitory and excitatory interneurons may connect laterally few or multiple glomeruli. In vertebrates, lateral inhibitory connections are provided by periglomerular cells whose dendrites are restricted to one glomerulus and by short axon cells which have dendrites and axons extending throughout several glomeruli. In addition, a second level of powerful inhibitory connections is provided by the interaction between granular cells and output cells to the OB.

The processed signal is further conveyed to higher-order centers by such output neurons, the projection neurons in insects and the mitral/tufted cells in vertebrates. Thus, once odors activate groups of receptor neurons, the information does not simply flow through the AL/OB to downstream areas via projection neurons or mitral cells. Instead, the presence of inhibitory neurons within the neural network of the AL/OB determines a global reformatting of odor representations, in the form of a stimulus-dependent, spatio-temporal redistribution of activity across the AL/OB [2].

The olfactory code is a spatio-temporal code in that it contains two complementary components, the spatial and the temporal dimensions. Each of these two dimensions has been studied using different techniques, mainly imaging for the spatial code, and electrophysiology for the temporal code. The impression that such different analyses correspond to separate, unconnected properties of the olfactory code should be avoided. Spatial and temporal properties of the olfactory code represent, in fact, different sides of the same coin.

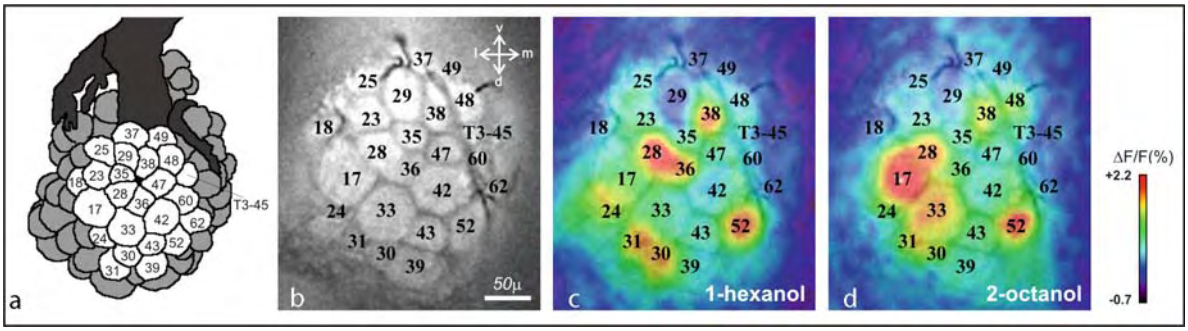
## Spatial Coding of Odors

Odors may be encoded at the level of the AL/OB in terms of a specific spatial pattern of glomerular activation (Fig. 1).

Such activity pattern constitutes an odor map, which is proper to each odor, symmetric between hemispheres and conserved between individuals [3]. Spatially distributed activity patterns relate to certain structural features of the odor molecules as molecules with similar structural properties are encoded in terms of partially overlapping activity patterns. Neural similarity, measured in terms of the amount of overlap of glomerular activation patterns, correlates directly with perceptual similarity, measured in terms of behavioral odor choices [4], i.e. odors judged as similar correspond to partially coincident odor maps.

Odor concentration affects the odor map as generally, the number of activated glomeruli increases with increasing concentrations of the stimulating odor. A critical question would be, therefore, how ►concentration invariance is achieved given the changing nature of this odor representation. A possible answer comes from the fact that, as mentioned above, spatial coding is not the unique form of translating chemical stimulus features into patterns of neural activity (see below "Temporal coding").

Quantifying glomerular activity requires identifying individual glomeruli across preparations in the same or different individuals. To this end, atlases of the primary olfactory center have been established in the case of the antennal lobe of some insects (honeybees, moths, flies) where such an approach is accessible due to a lower number of constitutive glomeruli.



**Odor Coding. Figure 1** Spatial coding of odors at the level of the antennal lobe of the honeybee *Apis mellifera*. (a) Atlas of the honeybee antennal lobe showing 24 glomeruli individually identified. (b) Example of an anatomical staining of the frontal part of a left antennal lobe with the 24 identified glomeruli (*d* dorsal; *l* lateral; *m* medial; *v* ventral). (c) Calcium-imaging recordings of neural activity *in vivo* upon odor stimulation of a honeybee. Superimposed activity map in response to the odor 1-hexanol, showing which glomeruli were activated. The colors (see scale on the right) represent activity levels in terms of fluorescence variation (ΔF/F %) with respect to a basal level (no olfactory stimulation). (d) Superimposed activity map in response to the odor 2-octanol. Each odorant is encoded by a specific spatial pattern of glomerular activation.

Olfactory maps can be visualized using different kinds of techniques allowing measurements of neural activity upon olfactory stimulation. Markers of neural activity vary from radiolabels ([$^{14}$C] 2-deoxyglucose) and antibodies (*c-fos*) to fluorescent dyes (voltage-sensitive or calcium reporters), or intrinsic optical properties of the tissue. Using some of these and other techniques it is possible to disentangle the contributions of olfactory receptors conveying the olfactory message to the brain from that of local interneurons and projection neurons conveying such a message to higher-order brain centers. In this way, the role of the different neural subpopulations in the elaboration of the odor map can be understood. Assessing the respective contributions of pre- and postsynaptic elements is crucial for understanding the computations carried out at the level of the AL/OB.

Activity maps in the AL/OB are not static but dynamic odor representations. Such a dynamics mostly reflects interglomerular interactions within the AL/OB. However, at the level of sensory afferences to the glomeruli of the OB, diverse, glomerulus- and odorant-dependent temporal dynamics are already present, thus showing that glomerular maps of primary sensory input to the OB are temporally dynamic, even before further processing within the bulb. These dynamics may contribute to the representation of odorant information and affect information processing in the central olfactory system.

## Temporal Coding of Odors

Comprehensive studies on the temporal coding of odors have been performed in several species but studies on locusts have been crucial to understand the principles governing this coding [2]. Such studies have shown that both monomolecular and complex odors are encoded combinatorially by dynamical assemblies of projection neurons. Information about odor identity is contained in the timing of action potentials in an oscillatory population response, rather than on the mere spiking frequency of the response.

Indeed, each projection neuron in an odor coding assembly responds with an odor-specific temporal firing pattern consisting of periods of activity and silence. Any two projection neurons responding to the same odor are usually co-active only during a fraction of the population response. The spikes of coactivated projection neurons are generally synchronized by the distributed action of local interneurons in the AL, which release GABA. Because projection neurons convey the olfactory information to higher-order structures, the mushroom bodies, the coherence of projection neuron activity can be measured in this target area in terms of local field potential (LFP) oscillations [2]. LFP oscillations have a frequency of 20–35 Hz. Each successive cycle of the odor-evoked oscillatory LFP can therefore be characterized by a co-active subset of projection neurons. As a consequence, each odor is encoded by a specific succession of synchronized assemblies [2]. The action potentials produced by a projection neuron during its odor-specific phases of activity are not necessarily all phase-locked to the LFP. For each odor–projection neuron combination, however, precise and consistent epochs of phase-locked or non-phase-locked activity can be identified (Fig. 2).

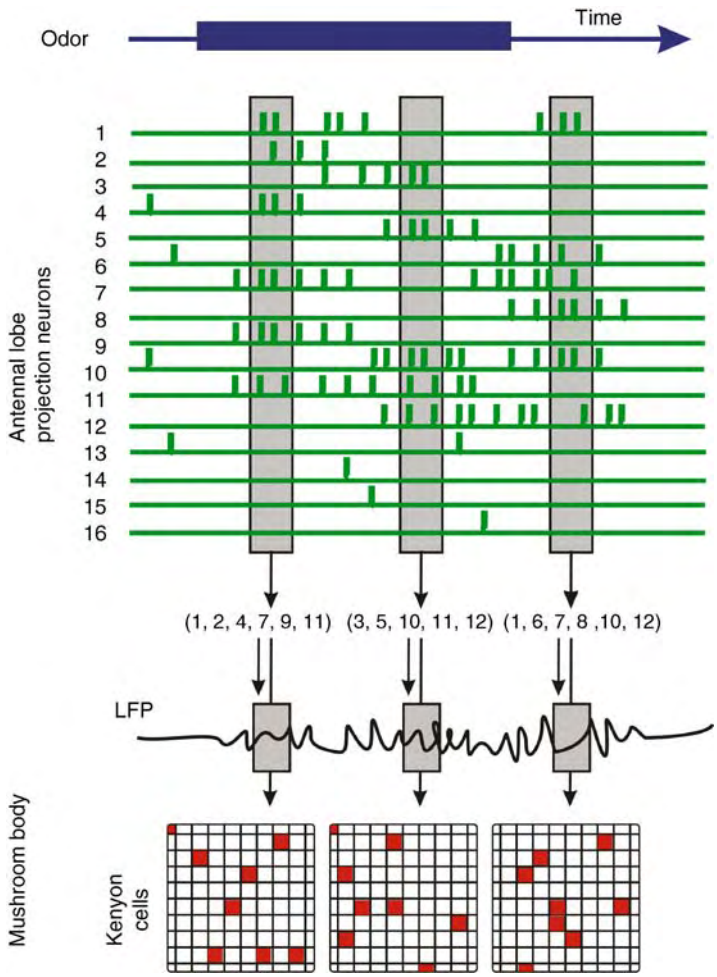
Increased odor concentration leads to changes in the firing patterns of projection neurons, similar to those caused by changes in odor identity, potentially confounding representations for identity and concentration. However, concentration-specific response patterns cluster by identity, resolving the apparent confound. Thus, odor encoding comprises three main aspects: the identity of the odor-activated neurons, the temporal evolution of the ensemble, and oscillatory synchronization.

Besides oscillatory synchronization, the odor-evoked responses of local interneurons and projection neurons also contain prolonged and successive periods of increased and decreased activity (slow response patterns), which are cell and odor specific and are stable from trial to trial. Hence, oscillatory synchronization and slow patterning together shape a complex, distributed representation in which odor-specific information appears both in the identity and in the time of recruitment and phase-locking of projection neurons.

Experiments on honeybees [5] showed that oscillatory synchronization between projection neurons is selectively abolished by picrotoxin, an antagonist of the $GABA_A$ receptor acting on GABA-ergic local interneurons of the antennal lobe, and that such a picrotoxin-induced desynchronization impairs the behavioral discrimination of molecularly similar odorants, but not that of dissimilar odorants. It was, therefore, suggested that oscillatory synchronization of neuronal assemblies is functionally relevant, and essential for fine, but not coarse olfactory discrimination. Interestingly, picrotoxin has no effect on the slow response patterns of projection neurons [2], thus showing that other sources of neural inhibition are at play at the level of the AL.

In vertebrates, three types of oscillatory rhythms have been distinguished in the activity of mitral cells, the pendant of insect projection neurons. Based on their frequency spectrum, one can distinguish three oscillation types:

1. θ oscillations (1–8 Hz) are generated by the respiratory rhythm and are correlated with increased and decreased stimulation of olfactory afferences upon inspiration and expiration, respectively. Different mitral cells may exhibit different response latencies to the same odorant and odor coding



**Odor Coding. Figure 2** Temporal coding of odors in the locust olfactory system.The presumed odor representation is combinatorial, spatially distributed and relies on synchronized and evolving neural assemblies. An odor stimulus elicits spiking activity in several projection neurons (1–16), which constitute the output to the antennal lobe. For each odor–projection neuron combination, however, precise and consistent epochs of phase-locked or non-phase-locked activity can be identified. The coherence of projection neuron activity can be measured at the level of the mushroom bodies in terms of local field potential (LFP) oscillations. Only few Kenyon cells, the constitutive cells of the mushroom bodies, are activated by projection neuron input (sparse coding) (adapted from Laurent G, Trends in Neurosci 19:489–496, 1996).

models have been proposed based on the phase relationship between action potentials of mitral cells and the phase of a θ cycle [6].

2. β oscillations (15–30 Hz) are induced by the inhalation of odor molecules and their origin is a matter of debate. While some theories posit that β oscillations originate not in the OB itself but in downstream structures (e.g., olfactory cortex) that feedback on it, other theories postulate that rhythmic input on granular cells induce these oscillations. The function of β oscillations is still unclear but it has been shown that olfactory learning and habituation can enhance the prevalence of β rhythm over γ rhythm in an odor-specific manner [7].
3. γ oscillations (40–80 Hz) are present in the olfactory system of several vertebrate species and can be related to those evinced in the olfactory system of insects (see above). These oscillations are generated in the olfactory bulb upon inhalation of odor molecules. Mitral cell activity is synchronized with γ oscillations and such synchronization arises from the interaction between mitral and granular cells. Glutamate released from mitral cell dendrites excites the dendrites of granule cells, which in turn mediate GABA-ergic inhibition back onto mitral cells [8]. Granular cells do not synchronize with γ oscillations; it has been proposed that they release GABA in a rhythmic manner and in absence of action

potentials [8]. Such a rhythmic inhibitory activity seems to play a fundamental role in the modulation of the oscillatory frequency.

Importantly, not all mitral cells are synchronized with γ oscillations during the response to an olfactory stimulus. In fact, the two neural populations, those exhibiting and those not exhibiting synchrony, encode different properties of the odor: non-synchronized action potentials allow encoding the fine identity of an odor while synchronized action potentials encode the category (ensemble of similar odor molecules) to which the perceived odor belongs [9]. Thus, different properties of an odor can be encoded by the same mitral cells depending on their synchronization with the neural population. The role of γ oscillations in olfactory perception in rodents has been demonstrated by experiments on transgenic mice presenting alterations of inhibitory activity in the OB. Such alterations result in significant changes in olfactory discrimination.

The picture emerging from studies on the temporal coding of odors in the AL/OB suggests that the transfer of odor-evoked signals from receptors to the AL/OB circuits is accompanied by a reshaping of odor representations so that stimulus-dependent, temporal redistribution of activity arises across these circuits. Such a reshaping exploits time as a coding dimension and results from the internal connectivity of the AL/OB circuits and from the global dynamics that these connections produce. Moreover, centrifugal connections from higher order centers (e.g. the mushroom bodies in insects, the olfactory cortex in vertebrates) to the AL/OB may also play an important role in reshaping of odor representations. This top-down process is specifically involved during learning condition in which neutral odorants are transformed into ►aversive or ►attractive ones.

## Conclusions

All in all, the antennal lobe of insects and the olfactory bulb of vertebrates act similarly upon olfactory stimulation: to prevent ►adaptation, they format and reshape odor representations, increase the signal-to-noise ratio and improve odor discrimination. It appears that spatial and temporal dimensions are complementary aspects of odor coding in the AL/OB circuits and that their separated analysis responds to the use of different recording techniques that have put the emphasis on one aspect or the other. As we have detailed above, temporal variations of the spatial code are observed in imaging experiments, and in the temporal code, odor-specific information appears also in the identity of the active projection neurons, i.e. a spatial-related property. For instance, synchronization of output neuron activity at specific sites within the odor map is crucial as shown by studies in the moth where odors elicit high synchrony of action potentials in paired cells connected to the same glomerulus but low synchrony in cells connected to different glomeruli [10]. Such studies revealed a strong relationship between recording positions, temporal correlations, and similarity of odor response profiles, thus supporting the notion that the olfactory system uses both spatial and temporal coordination of firing to encode chemosensory signals [10]. As shown by this example, future neurophysiological studies should bring the spatial and the temporal dimensions of the odor code together, using recording methods that allow both good spatial and temporal resolution. In this way, characterizing the fine relationship between the temporal and the spatial dimension of olfactory coding at the level of the AL/OB will be possible.

# Odor Detection

## Definition

The sensory process by which an external odorant stimulus elicits an odor sensation, without necessarily

identifying the exact quality of the detected stimulus. Odor detection is released when a stimulus reaches the detection threshold (or absolute threshold), that is the lowest stimulus capable of producing a sensation that something has changed in reference to a control stimulus. Odor detection can be conscious or unconscious. Conscious odor detection is ordinarily revealed by behavioral or verbal responses. Unconscious odor detections can be revealed by recording the alteration in the reactivity of the autonomous nervous system. Odor detection is compromised in many conditions, especially in Parkinson disease and the later stages of Alzheimer's disease and following damage to the olfactory mucosa or bulb.

►Alzheimer's Disease
►Olfactory Hallucinations
►Parkinson Disease
►Smell Disorders

## Odor Discrimination

### Definition

This is the ability to detect differences between odors. This is measured in several ways, all of which involve presenting two different smells and having the participant judge whether they are the same or different. Odor discrimination allows to extract an olfactory signal from a background and to make a distinction between different odorant molecules. Whilst compromised odor detection will always affect identification and discrimination, impaired discrimination (or identification) can occur independently of detection.

## Odor Identification

### Definition

This is the ability to correctly provide a name for an odor, when no other cue to its identity is present. This may be measured by simply asking a person to generate a name, or by providing a list of names from which the person has to choose. The most well established test of olfactory functioning, the Smell Identification Test (SIT), utilizes the latter method.

## Definition

Extraction of information from an odor stimulus is a multi-level task for the brain, involving levels of neuronal processing from the odorant receptors up to the olfactory cortex. Sensory modality at each level is represented by activity patterns in two-dimensional neural space. Various sensory signals activate topographically distinct subsets of neurons. Such patterns represent odor ►maps.

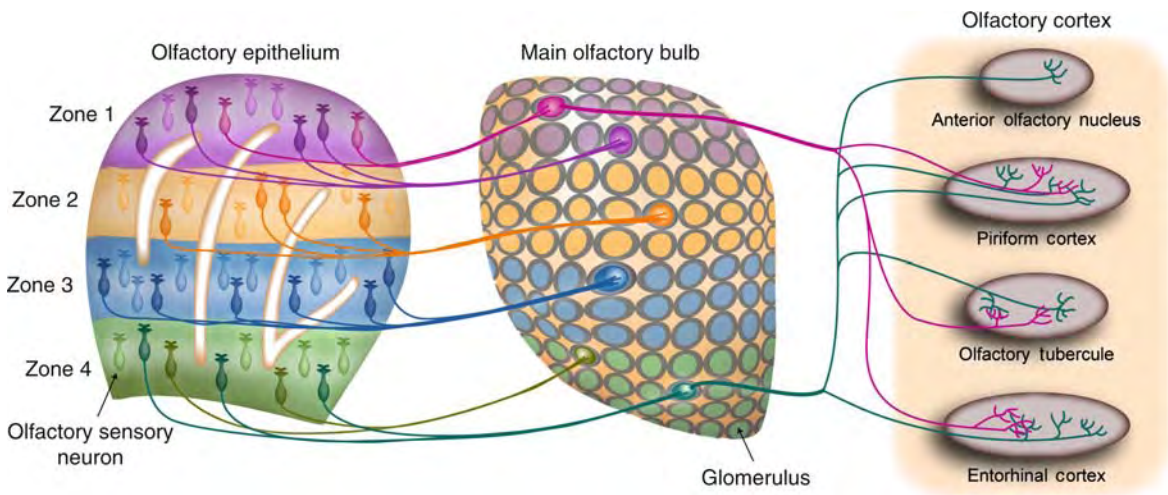
## Characteristics

### Olfactory Epithelium

Information processing begins with the mapping of an odorant to the subset of receptors that it activates. More than 400,000 compounds are thought to be odorous to the human nose; mammals have developed nearly 1,000 types of odorant receptors to cope with this huge variety of odorants. Odorant receptors are expressed on the cilia of olfactory sensory neurons situated in the nasal olfactory epithelium. Each receptor presumably detects particular ►molecular features of odorants and thus binds to a specific range of odorants sharing common features [1]. However, each odorant can bind to multiple, but specific, odorant receptors. Thus, an odorant or a mixture of odorants will activate a specific combination of odorant receptors located within the olfactory epithelium. At this level, the odor ►map may be considered a map of receptor space, providing practically unlimited coding capacity for the olfactory system. Olfactory sensory neurons usually produce only one odorant receptor type, so the odor map of receptor space directly translates to a map of activated olfactory sensory neurons. A spatial dimension is also present, at least in mammals in which olfactory epithelium is divided into four zones [1]. A given odorant receptor is only produced by sensory neurons distributed throughout one of the four zones (Fig. 1). Domains of receptor production have also been identified in fish and insects.

### Olfactory Bulb

In rodents, with few exceptions, olfactory sensory neurons producing the same odorant receptor converge onto two topographically fixed glomeruli, one in the lateral and the other in the medial part of the main olfactory bulb, arising from sensory neurons in the lateral and medial epithelium, respectively. In mice, there are approximately 2,000 glomeruli and their localization is roughly conserved among individuals. Each glomerulus represents a single odorant receptor; thus, the glomerular sheet of the olfactory bulb forms a map of odorant receptors [1]. Furthermore, neurons that are segregated in the epithelium extend to distinct regions of the bulb, such that the spatial topography of the nasal epithelium is preserved in the glomerular sheet, following the principle of a "zone-to-domain" projection (Fig. 1). Thus, two symmetrical sensory maps are generated; one is in the rostrolateral hemisphere and the other is in the caudomedial hemisphere. However, a zone-specific expression pattern in the olfactory epithelium is not present in a small group of odorant receptors. An individual odorant receptor of



**Odor Maps. Figure 1** *From odorant receptors to the olfactory cortex:* Olfactory sensory neurons expressing a given odorant receptor are distributed widely in one of the four zones and converge their axons onto a few topographically fixed glomeruli in the olfactory bulb. Each glomerulus represents a single odorant receptor. Mitral cells from the glomeruli form synapses with clusters of neurons in multiple olfactory cortical areas. Inputs from different odorant receptors overlap spatially. (*Olfactory bulb outputs from two glomeruli only are displayed for more clarity*).

this group is typically represented by a single glomerulus located at the most ventral portion of the bulb [2]. Thus, the non-zonal odorant receptors generate a small map at the most ventral part of each main olfactory bulb. Convergence is less strict in the accessory olfactory system (which processes some pheromones) and similar olfactory sensory neurons can converge onto multiple neighboring glomeruli. Nevertheless, odorant quality is represented through spatial patterns of glomerular activation in both cases, reflecting differential activation of olfactory sensory neurons (Fig. 1). This principle of odor mapping is widely observed in various vertebrate species and in invertebrates, including honeybees, moths and flies. Moreover, the odorant-specific spatial positions of activated glomeruli are conserved in animals of the same species.

Individual glomeruli in the olfactory bulb function as molecular-feature detecting units: they respond to a range of odorants sharing specific combinations of molecular features. Furthermore, glomeruli with similar response properties are located in close proximity and form molecular-feature clusters [1]. This is consistent with evidence that sensory neurons expressing homologous odorant receptor genes project their axons to neighboring glomeruli. A precise chemotopic organization is sometimes present within glomerular clusters. For instance, a chemotopic progression with increasing odorant carbon number has been detected in multiple response clusters [2]. So, the glomerular sheet of the bulb topographically represents the characteristic molecular features in a systematic, gradual and multidimensional fashion.

## Olfactory Cortex

Each glomerulus is a spherical neuropil containing the axons of several thousand olfactory sensory neurons that establish synapses with dendrites of approximately 50 mitral and tufted cells (the olfactory bulb projection neurons) and local interneurons. Axons of mitral cells carrying input from a given olfactory receptor synapse with multiple specific clusters of pyramidal neurons in the olfactory cortex, generating a stereotyped map of olfactory receptor inputs that is different from that in the olfactory bulb. The projections to the olfactory cortex are diffuse and have characteristics of a combinatorial array, with extensive overlap of afferent inputs and widespread intracortical association connections. Thus, inputs from different odorant receptors are mapped onto partially overlapping clusters of pyramidal neurons [3] (Fig. 1). It appears that individual neurons receive signals from various odorant receptors. Thus, although inputs from various odorant receptors are segregated in the olfactory epithelium and olfactory bulb, single neurons in the olfactory cortex seem to combine multiple inputs. The olfactory cortex is thought to be important for integrating signals from various molecular-feature-detecting units of the bulb.

## Mapping Methods

Several mapping methods have been used to identify odor-specific spatial activation patterns in the olfactory bulb in mammals [1]. These methods can be classified into two complementary groups, each with their advantages and disadvantages. The first group has the advantage that the responses are mapped over the entire bulb and includes methods involving functional MRI (fMRI) and assessment of 2-deoxyglucose uptake, expression of immediate early genes (e.g. *c-fos, c-jun, Arc* and *zif268*) and production of phosphorylated ERK. These methods allow investigation of how individual odorants are represented within the entire glomerular sheet of the bulb. The disadvantage of this group is that, with the exception of fMRI, these methods map the response to only one odorant in each animal.

On the contrary, the second group of methods facilitate mapping of the responses to many odorants in the same bulb of an animal. This group includes optical imaging of intrinsic signals, imaging with calcium-sensitive or voltage-sensitive dyes, imaging using pHluorin, electrophysiological recording of single neuron activity and fMRI. With these methods, it is possible to determine the range of odorants that activate an individual glomerulus. However, again except for the fMRI method, these methods allow us to map only the exposed surface of the bulb. Only the dorsal and posterolateral surfaces have been successfully mapped thus far.

## Functional Relevance of the Spatial Arrangement of Glomeruli in the Olfactory Bulb

If the spatial map is important to olfactory behavior, then disrupting the map should impair one or more olfactory functions. Slotnick and colleagues tested this hypothesis in a series of behavioral experiments and showed that ablations of large portions of the olfactory bulb and other destruction of olfactory inputs did not significantly impair odor discrimination and detection. Furthermore, animals trained before such manipulations can often still recognize the same odors after ablation. Even rats with no bulb can carry out olfactory discriminations, supported by olfactory nerve inputs that reinnervate areas of the olfactory cortex [4]. Rather than concluding that spatial maps have only a minor function in the olfactory bulb, it may be argued that discrimination and detection of odors are not the computations facilitated by these mechanisms.

Moreover, the chemotopic arrangement of glomeruli in the bulb seems to have a functional relevance. Even though the relationship between the molecular structures of odorants and their subjectively perceived odors is not entirely clear, odorants with similar combinations of molecular features tend to have similar odor qualities, at least for the human nose. Thus, it is possible that molecular-feature clusters of glomeruli are

part of the representation of basic odor quality [1]. There are various lines of evidence that favor this hypothesis. Measurements of spontaneous responses show that rats generalize between odor pairs with very similar glomerular activity maps, but not between odor pairs with different glomerular maps. However, rodents can be trained by differential reinforcement to discriminate between all odor pairs tested to date with high accuracy. Nevertheless, although discrimination performance in rats is always very good, there is still a significant correlation between glomerular map dissimilarity and discrimination accuracy. Lateral inhibition among neighboring glomeruli may allow mitral cells to respond to a narrower range of stimuli than their associated sensory neurons. This possibly permits a smaller overlap in the number of highly activated mitral cells responding to two similar odorants, thus facilitating their discrimination. Lateral projections of interneurons that are distributed more densely between neighboring than distant glomeruli confirm this hypothesis. Therefore, the spatial clustering of glomerular responses may coordinate the principle responses of bulbar projection neurons by way of center-surround functionality implicating inhibitory interneuronal networks.

Despite the accepted correlation between odor maps and odorant structural commonalities, this relationship breaks down if odorant concentration is included as a variable. If odorant concentrations are increased, more glomeruli respond and odor maps broaden and intensify [5]. The recruited glomeruli are located near the originally activated glomeruli due to chemotopic clustering of glomeruli with similar odorant specificities. Higher odorant concentrations recruit additional sensory neuron populations with progressively lower affinities for the presented agonist. However, the qualitative perception of odors is usually not affected by variability in concentration, suggesting that various neural normalization mechanisms can preserve concentration-independent odor quality information. Regardless of concentration, relative levels of glomeruli activation in the bulb are stable and the representation of odor quality may rely on these activity patterns [5]. The impact of stimulus concentration is not as high in mitral cells and increasing odorant concentrations do not monotonically increase their spiking rates. The mechanisms for normalization of olfactory representations are not precisely known, but it is possible that they do not rely on center-surround inhibition, as global normalization has to be carried out for the entire bulb.

## Development of the Glomerular Map in the Olfactory Bulb

Creation of the map begins prenatally when axons of olfactory sensory neurons navigate toward the bulb, resort in a receptor-specific manner and terminate in a broad area of the bulb surface, interdigitated with other axon populations. Only postnatally, the axons segregate into completely separate glomerular structures. This maturation process requires various amounts of time, ranging from a few days to about one month, depending on the glomerulus [6]. Very precise axonal targeting is achieved, even for populations expressing highly related odorant receptors and innervating neighboring glomeruli.

The complex processes of axon navigation, fiber sorting and cell recognition are governed by a hierarchical system of recognition and adhesion molecules. Attractive or repulsive interactions apparently drive the growing axons towards or away from regions of the bulb. However, the diversity of the guidance molecules that have been identified is not sufficient to explain the precise topographical glomerular map observed in the bulb. The odorant receptor protein is itself involved in axon guidance and may control the production of guidance molecules and adhesion molecules [7]. Whereas the initial (prenatal) process of glomerulization mainly requires molecular determinants, postnatal activity-dependent processes refine glomerular organization. Whether genetic or activity-dependent mechanisms are dominant in this process of map formation, it is clear that the cues organizing these connections must be present throughout the life of the animal and not only during the initial phases of olfactory development. The olfactory epithelium is continuously self-renewed and olfactory sensory neurons are continuously replaced by newborn neurons that can re-establish good glomerular connections. Thus, the glomerular map does not change throughout adulthood.

## Dynamics of the Odor Maps in the Olfactory Bulb

Odorant responses are often considered static spatial entities. However, various factors may influence the primary sensory input to the olfactory bulb and give rise to differences in the timing of glomerular responses to odorants. First, the nature of the airflow in the naris of rodents causes stimuli to arrive at receptors in various expression zones within the olfactory epithelium at different times [2]. There is a chromatographic effect in the nasal cavity and various odorants are chemically converted in the nasal mucosa before linking to their receptors. This may explain how various odorants can activate the same glomeruli with different kinetics. Furthermore, individual sensory neurons expressing the same odorant receptor may have identical odorant response profiles, but different activation thresholds and their axon terminals may be modulated presynaptically. This widens the range of population terminals converging into a single glomerulus. The dynamics of glomerular activation also depends on the breathing cycle and changes within a respiration cycle and from one cycle to the next [8]. Thus, whereas some glomeruli respond less strongly during the second breathing cycle, suggesting that adaptation occurs, others respond more

strongly, indicating that other processes also contribute to the dynamics observed. The active inhalation pattern of the animals also controls adaptive filtering to detect changes in odor landscape. Thus, neural representations of the same odorant sampled during low-frequency passive respiration and high-frequency sniffing differ [9]. Consequently, glomerular odorant responses differ in amplitude, latency and rise time in an odorant-specific manner and is also dependent on sniffing behavior for a particular odorant. Conjointly, mitral and tufted cell activities also demonstrate stimulus-specific temporal structure. Thus, a temporal code for odorant quality may be embedded in these temporal bulbar activation differences. Spatial distribution and the temporal structure of neuronal activity should therefore not be studied in isolation, but considered as a single entity of the same coding process. Currently, although there is increasing evidence for the importance of temporal structure in bulb odorant-evoked output, little is known about how this temporal patterning is translated within cortical neural ensembles.

Most studies on odor maps have been done with naive animals and have confirmed that they are conserved from one individual to another within the same species. Depending on the mapping method, these maps are not entirely similar because they require animals that are either awake or anesthetized. Anesthesia may itself modify odor processing. In animals that are awake, the output of the olfactory bulb represents the integration of odor stimuli and behavioral variables relevant to odor expectation, discrimination, context and predictive associations. Thus, a certain degree of map flexibility is expected, depending on the behavioral context and on the physiological state of the animal. The fact that the spatio-temporal output of the bulb is affected by learning is consistent with this theory. Training can modify the odor map [10], challenging the findings of studies that put in parallel behavioral performances of trained animals and odor maps of naive animals. Odor maps are dynamic and various changes, particularly those induced by training, may be long-lasting. The centrifugal fibers that richly innervate the bulb can modulate odorant perception and may affect spatial and temporal patterning of glomerular activation. Another factor of bulbar functional plasticity is the continuous neurogenesis occurring in the bulb. Learning induces changes in neurogenesis in the bulb, which may support long-lasting changes in odor maps.

## Definition

Odor-sampling designates a behavior by which animals actively collect air-borne or water-borne odor stimulus carrying information from the surroundings, in order to localize and/or identify the source of the emitted odor, and to respond in an adaptive manner (e.g. approach, avoidance) to the stimulation. To collect the odor stimulus, the organism may sniff, flick, fan, cough or bubble (according to the species and the environment), behaviors that consist in the active drive of air or water across or into the olfactory organ (sniffing, fanning, nasal sac compressing - coughing -, bubbling), or in the moving of the organ through the fluid carrying the stimulus (flicking).

## Characteristics

### Environment as a World of Odors

In the animal kingdom, odors are important vectors of information likely to elicit behavioral decisions supporting adaptive responses to social and feeding needs. Thus, from early to late development, olfaction is involved in detection and localization of, and communication with, conspecifics, detection of competitors and predators, selection of habitats, localization of preys and more generally of food.

However, animals are only intermittently exposed to odor stimuli. Indeed: (i) the olfactory organ (e.g. nose, antenna) is a structure which anatomically protects the substructures carrying the olfactory receptors, and therefore limits or blocks the continuous access of odor molecules to the receptors; (ii) informative odor cues (signals) are often sporadically emitted from odor sources spatially dispersed; (iii) odors are transported in the environment by wind or water currents submitted to physical turbulences (i.e. odors generally consist of plumes, patches or filaments in aerial and marine environments). In other words, odors in the ambient air or water are fluctuating both temporally and spatially. This creates the necessity for animals to sample their olfactory environment, i.e. to extract and gain access to the odor cues. Odor-sampling behavior responds to this necessity, in allowing a voluntary (intermittent) exposure to specific and ephemeral olfactory information emanating from the surroundings. In addition, odor-sampling behavior, coupled to the olfactory organ morphology, may form the first level of signal filtering, before its processing at the receptor then neural levels.

### Odor-Sampling Behavior in Terrestrial Environment

In humans, and mammals in general, odor-sampling that follows the detection of an odor is supported by a so-called “sniffing” behavior. During a sniff, air enters through the nostrils (anterior nares), and continues through the nasal cavity, then out the posterior nares to the top of the throat. Part of the airflow reaches the

olfactory epithelium, which lines the roof of the nasal cavity (below the cribiform plate). Usually, a single human sniff approximately has a duration of 1.6 s, an average inhalation velocity of 30 l/min (twice that of a normal inspiration), and a volume of 500 $cm^3$. However, humans generally take several successive sniffs to sample odors, thus displaying sniffing episodes rather than single sniffs. During an episode, each sniff has a reduced duration and volume as compared to a single sniff, but the average inhalation velocity remains the same. Multiple sniffs are quite surprising knowing that odor presence and intensity can be determined, in laboratory conditions, in a single sniff. But sniffing episodes are certainly necessary in natural conditions, where the localization, identification and discrimination of odors constitute difficult tasks due to air turbulences and exposure to complex mixtures (emanating from biological sources) [1]. Human odor-sampling may for instance impact scent-tracking abilities, and is correlated with food neophobia.

In rodents, nostrils act as flow diverters during sniffing, permitting to inspire air from the immediate front of the snout and to expire it backward. Such aerodynamics makes sense, allowing extracting odor cues from the environment while reducing the disturbance of the olfactory sample. The sniffing behavior by itself consists in a relatively stereotyped sequence divided in two successive phases. During the first phase, the animal fixes the head, protracts the vibrissae, inhales briefly, and retracts the tip of the nose. Then, during the second phase, it retracts the vibrissae, exhales and protracts the nose. Generally, the entire sequence is repeated, after repositioning of the head, at around 4–12 Hz and occurs in bouts lasting 1–10 s. Sniffing behavior is considered to be synchronized with whisking, head bobbing and heartbeat. Recently, it was suggested to be constituted, in rats, by two successive modes: type-I sniffing, displayed with a respiration frequency of 6–9 Hz, allowing the acquisition of odor information; then type-II sniffing (9–12 Hz), preparing the animal to display the behavioral response accompanying its final decision [2].

In insects, olfactory receptors are borne by chemosensory sensilla carried by the antennae. Usually, the sensilla form a dense boundary layer between the whole antennae and the receptors. To sample odors from the surroundings, animals display particular wing motions that induce pulses of air flowing to the body, from front to rear. The consequence is an increase in the interception of chemical signals on the olfactory sensilla, due to a decrease in the depth of the boundary layer. Typical wing motions allowing such sampling happen during flight (these motions differ in angle and amplitude from those typically used to fly), or during walking in flying and non-flying insects. Wing motions displayed by walking insects to sample odors are named "wing fanning". This latter behavior severely increases the air penetration and rate of interception of odorant molecules both into the antennae and the sensilla: in silkworm moth (*Bombyx mori*), the airflow produced is 15 times faster at the level of the antennae, and 560 times faster at the level of the sensilla [3], as compared to walking.

Whatever the species, and in addition to the increase in the capture rate of odorants, sniffing and wing fanning may also have a second function: to replace the fluid volume being sampled, i.e. the fluid volume adjacent to the surface of the chemosensory structures. Both functions may occur with a single increase in velocity of airflow, or with periodic fluctuations in velocity (thus minimizing ►habituation and ►familiarization processes) [3].

## Odor-Sampling Behavior in Aquatic Environment

Among arthropods, crustaceans present adaptations illustrating odor-sampling behavior. Crustaceans have different chemosensory organs, among which the lateral flagella of the first antennae (lateral antennules) constitute olfactory organs. In the American lobster (*Homarus americanus*) and Spiny lobster (*Panulirus argus*), for instance, olfactory sensilla (called aesthetascs) form a dense "toothbrush" on the distal half of the antennules. The brush forms, as in insects, a boundary layer which shields the receptors from odor access. When they perceive a chemical signal, lobsters generally wave their antennae and increase the rate of "antennule flicking" (the right and left antennules may flick independently). This behavior allows water to be driven at high velocity through the brush, the boundary layer to be decreased, and then stimulus access to the chemoreceptors (carried by the antennules) to be increased. In other words, antennular flicking is a form of "sniffing" in this taxon, and allows odor perception. It constitutes a behavioral expression which can be easily quantified, and which is therefore used to determine the biological relevance of stimuli. Antennular flicking is critical for efficient orientation behavior [4].

In fishes, odor-sampling behavior has often been thought to be relatively involuntary. In teleostean fishes, olfaction occurs when the water flow is sufficient to bring odor molecules in contact with the receptors embedded in the ciliated olfactory epithelium. The epithelium is located in two nasal sacs (situated in the dorso-anterior part of the head) opened by one or two nares. "Passive" increase of the water flow is induced by ciliary action of cells from the epithelium and by the increase in swimming speed (isosmate fishes), or by continuous pumping in the nasal chambers related to respiration (cyclosmates). However, voluntary sniffing behavior, named "coughing", has also been suggested. In pleuronectid flounders (e.g. *Lepidopsetta bilineata*, *Platichthys stellatus*; cyclosmates), coughing

consists in the rapid protrusion of the jaw, coupled with an expulsion of water from the mouth and an entrance of water in the nasal chambers through the nares. Then, the mouth closes, and water is rapidly expulsed from the nares. This behavior is usually displayed into a stereotyped behavioral sequence including the lift of the head off the substratum, and the orientation to the odor source. Coughing is, for instance, strongly displayed in response to food odorants. It is suggested to support voluntary and frequent sampling of small odorant patches, allowing to gain access to specific odor cues more efficiently than through the continuous circulation of water tied to respiration. Coughing may also have another function: the ejection of foreign material from the olfactory chambers or gills [5].

Finally, it is generally considered that mammals cannot sniff and smell in aquatic environment (except fetuses in the womb) since they are not able to inspire air. However, a recent study brings evidence that in semi-aquatic mammals, a particular mechanism may allow to sample odor underwater: the star-nosed mole (*Condylura cristata*) and the water shrew (*Sorex palustris*) are indeed able to exhale air bubbles onto objects or scent trails before re-inspiring these bubbles. The re-inspiration brings back into the nose the smell of the environmental targets contacted through the bubbles. Interestingly, the volume of air corresponding to these bubbles, the rate of airflow and the frequency characterizing this behavior appear similar to that related to sniffing in small rodents living above water. Such underwater sampling behavior can therefore be considered equivalent to sniffing in the air [6].

## Functional Aspects of Odor-Sampling

Odor-sampling behavior is not only dedicated to the transport of odorants from the environment to the olfactory receptors. It is a dynamic process which directly participates in the temporal and spatial coding of odor stimuli. More generally, it constitutes a main component of olfactory processing and influences olfactory percept. For instance, in humans, functional magnetic resonance imaging (fMRI) demonstrates that odor-sampling (sniffing) induces activity in the primary olfactory cortex, and that this activation reflects the encoding of air flow as a factor contributing to the computation of odor intensity and identity [7].

The changes in air flow induced by sniffing through the nasal cavity (in mammals) could influence the mechanical component of the odor perception: in the olfactory epithelium, olfactory neurons detect the chemical but also mechanical stimulation caused by odorant molecules. Regarding the olfactory perception per se, variations in air flow result first in distinct retention of the odorants carried by the flow, and therefore in distinct perception. Thus, high or low velocities respectively optimize perception of odorants presenting higher, or lower, sorption rate. Second, the air flow related to sniffing also influences the distribution of odorant molecules over the epithelium. By the way of this active mechanism, distinct odorants are spatially directed to distinct regions of the nasal cavity and to different populations of olfactory receptors, a process called "zonation" [8]. Subsequently, sniffing impacts the spatial representation of an odor at the level of the olfactory bulb, and influences the detection, identification, and discrimination abilities of animals.

Moreover, sniffing behavior carries temporal information about volatile cues throughout the olfactory system, from the olfactory bulb to higher cerebral structures. This impact is important knowing that temporal properties of an odor cue contribute to its representation. From this point of view, electrophysiological recordings reveal that odor-related activity in the olfactory bulb is strongly modulated by respiration and that the phase of spiking relative to the sniff cycle might encode information regarding odorant intensity and quality. Interestingly, the slow theta rhythm (4–12Hz in rats) generally recorded during sniffing in the mitral cell layer of the bulb, is also observed in the hippocampus, a structure involved in memory and orientation behavior. Such coherence in frequency between distinct brain areas might illustrate the cooperation of sensory, motor and cognitive cerebral regions expressed when the animal is engaged in an adaptive task. For instance, theta oscillations are both displayed in the olfactory bulb and dorsal hippocampus of rats that are sniffing during the initial stages of a reversal odor learning [9].

Finally, in complex natural scenes, sniffing plays a role in odor perception through successive sniffing cycles (even if a single sniff supports odor detection and identification). Successive samplings participate in progressive change of olfactory network dynamics which may then lead to a might converge, by the repetition of sniffing actions, in a more precise odor representation. From this point of view, multiple sniffs compose a synthetic memory-based system forming "perceptual gestalts" [10], which might be determinant for analysis of complex olfactory mixtures, identification of relevant odor cues and scent-tracking.

## Odor Selectivity

### Definition

Property of neuron responses (firing rate or other measure of odor response) that varies dependent on the odorant stimulus.

►Olfactory Information

## Odor Tracking (Localization)

### Definition

The chain of motor actions by which animals search and efficiently orient to a source of odor cues over short or long distances. The recipient organism displays general body movements (as in male moth approaching a female) or local head movements (as in mammalian newborns locating the mother's nipple) to create sensory asymmetry in the plumes released by an odor source in order to stimulate chemosensors located in or on bilateral organs (antennae, nasal fossae).

►Social Chemosignal

## Odorant

### Definition

An odorant is a volatile chemical molecule that that naturally exists as a component of an odor.and is sensed by the olfactory system. Odorants stimulate sensory neurons of the olfactory system in the nasal cavity by binding to odorant (olfactory) receptor proteins on the cell membrane, triggering an electrical response that can be transmitted to the brain. The ability of an odorant to bind to and activate an olfactory receptor protein depends on molecular features such as the size, shape and presence of functional groups. Naturally occurring odors may be composed of hundreds of odorants.

## Odorant-Binding Proteins

Loïc Briand
Unité Mixte de recherche FLAVIC INRA-ENESAD-Université de Bourgogne, Dijon, France

### Synonyms

Odor-binding proteins; Olfactory binding proteins

### Definition

Odorant-binding proteins (OBPs) are abundant small soluble proteins secreted in the ►nasal mucus of a variety of species, from insects to vertebrates including human beings. OBPs reversibly bind odorants with dissociation constants in the micromolar range and are good candidates for carrying airborne odorants, which are commonly hydrophobic molecules, through the aqueous nasal ►mucus towards olfactory receptors. Although the physiological function of vertebrate OBPs is not yet clearly established, their essential role in eliciting the behavioral response and odor coding have been demonstrated in the fruit fly [1].

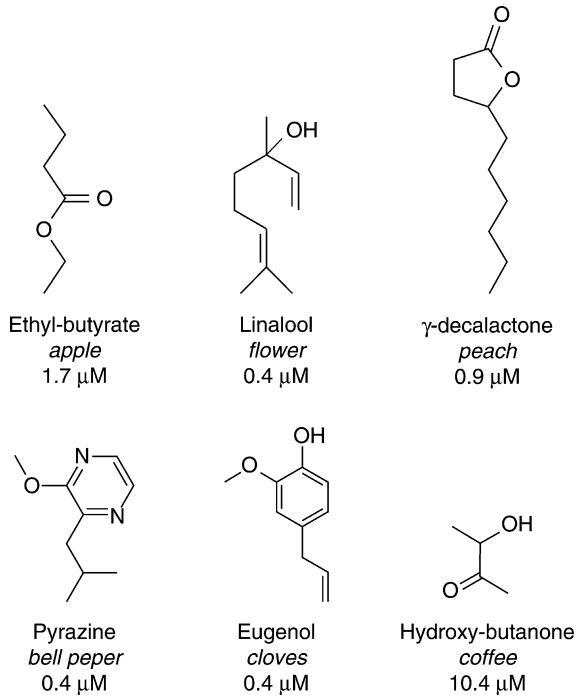
### Characteristics

#### General Properties of Vertebrate Obps

OBPs are secreted by the olfactory epithelium in the nasal ►mucus at high concentration (~10 mM). They reversibly bind odorants with dissociation constants in the micromolar range [2]. OBPs have been identified in a variety of vertebrates including cow, pig, rabbit, mouse, rat, xenopus, elephant and human beings [2–4]. Different OBP subtypes have been reported to occur simultaneously in the same animal species, two in pig, four in mouse, three in rabbit and at least eight in

porcupine. In rat, three OBPs have been cloned with quite different sequences and binding properties [5]. Molecular weights of OBPs fall within a narrow range (around 18 kDa). They are highly soluble proteins belonging to the lipocalin superfamily. As regards their quaternary structure, some OBPs were observed as monomers, such as porcine, rat OBP-3 or human OBP, while some others are found as dimers, such as bovine OBP, rat OBP-1 and OBP-2. OBP heterodimers have also observed in mouse. The typical isoelectric point of OBPs is in the acidic range, between 4 and 5. However, some rare OBPs exhibit a neutral or slightly basic isoelectric point, such as rat OBP-2 and human hOBP-2A. As sites of production, OBPs are synthesized within the nasal cavity, but in different glands and areas. Some OBPs have been clearly shown to be expressed in the olfactory area by the Bowman's glands.

OBPs are also found in the sensillary lymph of insect antennae. Although insect OBPs seem to play a similar role in olfaction, they do not share any amino acid sequences or structural similarities with vertebrate OBPs [5].



**Odorant-Binding Proteins. Figure 1** Examples of odorants presenting different odors, which bind tightly or weakly to rat OBP-1. The dissociation constants of these compounds for rat OBP-1 are indicated in italics.

## Human OBPs

Two putative human OBP genes (named $hOBP_{IIa}$ and $hOBP_{IIb}$) localized on chromosome 9q34 were first described before evidence of human OBP expression in the mucus covering the olfactory cleft [4]. The $hOBP_{IIa}$ gene codes for a protein, called hOBP-2A, which is 45.5% homologous to rat OBP-2. This gene is transcribed in the nasal cavity, in contrast to$hOBP_{IIb}$, which is transcribed in the genitals and codes a protein that is 43% identical to the human tear lipocalin-1. The presence of human OBP expression appears limited to the uppermost region of the ►nasal passage where odorant molecules are detected by olfactory receptor neurons.

## Ligand Binding Properties of OBPs

OBPs bind with high efficiency a large number of odorants belonging to different chemical classes (Fig. 1).

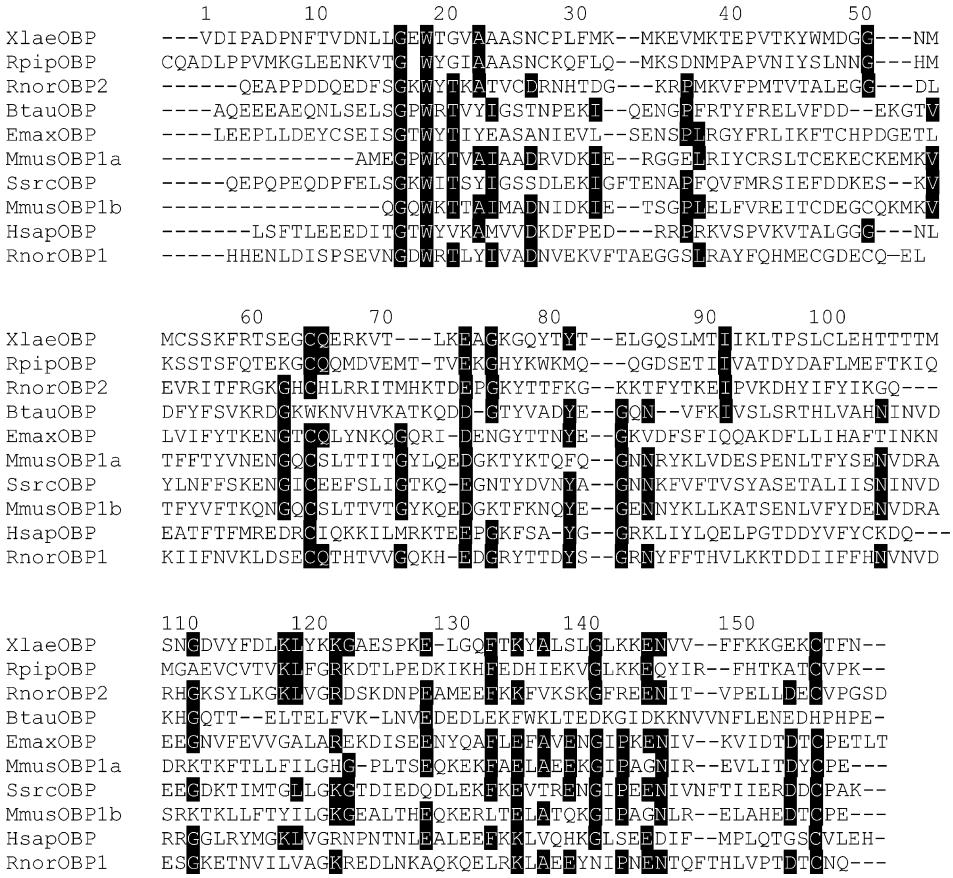
Although no preferential binding was observed with the porcine and bovine OBPs, a broad specificity was revealed by the study of the 3 rat OBPs, which are specially tuned towards distinct chemical classes of odorants. Rat OBP-1 preferentially binds heterocyclic compounds such as pyrazine derivatives and OBP-2 appears to be more specific for long-chain aliphatic aldehydes and carboxylic acids, whereas OBP-3 was described to interact strongly with odorants composed of saturated or unsaturated ring structure [6].

Human OBP-2A was observed to bind many diverse odorants with dissociation constants in the micromolar range, as found in all known vertebrate OBPs [4]. However, specificity of hOBP-2A is more restricted than those of porcine and rat OBP-1 and 3. A chemical specificity of this OBP for aldehydes, either aliphatic or aromatic, enhanced by the size of the odorant molecule, ir clear comparing odorant chemical series. Note that hOBP-2A can also be characterized by its low affinity for a very potent odorant, 2-isobutyl-3-methoxy pyrazine, and a very high affinity for large aliphatic acids.

## Consensus Sequence, Homology and Disulfide Bond

All known vertebrate OBPs belong to the lipocalin superfamily. All members of this family have low sequence identity, but few characteristic signatures allow their identification: a GxW motif at about 15–20 residues from the N-terminus, two cysteines in the middle and a glycine at the C-terminal end (Fig. 2).

One of the conserved cysteine residues, located on the fourth strand of the first $\beta$-sheet, forms a disulfide bridge tightening the $\alpha$-helix C-terminal domain and the $\beta$-barrel. When comparing OBP sequences, note that the percentage of identity among OBPs is low (21–26% on average) with the bovine and porcine OBP showing a maximal identity (42%), whilst rat OBP-2 exhibits the lowest identity (12–19%) when compared to all other OBPs. Consequently, tissue expression (i.e. in the olfactory epithelium) and ligand binding properties should be systematically taken into account in order to classify OBPs.



**Odorant-Binding Proteins. Figure 2** Sequence alignments of vertebrate OBPs. Conserved amino acid residues are shown white on black background. OBPs are: XlaeOBP (*Xenopus laevis* OBP), RpipOBP (*Rana pipiens* OBP), RnorOBP1 (Rat OBP-1), RnorOBP2 (Rat OBP-2), MmusOBP1a (Mouse OBP subunit IA), MmusOBP1b (Mouse OBP-1B), BtauOBP (Bovine OBP), EmaxOBP (Elephant OBP), SsrcOBP (Porcine OBP) and HsapOBP (Human OBP-2A).

## Structural Properties of OBPs

Vertebrate OBPs like other members of the lipocalin superfamily display low sequence similarities, but share a conserved folding pattern made of an 8-stranded antiparallel β-barrel linked together by seven loops, and connected to an $\alpha$-helix (Fig. 3). The $\beta$-barrel defines a central apolar cavity, called the calyx, whose role is to bind and transport hydrophobic molecules such as odorants [3].

Bovine OBP, which forms a dimer with an elongated shape, was the first OBP whose structure was deciphered through X-ray crystallography [7] and was therefore considered as the prototype of OBP, in spite of the absence of the second disulfide bridge. However, the molecule is not a classical lipocalin, since it exhibited a structural feature called domain swapping. The $\beta$-barrel of each monomer comprises its own strands 1–8, but the eighth strand originates from the other monomer. By this mechanism, the C-terminal part of one of the homodimers rotates and takes the place of that of the other. In addition to the buried cavity in the middle of the $\beta$-barrel, as in monomeric OBPs, a central pocket, composed of residues belonging to the $\beta$-barrel domains and to the C-terminal ends, is located at the dimer interface in communication with the solvent.

Porcine OBP is a monomer whose 3D-structure is typical of a lipocalin. Two cysteine residues form a disulfide bridge between the C-terminal and the loop joining strands 3 and 4 of the $\beta$-barrel [8] and a single cavity is observed inside the $\beta$-barrel, which does not communicate directly with the external solvent. A few amino acid side chains, which block the access to the solvent, would therefore have to move to make the binding of odorants possible. The cavity is mainly covered with hydrophobic and aromatic side chains.

## Structure of the Odorant-Binding Pocket

Up to now, only a few odorant-OBP complexes have been submitted to structural analysis. It has been observed that two odorant molecules could occupy

**Odorant-Binding Proteins. Figure 3** Ribbon representation of porcine OBP-1 forming a typical lipocalin eight-strand $\beta$-barrel, flanked by a single $\alpha$-helix. The color coding is according to the secondary structure; helices, red; L-strands, cyan; other motifs, green.

the $\beta$-barrel cavity of bovine OBP [8]. On the basis of porcine OBP data [9], the most likely binding site is inside the $\beta$-barrel, since this may be general for all OBPs. The size of the $\beta$-barrel pocket was found to be 780 $Å^3$ [8] for the bovine protein and about 500–550 $Å^3$ for the porcine OBP [9]. Using porcine OBP, a limited number of odorants, with relatively good affinity (affinity constants $> 10^6$ $M^{-1}$) and different chemical groups (aromatic ring, aliphatic chain or polar group) were co-crystalized with porcine OBP [9]). In the crystalline complexes, the odorant orientation inside the cavity have been proved to be opportunistic with no specific target patches for aromatic or charged group. Interactions between the different odorants and the $\beta$-barrel involve most of the residues in the cavity. Except for the two asparagines, which display a polar interaction between the amino acid side chain and the keto oxygen of benzophenone, all interactions are hydrophobic. The number of these interactions appears to be roughly related to the size of the odorant, but without any correlation with affinity measured in solution. Although the odorant-binding pocket is shielded from the solvent, openings have been observed using molecular simulations and it has been proposed that, tyrosine residue Y82 constitutes the door of the cavity. As regard human OBP-2A, its three-dimensional structure have not been yet described but a model has been proposed (Fig. 4). It has been shown using site-directed mutagenesis that affinity enhancement of OBP-2A for aldehydes compared to the corresponding aliphatic acids, could result from an interaction between aldehyde function and lateral chain of a lysyl residue K112, stabilizing odorant docking [10].

## Hypothetical Physiological Functions

In mammals and in insects, olfactory receptors are separated from air by a protective layer of hydrophilic secretion, the nasal mucus and sensillar lymph, respectively. Hydrophobic airborne odorants have to cross this aqueous barrier to reach their neuron receptors. OBPs, which have been hypothesized to play such a transporter role, likely appeared during the adaptation to terrestrial life. This carrier role is also supported by their relatively low affinity constant for odorants associated with their high concentration in the olfactory fluids. Their involvement in olfactory discrimination has also been proposed, because of the presence in the mucus of rat of three different OBP subtypes, specifically tuned toward distinct chemical classes of odorants [6]. In addition to the solubilization of odorants, various hypotheses have been proposed for other OBP functions [2]. They could either, (i) filter and buffer odorants in the mucus, then narrow the wide range of odorant intensities, (ii) eliminate odorants after olfactory receptor binding, or (iii) directly interact with olfactory receptors. The essential role of OBPs in eliciting the behavioral response and coding of odor has only been demonstrated in insects. It has been demonstrated that drosophila OBP LUSH is mandatory for the activation of pheromone-sensitive chemosensory neurons [1]. In mammals, it is stimm a

matter of debate whether there might be involved ►specific anosmia or ►parosmia.

# Odorant Receptor

Françoise Lazarini
Perception and Memory Unit, Neuroscience Department, Pasteur Institute, Paris, France

## Synonyms

Olfactory receptor; Odor receptor; Olfactory receptor protein; OBPs

## Definition

►Odorant receptor proteins are G protein-coupled seven transmembrane proteins, which number more than 1,000 in some mammalian species, and mediate the detection of thousands of volatile odorants. They are expressed, in mammals, in the cilia of the olfactory sensory neurons residing in the olfactory neuro-epithelium in the nasal cavity. They are located, in adult insects, on either the antennae or maxillary palp. They are expressed by sperm cells, and are thought to trigger ►chemotaxis toward the oocyte. A second class of odorant receptor proteins was described in 2001 for volatile amines, and called "trace amine-associated receptors" (TAAR). Most odorant receptors recognize multiple related odors and most odorants are recognized by several receptors.

## Characteristics

### Quantitative Description

In 1991, Buck and Axel discovered the odorant receptor gene family in rat [1]. In 2004, Linda Buck and Richard Axel won the Nobel Prize in Physiology or Medicine for this major discovery. Odorant receptors are seven-transmembrane-domain proteins encoded by large gene families. *Drosophila* has a highly diverse family of 60 odorant receptor genes [2]. In mammals, the odorant receptor family of genes, comprising some 1,100 functional genes in the mouse, 347 in the human, respectively, is the largest family of G protein-coupled receptors in the genome, which may make up as much as 3% of the genome. Only a small part of odorant receptor genes form functional ►odor receptors. In the mouse, 1,296 odorant receptor genes (including 20% pseudogenes) were found, which can be classified into 2,228 families [3]. Mouse odorant receptor genes are distributed in 27 clusters on all mouse chromosomes except 12 and Y. The distribution was not uniform, with more than half of the genes contained in a few large, compact clusters on chromosomes 7, 11 and 9. Class I odorant receptors correspond to fish-like receptors that bind water-soluble odorants, and separate clearly in the phyllogenetic tree from the classical, mammalian-specific class II odorant receptors. There are 147 Class I odorant receptors in the mouse odorant receptor subgenome, 120 of them potentially functional. All the class I odorant receptor genes are located in a single large cluster on chromosome 7 (cluster 7–3). Class I odorant receptors are prevalent in the mammalian genome and may be centrally involved in mammalian olfaction. In the mouse, they are expressed in the most dorsal zone of the olfactory epithelium. Conversely, Class II receptors have been found in all four zones.

Humans have lost nearly two-third of the odorant receptor genes as compared to mice, providing a possible explanation for the reduced sense of smells of humans compared to rodents. The human odorant receptor genome repertoire is organized similarly to the mouse one [4]. Human odorant genes are dispersed in more than 50 chromosomal locations and organized mostly in clusters. Most subfamilies are encoded by a

single locus and most loci encode a single or very few subfamilies. Odorant receptors of a single locus recognize structurally related odorants, suggesting that different parts of the genome are involved in the detection of different odorant type.

A second class of odorant receptors was described in 2001 for volatile amines, metabolic derivatives of classical biogenic amines, and called 'trace amine-associated receptors' (TAAR). Encoding TAAR are present in human, mouse and fish olfactory neurons [5]. They show sequence similarities to the receptors for the neurotransmitters serotomin and dopamine. TAAR1 is thought to be a receptor for thyronamines, decarboxylated and deiodinated metabolites of the thyroid hormones, while the mouse mTAAR2- mTAAR9 receptors are most probably olfactory receptors for volatile amines.

## Description of the Structure and Pharmacology

Odorant receptors are in every species heptahelical G-protein-coupled receptors. In mammals, odor receptors belong to class A of the G protein-coupled receptors that are characterized by a long second extracellular loop, containing an extra pair of conserved cysteins, and specific short sequences [6]. Odor receptors share a similarity from 40 to 90% identity. They also have a region of hypervariability, which is the binding site for ligands. This region consists in the third, fourth and fifth alpha – helical transmembrane regions, thought to face each other and form a pocket into the membrane. Mammalian odor receptors are related phyllogenetically to other chemosensory receptors (taste receptors, vameronsal receptors and gustatory receptors). Invertebrate odor receptors bear no homology to vertebrate odorant receptors. *Drosophila* odorant receptors have a mildly conversed region in the seventh transmembrane domain [2].

Odorant receptors bind to structures on odor molecules. They are generally able to recognize multiple related but not identical molecules. They are able to discriminate between thousands of low molecular mass, aliphatic and aromatic molecules with varied carbon backbones and diverse functional groups, including aldehydes, esters, ketones, alcohols, alkenes, carboxylic acides, amines, imines, thiols, halides, nitriles, sulphides and ethers. For many odors, the dose-response curves in single cells have relatively elevated EC50 values, or midpoint, ranging from 10 to 100 μM. They can be activated by multiple odors, and conversely most odors are able to activate more than one type of receptor.

Members of the TAAR family are activated by the trace amines found in the central nervous system (beta-phenylethylamine, tyramine, tryptamine and octopamine). Individual TAAR are specific for different amine structures; three of them are activated by volatile amines found in urine (a source of pheromonal cues of a variety of chemical compositions), some of which have been involved in regulating reproductive behavior [5].

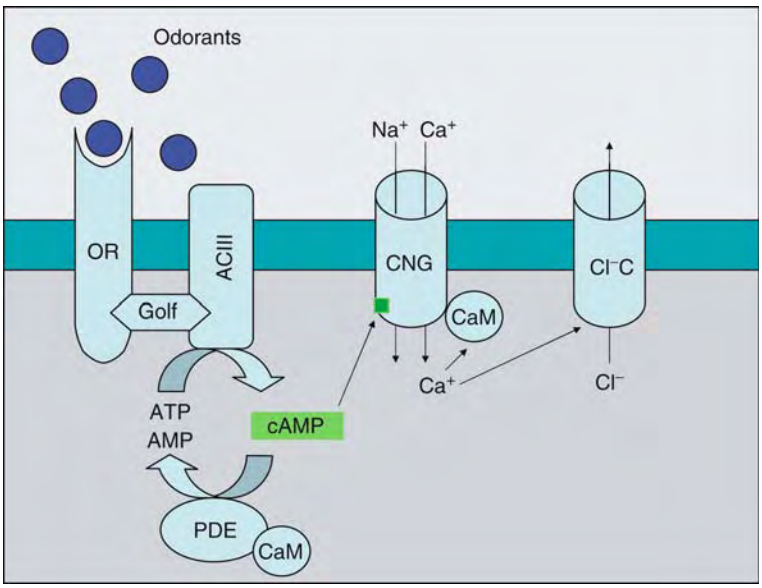
## Olfactory Signal Transduction

Odorant receptors are specialized to detect certain odorants and to convert external stimuli into intracellular signals [7]. Once the odorant has bound to the odorant receptor, the receptor undergoes structural changes and sequentially activates the specific olfactory-type G protein (Golf) and the lyase – adenylate cyclase type III (ACIII)- which converts ATP into cyclic AMP (cAMP), a molecule that has numerous signaling roles in cells. See Fig. 1.

The cAMP opens specific cyclic nucleotide-gated (CNG) channels, which allow calcium and sodium ions to enter into the cell, depolarizing the ►olfactory sensory neuron and triggering action potentials which then carry odor information to the olfactory bulb in the brain. The second-messenger cascade of enzymes provides amplification and integration of odor-binding events. The binding of one odor molecule to an odorant receptor activates tens of Golf proteins, each of which will activate an adenylyl cyclase III molecule able to produce about a 1,000 molecules of cAMP per second. Three cAMP molecules are sufficient to open a CNG channel, which can allow the crossing of hundred of thousands of cations, depolarizing the cell and inducing an action potential. The calcium ions entering through the CNG channels are capable of activating and thus opening channels permeable to negatively charged chloride ion ($Cl^-$). When the $Cl^-$ channels open, the $Cl^-$ efflux further depolarizes the olfactory sensory neuron, thus adding to the excitatory response magnitude. On the other hand, calcium ions entering through the CNG channels act on these channels, probably with calmodulin, to decrease their sensitivity to cAMP, thus requiring a stronger odor stimulus to produce sufficient cAMP to activate the channels. This negative feedback (inhibitory) pathway constitutes a crucial adaptation response allowing olfactory sensory neurons to adjust their sensitivity to odor stimuli. In invertebrates, both excitatory and inhibitory responses to odors have been described, suggesting the existence of multiple transduction pathways.

## Expression and Function

In insects, olfaction is a critical sensory modality for controlling behaviors such as mate selection, food choice and navigation toward suitable oviposition sites. Odorant receptors are located, in adult insects, in small subsets of olfactory receptor neurons in either the antenna or maxillary palps, which constitute the olfactory sensory organs. In mammals, the sense of smell is triggered by odorant receptors, which are expressed in the cilia of the olfactory sensory neurons of the olfactory neuroepithelium lining the nasal cavity. In mice, odorant receptors are also involved in mating and other social



**Odorant Receptor. Figure 1** ►Olfactory transduction. Within the olfactory sensory neuron, a cascade of enzymatic activity transduces the binding of an odorant molecule to an odorant receptor into an action potential that can be transmitted to the central nervous system. OR, odorant receptor; ACIII, adenylyl cyclase III; CNG, cyclic nucleotide-gated channel; Cl−C, negatively charged clhoride ion channel; CaM, calmodulin; PDE, phosphodiesterase.

behaviors. Moreover, in mammals, a subset of odorant receptors is specifically expressed in the testis and odorant receptors have been identified in spermatids and mature spermatozoa [8]. These odorant receptors may play a role in chemotaxis of spermatozoa toward the oocyte.

In *drosophila*, each sensory neuron express only a single odorant receptor, and all sensory neurons expressing the same receptor contact a single restricted target, named ►glomerulus in a relay station called the antennal lobe of the brain, analogous to the vertebrate olfactory bulb. *Drosophila* has about 50 types of olfactory receptor neurons, corresponding to about 50 identified glomeruli in the antennal lobe [2].

In mammals, with a few exceptions, each olfactory sensory neuron expresses only one of the 1,000 odorant receptor genes [9]. All cells expressing the same receptor converge onto one or a few glomeruli, in the olfactory bulb [6]. Glomeruli (nearly 2,000 in the rat) are spherical conglomerate of neuropil (diameter of 50–100 μ) that consists of the incoming axons of the olfactory sensory neurons and the dendrites of the main projection cells (mitral cells) in the olfactory bulb. Mitral axons of olfactory sensory neurons leaving the olfactory bulb project to higher brain structures including the piriform cortex, the olfactory cortex, hippocampus and amygdala, allowing for both the conscious perception of odors and their emotional and motivational effects. Lateral processing of the message occurs though two populations of inhibitory GABAergic interneurons in the olfactory bulb: periglomerular cells and granule cells. Each glomerular unit presents a receptive field that is thought to be defined by the molecular range, or pharmacological profile of each odorant receptor.

The mammalian olfactory system uses a combinational receptor coding scheme to encode odor identity and to discriminate odors [10]. A given odor activates a set of odorant receptors, and then a set of olfactory sensory neurons, and then a set of glomeruli in the olfactory bulb, forming a spatial map of sensory information. Different odors activate overlapping but non-identical patterns of receptors and thus glomeruli. Slight changes in the structure of an odorant or changes in its concentration results in changes in the combination of receptors that recognize the odorant. Receptors that recognize similar odors (such as ►enantiomers) generally map in the same area in the olfactory bulb. Individual TAAR are sparsely expressed in discrete subdomains of the neuroepithelium, and are co-expressed with neither other TAAR, nor probably the odorant receptors. In mice, TAAR may mediate behavioral and physiological responses to amine-based social cues present in urine, as urine from sexually mature male mice, but not from females or sexually immature mices, could stimulate mTAAR5, a receptor activated by trimethylamine [5].

# Odorant Receptor: Genomics

Jean-François Cloutier
Department of Neurology and Neurosurgery, McGill University, Montreal Neurological Institute, Montréal, QC, Canada

## Definition

►Odorant receptor genomics refers to the study of the structure and function of genes encoding receptors involved in the sense of smell. It includes defining the number and chromosomal arrangements of odorant receptor genes present in various genomes, as well as the molecular mechanisms that regulate their expression in an organism.

## Characteristics

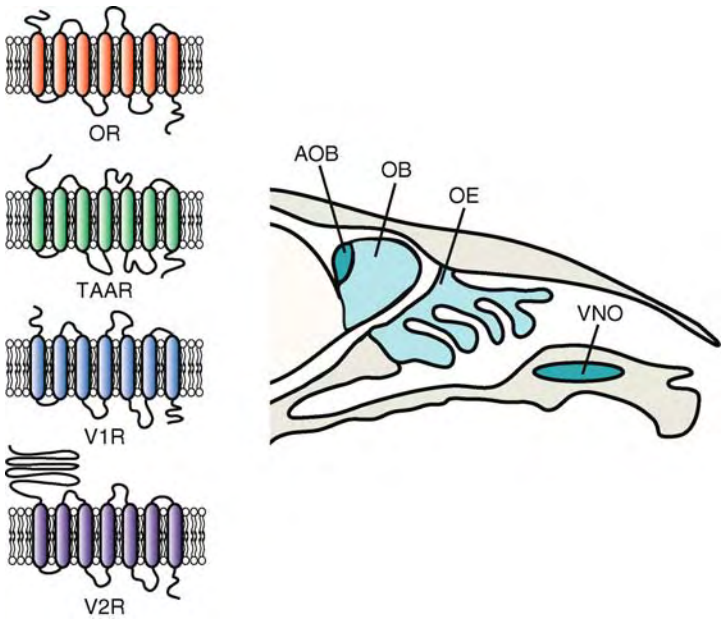
The survival and well being of most terrestrial vertebrates is dependent on their ability to detect ►odors in their environment and to respond to social cues. Neurons located in sensory epithelia of the nasal cavity detect volatile and water-soluble molecules and transmit the information gathered to the brain where it is further processed to generate odor perception and behavioral outputs. While the detection of volatile odorant molecules plays an important role in the modulation of acquired behavior such as food foraging, detection of ►pheromones is thought to control innate responses such as male-to-male aggression in many vertebrate species. The ►olfactory epithelium (OE) contains olfactory sensory neurons that express two classes of ►chemosensory receptors: the odorant receptors (ORs) and the trace amine-associated receptors (TAARs). While ORs recognize odor molecules, TAARs are proposed to detect compounds that can provide social cues. In contrast to the OE, the sensory epithelium of the vomeronasal organ contains sensory neurons that express two classes of putative pheromone receptors, the V1R and V2R families. Together, these families of seven-transmembrane G protein-coupled receptors (►GPCRs) allow organisms to detect a large range of molecules that regulate their behavior (Fig. 1).

## Odorant Receptors (ORs)

The ability of terrestrial vertebrates to discriminate thousands of complex odors in the environment relies on the detection of odorant molecules by ORs. A single OR can recognize a multitude of odorant molecules and a specific odorant can bind to several ORs perhaps eliciting different levels of neuronal activity. The combination of ORs activated by odorant molecules present in a complex odor leads to the propagation of signals that ultimately renders a representation of the odor in the central nervous system. In light of the complexity of this ►combinatorial code, it is not surprising that ORs represent one of the largest mammalian gene families.

In some terrestrial vertebrates that rely heavily on their sense of smell for survival, such as the mouse, larger OR gene repertoires have been described than in humans whose sense of smell is considered to be more aesthetic. The mouse genome contains ~1400 genes that are organized in clusters located on almost all chromosomes [1]. While the majority of these genes encode functional ORs, ~15% of them are ►pseudogenes. The coding region of OR genes consists of a single ►exon preceded by an ►intron that separates it from non-coding exons in the 5′ region. The coding exon gives rise to OR proteins that are 300–350 amino acids in size. ORs contain structural features that are common to most GPCRs such as the seven hydrophobic stretches that form the transmembrane domains and specific conserved cysteines that form potential disulfide bonds. In addition, ORs contain sequences that distinguish them from other GPCRs including a long second extracellular loop, as well as conserved amino acid motifs in an intracellular loop and in some of the transmembrane domains. The presence of these conserved features in ORs are usually enough to classify a gene as belonging to the large family of ORs. Nonetheless, aside from these conserved features, there is on average an overall low amino acid similarity (37%) between ORs. This may allow the OR repertoire to recognize a large number of structurally diverse odorants.

The OR superfamily is subdivided into two classes of receptors. Class I ORs were originally identified in fish



**Odorant Receptor: Genomics. Figure 1** Anatomy of the olfactory systems and structure of olfactory receptors. Olfactory sensory neurons located in the olfactory epithelium (OE) project axons that connect with second-order neurons in the olfactory bulb (OB). In contrast, vomeronasal neurons located in the vomeronasal organ (VNO) project their axons to the accessory olfactory bulb (AOB) where they form synapses with second-order neurons. The information processed by second-order neurons is relayed to various regions of the brain where an odor representation is generated. Olfactory receptors belong to the large family of G-protein coupled seven-transmembrane receptors. While odorant receptors (OR) and trace amine-associated receptors (TAAR) are expressed in the OE, two families of vomeronasal receptors (VR), V1R and V2R, are expressed in the VNO.

but later shown to represent approximately 10% of the mouse OR gene repertoire. In contrast, class II genes have so far been identified only in terrestrial vertebrates and represent the majority of the OR gene repertoire in mouse. While all Class I OR genes are segregated in a single cluster on chromosome 7, class II OR genes are located in clusters on all chromosomes except 12 and Y. The functional relevance of the sequence divergence observed between these two classes of receptors is still unclear. However, it has been proposed that Class I and II receptors bind volatile odorants that have low and high levels of hydrophobicity, respectively.

The gene structure and chromosomal arrangements of OR gene clusters observed in mouse is conserved in humans with an OR gene repertoire consisting of approximately 950 ORs [2]. While this total number may not seem that different from the number of OR genes present in the mouse genome, it is estimated that ~60–70% of these genes could be pseudogenes. Hence, humans may express approximately 300–350 functional ORs, three times less than are expressed in mice. The pseudogenization of the OR repertoire appears to parallel the evolution tree. The highest percentages of OR pseudogenes are observed in the human (~63%) and old-world monkey (~30%) genomes, while New World monkeys have a similar fraction of pseudogenes as found in the mouse genome (~20%). The increase in pseudogenes observed in humans, as well as in old-world primates, is likely the result of decreased selective pressure for olfactory function throughout evolution.

## Vomeronasal Receptors (VRs)

The ►accessory olfactory system plays a critical role in the detection of and responsiveness to pheromones. Vomeronasal sensory neurons located in the ►vomeronasal organ express members of the Vomeronasal Receptor (VRs) superfamily that are putative pheromone receptors. These receptors are seven transmembrane GPCRs that are distinct from the OR superfamily. Two large families of VRs have been identified, V1R and V2R. In mouse, the V1R and V2R families are respectively comprised of ~200 and ~60 putative functional genes that are dispersed across several chromosomes [1,3]. While V1Rs, as ORs, are encoded by a single exon, the V2R gene structure is more complex and contains several coding exons. This difference in gene structure is also reflected in the overall V2R protein structure. In addition to features common to ORs and V1Rs, such as the seven

transmembrane domains, V2Rs contain a large extracellular N-terminal domain that binds ligands.

In humans, the majority (95%) of V1R sequences identified are pseudogenes. Five V1R genes that are predicted to encode functional receptors have been described, with at least one of them observed at the mRNA level in human olfactory mucosa [4]. Moreover, no intact V2R genes have been reported in humans. The high occurrence of VR pseudogenes in humans, as well as in primates, suggests that pheromone detection in these species is either not prevalent or mediated through other families of receptors.

## Trace Amine-Associated Receptors (TAARs)

In addition to ORs, a second class of chemosensory receptors has been identified in the OE of mice. TAARs can recognize volatile amines and at least one of them is activated by urine from sexually mature male mice [5]. These observations suggest that TAARs may be implicated in the detection of social cues in mice. The mouse genome contains 16 TAAR genes, including 1 pseudogene, that are all located in a compact region of chromosome 10 and that share high sequence identities [6]. Of these 16 genes, 8 have so far been shown to be expressed in the OE. The coding region of TAAR genes consists of a single exon, which gives rise to proteins of approximately 350 amino acids that contain seven hydrophobic stretches of amino acids and conserved extracellular cysteine residues. In humans, 9 TAAR genes have been identified, including 3 pseudogenes [6]. It remains to be determined whether they are expressed in the human olfactory mucosa.

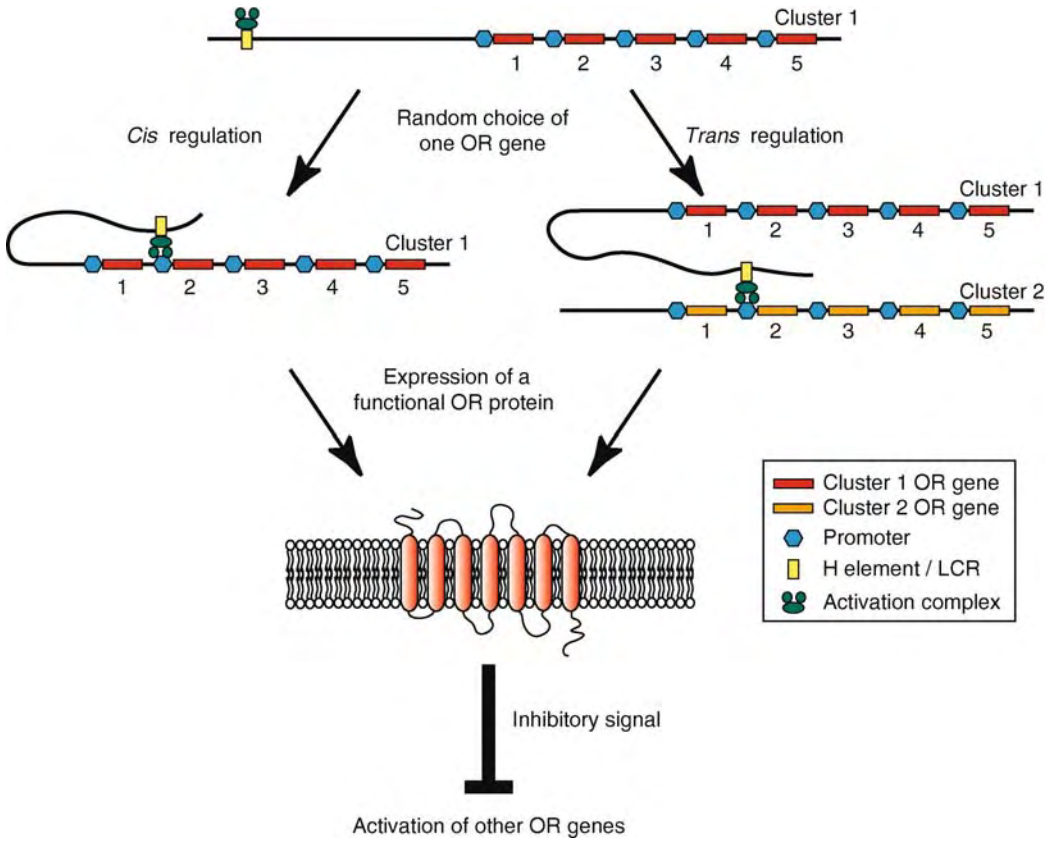
## Regulation of odorant receptor gene expression

The development of a functional olfactory system is dependent on the tight regulation of OR gene expression in olfactory sensory neurons. Each OR is expressed in a small subset of neurons that are distributed in one of four defined but partially overlapping expression domains within the OE. Within each of these domains, neurons expressing the same OR are randomly distributed and each neuron expresses a single OR gene from the large repertoire available. Furthermore, a functional OR is expressed from only one of two gene ►alleles in a process termed ►monoallelic exclusion. The expression of a single OR per neuron is critical to define the profile of odorants recognized by this neuron. In addition, expression of the OR has also been shown to play a role in the accurate elaboration of ►topographic connections in the ►olfactory bulb. Mechanisms must therefore exist to first determine which subgroup of ORs will be expressed in a neuron based on its location in the OE. This is followed by the stochastic expression of a single receptor and by inhibition of expression of other OR genes in the same neuron. The mechanisms underlying these two levels of regulation of OR gene expression are beginning to be unraveled.

The spatial regulation of OR genes in neurons of the OE may be achieved through the combinatorial expression of various families of transcription factors in different regions of the OE. For some class II OR genes, the presence of short sequences upstream of the transcriptional start sites have been shown to be sufficient to induce appropriate spatial expression of these ORs in the OE. These short sequences contain regions recognized by homeodomain-containing transcription factors and by Olf1/EBF (O/E) family transcription factors. The LIM-homeodomain protein, Lhx2, can bind to the promoter region of at least one OR gene and is required for expression of class II OR genes [7]. Three members of the O/E family, O/E-1 to 3, are expressed in developing olfactory sensory neurons and the presence of O/E binding sequences in several OR gene promoter regions suggests they may also control OR gene expression [8]. However, the overlapping expression of these three family members in olfactory sensory neurons has made it difficult to establish their requirement for OR gene expression using gene-targeting approaches in mice.

The stochastic selection of expression of a single OR in a neuron is first dependent on the positive activation of gene expression through a *cis* or *trans*-acting mechanism (Fig. 2). It has been proposed that a region of homology upstream of each OR gene cluster, termed H, can act as a ►locus control region (LCR) to regulate expression of these genes in *cis* [9]. A similar mechanism is used to regulate the expression of photopigment genes in the visual system. This LCR would recruit proteins to form an activation complex that can randomly promote transcription of a single gene within the locus following chromatin rearrangements. Such a regulatory sequence has been identified far upstream of the mouse MOR28 gene cluster. Alternatively, a single H region could also regulate expression of OR genes in *trans* through interchromosomal interactions. In support of this hypothesis, the H region found upstream of the MOR28 gene cluster has been shown to interact with the promoter of several OR genes located on different chromosomes [10]. However, while deletion of H from the mouse genome affects expression of OR genes proximal to the location of H, the expression of OR genes outside of this gene cluster is unaffected [11,12].

Since only one allele of an OR gene is expressed in a single neuron, a mechanism must also exist to prevent transcription of the other allele as well as to prevent expression of other OR genes in the neuron. This may be achieved through a negative feedback mechanism in OSNs [9]. Expression of a full-length mRNA giving rise to a functional OR protein



**Odorant Receptor: Genomics. Figure 2** Regulation of odorant receptor gene expression. Odorant receptor (OR) genes are arranged in clusters located on almost all chromosomes. A single OR gene is expressed per neuron through positive and negative mechanisms of regulation. An activation complex is recruited to a locus control region (LCR), termed H, located upstream of an OR gene cluster. Through chromosomal remodeling, this activation complex interacts in either *cis* or *trans* with a single OR gene promoter within a gene cluster to induce gene expression. This stochastic expression of a single OR protein leads to the generation of an unidentified signal that inhibits activation of other OR genes in the neuron by a negative feedback mechanism.

prevents the secondary activation of other OR genes. In contrast, expression of a full-length mRNA containing a premature stop codon from a pseudogene does not prevent activation of another OR gene. These observations suggest that expression of a functional OR protein leads to an as yet unidentified inhibitory signal that negatively regulates expression of other OR genes. In addition, the OR coding region contains regulatory elements importent to suppress expression of additional receptors [13]. Taken together, these mechanisms do not only prevent expression... Such a mechanism does not only prevent expression of two types of receptors in a single neuron but also serves to avoid the generation of receptorless neurons. The control of VR, and possibly TAAR, gene expression also ensures that a single receptor is expressed per neuron generated. Whether regulation of these families of genes is under the control of similar mechanisms to the ones identified for OR genes remains to be determined.

# Olfaction and Gustation Aging

Nicholas P. Hays
Nutrition, Metabolism, and Exercise Laboratory, Donald W. Reynolds Institute on Aging, University of Arkansas for Medical Sciences, Little Rock, AR, USA

## Synonyms

Senescence; Gerontology; Elderliness

## Definition

Elderly adults often have an impaired ability to detect and recognize ►tastes and ►odors. Olfactory and gustatory impairment can be particularly harmful in aged individuals, given the likely contribution of such dysfunction to poor appetite, lower dietary energy and nutrient intakes, and the consumption of inappropriate food choices such as spoiled food. These phenomena may in turn influence body composition, nutritional stores, immune function, and disease status. Olfactory dysfunction can also be dangerous as it may prevent the detection of smoke or natural gas odors during household emergencies. Although the precise mechanisms underlying age-related changes in taste and smell remain uncertain, physiological changes associated with the aging process itself, diseases, medication usage, trauma, and environmental factors are all possible contributors. Flavor enhancement, increased dietary variety, and other interventions have been identified that can improve food intake and enhance eating enjoyment. Given the projected increases in the size and longevity of the elderly population in the U.S. and worldwide, additional effective interventions that can maintain or improve chemosensory function in this vulnerable population are needed.

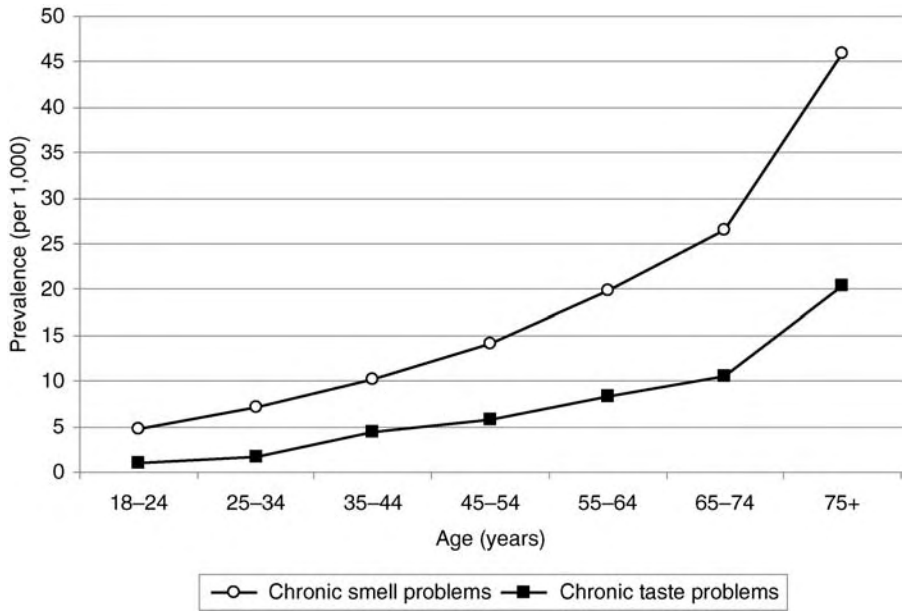
## Characteristics

### Introduction

It is generally accepted that all sensory modalities, including ►gustation, olfaction [see ►olfactory senses], vision [see ►binocular vision], audition [see ►auditory system], and somatosensation [see ►somatic sense] commonly decline with increasing age. Vision and auditory losses are perhaps most typically associated with the aging process, and these impairments are indeed highly prevalent among elderly adults, with approximately 34% of adults aged 65 years and older reporting vision and/or hearing impairment [1]. Taste and smell dysfunctions are also recognized as a common characteristic of old age, but frequently receive less attention, perhaps because their impact on mortality, morbidity, and functional status is less direct. Figure 1 illustrates the nearly exponential increase in self-reported taste and/or smell dysfunction with increasing age in a representative cohort of U.S. adults [2]. These data indicate that individuals aged 65+ years account for almost half (~41%) of the total number of individuals reporting chronic chemosensory problems. The prevalence of impairment is likely even higher when considering that self-reported data may underestimate the level of actual impairment as measured by objective testing.

The basic anatomy and neurobiology of the gustatory and olfactory systems have been fully described elsewhere [see taste, odor]. Briefly, taste signals are received by receptor cells located in ►taste buds in the ►gustatory papillae of the tongue and other structures of the oral cavity. Taste information is then transmitted to the ►gustatory cortex, orbitofrontal cortex [see ►cortex – orbitofrontal], ►amygdala, and lateral ►hypothalamus of the ►brain. Smell sensations are received by a small area of ►olfactory epithelial tissue located on the dorsal surface of the nasal cavity [see ►nasal passages], where odorants bind to receptors in olfactory neurons, which then transmit information about the identity and concentration of the chemical signal to the ►olfactory cortex in the brain.

Aging can influence different aspects of gustatory and olfactory sensory perception and sensitivity. Older individuals often require higher concentrations of an odorant or tastant to be present before detection and recognition of the chemical stimulus can be achieved. In other words, the detection and recognition ►thresholds for various tastes and smells are higher in older adults compared to younger. The magnitude of these changes can also vary across specific sensory qualities; salt taste [see ►taste – salt] thresholds appear to increase more during the aging process than sweet [see ►taste – sweet] thresholds. In addition, older individuals may have alterations in the ►suprathreshold perception of tastes and smells, such that more concentrated chemical stimuli are not perceived as more intense. Odor identification is also frequently poor among the elderly, although this may be due to both sensory impairment as well as cognitive and memory dysfunction resulting in difficulty with odor-naming tasks. In general, olfactory dysfunction is more common



**Olfaction and Gustation Aging. Figure 1** Age specific prevalence rates (per 1,000) of self-reported chronic (≥3 months duration) chemosensory problems among individuals living in 42,000 randomly selected U.S. households (1994 Disability Supplement to the National Health Interview Survey). Adapted from Hoffman et al. [2] with permission © 1998 New York Academy of Sciences.

than taste dysfunction among the elderly population and individuals who describe problems with their sense of "taste" typically exhibit olfactory and not gustatory dysfunction, since it is difficult to distinguish true taste from ►retronasal olfaction [3]; strictly defined changes in taste alone are rare. Olfactory perception, however, declines with increasing age even in generally healthy men and women. As shown below, smell and taste changes associated with aging can manifest along a continuum of sensitivity, and can range from the total absence of sensation (e.g. ►ageusia) to a diminished or distorted sensation (e.g. ►hypogeusia, ►dysgeusia).

*Terminology*

| | |
|---|---|
| Gustation | |
| Normogeusic | Normal taste sensory function |
| Hypogeusia | Diminished sensitivity of taste |
| Dysgeusia | Distortion of normal taste |
| Ageusia | Absence of taste |
| Olfaction | |
| Normosmic | Normal smell sensory function |
| Hyposmia | Diminished sensitivity of smell |
| Dysosmia | Distortion of normal smell |
| Parosmia | Distortion of odor perceptions when odor is present |
| Phantosmia | Odor sensations in absence of odor stimulus (i.e. olfactory hallucination) |
| Anosmia | Absence of smell |
| Cacosmia | Feeling ill in response to odors |

## Etiology

The causes of taste and smell dysfunction among elderly individuals are not completely understood. The olfactory epithelium is particularly vulnerable to age-associated dysfunction because of its anatomical location and proximity to environmental trauma, as well as a greater susceptibility to decreased ►neurogenesis secondary to its relatively small size (1–2 $cm^2$) and thinness. Declines in taste sensitivity were thought historically to result from a loss of functional taste buds over time, but more recent work indicates that taste bud numbers do not decrease with age and thus declines may be due to changes in taste cell membrane ion channels and receptors. The etiology of age-associated chemosensory dysfunction is further complicated by the varied environmental and medical factors that can also influence these systems and which frequently impact the elderly. Several possible causal factors are briefly described below:

*Normal aging.* One hypothesis for the decline in taste sensitivity with age is reduced taste receptor cell turnover rate, resulting in alterations in taste bud structure and subsequent dysfunction in older subjects. In addition, the olfactory mucosa may be gradually replaced by respiratory epithelium during the normal aging process, reducing smell perception and sensitivity. Animal data suggests that menopause may be associated with changes in olfactory perception, potentially contributing to further alterations in olfactory function among older women.

*Diseases/infection.* Acute or chronic nasal and sinus problems can lead to olfactory dysfunction by obstruction of the nasal passage, by viral-mediated damage to the olfactory receptors, and by altering the amount or composition of the mucus layer that odorants must traverse to reach the olfactory epithelial surface [3]. Neurodegenerative diseases such as ►Alzheimer's and ►Parkinson's disease have been associated with olfactory deficits. Recent work indicates that difficulty in odor identification predicts the transition from normal to mildly impaired cognition [4], and from mildly impaired cognition to Alzheimer's disease, suggesting that tests of olfactory perception may be useful in identifying apparently healthy and cognitively intact individuals who are at increased risk of developing severe cognitive impairment. Other representative diseases associated with impaired olfaction and gustation are listed below.

### Medical conditions associated with taste or smell dysfunction

Neurological
- Alzheimer's disease
- Bell's palsy
- Damage to the chorda tympani
- Down's syndrome
- Epilepsy
- Familial dysautonomia
- Guillain-Barré syndrome
- Head trauma
- Korsakoff's syndrome
- Multiple sclerosis
- Parkinson's disease
- Raeder's paratrigeminal syndrome
- Tumors and lesions

Nutritional
- Cancer
- Chronic renal failure
- Liver disease including cirrhosis
- Niacin deficiency
- Thermal burn
- Vitamin $B_{12}$ deficiency
- Zinc deficiency

Endocrine
- Adrenal cortical insufficiency
- Congenital adrenal hyperplasia
- Cretinism
- Cushing's syndrome
- Diabetes mellitus
- Hypothyroidism
- Kallmann's syndrome
- Panhypopituitarism
- Pseudohypoparathyroidism
- Turner's syndrome (gonadal dysgenesis)

Local
- Allergic rhinitis, atopy, and bronchial asthma
- Glossitis and other oral disorders
- Leprosy
- Oral aspects of Crohn's disease
- Radiation therapy
- Sinusitis and polyposis
- Xerostomic conditions including Sjögren's syndrome

Viral infections
- Acute viral hepatitis
- HIV infections
- Influenza-like infections

Other
- Amyloidosis and sarcoidosis
- Cystic fibrosis
- High altitude
- Hypertension
- Laryngectomy
- Psychiatric disorders

*Medication usage.* Taste alterations can be a common side effect of many medications. Medications typically do not produce total taste losses, but may produce metallic or bitter dysgeusias. Certain medications can be absorbed and then excreted in the saliva, where they can stimulate an adverse taste sensation or alter normal taste signal transduction. Other medications can diminish salivary output, decreasing the ability of tastant molecules to be dissolved and carried to the taste buds, or alter the composition of the olfactory mucus layer, modifying the absorption of odorants [6]. More than 250 medications are thought to interfere with smell and taste acuity, with selected medications listed below.

### Medications associated with taste or smell dysfunction

Antianxiety agents
- Alprazolam (Xanax)
- Buspirone (BuSpar)

Antibiotics
- Ampicillin
- Azithromycin (Zithromax)
- Ciprofloxacin (Cipro)
- Clarithromycin (Biaxin)
- Enalapril (Vaseretic)
- Griseofulvin (Grisactin)
- Metronidazole (Flagyl)
- Ofloxacin (Floxin)
- Terbinafine (Lamisil)
- Tetracycline
- Ticarcillin (Timentin)

►Anticonvulsants
- Carbamazepine (Tegretol)
- Phenytoin (Dilantin)

►Antidepressants
- Amitriptyline (Elavil)

- Clomipramine (Anafranil)
- Desipramine (Norpramin)
- Doxepin (Sinequan)
- Imipramine (Tofranil)
- Nortriptyline (Pamelor)

Antihistamines and decongestants
- Chlorpheniramine
- Loratadine (Claritin)
- Pseudoephedrine

Antihypertensives and cardiac medications
- Acetazolamide (Diamox)
- Amiloride (Midamor)
- Amiodarone (Pacerone, Cordarone)
- Betaxolol (Betoptic)
- Captopril (Capoten)
- Diltiazem (Cardizem)
- Enalapril (Lexxel, Vasotec, Vaseretic)
- Hydrochlorothiazide (Esidrix)
- Nifedipine (Procardia)
- Nitroglycerin
- Propafenone (Rythmol)
- Propranolol (Inderal)
- Spironolactone (Aldactone)
- Tocainide (Tonocard)

Anti-inflammatory agents
- Auranofin (Ridaura)
- Beclomethasone (Beclovent, Beconase)
- Budesonide (Rhinocort)
- Colchicine
- Dexamethasone (Decadron)
- Flunisolide (Nasalide, AeroBid)
- Fluticasone (Flonase)
- Gold (Myochrysine)
- Hydrocortisone
- Penicillamine (Cuprimine)

Antimanic drugs
- Lithium

Antimigraine agents
- Dihydroergotamine (Migranal)
- Naratriptan (Amerge)
- Rizatriptan (Maxalt)
- Sumatriptan (Imitrex)

Antineoplastics
- Cisplatin (Platinol)
- Doxorubicin (Adriamycin)
- Levamisole (Ergamisol)
- Methotrexate (Rheumatrex)
- Vincristine (Oncovin)

Antiparkinsonian agents
- Levodopa (Larodopa; with carbidopa: Sinemet)

►Antipsychotics
- Clozapine (Clozaril)
- Trifluoperazine (Stelazine)

Antithyroid agents
- Methimazole (Tapazole)
- Propylthiouracil

Antiviral agents
- Ganciclovir (Cytovene)
- Interferon (Roferon-A)
- Zalcitabine (HIVID)

Bronchodilators
- Bitolterol (Tornalate)
- Pirbuterol (Maxair)

Lipid-lowering agents
- Atorvastatin (Lipitor)
- Fluvastatin (Lescol)

*Trauma/surgical interventions.* Olfactory sensory information is transmitted by a single nerve (►cranial nerve I) which can be severed by a sharp upward blow to the nose (e.g. during an automobile accident or severe fall) proximal to the location where the nerve passes through the ethmoid bone. Gustatory sensation is transmitted via three cranial nerves (VII, IX, X) and thus is more resistant to trauma-induced dysfunction. In fact, even if one taste nerve is damaged or severed during surgery of the middle-ear region, the remaining nerves appear to compensate for the resultant loss of taste in that area of the mouth, thereby preserving overall taste perception [3].

*Environmental factors.* Olfactory neurons are the receptors for odorant chemical signals and therefore are directly exposed to potential airborne environmental toxins; taste receptors are specialized cells and thus the taste neurons are protected from this type of direct exposure. As a result, the olfactory system is vulnerable to damage from chemical fumes or metallurgical dust from occupational, industrial, household, or ambient sources. Tobacco smoke-induced hyposmia has also been documented.

*Oral health and hygiene.* Poorly fitting dentures or other dentition problems that impair chewing and mouth movements during eating can negatively impact retronasal olfaction by reducing the volatilization and movement of odor molecules from the oral cavity to the olfactory epithelium. Dentures may also cover the taste buds located in the soft palate in the roof of the mouth.

## Consequences

Age-related losses of taste and smell perception can result in poor appetite, reduced energy and nutrient

intakes, and diminished eating enjoyment and motivation to eat. Consequently, chemosensory losses can lead to impaired nutritional status, reduced immune function, protein-energy malnutrition, involuntary weight loss, increased disease susceptibility or exacerbation of existing disease states, and overall decreased quality of life [6]. Poor taste and smell perception may lead to consumption of spoiled food and subsequently increased likelihood of food-borne illness. Taste and smell signals are important factors in meal initiation (via cephalic-phase stimulation of salivary, gastric, and pancreatic secretions; see ►food anticipatory behavior), continuation of food intake during a meal, and meal termination (via sensory-specific satiety). Taste and smell enhance enjoyment of meals and are the primary reinforcements of eating; maximal chemosensory acuity is thus especially important in elderly individuals for whom other sources of personal gratification may be infrequent.

The evidence for alterations of food intake as a result of olfactory or gustatory dysfunction alone is limited, however. Although chemosensory disturbances likely play an important role, other factors may also contribute to food intake dysregulation among older adults. Additional physiological factors, such as delayed gastric emptying and altered digestion-related hormone secretion and hormonal responsiveness, often act concurrently with chemosensory losses as well as with social, psychological, and medical factors to reduce food intake and promote weight loss in elderly adults.

Other consequences of taste and smell dysfunction include a decreased ability to detect natural gas leaks, volatile chemical fumes, and fires, which can result in increased risk for serious injury and death among elderly adults, their family members, and the general public. Elderly adults can have a heightened concern with personal hygiene and may overuse perfumes and colognes as a result of a lack of ability to detect offensive bodily or breath odors.

## Therapeutic Strategies

While specific medical or pharmacological causes of olfactory and/or gustatory dysfunction can be resolved via appropriate treatment or pharmacotherapeutic modifications, chemosensory dysfunction that results from more intractable causes such as increasing age or environmental damage may be more resistant to improvement. In these cases, therapeutic strategies have been developed that improve food palatability and food intake, but do not alter impaired chemosensory pathways directly.

One intervention that is commonly employed is the use of flavor enhancements. Naturally-derived or chemically-synthesized concentrated odorants and flavorings can be added to individual foods to amplify or supplement the sensory signals provided by these foods. Flavor enhancement has been shown to increase the appeal of certain foods, attenuate decreases in energy intake, and improve immune status among elderly individuals [e.g. 8]. Many of these studies are limited by small sample sizes, short duration, and a lack of data regarding total dietary energy intake or nutritional status, and thus additional research is warranted. Olfactory declines tend to result in the predomination of ►bitter tastes, but this bitterness can be masked with salt, sweet, or flavored (e.g. coffee, chocolate) extracts. Other flavor enhancements such as spices, herbs, salt, or other compounds (e.g. monosodium glutamate, concentrated meat flavor, etc.) can improve food palatability and increase dietary intake. Recent media reports examining the increasing availability and marketing of spicy and highly flavored foods in U.S. groceries and restaurants attribute this national trend to an aging population and a resultant demand for spicier foods to overcome age-related sensory declines.

Another commonly employed strategy is to alter patterns of dietary variety in order to decrease sensory specific satiety and increase food intake. A recent study examined potential associations between low dietary variety and low body mass index (BMI) and dietary energy intake in older adults. In contrast to some but not all previous reports suggesting that dietary variety typically decreases with age, adults 61 years of age or older were shown to consume a greater total food variety compared with adults 60 years or younger [9]. However, older adults with low BMIs (<22 kg/m$^2$) consumed a lower variety of energy-dense foods and had a lower overall energy intake compared to older adults with higher BMIs [9]. Thus the results of this study suggest that consumption of a diet containing a high variety of energy dense foods may be associated with higher energy intake and greater body weight in older adults. Presentation of a variety of palatable foods with different textures, temperatures, and appearances can also promote increased intake even though the chemosensory characteristics of the foods are not altered. The order of foods eaten can also be rotated to stimulate intake and reduce sensory-specific satiety.

Zinc supplementation and hormone replacement therapy have been suggested as additional therapeutic methods for improving taste and smell function, respectively. Hormone replacement in healthy postmenopausal women does not appear to improve performance on olfactory detection, discrimination, or recognition tasks. A recent randomized, double-blind, placebo-controlled study examining zinc supplementation in older Europeans aged 70–87 years demonstrated that supplementation with 30 mg zinc per day resulted in increased salt taste acuity, but not sweet, sour, or bitter taste acuity, among subjects recruited in one of two geographical regions [10], suggesting the efficacy of this approach may be limited to individuals with poor

baseline zinc status or another trait common to those subjects examined in this region.

Audible and visual gas detection systems exist that will notify an individual of a natural gas leak; these systems are especially important for elderly individuals with olfactory losses who may be unable to detect the "rotten-egg" smell of mercaptan which is added to natural gas as a warning agent. Novel mechanisms for visually indicating the presence of food-borne pathogens, via sensors or temperature logs integrated within food packaging materials, are in development and may ultimately help older adults who cannot discriminate spoiled from wholesome food using taste or smell cues.

## Conclusion

An awareness of changes in taste and smell in association with increased age has existed for thousands of years – the Roman statesman Cicero (106–43 BC) stated that "I am grateful to old age because it has made me less interested in good food and more interested in good conversation." Projected increases in both the size and average lifespan of the elderly population in the U.S. and worldwide will lead to an increased prevalence of chemosensory dysfunction, with a concomitant increase in the negative health consequences of these dysfunctions. Additional effective interventions that can maintain or improve chemosensory function in this vulnerable population are needed.

# Olfaction/Gustation Sensing Chemical Stimuli

Pierre-Marie Lledo
Pasteur Institute, Laboratory for Perception and Memory, Paris Cedex, France

## Introduction

The ►sensory systems are the devices with which we perceive the external world, while sensory perception amounts to the deconstruction of this external world for subsequent reconstruction of the internal representation. Animals indeed discriminate and recognize numbers of physical and chemical signals in their environment, which profoundly influence their behavior and provide them with essential information for survival [1].

A number of sophisticated sensory ►modalities available for that purpose all rely on a specific ►coding, that is a set of rules by which information is transposed from one form to another. For the ►chemical senses, this transposition concerns the ways by which chemical information give rise to specific neuronal responses in a dedicated sensory organ [2]. ►Olfaction is applied to chemosensory systems that detect chemicals emanating from a distant source. In contrast, when chemical senses require physical contact with the source for detection, they are called ►gustatory.

The origin of chemical detection (also called ►chemosensation) dates back to prokaryotes and has evolved into four distinct modalities in most vertebrates [3]. As we shall see below, the ►main olfactory system, the ►accessory olfactory system, the gustatory system and the so-called ►common chemical sense mostly carried by ►trigeminal sensory ►neurons, all differ with respect to receptor molecules, ►receptor cells and wiring of the receptor cells with the central nervous system (CNS).

Unlike most animals, humans primarily rely on ►vision and ►audition. The relevance of these two senses for human life have driven intense research into

the elucidation of visual and auditory perception, leaving the understanding of the more primitive chemical senses behind. Nevertheless, during the last two decades, modern neuroscience has made considerable progress in understanding how the brain perceives, discriminates, and recognizes ►odorant molecules. This growing knowledge took over when the chemical senses were no longer considered only as a matter for poetry or the perfumes industry [4]. Over the last decades, chemical senses captured the attention of scientists who started to investigate the different stages of chemosensory systems. Distinct fields such as genetic, biochemistry, cellular biology, neurophysiology and ethology have contributed to provide a picture of how chemical information is processed in the olfactory and gustatory systems as it moves from the periphery to higher areas of the brain. So far, the combination of these approaches has been most effective at the cellular level but there are already signs, and even greater hope, that the same is gradually happening at the systems level. ►Taste and olfaction researches caught up with the advance in other sensory systems through dramatic developments achieved in a recent past. All these advances started with the discovery of the genes encoding the chemosensory receptors of the olfactory [5] and taste [6] systems. Then, further achievements were performed following the development of new experimental tools brought into play by geneticists and molecular biologists and subsequently used by the physiologists.

Although far from being complete, to date we have a fairly comprehensive view about how chemicals interact with their cognate receptors to initiate signal ►transduction in the sensory receptor cells [7]. We know now how the sensory information is first transduced in the olfactory and gustatory systems by specialized ►receptor neurons located in dedicated sensory organs. Among the different relays along the olfactory and gustatory pathways, local circuits in the second- and third-order brain areas then process the simple mono-phasic sensory signal conveyed by the sensory neurons [8] to convert it into a multi-dimensional code, including among others a ►combinatorial coding. We are now about understanding how chemical information is encoded and processed, but it is the challenge for the next decade to uncover how sensory information triggers specific behavioral outputs.

## Two Distinct Chemical Stimuli

According to the phylogenetic position of the species, a number of very different but sophisticated ways, based on distinct sensory channels, have risen in order to process information from the external world in subsequently reformatted internal states [8,9]. The following synopsis describes the contributions of our understanding of chemical sensory systems that encompasses two intermingled senses: olfaction and taste. For the sake of clarity, these two modalities are presented separately, although they act, most often, in a concerted manner that gives rise to the so-called ►flavor [10,11]. Although chemical perception of a food or a flower arises from the central integration of multiple sensory inputs, it is possible to distinguish the different modalities contributing to it, especially when attention is drawn to particular sensory characteristics. Nevertheless, our experiences of the flavor or a fragrance are simultaneously of an overall unitary perception [11]. Research aimed at understanding the mechanisms behind this integrated chemical perception is, for the most part, relatively recent. However, ►psychophysical, neuroimaging and neurophysiological studies on cross-modal sensory interactions involved in olfaction and taste perception have started to provide an understanding of the integrated activity of sensory systems that generate such unitary perceptions, and hence the mechanisms by which these signals are functionally united when anatomically separated. Below I present the emerging picture that originates from the recent researches on ►odor and taste. The current model of chemosensory information processing supposes a particular combination of sensory inputs, ►temporal and ►spatial concurrence, and ►memory functions [12].

## The Sense of Smell

Mammalian olfactory system regulates a wide range of multiple and integrative functions such as physiological regulation, emotional responses (e.g., anxiety, fear, pleasure), reproductive functions (e.g., sexual and maternal behaviors) and social behaviors (►social chemosignals are involved in the recognition of conspecifics, family, clan or outsiders, for examples) [13]. To achieve this large variety of functions, two anatomically and functionally separate sensory organs are required. First, the ►vomeronasal organ is specialized to sense chemical compounds (e.g., ►pheromones), specific regarding the origin of the source. By transferring information through the ►accessory olfactory bulb, this sensory organ provides information about the social and sexual status of other individuals within the species. However, recent evidence also suggests some cross-talk between the main and accessory systems. Recent molecular and neurophysiological approaches have offered new insights into the mechanisms of pheromone detection in rodent and into the sensory coding of pheromone signals that lead to the gender discrimination or aggressive behavior, for example. They show that the vomeronasal organ does not have an exclusive function with regard to pheromone recognition but it responds also to molecules other than pheromones, at least in rodents. Thus, it is highly debated today, to what extent only the vomeronasal organ can detect

pheromones, and also to what extent it can only detect pheromones [14].

In mammals, the second sensory organ is represented by the ►olfactory epithelium, which recognizes more than a thousand airborne volatile molecules called odorant compounds (or odorants) [15]. This neuroepithelium is connected to the next central station for processing ►olfactory information: the main olfactory bulb (referred to below as the olfactory bulb). While advances in understanding olfactory transduction were taking place, interest in the olfactory bulb, was also intensified [15]. This growing interest has been spurred on by discovering the way the sensory organ connects to the olfactory bulb. Finally, several observations indicate that descending forebrain axons from various areas can selectively modulate olfactory bulb odorant-evoked responses. These data clearly show, at the very least, that olfaction processing does not involve simple feed-forward pathways. Rather, in real world situations where information has to be continually updated, olfactory responses that originate from the periphery are modulated by forebrain circuits and their projections to the olfactory bulb circuit.

## Evolutionary Dimensions of Olfaction

The main olfactory system detects only volatile odorants, whereas the accessory system picks up less volatile or even water-soluble odorants. It is generally thought that the accessory system specializes in pheromone detection, whereas the main system detects common odorants [2]. In terrestrial environments, chemical signals can be either volatile or non-volatile. Accordingly, terrestrial vertebrates have two functionally and anatomically distinct olfactory systems: one detecting volatile cues (the main olfactory system) and another thought to process mostly non-volatile signals (the ►vomeronasal system). Such a dichotomy has been brought into play to support the long-standing hypothesis according to which the vomeronasal system evolved as an adaptation to terrestrial life. Today, accumulated evidence rather contests this assumption. The evolution of a vomeronasal system in aquatic species might rather provide a selective advantage for terrestrial life, and consequently it could have been retained in many species of terrestrial vertebrates. In spite of this, anatomical studies, and most recently molecular studies indicate that the selective pressure to retain vomeronasal chemosensory input has been lost in higher primates. As a result, Old World primates, apes and humans might not have retained a functional vomeronasal system. Alternatively, species without a distinct vomeronasal system may still have an accessory olfactory system intermingled within the main system. Thus, it is yet possible that the accessory system did not "arise" at some point of the vertebrate evolution, but rather it just became anatomically separated from the main system [16].

As our knowledge about the neurobiology of olfaction is growing, it is becoming incredibly evident that the main olfactory systems of animals in disparate phyla have many striking features in common. For instance, vertebrate and insect olfactory systems display common organizational and functional characteristics [17]. Further recent works that were undertaken to broaden this scope to include nematodes, mollusks and crustaceans have only strengthened this assumption. The initial common event, shared by all odorant detection systems, requires the specific interaction of odorant molecules with specific receptors expressed on the cilia of sensory olfactory neurons before conveying information to central structures [18]. Basically, four features are shared by all olfactory systems. They include: (i) the presence of ►odorant binding proteins [19] in the fluid overlying the receptor cell dendrite; (ii) the requirement of ►G-protein-coupled receptors (GPCRs) [20] as ►odorant receptors ([5,21]; even though some sensory neurons may use transmembrane guanylate cyclase receptors such as in *C. elegans* and mammals); (iii) the use of a two-step signaling cascade in odorant transduction; and (*iv*) the presence of functional structures at the first central target in the ►olfactory pathway. All these characteristics may represent adaptations that have evolved independently, and therefore might provide us with valuable information about the way the nervous system processes odorant stimuli. Alternatively, these shared properties may instead reflect underlying homology, or could have arisen independently due to similar constraints.

Similarly, the perception of odorant molecules arises from invariant series of information-processing steps that occur in anatomically distinct structures. In mammals, the olfactory epithelium contains several thousands of bipolar olfactory sensory neurons, each projecting to one of several modules in the olfactory bulb. These discrete and spherical structures, called ►olfactory glomeruli, are both morphological and functional units made of distinctive bundles of neuropil. This term reflects both the homogeneity of the sensory inputs conveyed by the ►olfactory nerve, and the degree to which the neurons in the same glomerular unit are interconnected. In different species, each glomerular structure results from the convergence in the olfactory bulb of 5–40,000 axon terminals of sensory neurons that express the same odorant receptor. As each group of glomerulus-specific output neurons is odorant receptor-specific, they form a morphologically defined network somewhat analogous to ►ocular-dominance columns in ►visual cortex or to ►barrels in the ►somatosensory cortex [22]. It is also worth noting that a number of mechanisms have evolved to ensure that only a single odorant receptor is expressed per sensory cell. In rodents, tight transcriptional control results in the choice of one among a possible thousand odorant receptor genes. This

extremely large repertoire of odorant receptors is undergoing rapid evolution, with at least 20% of the genes lost to frame-shift mutations, deletions and point mutations that are the hallmarks of ►pseudogenes [3,4]. Facing a changing environment, this characteristic may reflect the pressure made on a gene family to diversify and generate large numbers of new receptors that might confer new selective advantages. Interestingly, approximately 50% of human odorant receptor genes carry one or more coding region disruptions and are therefore considered pseudogenes. This massive pseudogenization of the odorant receptors repertoire in humans and Old World primates is preceded by a moderately high level of pseudogenes (approximately 30%). Thus, there has been a decrease in the size of the intact odorant receptor repertoire in apes relative to other mammals, with a further deterioration of this repertoire in humans. Since such decline occurred concomitant with the evolution of full ►trichromatic vision in two separate primate lineages, it is possible that the weakening of olfaction results from the evolution of full ►color vision in our primate ancestors [23]. However, several overlooked human features such as the structure of the nasal cavity, retronasal smell, olfactory brain areas, and language call for reassessing the status of the sense of smell in human beings [24].

## From Odorant Molecules to Cortical Centers

The olfactory system is responsible for correctly coding sensory information from thousands of odorous stimuli. To accomplish this, odor information has to be processed throughout distinct levels. At each one, a modified representation of the odor stimulus is generated. To understand the logic of olfactory information processing, one has first to appreciate the coding rules generated at each level, from the odorant receptors up to the level of the ►olfactory cortex [25,26]. In mammals, the initial event of odor detection takes place at a peripheral olfactory system, the olfactory epithelium of the nasal cavity. There, olfactory transduction starts with the activation of some of the thousand different types of odorant receptors located on the cilia of sensory neurons that comprise the olfactory neuroepithelium. The sensory neurons project to a small number of olfactory glomeruli paired on both the medial and lateral aspects of the olfactory bulb. About 20–50 second-order neurons emanate for each glomerulus and project to a number of higher centers, including the olfactory cortex. Using a trans-synaptic tracer expressed in olfactory receptor neurons under the control of two specific olfactory receptor promoters, it was possible to demonstrate that the projection of bulbar output neurons receiving sensory inputs from homologous glomeruli, form reliable discrete clusters in different regions of the olfactory cortex. Such clusters can be partly overlapping, but clearly distinct between odorants (a process called ►odor maps). A certain overlap between more diffuse projections to higher olfactory centers may constitute the anatomical basis for crosstalk between information strands emanating from different odorant receptors. This characteristic is probably helpful to integrate multiple modules of olfactory information into a composite ►gestalt, specific for a particular scent made of numerous chemical compounds.

## From the External World of Odorants to Internal States

Even in humans, during the first hours of life in the open air, the newborn child behaves like a macrosmatic animal. Meanwhile, the human being is totally dominated by ►affect. During the rest of the development period and all of adult life, olfaction will remain the sense that opens the most direct route to the affective sphere [27].

To achieve this privileged relationship between olfaction and affect, the two olfactory systems connect different areas. The vomeronasal system mainly projects to the ►hypothalamus and ►amygdala that are known to control innate endocrine or behavioral responses. In contrast, in the main olfactory system, information is processed in cortical areas, which may give rise to the conscious representation of odorant molecules. In primates, the projections from the olfactory bulb reach medial olfactory areas including the ►piriform (►primary olfactory) ►cortex, ►entorhinal cortex, cortico-medial nucleus of the amygdala, and ►olfactory tubercle. From the ►piriform cortex (Primary olfactory cortex), projections reach ►area 13, a part of the caudal ►orbitofrontal cortex, and from there on to different orbitofrontal areas.

Odors are important in emotional processing; yet relatively little is known about the representation of the affective qualities of odors in the human brain. Recent results suggest that there is a ►hedonic map of the sense of smell in brain regions such as the orbitofrontal cortex [26,27]. These results have implications for understanding the psychiatric and related problems that follow damage to these brain areas. It is remarkable that amongst all the senses, olfaction possesses a particular link with the ►limbic system that was taken to be the "nose-brain" (the actual meaning of ►rhinencephalon). Today, it is clear that the primary olfactory cortex projects to the entorhinal area, which in turn projects to the ►hippocampus. Thus, we see reintroduced, after years of fervent affirmation followed by years of fervent denial, the idea that the hippocampus receives olfactory inputs. The pathway that links olfaction to the limbic system seems to be privileged. The path from the olfactory epithelium is more direct than the path from sensory surfaces such as the skin. Moreover, the primary olfactory cortex projects to the amygdala, in large part onto a particular cell group, the lateral nucleus

of the amygdala, by bypassing the neocortex. However, while it is clear that the olfactory bulb projects to the amygdala in rodents, one wonders whether such a connection is still present in humans. For instance, the vomeronasal organ and the corresponding region of the accessory ►olfactory bulb are thought to form an apparatus dedicated to the processing of sexually significant odors, but in the fully formed human body none of these structures has been identified.

Non-invasive functional imaging studies of the human olfactory system revealed that the sense of smell is organized similarly to other sensory modalities, and that the specific psychological characteristics of olfaction should be attributed to an early involvement of the limbic system rather than a conceptually different mode of processing. Taking into account the high connectivity of limbic structures and the fact that activation of the amygdala immediately induces ►emotions and facilitates the coding of memories, one should not be so surprised to uncover the special relationship that links olfaction with emotions and memory.

In sum, as a result of unprecedented developments in methods for examining the structure, function, and neurochemistry of olfactory system circuits, research in olfaction has progressed dramatically in recent years. Applying new technologies, including those of neurophysiology and functional imaging should help to unravel the mysteries of how chemical perception gives rise to unique olfactory experiences such as those triggered by the exquisite fragrance of jasmine.

## The Sense of Taste

The ►gustatory sense enables animals to detect and discriminate among foods, to select nutritious diets, and to initiate, sustain and terminate ingestion for the purpose of maintaining energy balance [11]. For most mammals, the decision to ingest a particular food depends not only on its taste but also on its appearance, familiarity, odor, texture, temperature and, importantly, its post-ingestive effects (for example, the ability to reduce hunger). For humans, such factors also include cultural acceptance as well as the social, emotional and cognitive contexts under which a given food is eaten. Revealing the logic of the neural mechanism of gustation is currently a major topic in modern neurobiology, given the efforts made so far towards the understanding of how complex feeding behaviors can become dysfunctional (as in the case of anorexia or obesity) [28].

In marked contrast to the olfactory system, the gustatory system has little discriminative power. Sapid stimuli come as five basic tastes, sweet, umami, bitter, salty and sour while the olfactory sensory organ recognizes about 10,000 airborne volatile molecules, in human beings. Taste stimuli are detected by assemblies of about 100 cells that form well-known specialized morphological structures, the ►taste buds, which are located in the chemosensory papillae on the tongue. However, we know astonishingly little about the precise function of these small chemosensory organs. Their characterization has largely relied on cytological and ultrastructural data [29].

### The Peripheral Gustatory System

Although the sense of taste is generally associated solely with the activation of taste buds, placing food or drinks in the mouth automatically elicit responses from several distinct systems that monitor the temperature, the sound when chewing, and texture of the food. In this regard, gustation is inherently multisensory [30]. Every gourmet worth his/her salt is aware that the list of the five basic tastes should also include further perceptual categories such as astringent, fatty, tartness, water, metallic, starchy, cooling, tingling and pungent. The subjective sensations associated with these non-primary tastes result from the co-activation of taste and specialized somatosensory neurons located in the oral cavity. These specialized neurons surround taste buds, and include different classes of mechano- and chemoreceptors that transmit information on the food's texture, weight and temperature to the brain mainly via the ►trigeminal system.

### Transduction Pathways for Primary Tastes

In the oral chemosensory epithelia, taste buds contain about 50–100 ►taste receptor cells (TRCs) of various types. These TRCs are embedded in stratified epithelia and are distributed throughout the tongue, palate, epiglottis and esophagus. On their apical end, taste cells make contact with the oral cavity through a small opening in the epithelium called the taste pore, which is filled with microvilli. The plasma membranes of these microvilli contain many of the receptors responsible for detecting the presence of various tastants. Small clusters of TRCs are electrically and chemically coupled by ►gap junctions allowing their synchronous activation.

On the palate and the anterior tongue, TRCs are innervated by the ►chorda tympani nerve and greater superior petrosal branches of the ►facial nerve, respectively. These nerves transmit information about the identity and quantity of the chemical nature of the tastants. On the epiglottis, esophagus and posterior tongue, TRCs are innervated by the lingual branch of the ►glossopharyngeal nerve and the superior laryngeal branch of the ►vagus nerve. These nerves are responsive to tastants and participate primarily in the brainstem-based arch reflexes that mediate swallowing (ingestion) and gagging (rejection). TRCs transmit information to the peripheral nerves by releasing ►ATP to ►P2X purinergic receptors located on the postsynaptic membrane of primary afferents. Other transmitters

such as ►serotonin, ►glutamate and ►acetylcholine might also be released.

The key to understanding how TRCs transduce chemical stimuli lies in determining the identification and operation of different types of taste receptor and their downstream signaling pathways. As for olfaction, proteins belonging to the G-protein-coupled receptor superfamily have been established as the receptors for sweet tastants (taste receptor, type 1, member 2 (T1R2)/T1R3), amino acids (T1R1/T1R3) and bitter (T2Rs) tastants. The sensations associated with the other two primary tastants, sour and salt (NaCl), are mediated by ion channels of the ►transient receptor potential (TRP) and ►epithelium sodium channel (ENaC) superfamilies, respectively.

## Taste Pathway

Receptor cell depolarization leads to the release of neurotransmitter, which generates first post-synaptic potentials and then action potentials in the associated nerve endings. The axons, whose cell bodies lie in the sensory ganglia of the cranial nerve, enter the medulla and synapse in the region of the ►nucleus of the solitary tract (N. tractus solitarii). The nerve cells in this part of the medulla are important in mediating salivation and other gastrointestinal reflexes. Their axons also cross over, and relay via the contralateral ►medial lemniscus, to the ►thalamus, and thence to the post-central gyrus in the region of the ►insula.

## Coding in the Periphery

Two schemes have been proposed to explain how taste processing is achieved through the interaction of TRCs with their associated afferent nerve fibers: the ►"labeled line" model and the "►across-fiber pattern" (or "distributed") model [11]. The assessment of experimental data supporting either of these hypotheses constitutes an important source of debate in the field of gustatory physiology. The ►labeled line hypothesis (model) implies that sensory information is processed through segregated and feed-forward circuitry that connects peripheral sensory receptors to higher-order structures in the CNS. By contrast, across-fiber pattern models propose that sensory fibers (or neurons) are broadly tuned, in such a way that stimulus identity and intensity are specified by a unique combinatorial pattern of activity distributed across populations of neurons.

At the peripheral level one can find experimental support for both labeled line and across-fiber pattern models, but recent data from genetic studies strongly favor the existence of labeled lines. The validity of either model at the periphery should not necessarily be generalized to CNS circuits. In contrast to the periphery, the CNS possesses the anatomical structure required for ►multisensory integration and this ability might determine a difference in coding strategies between the CNS and peripheral nervous system (PNS). In fact, much of the current neurophysiological data describe gustatory processing as multisensory and distributed across several brain regions [31].

In contrast to the highly specialized information transfers performed by TRCs and peripheral fibers, central gustatory processing seems to be distributed, probably as a result of its capacity for ►multimodal (multisensory) integration. Approaching the encoding of a gustatory stimulus in this manner will provide new insights into how information is encoded, beyond the theories that have been historically proposed to model the mechanisms by which taste quality is coded in the periphery. Indeed, how these sensory modalities are synthesized into a single percept, which allows animals to rapidly decide whether to ingest or reject a particular food, is the greatest challenge for the near future in gustatory physiology.

The growth of our knowledge in gustation has not yet reached the level of olfaction. Many fundamental problems in the emerging field of taste are still to be resolved. For example, what is the coding logic for multisensory integration? How is a taste percept generated from activation of labeled- or distributed-lines? Answers to these basic questions might help us understand how the brain makes sense of chemical compounds that we daily place in the mouth.

## Concluding Remarks

Smell and taste problems can have a big impact on our lives. Because these senses contribute substantially to our enjoyment of life, our desire to eat, and be social, smell and taste disorders can be serious. When smell and taste are impaired, we eat poorly, socialize less, and as a result, feel worse. Many older people experience this problem. But not only chemical signaling make us happier, smell and taste also warn us about dangers, such as fire, poisonous fumes, and spoiled food. Certain jobs require that these senses be accurate – chefs and firemen rely on taste and smell. Loss or reduction of the sense of smell (►anosmia or ►hyposmia) may be due to damage to the olfactory mucosa (e.g., in smoking) or to the olfactory bulbs or tracts. CNS disorders (e.g., some types of ►epileptic seizures) can cause ►parosmia (disturbed sense of smell). Like olfaction, the sense of taste is important in regulating appetite and to some degree, dietary intake. Loss or reduction of the ability to taste is termed ►ageusia or ►hypogeusia and is a widely distributed feature of ageing as more than 200,000 people visit a doctor with smell and taste disorders every years in the United States.

Strikingly, olfactory and gustatory systems are endowed with rejuvenating properties throughout life. Olfactory and taste cells are one of the few cell types of the nervous system to be continuously replaced when the sensory organs become old or damaged. Scientists are examining this phenomenon,

called adult ►neurogenesis [32], while studying ways to use this potential to replace other damaged nerve cells of the CNS.

Smell and taste have here been presented separately but one should keep in mind that about 75% of what we perceive as taste actually comes from smell. It is the odor molecules from food that give us most of our taste sensation as taste buds allow us to perceive only five flavors. Of all our senses, smell is our most primal. Animals need the sense of smell to survive. Although a blind rat might survive, a rat without its sense of smell can't mate or find food. For humans, the sense of smell communicates many of the pleasures in life–the aroma of a pot roast in the oven, fresh-cut hay, a rose garden. Although our sense of smell is our most primal, it is also very complex. To identify the smell of a rose, the brain analyzes simultaneously over 300 odor molecules. The aroma of a baking apple pie sends one message when someone is hungry and quite another when that person has just finished a six-course meal!

Although recent discoveries in the field of molecular biology raise the hope of a future understanding of the transduction and peripheral coding of odors and tastes, it seems that they imply a risk: to make us forget that in the other extreme of knowledge, that of maximal complexity, the evolution of cognitive sciences allows an epistemologically fruitful reformulation of information-processing problems. In the future, we have to try to find out to what extent higher-order processes interact with the sensory level in order to produce sufficiently reliable representations, as compared with what we know about vision and audition, for instance. After all, we should not forget what Sigmund Freud, addressing the members of the Vienna Psycho-analytical Society, said about olfaction: "*the organic sublimation of the sense of smell is a factor of civilization*."

### Definition
The olfactory bulb is the first relay station in the olfactory pathway, situated at the rostral end of the brain. It receives sensory input from olfactory receptor neurons located in the nasal cavity and sends output fibers to a group of hemispheric regions collectively termed the olfactory cortex.

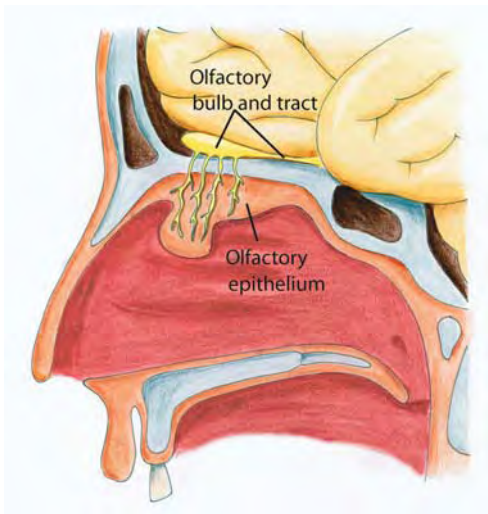
## Characteristics

The olfactory bulbs develop from the ventral surface of the cerebral hemispheres and in the large majority of vertebrates they represent the most rostral extension of the neural axis. In apes and humans, however, the olfactory bulbs lie on the ventral surface of the frontal lobes, just above the nasal cavities, from which they are separated by the cribriform plate of the ethmoid bone (Fig. 1).

The unmyelinated axons of the olfactory nerve pass through this bone and reach the olfactory bulb, where they terminate in spheroidal regions of neuropil called glomeruli. Head trauma can lesion the olfactory nerve fascicles as they traverse the cribriform plate, resulting in anosmia. The olfactory tract leaves the posterior pole of the olfactory bulb. It contains the output projections of the bulb as well as afferent fibers originating from a variety of brain regions.

In most vertebrate species, the olfactory bulb is organized according to the same basic plan and, as in other cortical regions, it shows a laminated structure, consisting of seven concentric layers (Fig. 2).

The principal (output) neurons of the bulb are the mitral and tufted cells (M/T cells), which can be divided into multiple subtypes based on position, dendritic morphology and axonal projection patterns. Mitral and tufted cells receive excitatory sensory inputs in the glomerular layer and send their axons to different regions of the olfactory cortex. Apart from this straight-through pathway, there are other neurons that act locally and make predominantly inhibitory connections with the principal cells. Synaptic inhibition plays a crucial role in the processing of olfactory information before it is transmitted to the olfactory cortex (see below).



**Olfactory Bulb. Figure 1** The olfactory bulb is a small ovoid structure that lies on the cribriform plate of the ethmoid bone. It receives input from olfactory sensory neurons located in the nasal cavity and projects to the olfactory cortex through the olfactory tract. (Courtesy of Dr. Alessandro Ciccarelli.)

It should be noted that neuronal excitation in the olfactory bulb is mediated primarily by glutamate, whereas GABA is the principal inhibitory neurotransmitter. In addition, the olfactory bulb is rich in several other neuroactive substances, which likely exert a neuromodulatory function.

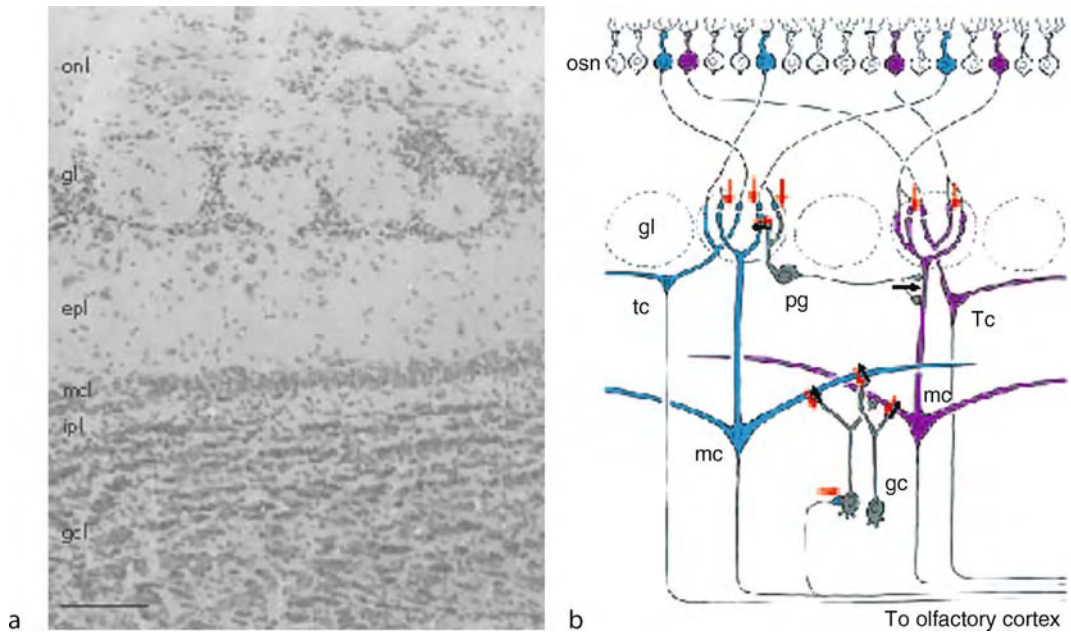
The circuit organization of the olfactory bulb can be conveniently separated into two distinct levels [2]. Sensory inputs from the ▶olfactory sensory neurons are first processed within the glomeruli, where they are subject to amplification and attenuation. The second level of processing involves reciprocal interactions between the principal neurons and local interneurons, which provide GABAergic inhibition through dendro-dendritic synapses.

## Input Processing

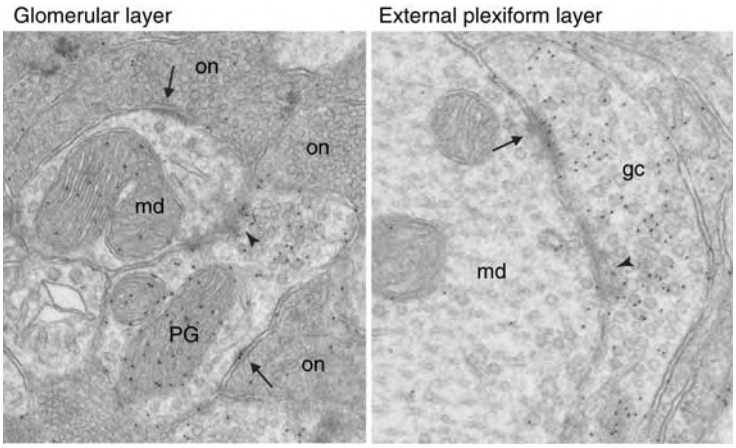
Within the glomeruli, sensory axons make excitatory synaptic connections with the apical dendrites of the output neurons and a heterogeneous class of intrinsic neurons called periglomerular cells (▶periglomerular cell in olfactory bulb) (PG) (Fig. 3).

In addition, PG cells are interconnected with M/T cells through dendro-dendritic synapses. Several types of dendro-dendritic synapses have been described, including excitatory synapses from M/T cells to PG cells, inhibitory synapses from PG cells to M/T cells, and synapses between distinct subtypes of PG cells. While there is no evidence for dendro-axonic synapses onto olfactory nerve axons, it has been shown that GABA and dopamine inhibit glutamate release from these axons by activating presynaptic receptors ($GABA_B$ receptors and dopamine $D_2$ receptors, respectively). It is likely that the paucity of glial barriers within the glomerular neuropil facilitates the diffusion of neurotransmitter and the occurrence of nonsynaptic interactions. The current model suggests that intraglomerular microcircuits contribute to regulate transmission from the olfactory nerve to M/T cells and thus serve as a gain control mechanism of incoming sensory signals.

A remarkable specificity exists in the projection pattern of olfactory receptor neurons to the glomeruli. First, each glomerulus is the site in which thousands of sensory axons converge on the dendrites of just ~20–50 relay neurons. A notable feature is that the axon of each sensory neuron terminates in only one glomerulus and, similarly, the apical dendrite of each principal neuron (mitral or tufted cell) arborizes into a single glomerulus. Second, all of the olfactory axons terminating in a glomerulus express the same odorant receptors (out of a repertoire of ~1,000 genes in rodents). Third, olfactory sensory neurons expressing a specific type of odorant receptor usually innervate two distinct glomeruli, which



**Olfactory Bulb. Figure 2** (a) Coronal section of the rat olfactory bulb illustrating the laminar organization. Scale bar: 100 μm. (b) Circuit diagram summarizing the basic synaptic organization of the olfactory bulb. Two glomerular units are shown, each receiving input from olfactory sensory neurons (osn) expressing a given type of odorant receptor and connecting to a subset of mitral cells (mc) and tufted cells (tc). Periglomerular cells (pg) and granule cells (gc) mediate feedback and lateral inhibition of principal neurons through axo-dendritic and dendro-dendritic synapses. *Red arrows* indicate excitatory synapses, and *black arrows* indicate inhibitory synapses. (Adapted from [1]; courtesy of Dr. Alessandro Ciccarelli.)



**Olfactory Bulb. Figure 3** Synaptic connections of the olfactory bulb as shown by electron microscopy after postembedding immunogold labeling with an antiserum against GABA (courtesy of Dr. Patrizia Panzanelli). Gold particles of 10 nm identify GABA-immunopositive structures. In the glomerular layer, olfactory nerve axons (on) make asymmetrical synapses (*arrows*) with two dendritic profiles. One dendrite is GABA-positive and therefore belongs to a periglomerular cell (pg). The other dendrite (md) likely belongs to a mitral/tufted cell. Note that the pg dendrite also makes a dendro-dendritic synapse (*arrowhead*) with the md profile. External plexiform layer. A reciprocal dendro-dendritic synapse between a mitral cell dendrite (md) and a granule cell spine (gc) is shown. Note that the granule cell spine is GABA-positive. The mitral-to-granule synapse (*arrow*) is asymmetrical, whereas the granule-to-mitral synapse (*arrowhead*) is symmetrical.

are bilaterally symmetrical and similarly located in the olfactory bulbs of different animals [3]. Therefore, a glomerulus can be defined as a convergence center for inputs originating from a given type of odorant receptor. This specificity implies that glomeruli represent basic functional units, analogous to cortical columns, and that different odors are represented by different patterns of spatial activity in such glomerular units [1] (see glomerular map).

## Inhibitory Control of Mitral/Tufted Cells

The second level of information processing in the olfactory bulb is based on reciprocal synapses between the principal neurons and the granule cells (Fig. 3). Granule cells are axonless neurons, whose cell bodies give rise to an apical dendrite that extends radially in the external plexiform layer [4]. The dendrites of granule cells are characterized by the presence of large spines (also called gemmules), that establish reciprocal synapses with the dendrites of M/T cells [5]. In these reciprocal connections, both sides of the synapse are dendrites capable of releasing neurotransmitter. The dendrites of M/T cells release glutamate and excite the spines of granule cells, which in turn release the inhibitory neurotransmitter GABA back onto the principal neurons (Fig. 2). As a result, activated M/T cells can inhibit themselves (feedback inhibition), as well as their neighbors (lateral inhibition).

There is compelling evidence that lateral inhibition is crucial in refining olfactory information, as it enhances the contrast between the activity of M/T cells connected to different glomerular units, and thus sharpens the tuning specificity of the output neurons to different odor molecules [1]. In other words, activation of M/T cells associated with one glomerulus results in inhibition of other glomerular units through the reciprocal dendrodendritic interactions. Therefore, the lateral inhibition mediated by granule cells enhances the contrast between strongly activated and faintly activated glomerular units and increases the specificity of individual M/T cells to odor molecules. Given that the basal dendrites of mitral cells have a projection field with a radius of about 1 mm, they potentially can influence the activity of glomerular units over long distances. This is consistent with experimental evidence that odor maps are widely distributed in the glomerular layer [6].

Lateral inhibition is also important for synchronizing the output responses of M/T cells connected to functionally related glomeruli. It has been known for a long time that stimulation with odor molecules elicits γ-frequency (30–80 Hz) oscillations of local field potentials, reflecting synchronized spike discharges of the principal neurons. This synchronization likely serves as a mechanism for temporal summation of signals from different glomerular units, and may play an important role in odor discrimination [7]. Of particular interest is the possibility that plastic changes in the strength of dendro-dendritic synapses may represent one mechanism underlying olfactory learning.

## Other Neuronal Populations

In addition to PG cells and granule cells, there is a relatively small population of short-axon cells, which are distributed in the glomerular and granule cell layers. Recent studies suggest that interglomerular interactions mediated by short-axon cells represent a mechanism by which activated glomeruli can influence the activity of other glomerular units and contribute to enhance the spatial responses to odors [8]. In addition, one type of short-axon cell located in the granule cell layer provides GABAergic inhibition onto granule cells and therefore can control the strength of feedback and lateral inhibition onto the principal neurons [9].

## Centrifugal Afferents

The olfactory bulb receives a prominent innervation by centrifugal fibers from a variety of sites in the brain. The best characterized are cholinergic fibers arising from the basal forebrain and noradrenergic and serotoninergic fibers arising, respectively, from the *locus coeruleus* and the mesencephalic raphe nucleus. These centrifugal afferents mediate a considerable degree of control over olfactory processing, which seems to be important for adapting olfactory function to different behavioral states. Of particular interest is the action of noradrenaline, which suppresses granule cell inhibition of M/T cells. Noradrenergic modulation of dendro-dendritic inhibition has been involved in some forms of olfactory learning.

## Parallel Processing of Olfactory Stimuli

As in other sensory systems, the olfactory bulb contains several parallel pathways for processing olfactory information. An obvious case is the accessory olfactory bulb, a structure present in most terrestrial vertebrates that receives sensory inputs from the vomeronasal organ. Within the main olfactory bulb, there is evidence for specialized glomerular units that process certain types of olfactory stimuli. For instance, the so called "modified glomerular complex" has been implicated in suckling behavior in neonatal animals. Mitral and tufted cells also appear give rise to parallel output pathways from the olfactory bulb. These neurons interact with different subpopulations of granule cells and project their axons to different cortical regions [10]. However, our understanding of how mitral and tufted cells process distinct aspects of olfactory information is still preliminary.

## Plasticity

The olfactory bulb is one of the few brain regions in which neurogenesis in maintained throughout life.

Bulbar interneurons are continuously replaced from a population of stem cells located in the subventricular zone of the lateral ventricle. Neuroblasts generated in this area migrate along the rostral migratory stream to the olfactory bulb, where they complete their differentiation into GABAergic neurons. Similarly, olfactory sensory neurons undergo continuous turnover during adult life. Remarkably, these neurons can reestablish functional synaptic connections with their target cells in the olfactory bulb. This degree of plasticity is unmatched in the brain and makes the olfactory bulb a unique model for studying the mechanisms of neural development and cell replacement.

## Olfactory Bulb Glomerulus

### Definition

An olfactory glomerulus is a compartmentalized mass of neuropil in the glomerular layer of the olfactory bulb that contains synapses between olfactory sensory neuron axon terminals and dendrites of both projection neurons (mitral and tufted cell apical dendrites) and local periglomerular cell inhibitory interneurons. Glomeruli also contain numerous dendrodendritic synapses between mitral or tufted cells and both periglomerular and so-called short-axon cells. A typical rodent olfactory glomerulus receives convergent projections only from sensory neurons expressing the same odorant receptor gene. At the neuronal circuit level, an individual glomerulus in the olfactory bulb may function as a molecular-feature detecting unit.

## Olfactory Bulb Granule Cells

### Definition

These are a large population of small GABAergic interneurons in the vertebrate olfactory bulb that do not receive sensory input directly. They form dendrodendritic reciprocal synapses with mitral cell lateral dendrites and also receive axodendritic synapses from mitral cell axon collaterals and centrifugal fibers. Most of their inputs are glutamatergic, but they also receive GABAergic inputs. Most olfactory bulb centrifugal inputs target the granule cells.

## Synonyms

Downstream neural structure of the olfactory bulb

## Definition

Referring to multiple structures receiving olfactory information and presenting the classical cyto-architecture of nervous cortex, "olfactory cortices" is a more correct definition of the topic of this article.

*Stock of knowledge.* Details of the ►primary cortical projections of the olfactory system indicate the diversity of the structures that are directly connected to the olfactory bulb neurons (Fig. 1).

## Characteristics

The graph is soon a divergence from the canonical hierarchical organization of a sensory pathway. The bulbar output is conveyed by the lateral olfactory tract. On the functional point of view, we do assume that a topographical representation of the olfactory stimulus based on the chemical features takes place in the glomerular layer of the olfactory bulb.

From the receptor level, the primary ►olfactory cortex is reached through two synapses only. The receptor neurons are connected to mitral and tufted cells in the olfactory bulb. These relay neurons feed the pyramidal cells of the cortex, a three-layered paleocortex. The primary olfactory projections are annexed to the ►limbic system, an associative area. This system plays a role in social and emotional processing and supports some of the mechanisms of the memory.

Two neurons, two synapses: It is noticeable that this short pathway bypasses the thalamus before displaying cortical representations of the stimulus. This peculiar arrangement differing from those observed in other sensorial modalities can be explain by the fact that olfactory modality got ahead the emergence of the thalamic structures in the phylogenesis. On a functional point of view, this also means that probably in the olfactory system the processes fulfilled by the thalamus are implemented in other structure(s), and logically, in the downstream structures (thus the olfactory bulb) and/or the structures described the present chapter. It looks likely as both olfactory bulb and olfactory cortices receive modulating influences from diverse centers, including for instance the arousal or the satiety control systems.

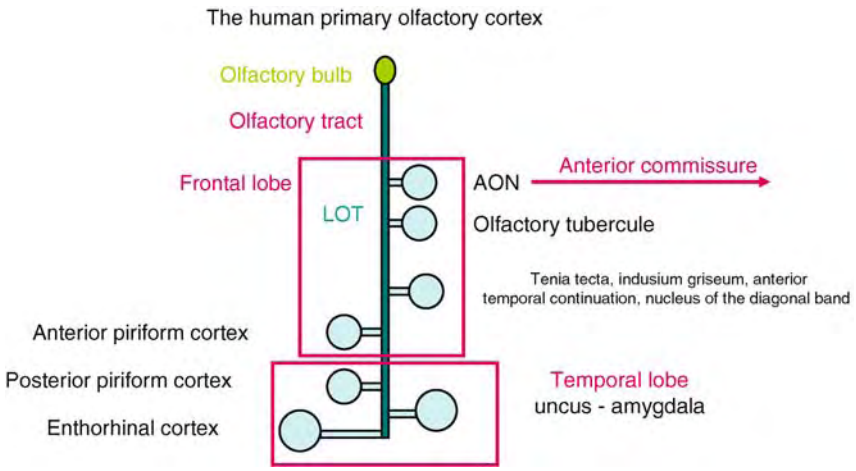
Focusing on the functional properties of the olfactory cortices, they are considered both as the targets of relay neurons from the olfactory bulb and as the origin of neurons contacting neocortical associative territories such as the orbito-frontal cortex, the neocortical temporal cortex … and even parts of the thalamus!

The ►primary olfactory cortex includes contiguous or dispersed structures in the medial aspect of the temporal lobe of the brain which homologous equivalents are not easy to identify among different species. In order to describe the functions of the olfactory cortex, we get information from different animal models, rat, mouse, rabbit or frog, including man. In the view of this complexity, the terminology itself can be misleading: For instance the anterior olfactory nucleus which is funded by the fibers of the lateral olfactory tract, is a true cortex, characterized by the presence of pyramidal neurons. For those reasons, we have limited the description to the main structures: the anterior olfactory nucleus, the piriform cortex, the olfactory part of the amygdala and the entorhinal cortex. A ►secondary olfactory cortical area taking information from ►primary olfactory cortices, the orbito-frontal cortex will be also envisaged in the article.

With the olfactory cortex processing, important integrations of the olfactory signal follows the first sharpening of the information captured from the chemical environment by the receptor organ. If in the olfactory bulb the chemical nature of the stimulus is decomposed (de-constructed representation of odorants), in the olfactory cortex several tasks of reconstruction (re-constructed representation) take place, add memorized information and finally these levels of processing tend to confer a "meaning" to the actual olfactory message.

## Primary Cortical Projections

*Anterior olfactory nucleus.* Natural odorants are mixtures of chemicals. To imagine the integrative processes of the neurons, one can test how the neurons are responding to chemical mixtures and to their isolated components. While bulbar neurons show a



**Olfactory Cortex. Figure 1** The human primary olfactory cortex: The hierarchical representation of the olfactory pathway describes a multi-unit network: The olfactory tract is constituted of the mitral and tufted-neuron axons, the relay neurons directly connected to the receptor neurons from the olfactory receptor organ in the olfactory bulb. By this pathway a number of cortical structures receive direct sensory inputs. They are distributed in different parts – frontal temporal – of the cerebral cortex. These primary cortical elements are largely interconnected and receive modulations from different higher centers (arousal, satiety…). The first part, anterior olfactory nucleus and piriform cortex are concerned by sharpening of the sensory message. The other units are involved in control of emotional responses, behavioral responses to odorant stimulations and in olfactory learning.

sparse responsiveness they show high selectivity and they often respond to only one of the components in a mixture. In the anterior olfactory nucleus, the majority of neurons can respond to mixture of dissimilar chemicals and to their isolated components. In addition, the responses to the mixture exceed the simple sum of the responses to each of its components [1]. These properties point out a first kind of integrative process that the neuronal populations of ►primary cortical olfactory level are able to realize: This is a simple sharpening of the sensory input message.

*Piriform cortex.* Extensively connected with higher-order cortical areas, the piriform cortex received also direct afferences from the olfactory bulb. The receptor fields of its neurons have been characterized by neuronal tracing, giving a spatial idea of the coding of the odorant stimuli [2] while electrophysiological recording of the neuronal responses to odorants gave a functional view [3]. As a ►primary cortex, it could take part to the extraction of specific features from the olfactory message, thus used the combinatorial analytic representation of the sensory signal provided by the olfactory bulb. At this level, some neurons require particular combinations of chemicals to respond, thus suggest a combination of signals from distinct samples of bulbar neurons [4]: The cortex plays a role in discrimination of odorant signals. Nevertheless, at this early level, some modulations of the neuronal responses in behaving rats by non olfactory information (reward, expectation) were found, adding associative functions to its competences. In that sense, this "►primary" cortex differs from primary cortices (►primary, secondary cortices) of the other sensorial modalities, which are rather dedicated to sharpen the input message. The olfactory piriform cortex must be regarded as a piece of olfactory learning and memory [5] It is of great importance to note that the receptive fields of the neurons in this cortex change with the experience: This property is indicative of upper-stream associative areas in the other sensorial modalities.

According to neuronal tracing, the partial overlapping of the projections from different receptor channels in the piriform cortex suggests that the cortex is able to merge different elements of the peripheral signal. In the anterior olfactory nucleus or in anterior piriform cortex, the selectivity of neurons to diverse chemical or perceptual categories appears to be broader than that of the bulbar relay neurons. This is true assuming that, due to the functional convergence of receptor neurons on bulbar glomeruli, the output neurons, mitral and tufted cells, have relatively narrow ►selectivity profiles. (We must notice some discrepancy about the chemical selectivity of the bulbar neurons reported in different studies). Nevertheless, the complex selectivity profiles of the cortical output neurons means that these neurons integrate several odorant features.

*Odorant quality coding in the olfactory piriform cortex.* Tracing the projections area of the output bulbar neurons, it is possible to discriminate an anterior part and an posterior part of the piriform cortex [2]. This is confirmed by functional observations of the spatial organization of the responses to hedonic contrasted chemical stimuli in human [6]. While the

anterior part seems to encode the chemical features, the posterior part could discriminate stimuli along a qualitative dimension, i.e. their odor. Following the partial functional convergence shown by the bulbo-cortical relationships, the anterior piriform Cortex could reconstruct the complex environmental stimuli that have been decomposed by the topographic arrangements of the bulbar projections of the hundreds of specific olfactory receptors. The mechanisms or the rules of this reconstruction are not known. In this debate, the representation suggested by the topographical combinatorial theory plays a central role. However, one must notice that several studies on electrophysiological reports confirms that the selectivity of the bulbar neurons is scarce, but indicate that these neurons convey activations elicited by very different chemical structures [3,4]. The integration of this information on the discrimination processing by the cortical neuronal population must be further examined.

*Contributions of olfactory cortices to behavioral controls.* Several other olfactory cortices, recruiting even a larger amount of influences, are also directly connected to the olfactory bulb.

The amygdala is in fact a series of nucleus, receiving inputs from multiple ascending sensory pathways, including olfactory, gustatory, visual, auditory and visceral information, more or less directly from the sensory organ, thus after more or less stages of treatment. Here again the afferent olfactory pathway is the shortest. Extending influences on the hypothalamus, the medulla or the spinal chord, the amygdala is implicated in the modulation of the visceral functions in relation with emotional status. By its connections with the nearest olfactory structures in the rostral temporal lobe, it modulates their activity according to the mood or the emotional life of the animal.

Different implications of the olfactory amygdala on animal behavior have been investigated. In fact the different cortical olfactory structures, including amygdala, entorhinal cortex, perirhinal cortex are interconnected: Consequently, the exerted controls supported by olfactory cues are the effects of a network of specialized structures.

Fear olfactory conditioning or olfactory conditioned food or beverage aversion are examples that can give an idea of the functions of these networks.

Differential implication of theses area has been shown in their contribution to olfactory and contextual fear conditioning. The amygdala participates in the acquisition and the expression of fear conditioned to both an olfactory conditioned stimulus and to the training context. The perirhinal cortex participates to olfactory, but not contextual, fear conditioning. In addition, the perirhinal cortex seems to play a prominent role in recognition of the conditioned stimuli [7].

Another behavioral register is intensively explore: the ►odor conditioned aversion. Several parts of the primary olfactory cortex are implicated in its mechanisms. For instance, the effects of lesions of the entorhinal cortex are coherent with a role of this cortex in conditioned odor-aversion learning. A subdivision of this cortex as indicated by the heterogeneity of its connections is confirmed by functional arguments. The lateral part only is involved in the control of the olfactory memory trace during the conditioned olfactory aversion process. In addition the data are consistent with the idea that the lateral part represent the input of the structure while the medial part represent the output to hippocampus [8]. Here again, an olfactory cortex network is implicated. Interestingly, it has been shown that electrophysiological stimulations of the lateral entorhinal cortex is able to inhibit the olfactory input from the amygdala.

*Integration.* The primary olfactory cortex is of course inserted in a larger cerebral network and is a target for numerous modulating impacts. For instance, in the rat, 800 neurons from the anterior hypothalamus are secreting the peptide ►GnRH. Influence of these neurons on primary cortical structures of the olfactory system: Some neurons of the anterior olfactory nucleus, anterior and posterior piriform cortex, anterior cortical amygdaloidal nucleus and the lateral entorhinal cortex as it is shown by anterograde barley lectin labeling receive projection of the hypothalamic GnRH neurons [9]. This particular pathway illustrates one of the nervous supports of the integration of the olfactory sensitivity in the physiology and behavior. Odors signals or pheromones could have effects on the neuroendocrine status but in return, mediated by cerebral feed-back loops under the influence of sexual or reproductive hormones, other parts of the brain could modulate the olfactory abilities.

## Secondary Cortical Areas

Axons of neurons from the primary cortical areas reached a number of others brain structures. Focusing on the olfactory sense, the orbito-frontal cortex and temporo-lateral neocortical structures are the most extensively studied. At this level, it is a neocortex that receives and processes the olfactory information.

As a main property, the *olfactory orbito-frontal cortex* receives afferent axons from several other sensorial sources. Among the other important influences, the cortex receives information from the gustatory pathway and had been explored as a centre related to feeding behavior and food choice. As seen using brain imagery, the orbito-frontal cortex is consistently activated by olfactory stimuli [10] and is sensitive to context. These are functional characteristics of a secondary cortex (primary, secondary cortices). Moreover, in this cortex, we find converging fibers from multiple sensory areas, i.e. the primary somatosensory cortex, the primary taste cortex (frontal operculum), the inferior temporal visual cortex, the striatum, the amygdala and the olfactory piriform

cortex. Additional fibers from ►hunger neurons confer to this area a central role in the food-related evaluation of odor and taste. Some neurons of this cortex are responsive to odor and taste for instance. Some of them decrease their response to food eaten to satiety.

This last remark illustrates an important view of the sensory physiology: The multimodality appears as an ultimate refinement of the environment representation. In the orbito-frontal cortex, representations of taste and other mouth feels, smell sight are converging. This is why the representation of food stimuli, and finally appetite, are modulated by sensory-specific controls, involving olfactory cues.

# Olfactory Cortex – Piriform Cortex

Alfredo Fontanini
Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, NY, USA

## Synonyms

Piriform cortex; Pyriform cortex; Prepyriform cortex

## Definition

At a very general level the term "olfactory cortex" can be used for all those areas in the rostro-ventral portion of the forebrain which receive direct projections from the olfactory bulb. These areas are: the anterior olfactory nucleus (also called anterior olfactory cortex), the olfactory tubercle, the ►piriform cortex, the entorhinal cortex, the insular cortex and the amygdala [1]. More specifically, however, the term has been – and will be, in the context of this entry – used in reference to the piriform cortex, by far the largest cortical area primarily involved in perception and learning of olfactory stimuli.

## Characteristics

### Introduction

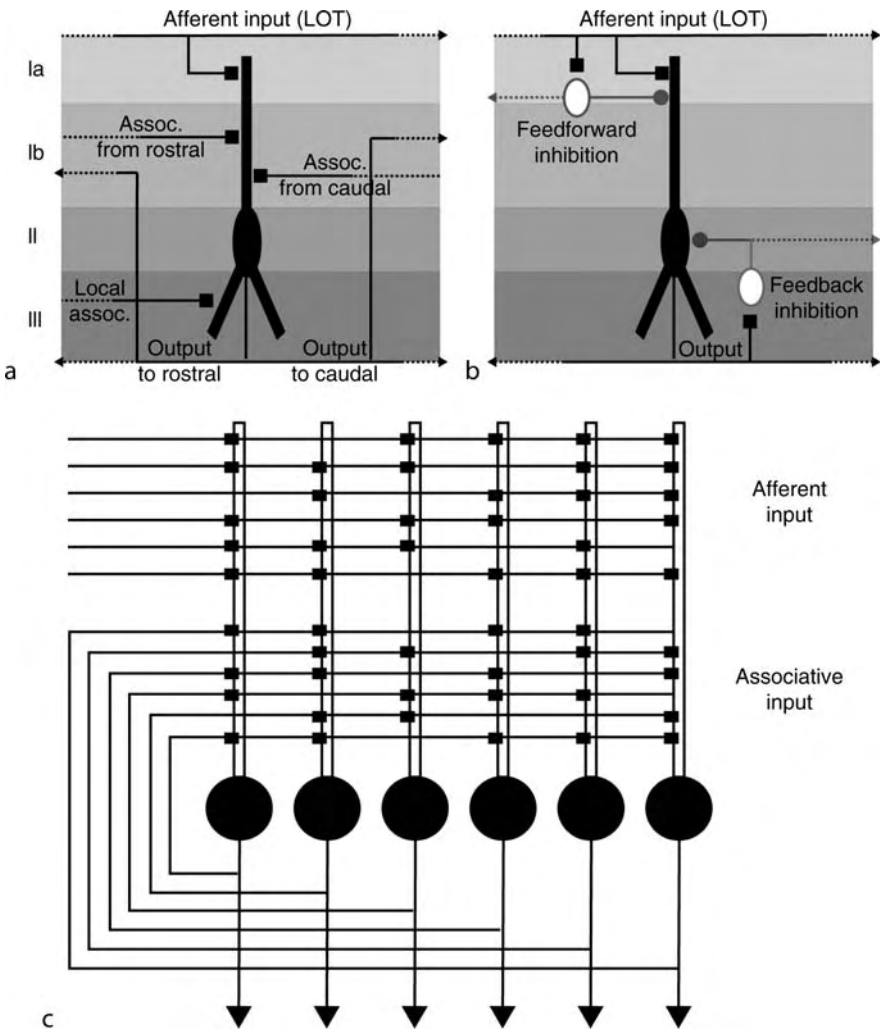
The piriform cortex, also referred to as paleocortex for its old phylogeny, has an evolutionarily well-conserved cellular and synaptic organization [2]. Differently from the neocortex, which appeared more recently in evolution and has a complex multilayered architecture [3], the olfactory cortex is organized in a simpler and experimentally more tractable three layered architecture. Despite this different organization, however, the olfactory cortex and neocortical sensory areas share many functional properties [4]. The study of the olfactory cortex offers, therefore, the unique opportunity to understand how general properties of cortical organization and functioning can be produced by simpler and phylogenetically older structures. As such, a deep understanding of the olfactory cortex will not only help us in the study of olfaction, but also likely advance our knowledge of the general functional organization of the cerebral cortex [4].

### Cytoarchitecture

The olfactory cortex is vertically organized into three layers, each characterized by a different composition of cell types and axonal fibers which spread horizontally [1]. Layer I, the most superficial, is a low cell-density layer composed, in its most superficial part (Ia), by afferent sensory fibers horizontally organized and coming from the olfactory bulb through the lateral olfactory tract (LOT), and in its deeper portion (Ib) by cortico-cortical (associative) horizontal axons coming from other parts of the olfactory cortex and other olfactory areas. Afferent and associative fibers contact the apical dendrites of excitatory neurons located in layer II and III and dendrites of inhibitory interneurons. The next layer, layer II, is composed by densely packed somata of excitatory (pyramidal and semilunar) and inhibitory (stellate and bipolar) cells. Finally, layer III shows a gradual decline in cell density with increasing distance from layer II, and contains somata and dendrites of deep pyramidal neurons, multipolar interneurons, basal dendrites of layer II pyramidal cells and cortico-cortical associative fibers.

As in the case of neorcortex, the circuit of the olfactory cortex is organized around principal excitatory neurons. The different subtypes of excitatory neurons, which are characterized by distinct functional properties, are all embedded in the same, apparently stereotyped, circuit (Fig. 1a) [1]: pyramidal and semilunar neurons receive feed-forward excitatory input from mitral cells in the olfactory bulb and recurrent associative excitatory inputs from other principal neurons within the olfactory cortex, in turn, they send their outputs within the olfactory cortex itself and to other cortical areas (entorhinal and perirhinal cortices, hippocampus, amygdala and orbitorfrontal cortex among them [1]).

Principal neurons are also embedded into two inhibitory circuits (Fig. 1b) [1]: one of which is based on a feedforward input from inhibitory cells in layer I directly activated by afferents from the bulb, the second is a feedback inhibitory loop carried by inhibitory interneurons in layer Ib and III which are activated by associative recurrent fibers from pyramidal cells. Bipolar interneurons, which receive both afferent and associative inputs can take part to both circuits. This



**Olfactory Cortex – Piriform Cortex. Figure 1** Architecture of the olfactory cortex and of an autoassociative network. (a) Excitatory inputs and outputs of a pyramidal neuron. All fibers are organized vertically and segregated in different layers. Afferent inputs come from the LOT, associative inputs can come from distant or be local. Black squares represent excitatory synaptic contacts, lines with arrows represent the outputs of the circuit or, in case of the LOT, the signal propagating caudally. (b) Simplified inhibitory circuit impinging on pyramidal neurons. White circles are feedforward and feedback inhibitory interneurons; grey circles represent inhibitory contacts. (c) Schematic of an autoassociative network: synaptic contacts from afferent and associative inputs are represented as black squares contacting the neural units. (a) and (b) modified from [1].

structure, which is the foundation of the olfactory cortex basic electrophysiological behavior, is however far from rigid and immutable. Previous patterns of activity, sensory experience, as well as neuromodulators play a major role in inducing synaptic plasticity at different sites, shaping this architecture and resulting in different functional configurations [5].

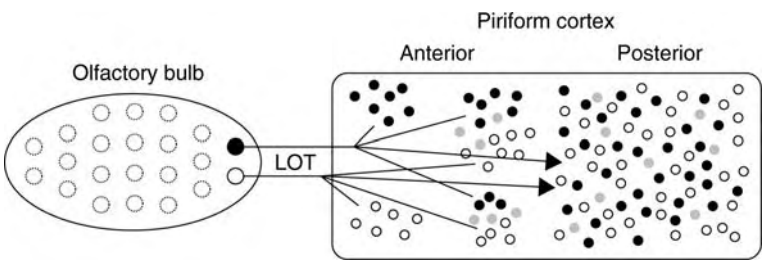
## Functional Organization

The characteristic extension of the associative system, and the suggestion that afferent inputs might be diffuse and without major topographical organization lead to the formulation of the most influential functional view of the olfactory cortex to date [5,6]. According to this view, the olfactory cortex can be seen as a biological analogue of a typical autoassociative artificial neural network. These types of artificial neural networks, characterized by neural units (or nodes) receiving sparse external inputs and also recurrent autoassociative inputs coming from the nodes themselves (Fig. 1c), are ideally suited for performing tasks analogous to those thought to be performed by the olfactory cortex: they can detect and discriminate complex mixtures of odors, reconstruct known mixtures on the basis of some of its components and dynamically switch between processing, storing and recalling of inputs and memories. Learning and dynamics are ensured, in this artificial network as well as in the olfactory cortex, by plasticity and neuromodulation of afferent and associative synapses [5].

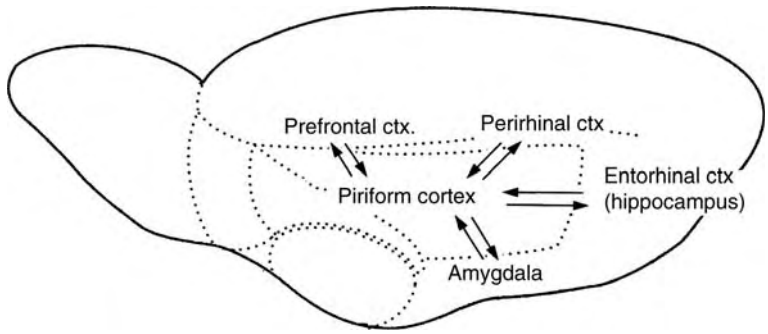
This functional view of the olfactory system has been recently challenged by new results coming from genetic tracing and showing that the organization of the cortex is not as homogeneous as previously believed, but rather individual odors are processed by spatially organized quasi-specific subsets of neurons (Fig. 2) [7].

These results have given strength to a different view of the cortex, according to which odors are represented by the feedforward activation of specific sets of partially overlapping neural populations (labeled lines) and that complex mixtures are coded – and learned – by patterns of coactivation of the subset of neurons receiving convergent inputs.

In reality these two views, the distributed/associative versus the labeled-line/feedforward, can be integrated in several ways. The olfactory cortex is divided into an anterior part and a posterior part [1]: the anterior olfactory cortex is principally driven by afferent bulbar inputs which are functionally organized into large (and to some degree also overlapping) patches; the posterior part, on the other hand, is less driven by afferent inputs and they are organized in a more distributed fashion. Taking this evidence into account it is possible to imagine that the organization of each of the two subdivisions could be biased toward one or the other coding scheme. Additionally, and more importantly, while genetic tracing shows that specific cells code for a specific odor, the degree of convergence seen in the cortex for inputs carrying information for different odors is remarkable and compatible with the model of an autoassociative network. Therefore some of the properties of the autoassociative framework, like the importance of associative fibers, the complex temporal evolution of processing due to cortico-cortical associative connections and the ability to dynamically switch between different network configurations, can be incorporated in the feedforward theory to add complexity, flexibility and ecological realism. Recent work employing simultaneous recordings from multiple neurons in the olfactory cortex has shown that odors activate spatially scattered populations of neurons, which are only partially non-overlapping, and that the patterns of activity become more complex and overlapping as the time course of the response evolves [8]. These results provide support to the fact that the simple labeled line feedforward processing scheme needs to be integrated into a more complex distributed coding paradigm.



**Olfactory Cortex – Piriform Cortex. Figure 2** Topographical organization of bulbar inputs to the olfactory cortex. Outputs from different glomeruli project to partially overlapping but overall spatially distinct patches of neurons in the anterior olfactory cortex. Projections to the posterior cortex are more distributed. Black and white circles in the piriform cortex represent cells activated by distinct glomeruli, grey circles are cells receiving convergent inputs. Modified from [7].



**Olfactory Cortex – Piriform Cortex. Figure 3** Bidirectional connections between the piriform cortex and other high order cortical areas. Modified from [1].

## Macroscopic Dynamics

Regardless of the coding scheme, electrophysiological recordings from the olfactory cortex of animals engaged in purposeful behaviors have revealed an even more complex picture: odor processing is inherently dependent on the behavioral and environmental context. Pioneering work from Walter Freeman [see for a review 9], for instance, has shown that the olfactory cortex produces different patterns of activity depending on the physiological and cognitive state of the animal: odors presented to hungry or thirsty cats, for instance, produce oscillatory activity larger than the one evoked by the same stimuli presented to satiated animals. These and other more recent observations imply that olfactory coding mechanisms are constantly modulated by dynamic activity from other brain areas involved in different cognitive states [10]. The anatomy is consistent with this view, as the olfactory cortex receives direct or indirect inputs from high order brain areas, such as the hippocampus, entorhinal cortex, orbitofrontal cortex, amygdala and hypothalamus; additionally several brainstem neuromodulatory nuclei provide noradrendergic, cholinergic, serotoninergic and dopaminergic modulation [1]. These projections are the anatomical substrate through which emotional states (sustained by amygdala), memories (hippocampus), expectations (amygdala and orbitofrontal cortex), hunger and thirst (hypothalamus) and arousal levels (neuromodulatory nuclei) could influence patterns of spontaneous and odor-evoked olfactory cortex activity (Fig. 3).

## Summary

The olfactory cortex is the largest area devoted to processing of olfactory information. It shares many functional properties with other sensory areas, but it has the advantage of a relatively simpler organization. The enhanced experimental and conceptual tractability deriving from this simpler organization has favored the use of the piriform cortex as a study model for complex issues such as sensory coding and behavioral modulation of sensory responses. Future studies of the olfactory cortex will therefore help us understand not only olfaction, but also fundamental functional properties of sensory systems in general.

## Olfactory Ensheathing Cells

### Definition

Glial cells unique to the olfactory system, which ensheath the axons of the olfactory receptor neurons, without providing full myelination. The primary olfactory system is an unusual tissue in that it can support neurogenesis throughout life. This unique regenerative property depends, in part, on the presence of olfactory ensheathing cells, and has recently been shown to have a remarkable ability to repair spinal cord injury.

►Myelin
►Regeneration

## Olfactory Epithelium

### Definition

The olfactory epithelium is a specialized chemosensory portion of the nasal epithelial tissue that contains the olfactory sensory neurons. In humans, it occupies an area of about 5 $cm^2$ covering the posterior part of the roof of each nasal cavity and the superior nasal concha. The olfactory epithelium is composed of three types of cells: the olfactory sensory neurons, which transduce odorants into electrical signals, the supporting, glia-like cells and the basal cells, which are stem cells capable of replacing the olfactory cell population. Because of this regenerative capacity, damage to the olfactory epithelium may results in only temporary anosmia.

## Olfactory Glomerular Module

### Definition

Also known as a glomerular domain, an olfactory glomerular module is a spatial cluster of olfactory glomeruli responding to chemically similar odorant stimuli. Spatial clustering of glomeruli with similar response profiles into glomerular modules may facilitate the use of local center-surround lateral inhibitory networks to restrict the molecular receptive range of mitral cell projection neurons to a more narrow range of stimuli. Thus, odorants that stimulate strongly overlapping sets of receptors may be represented by a smaller set of mitral cells.

## Definition

An olfactory hallucination is a subjective experience of smell, which occurs in the absence of an appropriate stimulus.

## Characteristics

Olfactory hallucinations (OHs) can occur in normal participants, as an unaccompanied primary symptom (phantosmia), and as a secondary symptom in a range of medical and psychiatric disorders [1]. Whilst the term simple or complex has been used to classify hallucinations in the auditory and visual domains (e.g., spots of light vs. an elephant) this distinction does not readily transfer to OHs. Most OHs appear to be complex, in that the person perceives a fully formed odor object (e.g., the smell of cooked chicken) rather than an unformed olfactory event. However, something akin to the simple versus complex distinction may be reflected in the integration of the OH with other concurrent events (real or hallucinated). For example, a Charles Bonnet syndrome patient reported hallucinating both a visual image of a girl *and* the smell of her perfume.

There are several other characteristic features of OHs. First, they show the same range of odor qualities (what it smells like) as real odors and they vary in intensity and hedonics, with most OHs reported as unpleasant. Second, when an OH is first experienced, they may be accompanied by highly odor-appropriate behavior, such as searching for a "gas leak." This is the only objective evidence we have for the presence of an OH. Third, where OHs occur repeatedly, the person may gain insight into the nature of these experiences, although this may depend upon whether there is an underlying psychopathology (e.g., insight appears more common in epileptic than in schizophrenic OHs).

There are two other features that warrant comment. The first is the perceived locus of the OH. This can be in the nose or mouth, on the surface of the body or in the external environment. A defining feature (more below) of some forms of OH is their location, notably in olfactory reference syndrome, in which a person is convinced that their own body emanates a foul smell. In these cases, the person may not in fact be hallucinating a smell, rather the person infers the presence of a smell from other peoples reaction to them.

## Presentation

### Healthy Adults

Olfactory hallucinations (OHs) are widely reported in healthy adults. A large study of the frequency of all types of hallucination, conducted in Western Europe, revealed that 8.6% of the sample had experienced an OH, and that 0.9% of the sample experienced these several times a week [2]. OHs were the commonest reported daytime hallucination across all modalities. Other studies of non-clinical populations have found that OHs occur more frequently in individuals scoring higher on measures of psychosis-proneness.

### Primary Symptom

OHs can occur as a sole presenting symptom in the condition termed phantosmia. The prevalence of phantosmia is unknown, but according to Leopold [3] it occurs more frequently in women, and is a progressively worsening, relapsing and remitting condition, with lifelong duration. Whilst OHs may be brief, phantosmia may be considerably more persistent, in some cases the hallucination may last hours or days, nonetheless even with this different time-course, it still fulfils the general definition of an OH.

### Secondary Symptom

Schizophrenia: With the exception of epilepsy (more below), OHs have been studied most extensively in schizophrenia. An early view was that the presence of OHs was indicative of a poor prognosis, but there does not appear to be any substantial support for this notion. Rather, OHs appear to co-occur with tactile hallucinations and other positive symptoms of the disease. Phenomenologically, schizophrenic OHs are qualitatively varied, but may occasionally include descriptions, which suggest a delusion rather than an OH (e.g., smell of aliens, devils breath and angels). In most cases the OHs are reported as unpleasant or disgusting. Prevalence estimates vary between 2–35%. Most OHs are attributed to an external source (with some notable exceptions – see [4], for an excellent and representative set of examples), are of a similar time-course to real olfactory experiences and can result in behaviors consistent with the OH (e.g., escaping a building smelling of smoke).

Epilepsy: OHs can occur in the hours or days before a seizure (prodromal) or immediately, within minutes, preceding a seizure. These experiences are usually termed auras and estimates vary as to their prevalence (1–30%; [5]). Phenomenologically, these OHs cover all odor qualities, are brief, localized to the environment, and are predominantly unpleasant. An interesting feature is that they may be repetitive, in that the same person always experiences the same OH.

Migraine: OHs can occur prior to a migraine (again described as auras), with the same time course and features (immediate vs. prodromal) as in Epilepsy.

Post-traumatic stress disorder (PTSD): Several papers have documented OHs in PTSD under circumstances where the person is re-exposed (or imagines) to contextual cues associated with the event (e.g., smelling smoke/gasoline whilst traveling in a car following a traumatic motor vehicle accident). In all cases, the OH appears specific and appropriate to the traumatic event.

Brain injury: Both traumatic brain injury, stroke and aneurysm can result in OHs. In some cases these more

closely resemble phantosmia (and may share similar causation via damage to peripheral olfactory structures) whilst in others, especially aneurysm and stroke, the OHs may be complex (integrated) and hedonically varied.

Drug abuse: OHs have been reported in both chronic cocaine and alcohol users, but studies are few and so prevalence cannot be estimated. These reports indicate a presentation akin to that observed in Epilepsy – predominantly negative, brief and qualitatively varied OHs.

Miscellaneous: OHs have also been described, albeit rarely, in Parkinson's disease, Charles Bonnet syndrome, Depression and Alzheimer's disease.

## Cause

Whilst there has been fairly long history of theoretical and empirical work on visual and auditory hallucinations, especially in schizophrenia, relatively little work has been undertaken in respect to olfactory hallucinations (OH). This section starts by examining the association between the olfactory system and the two clinical conditions in which OHs are most well documented (epilepsy and schizophrenia), and then outlines theories that may account for OHs in these conditions. The second part of this section examines phantosmia, and the final part OHs in normal participants.

### *Epilepsy and Schizophrenia*

The neural basis of epilepsy and schizophrenia can overlap with brain areas known to be involved in olfactory function. In epilepsy, olfactory abnormalities tend only to accompany the disorder when the focus for the seizure is in the temporal lobe. Here the seizure may start or propagate to the amygdala and uncus and then into primary olfactory processing areas located on the boundary of the frontal and temporal lobes. Not surprisingly then, OHs (auras) tend to be associated with temporal lobe epilepsy. In schizophrenia, abnormalities have been detected in the orbito frontal cortex (OFC), amygdala and medio-dorsal nucleus of the thalamus (MDNT). Respectively, the OFC is secondary olfactory cortex, the amygdala is involved in processing the hedonic valence of odors and the MDNT is one of the routes by which information flows from primary olfactory cortex to secondary olfactory cortex, and may be instrumental in attributing the source of sensory stimulation ("that's a smell").

There are several contemporary theories of hallucinations [6], including cortical irritation, cortical release, intrusion of imagery or dreams, and attentional/sensory impairment theories. How well do these models account for OHs in epilepsy and schizophrenia? Cortical irritation is the oldest hypothesis and suggests that excess neural activity at a particular brain loci results in the activation of memory traces that are then experienced as real events. Whilst this was heavily based on electrical brain stimulation (EBS) studies, it turns out that EBS results in *very few* olfactory-related experiences. This conclusion is based upon a large number of reported studies, stimulating many regions in the temporal/frontal regions. The rarity of these events suggests that focal irritation in brain areas known to be abnormal, especially in temporal lobe epilepsy, is an unlikely explanation.

A second class of explanation (of varying form) is that hallucinations arise as a result of abnormal – typically reduced – sensory input. This results in cortical release or hyperexcitability, causing memories of prior sensory experience to be re-experienced as real. There is one major problem with this account for OHs in epilepsy and schizophrenia. This is that patients who experience OHs may not have reduced sensory input. Three studies have examined schizophrenic participants with OHs. They find no consistent deficit in ►odor detection, no abnormal changes to olfactory mucosa, and no history of disease states that might affect olfactory function. With epilepsy, the picture is less clear, with no systematic studies as yet. However, olfactory deficits in temporal lobe epilepsy are usually indicative of central (i.e., ►odor identification and ►odor discrimination) rather than peripheral pathology (i.e., detection is typically intact). Thus there is likely to be no reduction of sensory input that this class of theory would require.

The third class of explanation suggests that hallucinations result from the intrusion of dreams into the waking state or the misattribution of imagery to the external environment, rather than correctly to oneself. Whilst both of these types of explanation have been extensively explored, especially in respect to auditory hallucinations of people conversing, they have significant obstacles to overcome as an account of OHs. Whilst olfactory dreams and images certainly do occur, the former are rare and the latter are hard to generate [7]. Indeed, some argue that we may have no capacity to consciously experience odor images at all. In this case, misattribution accounts may not have much utility in explaining OHs.

A further, and more recent class of model suggests that hallucinations arise from a combination of attentional deficits and impaired sensory functioning. As noted above, impaired sensory functioning (detection) does not appear to be a salient feature of either epilepsy or schizophrenia.

Finally, there are a number of other possible causes of OHs in epilepsy and schizophrenia that have not been widely canvassed. First, impaired odor identification might lead to what *appears* to be an OH (e.g., misidentifying the smell of table polish for smoke). Second, the likely presence of amygdala abnormalities in schizophrenia and epilepsy, the predominantly unpleasant nature of OHs and the amygdala's role in mediating aversive reactions to odors, might suggest

this as a possible neural locus for these events. In summary, there is at present no well-defined model of OHs and there is a need to test the various theoretical accounts described above more directly.

### *Phantosmia*

Whilst epileptic and schizophrenic OHs likely involve a dominant central cause, phantosmia almost certainly derives from a combination of both peripheral and central causes [3]. Evidence favoring a peripheral basis for phantosmia is that it typically disappears if the olfactory mucosa is treated with a local anesthetic and that examination of excised mucosal tissue from phantosmia patients reveals disordered axon growth and an abnormal ratio of mature to immature neurons. Evidence favoring a central locus comes from the finding that many phantosmia patients have no detectable abnormality in odor detection and that such patients typically have no history of upper respiratory tract infection or head injury prior to onset. Interestingly, magnetic resonance spectroscopy imagining has revealed significantly lowered GABA levels in several central sites, including the amygdala [8]. Given the overwhelming predominance of unpleasant OHs in phantosmia, this again suggests possible amygdala pathology as a common feature of OHs.

### *Normal Participants*

Several studies suggest that OHs are more common in healthy individuals who score higher on measures of schizotpy or psychosis-like dimensions, although it is not currently possible to estimate the proportion of variance accounted for by this variable [9]. What it does suggest, however, is that normal variation in schizotypy may reflect proneness to OHs, implying a similar causal explanation to those described above for schizophrenia. In addition, a proportion of OH-like experiences may also be accounted for by more mundane failures to identify an odor source, misperceptions (which may be more common in olfaction than in other senses), illicit drug use, alcohol, anxiety and depression, and lack of sleep [2].

## Conclusion

The study of hallucinations can offer important insights into clinical conditions such as schizophrenia, as well as revealing much about routine perceptual processing. The study of OHs is not well advanced, empirically or theoretically, but it will be important in testing the generality of current theories of hallucinations.

# Olfactory Information

Leslie M. Kay
Department of Psychology, Institute for Mind and Biology, The University of Chicago, Chicago, IL, USA

## Synonyms

Odors; Odorants; Odor code; Olfactory system dynamics

## Definition

Olfactory information can refer to the chemical stimuli (odorants), the perceptual effect of the stimuli (odors), the individual neural responses which receive this input (odor code), and the dynamical interaction of the many brain subsystems which comprise the central olfactory pathways (olfactory system dynamics).

## Characteristics

►Odor signals can be viewed as stereotyped activation maps defined by neuronal ►receptive fields and also as perceptual objects in which the odorant stimuli are associated with meaning, behavior and experience. The anatomy and physiology of the mammalian olfactory system has been studied from both perspectives. The ►olfactory bulb receives direct input from ►olfactory receptor neurons in the olfactory epithelium. These neurons project in a "receptor-topic" arrangement, such

that an individual ►glomerulus receives input from only one type of receptor (Fig. 1).

Because an individual odorant can activate multiple ►olfactory receptors, glomerular input maps are fragmented and highly distributed representations in the form of glomerular activation patterns. The patterns also have a dynamic structure which can be seen using ►$Ca^{++}$ imaging.

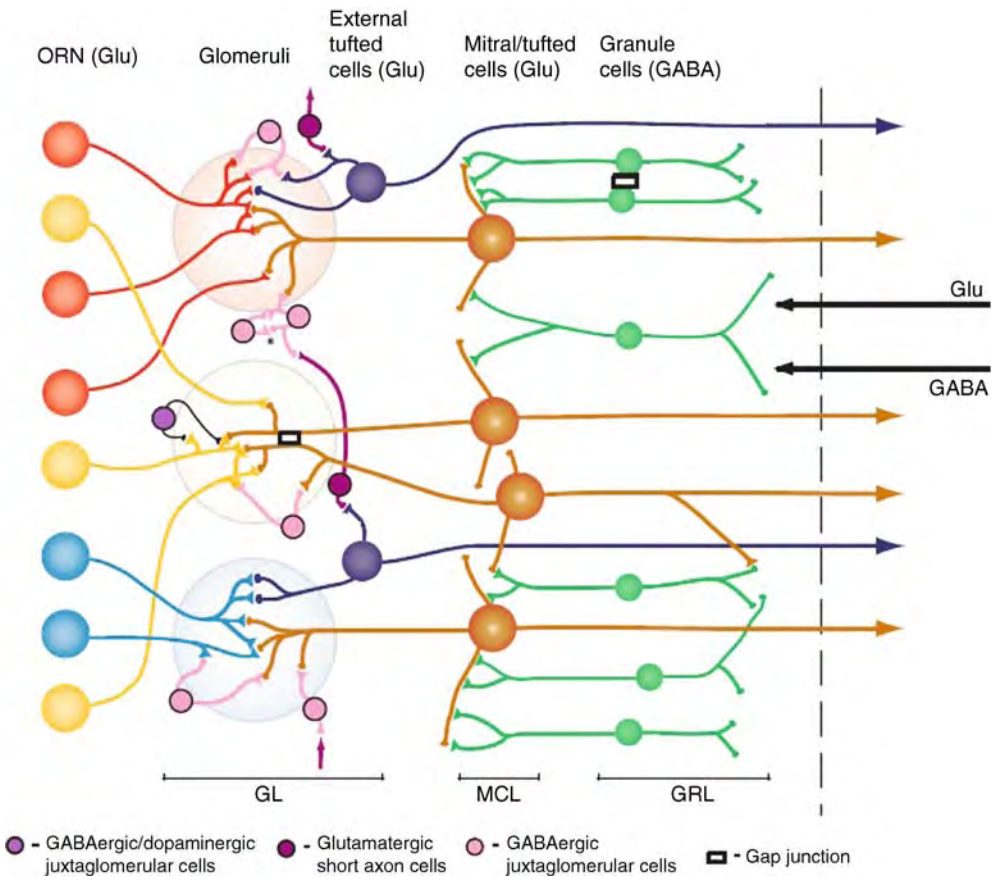
The mammalian ►olfactory system is also characterized by dense bidirectional connectivity among its many structures. The ►olfactory bulb may receive more synaptic input from the brain than it does from the olfactory receptor sheet, similar to a comparison of retinal and V1 projections to the thalamic ►lateral geniculate nucleus. Olfactory bulb structure has been likened at different times to the ►retina, primary visual cortex and more recently the sensory ►thalamus [2]. This essay concentrates on the mammalian system, but some references to the analogous insect systems are made [1]. The peripheral input structure, glomerular architecture and ►centrifugal input all have perceptual and physiological consequences.

## Odor Psychophysics in Animals

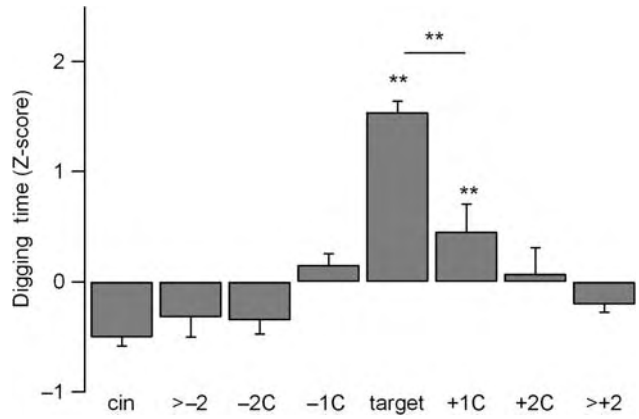
Psychophysical studies examining odor similarity use generalization methods, in which animals are trained to recognize one odorant, and similarities are judged by generalization of a behavioral response to other odors. Taking the ►glomerular input maps produced by various imaging methods and ►mitral cell responses corresponding to these areas as a guide, many compounds have been shown to exhibit similarity gradients along changes in molecular features, such as carbon chain length [3].

Thus, there are similarities in chemical composition, receptor activation and input patterns, which then correspond to similarities in odor quality. On the other hand, most animals are also very good at distinguishing even very similar odorants, and ►reinforcement learning can help an individual to discern even very small differences in glomerular activation patterns (Fig. 2).

Psychophysical responses to monomolecular odorants are relatively stable over a range of concentrations, due in part to mechanisms within the input layer. A subpopulation of ►GABAergic periglomerular cells



**Olfactory Information. Figure 1** Schematic of olfactory bulb architecture. GL – glomerular layer; MCL – mitral cell layer; GRL – granule cell layer. Pial surface on the *left*, centrifugal inputs on the *right* (Reprinted from [1] with permission; Elsevier).



**Olfactory Information. Figure 2** Example of carbon chain length generalization pattern for a series of aldehydes. Mice trained to dig in cage bedding scented with a single aliphatic aldehyde (target) generalize the response to a nearby aldehyde (1 carbon difference in chain length). Digging times are compared to other aldehydes of chain lengths longer and shorter than the target and a control odor (cin – cineole).

receives direct input from the ►olfactory nerve and mediates feedforward inhibition onto the ►mitral cell apical dendrites. Release of ►dopamine by ►juxtaglomerular cells and ►acetylcholine by the horizontal nucleus of the diagonal band of Broca in the ►cholinergic basal forebrain also modulate the incoming ►afferent activity. ►Excitatory and ►inhibitory connections among glomeruli and lateral inhibition between mitral and granule cells have been proposed as mechanisms for ►contrast enhancement and ►gain control.

Odor mixtures present a more complex picture, and two behavioral methods have been used to investigate their perceptual properties in animals. The first looks at mixture quality, in which ►associative learning or ►habituation is used to train an animal to recognize a given mixture, and components are then tested in a ►generalization paradigm. These studies suggest a general theoretical principle: odors that smell alike or activate significantly overlapping receptor or glomerular populations produce a ►synthetic or ►configural (►Configural/Configurational) quality. Mixtures of dissimilar or nonoverlapping odors produce ►elemental qualities. However, there is growing evidence that mixture perception may not be so simple, as compounds with similar structures can produce elemental responses, and those with very different structures can produce synthetic responses in binary mixtures. Furthermore, as the number of compounds in a mixture grows, humans experience more synthetic effects. Concentration and pungency also significantly affect mixture perception.

The second method of assessing mixture perception addresses animals' ability to recognize the ratio of various odor components, in which they choose a response associated with the component represented at higher concentration [4]. Responses in this case follow a ►psychometric curve (►Psychometric Curve/Psychometric Function). This method does not specifically address odor mixture quality, but it can be used to manipulate odor discrimination difficulty. What this method has been able to show is that rodents can identify some odors in 1–2 sniffs, but as discrimination becomes more difficult this brief sampling time results in poorer performance. Training rats to sniff longer results in greater performance levels in more difficult discriminations; this suggests a ►speed-accuracy tradeoff in odor sampling.

The mechanisms for learning differences between odors in a behavioral context involve areas of the brain beyond the ►glomerular maps and are addressed at the physiological level.

## Physiology of Olfactory Information

Ease of access to the olfactory bulb and the importance of olfactory information for rodents drove this research to very deep levels even before single unit recordings in waking and mobile animals became technically feasible or practical. Thus, this field proceeded from its beginning at the systems level, only more recently addressing issues such as ►odor coding and ►receptive fields. However, because of the high-dimensional nature of olfactory stimuli, we still know relatively little about the relative importance of salient molecular features, concentration, ►pungency or even the existence of odor ►categories. (Much of the anatomical, physiological and computational background is reviewed in a few sources [1,5,6].)

### *Individual Neuron Responses*

►Mitral cells in the ►olfactory bulb typically respond in a ►burst-like manner around the peak of inhalation. They receive input from a single ►glomerulus, and

those with dendrites in the same glomerulus can excite each other. In anesthetized mammals, mitral and ►tufted cells in the ►olfactory bulb and ►pyramidal cells in the ►piriform cortex can respond with an increase or decrease in firing rate upon presentation of odorants in front of an animal's nose. In this situation mitral cells show relatively stable odor responses that correspond roughly to the ordered representations suggested by mapping studies. However, there are exceptions to this simple ordering, since many mitral cells respond to many different odor classes, and in any given place in the olfactory bulb, one can often find cells that respond to an odor class.

Mitral and tufted cells in the olfactory bulb respond in a graded fashion to similar odorants, reminiscent of classical ►receptive fields with broad ►tuning curves that can be shifted by prolonged exposure to non-optimal odorants within a cell's ►receptive field. This plasticity is similar to that in other sensory systems, such as receptive field ►learning-induced plasticity in ►auditory cortex. Mitral cells show significant cross-habituation to odors within their receptive fields. Odor responses of pyramidal cells in piriform cortex of anesthetized rats are somewhat different. While these cells exhibit tuning curve properties similar to mitral cells, the responses of single neurons to related odorants do not cross-habituate, suggesting that odor responses within the piriform cortex are more selective overall than those within the olfactory bulb.

Waking mammals present a somewhat different picture. ►Odor selectivity has been recorded in a handful of studies, limited by the difficulty of recording isolated mitral cells in waking mammals. The phase of the respiratory cycle in which a mitral cell fires during periods of slow breathing (< 5 Hz in rats) represents the identity of a relatively long (5 s) odor stimulus associated with reinforcement. However, when rats perform odor discriminations with a briefer sampling time (1–2 s), they sniff at high rates (6–12 Hz), and mitral cells uncouple from the respiratory cycle. Firing rate responses in waking rats predict behavior most strongly, and only a small part of a cell's response varies with odor. When the behavioral association (positive or negative reinforcement) of an odor is changed, a cell's odor selectivity also changes. Studies of single neuron firing patterns in the ►piriform cortex of waking mammals are scarce, but odor responses there are also modified by changes in behavioral associations.

### *Population Activity*

Population physiology presents a window into system-level dynamics. The ►local field potential has been very useful for understanding how the various parts of the olfactory and limbic systems interact with and control each other. Many early studies described the parameters which govern oscillatory responses in many parts of the olfactory system and those which relate local field potentials to single neuron activity [7,8]. The olfactory bulb exhibits two major classes of oscillations, slow (< 12 Hz) and fast (>12 Hz) (Fig. 3).

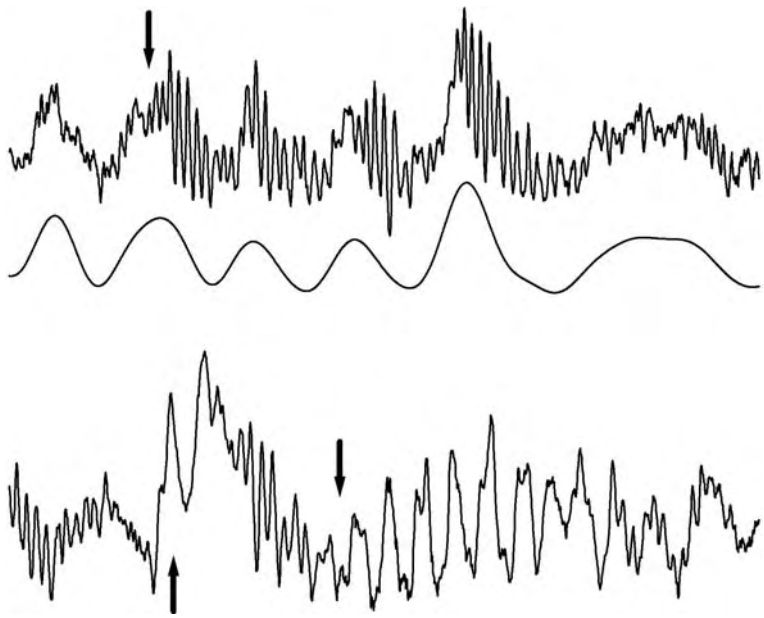
### Slow Temporal Structure

Slow oscillations are in the ►theta frequency range (2–12 Hz in the olfactory bulb) for rodents and are generally correlated in phase and frequency with the respiratory cycle and with mitral cell burst firing. They are supported by afferent input and by intrinsically bursting cells like the ►external tufted cells in the ►glomerular layer. The burst behavior of mitral cells leads to a loose temporal structure within the olfactory bulb, in which within a 100–150 ms time window many cells are activated, and in the exhalation phase and prior to the next inhalation fewer cells are activated. Thus, the ►theta oscillation in the olfactory bulb represents these high and low firing states. At low respiratory rates, this leads to a sampling of the olfactory environment in the nose approximately every 300 ms in a ►saccade-like fashion. However, respiration does not completely describe these rhythms or mitral cells' firing patterns even in anesthetized animals, and there is evidence that ►centrifugal inputs can modulate both. During fast sniffing, mitral cells tend to fire ►tonically and the theta rhythm no longer represents high and low firing rates in the mitral cell population. Also during fast sniffing coupling between the hippocampal theta rhythm and sniffing or olfactory bulb oscillations in the high theta range (>5 Hz) have been associated with learning and performance of odor discriminations. Otherwise, these two rhythms are uncorrelated. This low frequency coupling may aid information transfer between the olfactory and hippocampal systems.

### *Fast Temporal Structure: Circuit Properties*

Within the respiratory cycle there is structure at a finer timescale. At the end of inhalation the ►gamma oscillation (~40–100 Hz) is initiated. This odor-evoked oscillation was first described by Adrian [9]. The gamma burst lasts for 60–100 ms at low respiratory rates (~6–8 cycles per burst; Fig. 3). These fast odor-evoked oscillations have been well-studied at the physiological and computational levels in this system and in the analogous insect system [5]. Most researchers agree that olfactory bulb gamma oscillations arise from the reciprocal dendrodendritic (►Reciprocal Dendro-dendritic Synapse) interaction between mitral and granule cells in the ►external plexiform layer in a ►negative feedback circuit. Olfactory bulb mitral cells' firing times are probabilistically related to the popula-tion-level gamma oscillation (Fig. 4).

While this oscillation is often referred to as a source of ►synchrony between individual neurons, it more



**Olfactory Information. Figure 3** Olfactory bulb oscillations (local field potential; each trace is 1 s long). *Top* trace shows gamma oscillations initiated at the peak of inhalation (*downward arrow*). The ►theta band part of the signal is shown just below, with each cycle representing a sniff. *Bottom* trace shows an odor-evoked beta oscillation. *Upward arrow* is the ►sensory evoked potential, and *downward arrow* shows the onset of the ►beta oscillation.

precisely represents the level of synchrony between individual neurons and the ►emergent local field potential. In this case, an increase in gamma oscillation power and a decrease in spectral width are associated with mitral cells firing in more restricted time windows, rather than precise temporal synchrony between neurons. This suggests increased precision in the temporal structure of the olfactory information.

Odor-evoked oscillations also occur in the insect ►antennal lobe, which is an analogue of the olfactory bulb, with very similar circuit properties. While insect oscillations are ~20 Hz, they are similar to mammalian gamma oscillations in the relationship of the principal neurons' firing patterns to the oscillatory local field potential and the dependence of the oscillations on the interaction between excitatory ►projection neurons and the ►GABAergic local neurons. In the insect system it has been shown that a group of projection neurons fires in an odor-specific temporal pattern across cycles of the fast oscillations [1], which has led some to conclude that the mammalian system may use a similar mechanism during periods of high amplitude gamma oscillations.

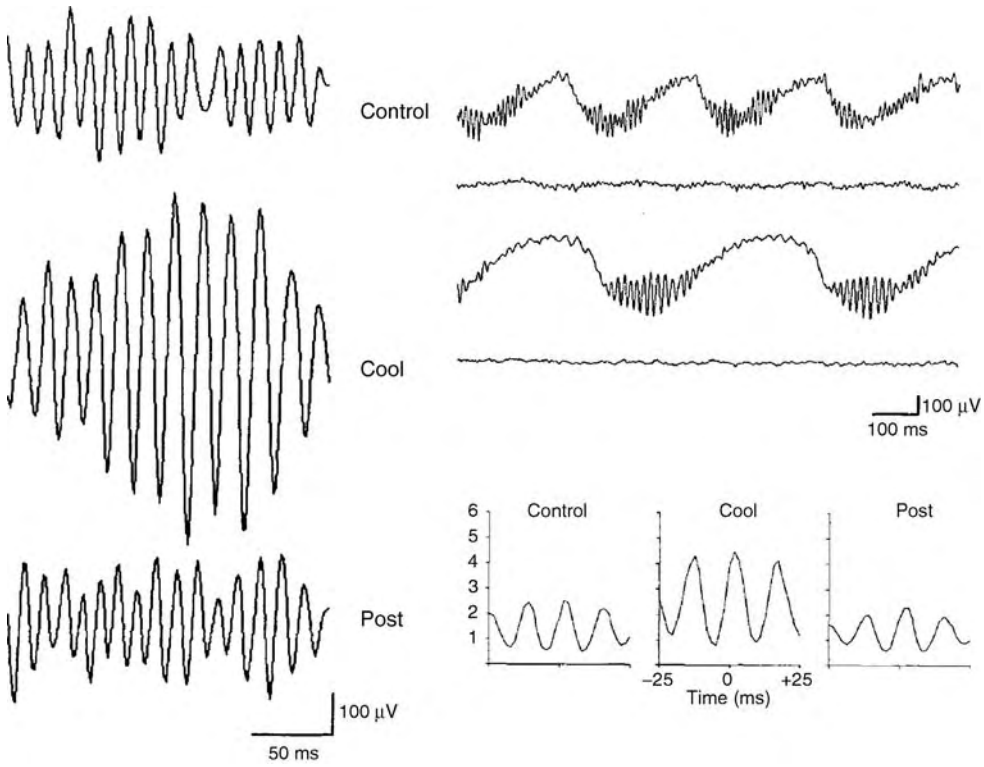
In the mammalian system, sources of ►desynchronization of the local field potential associated with this system lie in the centrifugal and intrabulbar sources of drive to the ►granule cell layer, both ►GABAergic and ►glutamatergic (Fig. 4). Desynchronization is seen as a source of stability and flexibility in this system, and may be important for understanding the functional differences between the mammalian systems and the simpler insect system.

In waking rats and mice, the gamma band has been further subdivided into two bands that are distinct in their behavioral associations but sometimes overlap in frequency. Gamma 1 (~70 Hz in waking rats and mice) is used to refer to the classical odor-evoked gamma described above. Gamma 2 (~55 Hz) is used to refer to the somewhat lower frequency oscillation that occurs between breaths during periods of alert immobility and low breathing rates. The source of gamma 2 oscillations is different from that of gamma 1, likely arising from ►GABAergic drive to the granule cells. The functional association of these oscillations is unknown, but may be related to attentional processes or dynamic stability.

## Fast Temporal Structure: Perceptual Properties

Activity in the ►gamma frequency band has been associated with odor discrimination circuitry in many species. Walter J. Freeman and colleagues showed that over the surface of the olfactory bulb there is a common ►gamma band waveform of the ►EEG [10]. The spatial patterns of amplitude of this waveform were the best indicator of an odor, and the patterns were produced reliably only when meaning (positive or negative reinforcement) was associated with an odor.

Gamma band (and gamma-like) oscillatory population synchrony is one specific mechanism associated with more difficult or highly overlapping odor discriminations



**Olfactory Information. Figure 4** Centrifugal input to the olfactory bulb causes desynchronization of the local field potential. Cooling the rear portion of the olfactory bulb effectively blocks input from the rest of the brain and produces a large increase in ►gamma oscillation power. Pulse probability density (*bottom traces*) shows that single mitral cells are more strongly coupled with the local field potential gamma oscillation without centrifugal input (Compiled and reprinted with permission from Springer, Gray and Skinner, *Exp Brain Res* 1988. 69(2):378–386.).

in rodents and insects. Disruption of these oscillations in honeybees leads to a selective decrease in discriminating highly overlapping odorants (fine discrimination). Increased olfactory bulb gamma power in β3 knockout mice leads to a selective increase in fine odor discrimination. In both studies, coarse discrimination was unaffected. Unmanipulated rats dramatically increase the power of gamma oscillations when performing fine odor discrimination, relative to coarse discrimination in a two-alternative choice task, suggesting that temporal precision in mitral cell firing patterns is enhanced.

Odor-associated beta band oscillations (15–30 Hz) are also seen in waking rats, where they predict the onset of correct performance in Go/No-Go odor discrimination tasks. Beta oscillations occur concurrently in the ►olfactory bulb, ►piriform cortex, ►entorhinal cortex, and dorsal and ventral ►hippocampus. Similar oscillations occur in the olfactory bulb, piriform cortex, entorhinal cortex and hippocampus during repeated passive odor stimulation in a ►sensitization-like fashion (Fig. 3). Beta oscillations differ significantly from gamma oscillations in that they require a complete bidirectional loop between the olfactory bulb and the rest of the olfactory system, suggesting temporal structure distributed across many brain areas. In anesthetized rats, beta oscillations occur at the end of exhalation, and this period has been associated with enhanced firing in the granule cell layer.

## Summary

The combination of ordered but highly complex input maps combines with centrifugal input to the olfactory bulb and oscillatory dynamical states to produce odor perception. Input pattern overlap predicts odor similarity and discrimination difficulty, and animals can adjust their sniffing behavior along with changes in the olfactory system to interpret and respond to odors. Fast oscillations represent cell assemblies that process odors within and between olfactory areas, and slow oscillations at the respiratory frequency can serve momentary system wide coupling possibly to facilitate information transfer.

### Synonyms

First cranial nerve; Olfactory sensory inputs

### Definition

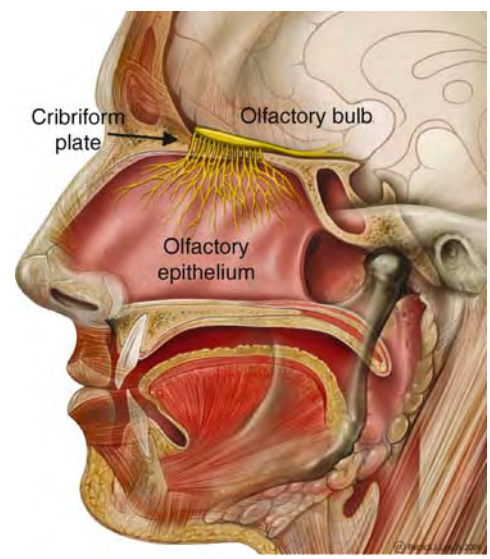
The olfactory nerve consists of the axonal projections of olfactory sensory neurons, which extend from the olfactory epithelium in the nose through the cribriform plate of the skull to contact postsynaptic targets in the glomeruli of the olfactory bulb. Uniquely among pathways in the central nervous system, the entire nerve is continuously regenerated throughout adult life and has a remarkable capacity for recovery from injury.

### Characteristics

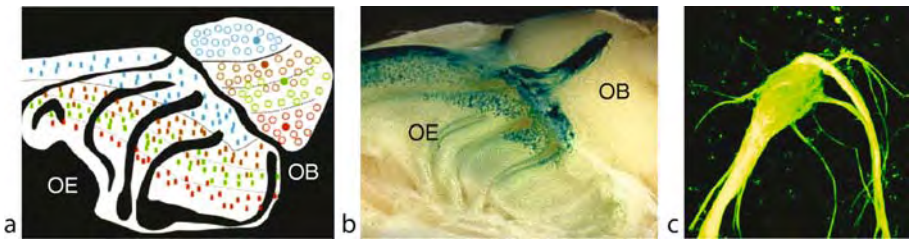
#### Anatomy, Morphology, and Molecular Characteristics

The olfactory nerve is the shortest of the cranial nerves, and is one of only two – along with the optic nerve – which do not project to the brainstem. It is composed primarily of the axons of olfactory sensory neurons (OSNs), which sit in the olfactory epithelium (OE) of the nasal cavity and whose job is to transduce information in airborne odorant molecules into electrical signals that are sent to the brain's olfactory bulb (OB). OSN axons are small (~0.2μm diameter) and unmyelinated, and extend from the OE into the underlying lamina propria of the olfactory mucosa, where they coalesce into small-sized bundles. These bundles increase in size as they exit the lamina propria, and form branches of the olfactory nerve that cross through perforations of the skull's cribriform plate before entering the outer nerve layer (ONL) of the OB (Fig. 1).

Having crossed the boundary between the peripheral and central nervous systems, OSN axons then exit the



**Olfactory Nerve. Figure 1** Olfactory nerve. The axons of olfactory sensory neurons in the olfactory epithelium, shown here in yellow, project through the cribriform plate of the skull to the olfactory bulb, also shown in yellow. Illustration © PJ Lynch and CC Jaffe.



**Olfactory Nerve. Figure 2** Organization of olfactory nerve inputs to the olfactory bulb. (a) Zones in the olfactory epithelium (OE) project to particular regions of the olfactory bulb (OB). (b) Axons from olfactory sensory neurons that express a single type of olfactory receptor, labeled here in blue, project onto a single glomerulus in the medial OB. (c) Inputs to a single glomerulus are untidy, with axons entering the structure from all angles. (a) and (b) reprinted with permission from [1], (c) reprinted with permission from [2].

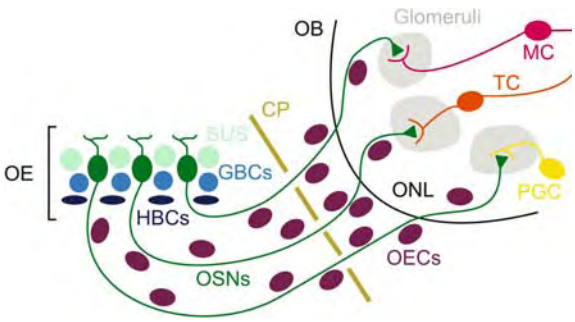
ONL to terminate in OB glomeruli (►Olfactory bulb glomeruli), specialized and highly complex arrangements of axons and ►dendrites that host the very first steps in odor information processing.

The organization of axons within the olfactory nerve is based on the olfactory receptor (OR) molecules expressed by OSNs. Each OSN expresses a single OR, and OSNs that express a particular OR lay scattered randomly within one of four OE zones. Each zone provides OSN axons that project to a particular region of the OB, although while the dorsal zone of the OE projects exclusively to the anterior dorsal bulb, the projections from other OE zones overlap somewhat [1] (Fig. 2a).

More striking is the astonishingly precise projection of OSN axons onto individual glomeruli: all of the OSNs expressing a given OR project onto only 2, mirror-symmetric glomeruli per bulb, and each glomerulus receives input only from axons expressing a single OR [1,3] (Fig. 2b). This huge OR-specific convergence only begins when the olfactory nerve reaches the ONL. Up to this point, axons from OSNs expressing different ORs are all completely intermingled, but on entry to the OB they begin a process of ►homotypic fasciculation whereby axons from OSNs with the same OR run together in bundles. These bundles then converge onto individual glomeruli, a highly specific process which is nonetheless surprisingly untidy [2] (Fig. 2c).

Once in the correct glomerulus, OSN axons make glutamatergic, excitatory synaptic connections with the dendrites of three main types of OB neuron (Fig. 3). Mitral cells (►Olfactory bulb mitral cells) and ►tufted cells are glumatergic projection neurons that receive olfactory nerve input and project directly to olfactory cortex. ►Periglomerular cells, in contrast, constitute a heterogeneous population of local interneurons that receive olfactory nerve input and make modulatory connections within and between glomeruli.

Along their route from OE to OB, OSN axons are surrounded and supported by the processes of



**Olfactory Nerve. Figure 3** Cell types associated with the olfactory nerve. *OE* olfactory epithelium; *OB* olfactory bulb; *ONL* outer nerve layer; *CP* cribriform plate; *SUS* sustentacular cells; *GBCs* globose basal cells; *HBCs* horizontal basal cells; *OSNs* olfactory sensory neurons; *OECs* olfactory ensheathing cells; *MC* mitral cell; *TC* tufted cell; *PGC* periglomerular cell.

►olfactory ensheathing cells (OECs), glia that are unique to the olfactory nerve and which possess characteristics of both Schwann cells and astrocytes [4] (Fig. 3). OECs do not provide proper Schwann cell-style myelination, but instead extend thin processes which each wrap up to 200 OSN axons, providing them with mechanical and metabolic support. In addition, it appears that OECs are essential for the growth-permitting environment of the olfactory nerve, expressing guidance cues and neurotrophic factors which allow new OSN axons to make their way to the OB. Indeed, OECs have been used successfully to promote axon outgrowth and repair in models of CNS injury [4].

As well as possessing unique glia, the olfactory nerve also contains unique axons. Adult OSN axonal compartments contain molecules that are not found in most other axons of the mature CNS. These include mRNA, which appears to be transported along OSN axons rather than locally translated, transcription

factors, and cytoskeletal proteins such as MAP5 and vimentin which are more commonly found in developing neuronal processes [5]. OSN axons also contain ►olfactory marker protein (OMP), a molecule expressed strongly, ubiquitously, and uniquely throughout the olfactory nerve, but whose function remains obscure. Along with the permissive environment created by OECs, these unique axonal features of the olfactory nerve may underlie, or at least reflect, its regenerative capacity (see Adult Neurogenesis below).

## Development

The olfactory nerve is initially established in rather early prenatal development. In mice, the first OSN axons arrive in the brain around embryonic day (E) 12, having extended from the OE through a "migratory mass" that includes OEC progenitors and guidepost mesenchyme cells [1]. Just before entering the presumptive OB, growing OSN axons wait for a short time before entering the ONL and fasciculating with other axons expressing the same OR. Fasciculated bundles are then directed to the region of their appropriate target glomerulus by molecular guidance cues including semaphorins, ephrins, and surface carbohydrates [1], with axons reaching specific domains in the presumptive glomerular layer as early as E15.5. The precise direction of OSN axons to their appropriate glomeruli depends at least in part on the particular ORs they express: aberrant glomerular targeting results when OR expression is genetically altered in a subset of OSNs [1]. Spontaneous, but not sensory activity in OSNs also appears necessary for the correct initial formation of OB glomeruli [6,7].

By postnatal day (P) 0, glomeruli in the rostral OB are clearly formed, while it takes a further 2–3 days for those in the caudal OB to catch up. However, the development of the olfactory nerve does not end there: at this stage, many OSNs axons expressing a particular OR terminate in two or more glomeruli. Over the next month or so of postnatal maturation, these diffuse projections are pruned to produce a tight, single glomerular target structure in each half-bulb (Fig. 4), a process that is highly dependent upon olfactory sensory experience [7].

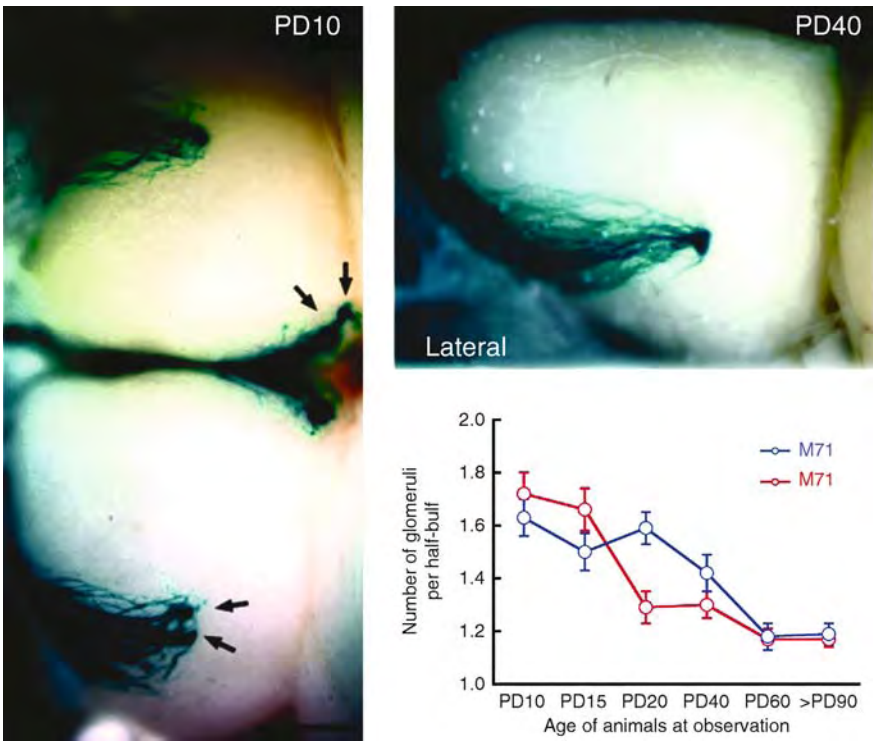
## Adult Neurogenesis

The olfactory nerve is unique among CNS axon tracts in that its generative capacity extends past postnatal development and continues throughout adult life. Unlike other CNS neurons, the nature of OSNs' function as detectors of airborne odorants means they are directly exposed to the external environment, and thus to the accompanying risk of damage by toxins and pathogens. In order to maintain normal olfactory nerve function in the face of this threat, OSNs keep fresh by a process of continual turnover – after a lifetime of around 3 months, those that have not been killed already undergo programmed cell death and are replaced by new OSNs born from stem cells residing in the basal layer of the OE [8]. These cells migrate up to more superficial layers of the OE and extend an axon towards the OB, taking approximately 1 week post-mitosis to express mature markers such as OMP and to form functional glomerular synapses [8]. This normal replacement occurs with very high accuracy – there is no sign of degradation in the glomerular map with routine ageing. In addition, if a subpopulation of OSNs expressing the same OR is specifically removed, the replacement population extends axons to the OB and forms a glomerulus in precisely the right location. This entire process of OSN regeneration, and particularly the regrowth of olfactory nerve axons, probably involves many of the guidance factors and activity-dependent processes that orchestrate the initial formation of the olfactory nerve during brain development. In particular, OECs appear crucial to the growth-permissive status of the olfactory nerve environment throughout adult life.

The continual turnover of OSNs, and the presence of stem cells in the OE mean that the olfactory nerve is unique in the CNS in being able to recover from injury. After even drastic interventions such as section of the olfactory nerve or chemical lesion of the entire OE, recovery is possible – new OSN axons can extend and find the correct target zone of the OB after ~2–3 weeks [8]. There, recovery is not perfect: there are substantial targeting errors in an en-masse regenerating ON, producing multiple glomerular foci and incorrect terminal locations. However, although we currently know nothing about how the olfactory nerve functions following recovery from injury, we do know that olfactory behavior recovers extremely well. Whilst not anatomically perfect, then, the recovery capability of the olfactory nerve is easily good enough to restore useful olfactory function. Unsurprisingly, this unique ability has been the spur for many studies looking to use elements of the olfactory nerve niche to promote recovery in other models of CNS injury. Indeed, promising results have so far come from approaches involving ectopic transplantation of OECs.

## Physiology and Function

The fundamental function of the olfactory nerve is to transmit olfactory information from its site of transduction in the OE to the site of its first processing in the glomeruli of the OB. This information is carried solely in the form of sodium-based action potentials, which are propagated along unmyelinated OSN axons at a speed of ~0.5m/s. Whether or not an action potential occurs in a given OSN axon depends on the particular OR expressed by the cell, and the presence of particular odorants in the olfactory environment. Individual OSNs are actually rather broadly-tuned



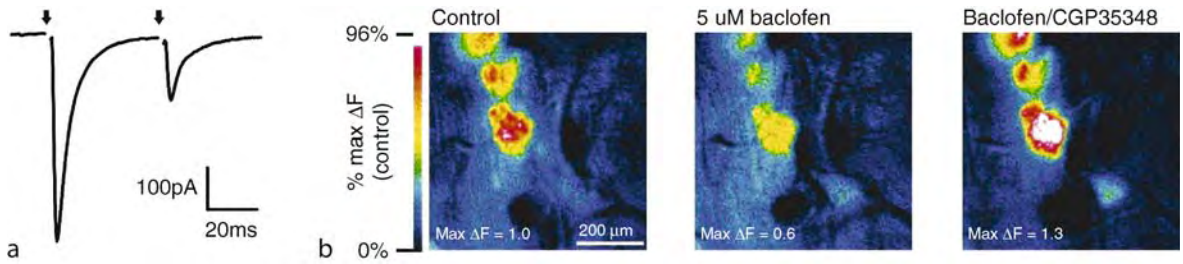
**Olfactory Nerve. Figure 4** Postnatal refinement of olfactory nerve projections in mice. At postnatal day (PD) 10 (*left*), axons from olfactory sensory neurons expressing a single olfactory receptor type converge onto multiple glomeruli in the medial and lateral olfactory bulbs (arrows). By PD40 (*right*, *top*), axons converge onto a single glomerulus in the lateral bulb. The plot at bottom right shows the refinement of glomeruli with postnatal development for two distinct olfactory receptor types. Reprinted with permission from [7].

0

to odorants, since ORs can bind a relatively large number of different odorant molecules. Furthermore, even within a subgroup of OSNs that all express the same OR, variations in transduction processes mean that odorant responses can be markedly different. This means that the information carried by any one olfactory nerve axon actually says very little about which odorants are present or absent in the environment. Only a combinatorial code for odors, embedded in the activity of the ensemble of fibers constituting the olfactory nerve, can allow olfactory detection and discrimination to take place.

As well as the type of odorant stimulus present, the information carried by the olfactory nerve also depends on the strength of the activating odorants. As in all sensory systems, increasing the intensity of the stimulus produces an increase in firing frequency in olfactory nerve fibers. But this may not be the only temporal code present in the pathway, since different odorant concentrations are also known to evoke different firing *patterns* in olfactory nerve fibers. In addition, recordings of calcium activity in olfactory nerve axon terminals have revealed glomerulus-specific dynamics – some glomeruli are quicker, or longer-lasting than others. These differences in temporal dynamics are consistent for the same glomeruli across individual animals, and are only weakly correlated with odorant strength, suggesting they might represent another way, as well as firing frequency, that olfactory information is coded in the axons of individual OSNs.

Finally, coding in the axons of the olfactory nerve may be influenced by a rather unique process in the brain – ►ephaptic interactions between fibers. In most major axon tracts, firing in component axons is kept independent by myelination. The olfactory nerve, however, consists of bundles of hundreds of small axons loosely held together by the processes of OECs, meaning that the insulation of individual axons may not be very good. In these conditions, action potentials in one OSN axon could spread passively to activate other neighboring OSN axons. Indeed, mathematical models of the olfactory nerve suggest that such ephaptic interactions are possible, and even likely. Since OSN axons are not sorted by OR types until they reach the OB, these ephaptic effects could only act to disrupt OR-specific activity in particular fibers. If ephaptic interactions do occur in the real olfactory nerve, then, they may render the transmission of olfactory information from the nose to the brain far less than perfect.



**Olfactory Nerve. Figure 5** Physiology of olfactory nerve terminals. (a) Evoked glutamatergic responses recorded in a periglomerular cell after paired stimulation of olfactory nerve inputs (arrows). Closely-spaced stimulation produces a depression of the second response, a feature characteristic of high release probability at olfactory nerve synapses. (b) Modulation of glutamate release at olfactory nerve synapses by $GABA_B$ receptors. Each blob shows release levels in an entire glomerulus in response to odorant stimulation. Release at olfactory nerve terminals is decreased by the $GABA_B$ receptor agonist baclofen, and increased by the $GABA_B$ receptor antagonist CGP35348. (a) recorded by the author, (b) reprinted with permission from [10].

In other sensory systems, primary sensory neurons transfer freshly-transduced electrical information about the world to their postsynaptic target cells via very reliable and morphologically specialized synaptic connections. In contrast, the connections of the olfactory nerve with its postsynaptic targets in OB glomeruli appear, structurally, to be rather normal glutamatergic synapses. However, functional experiments in OB slices have shown that these connections too are extremely reliable. Unusually for the brain, olfactory nerve terminals have very high release probability – ~0.8 or more [9] (Fig. 5a) which should ensure the highly reliable transfer of olfactory information from the OE to the brain. The underlying mechanisms subserving such high release probability are not known, although it is not due to multivesicular release, and the relationship between calcium entry and glutamate release appears to be nearly linear [9].

Whilst they transmit presynaptic activity with high fidelity, olfactory nerve terminals are unique among primary sensory afferents in being sites of extensive modulation. Although ultrastructural experiments have found no synapses *onto* olfactory nerve terminals in the OB, electrophysiological experiments have revealed strong modulation of release probability by GABA acting through $GABA_B$ receptors (Fig. 5b), by dopamine acting through $D_2$ receptors, and by cyclic nucleotides acting through terminally-expressed cyclic nucleotide-gated channels. This modulation is almost all intraglomerular, meaning that the immediate periglomerular cell postsynaptic targets of olfactory nerve terminals can release either GABA or dopamine, or both, to influence both their own inputs and others in the vicinity [10]. Such feedback modulation may ensure that, despite the high release probability at olfactory nerve synapses, the dynamic range of the terminals is maintained. In other words, the modulation ensures that the OB can still respond to a range of odorant concentrations, even after repeated or prolonged presentation of a strong stimulus.

Olfactory structures; Olfactory cortical areas; Olfactory cortex

## Definition

The perception of a smell is an integration of various sensations (olfactory, trigeminal, tactile, thermal, as well as gustatory sensations). This article is engaged with the olfactory pathways in particular. The human olfactory pathways can be divided into three parts [1,2] (Fig. 1):

(1) The olfactory receptors are located in the mucosa of the nasal cavities. From there olfactory nerves run to the olfactory bulb which is located inside the bony skull beneath the orbital forebrain. From an evolutionary point of view the olfactory bulb is not a ganglion but a part of the telencephalon, one of the oldest portions of the brain. Following this it is postulated that the olfactory bulb constitutes the genuine primary olfactory cortex [3], which is contradictory to the common literature.
(2) The olfactory tract connects the olfactory bulb to secondary olfactory cortex consisting of the anterior olfactory nucleus, the ►olfactory tubercle, the piriform cortex, parts of the amygdala (►peri-amygdaloid cortex, anterior and posterior cortical nuclei, nucleus of the lateral olfactory tract) and a small anteriomedial part of the entorhinal cortex. Since the recognition of the olfactory bulb as a cortical structure these areas are called secondary olfactory cortex [3].
(3) Regions known to receive projections from the secondary olfactory cortex include the orbitofrontal cortex, agranular insular cortex, additional subnuclei of the amygdala, medial and lateral hypothalamus, medial thalamus, basal ganglia, and hippocampus. These regions are termed tertiary olfactory regions.

Although the current understanding of the organization of the olfactory pathways depends basically on observations made in rodents and non-human primates, it is generally assumed that the human olfactory system owns the same basic organization.

## Characteristics

### Olfactory nerves/Primary Olfactory Cortex (POC)

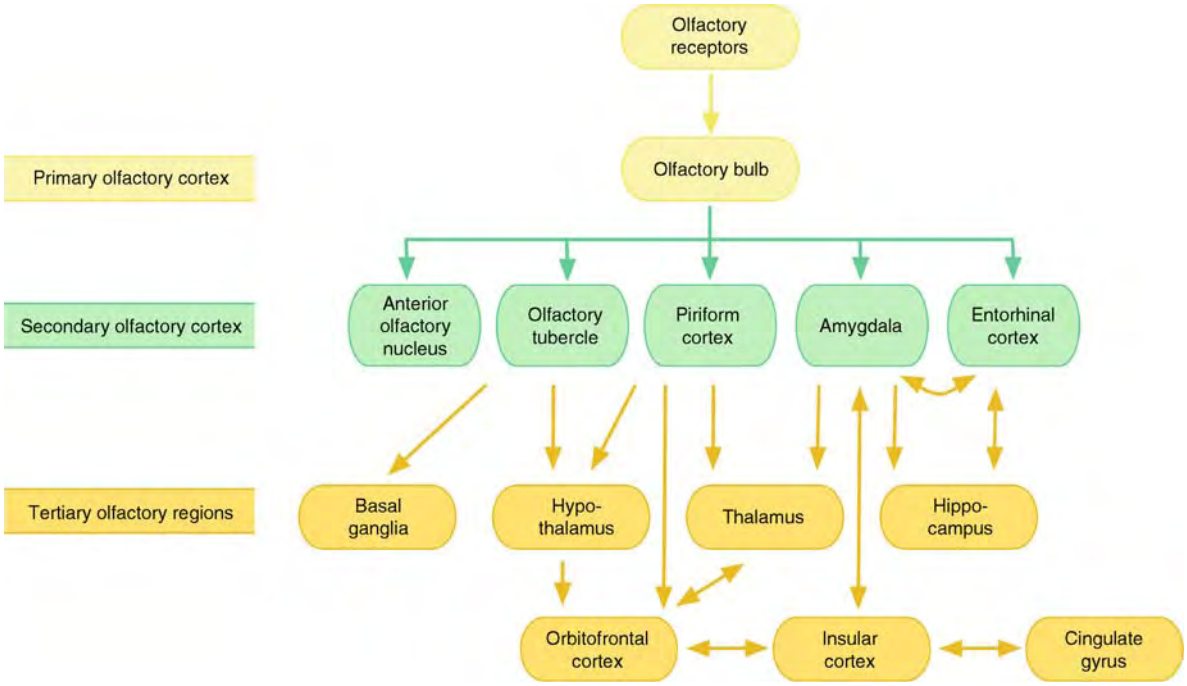
►Olfactory receptors (OR): Olfactory receptor neurons are located in the olfactory epithelium, on the roof of the nasal cavity, above or below the anterior middle turbinate insertion, and are covered by a layer of olfactory mucosa. In humans, several million olfactory receptor neurons are found in both nasal cavities constituting the first-order neurons of the olfactory system. Olfactory receptor neurons are the only sensory neurons in the human body that are directly exposed to the external environment and can therefore be damaged by external harmful substances. Thus the average lifetime of the neurons is only a few months. Afterwards they are replaced through differentiation of neuronal stem cells [4]. It is known that cAMP or cGMP gated ion-channels activated by $G_{olf}$-protein coupled receptor proteins are responsible for odor induced activity of olfactory receptor cells. Between 350 and 400 different types of olfactory receptors are found in the human nasal mucosa. Every olfactory receptor cell expresses only one or maybe two of odorant receptor types. In addition, all neurons expressing the same receptor protein send their axons to the same two glomeruli in each olfactory bulb. In vertebrates, an olfactory stimulus, e.g., the odor of roses, does not activate one specific OR only. Instead, a large number of receptors are activated, although the intensity of activation differs between all of them. A different olfactory stimulus will activate a different set of ORs, of which some may have been activated by the first stimulus as well, while others may not. Again, however, there is a characteristic intensity pattern of the activated receptors. Hence, quality coding seems to be related to neuronal analysis of the topographical distribution of activated receptor proteins [5].

►Olfactory nerves: The axons from the olfactory receptor neurons group into small bundles to form the olfactory nerves, or Fila olfactoria. On average, 12–16 branches of olfactory nerves run along the nasal septum on each side medially and additionally 12–20 branches course along the lateral wall of each nasal cavity [2].

►Olfactory bulb: The olfactory nerves run upwards through the foramina of the cribriform plate of the ethmoid, entering the anterior cranial fossa. On the way from epithelium to olfactory bulb the axons regroup to form more homogeneous bundles. The olfactory nerves terminate at the ipsilateral olfactory bulb. The two olfactory bulbs, one on each hemisphere, lie in a bony groove formed by the cribriform plate. In the olfactory bulb, the axons of the olfactory receptor neurons synapse with dendrites of second-order neurons in the olfactory system (mitral and tufted cells) forming discrete glomeruli.

### Secondary Olfactory Cortex

The olfactory bulbs are connected to the secondary olfactory cortex via the ►olfactory peduncles. The olfactory peduncles consist of the olfactory tracts as well as a thin layer of grey matter which belongs to



**Olfactory Pathways. Figure 1** Schematic illustration of the major central nervous projections of the olfactory receptor neurons. Shown are the three parts of the olfactory pathways (olfactory receptors/primary olfactory cortex, secondary olfactory cortex, and tertiary olfactory regions) and their connections.

the anterior olfactory nucleus. The postsynaptic axons of the mitral and tufted cells leave the olfactory bulb forming the lateral olfactory tract, one on each hemisphere. The lateral olfactory tract is situated in the ►olfactory sulcus of the orbital surface of the frontal lobe, lateral to the gyrus rectus. It transfers olfactory information to a number of ipsilateral brain areas within the posterior orbital surface of the frontal lobe and the dorsomedial surface of the temporal lobe [5]. Unlike in several non-mammalian species, there is no medial olfactory tract in mammals, including primates [4]. The lateral olfactory tract runs along the olfactory sulcus until it reaches the rostral part of the ►anterior perforated substance, where it divides into three roots, or striae. This area is called the ►olfactory trigone. The medial olfactory stria curves upwards to the ►septal region. The lateral olfactory stria curves laterally and leads to the medial surface of the temporal lobe. Delineated by the medial and lateral striae is the anterior perforated substance. The posterior border of the anterior perforated substance is delimited by a band of fibers that passes from the amygdala to the ►septum pellucidum. This band is called the diagonal band of Broca. The intermediate olfactory stria continues onto the anterior perforated substance, ending at the olfactory tubercle. Although well documented in animals, the intermediate and medial striae are extremely rudimentary in humans. Thus the lateral olfactory stria provides the only source of bulbar afferents to the brain. All areas receiving a direct projection from the lateral olfactory stria constitute the secondary olfactory cortex, consisting of the anterior olfactory nucleus, the olfactory tubercle, the piriform cortex, parts of the amygdala (periamygdaloid cortex, anterior and posterior cortical nuclei, nucleus of the lateral olfactory tract) and a small anteriomedial part of the entorhinal cortex.

►Connections within the secondary olfactory cortex: In rodents and carnivores, it has been shown that there is an extensive system of associational connections within the areas of the secondary olfactory cortex [4]. These fibers originate in all of the olfactory areas except the olfactory tubercle. Many of the associational fibers also extend into cortical regions beyond the areas that receive fibers from the olfactory bulb, including portions of the entorhinal, perirhinal, and insular cortex, and the medial amygdaloid nucleus.

►Contralateral connections: The projection of the olfactory bulb itself is entirely unilateral. However, fiber bundles from the olfactory peduncle cross in the ►anterior commissure to reach the contralateral olfactory bulb and cortex, providing the major route of interhemispheric olfactory information transfer. Although these fibers run with the olfactory tract, they do not originate from mitral or tufted cells of the olfactory bulbs. Instead, they originate from those cells of the anterior olfactory nucleus, which are located

in the olfactory bulb. Similar commissural fibers also originate more caudally, in the anterior part of the piriform cortex [4]. In humans all contralateral olfactory projections exert inhibitory effects only.

►Centrifugal projections to the olfactory bulb: Many of the olfactory cortical areas, including the anterior olfactory nucleus, piriform cortex, and periamygdaloid cortex send fibers back to the olfactory bulb. The projection of the anterior olfactory nucleus is bilateral. There is also a substantial projection from the nucleus of the horizontal limb of the diagonal band to the superficial layers of the olfactory bulb.

So far, a clear transformation of the highly ordered topographic map of the bulb onto the olfactory cortex has not been demonstrated. Small areas of the olfactory bulb project to virtually the entire olfactory cortex, and small areas of the cortex receive afferents from virtually the entire olfactory bulb [6]. However the results of a recent genetic tracer study in rodents indicate that a given olfactory receptor subtype projects to discrete neuronal clusters within the olfactory cortex, suggesting a topographical organization in olfactory cortex which is similar to the bulbar organization [7].

►Piriform cortex: The piriform cortex is the largest olfactory cortical area in humans as well as in most mammals. It is situated along the lateral olfactory tract on the caudolateral part of the orbital cortex, near the junction of the frontal and temporal lobes, and continues onto the dorsomedial aspect of the temporal lobe. Due to this it is defining two subdivisions: the anterior (frontal) piriform (or "prepiriform") cortex and the posterior (temporal) piriform cortex. Both parts of the piriform cortex are histologically identical. However it has been suggested that human frontal and temporal piriform cortex are functionally distinct [5]. The piriform cortex is activated by olfactory stimuli but habituates rapidly to repetitive stimulation. It has been shown "that sniffing, whether an odorant is present or absent, induces activation primarily in the piriform cortex" [8] leading to the assumption that the sniff primes the piriform cortex for an optimal perception of an odor [5]. It is suggested that the temporal part of the piriform cortex mediates basic odor perception independent of odor valence while the frontal part of the piriform cortex is receptive to hedonic value of the odor. Additionally the piriform cortex is involved in olfactory learning and memory [5].

►Amygdala: Projections from the olfactory bulb terminate in several discrete portions of the amygdala (periamygdaloid region, anterior and posterior cortical nuclei, nucleus of the lateral olfactory tract). The cytoarchitectonic transition from the amygdala to the temporal piriform cortex is poorly demarcated. The olfactory areas of the amygdala send projections back to the bulb as well as provide direct input to lateral, basolateral, central amygdaloid nuclei and to basal ganglia, thalamus, hypothalamus, and prefrontal cortex [5]. It is suggested that the amygdala is highly responsive to odor stimulation. The amygdala is proposed to play an important role in affective responses in general, and in olfactory hedonics in particular. The amygdala is responsible for the interaction between valence and intensity of an odorant, as well as for olfactory memory. Of all the senses, olfaction possesses the most intimate relation with the amygdala.

## Tertiary Olfactory Regions

From secondary olfactory cortex, information is transmitted to several other parts of the brain, including orbitofrontal cortex, agranular insular cortex, additional subnuclei of the amygdala, medial and lateral hypothalamus, medial thalamus, basal ganglia, and hippocampus. These areas have been referred to as tertiary olfactory regions. Projections to and among these areas are complex and cannot be discussed here in detail. Most of these areas are not specific for processing of olfactory stimuli and show activation by other sensory inputs as well. This complex network of brain areas provides the basis for odor-guided regulation of behavior, feeding, emotion, autonomic states, and memory [5].

►Orbitofrontal cortex (OFC): The OFC is situated at the basal surface of the frontal lobes. It receives input from all secondary olfactory regions (except the olfactory tubercle) in the absence of an obligatory thalamic intermediary and in turn provides feedback connections to each of these regions. The OFC represents the main neocortical projection site of the olfactory cortex and is responsible for initial processing of olfactory information [5]. There is converging evidence that specialized areas within the OFC are engaged depending on the specific task of olfactory processing and that there is some functional lateralization. The posterior OFC is known to be associated with low-level aspects of olfactory processing, such as passive smelling and odor detection whereas the anterior OFC is engaged with higher-order olfactory processing, including associative learning, working memory, and odor recognition memory. Additionally there is evidence for different brain activation associated with odorants of different pleasantness. Whereas pleasant odors evoke activity in medial OFC, unpleasant odors lead to an activation in lateral OFC. Furthermore the OFC receives input from other sensory areas, especially from gustatory, visual, and visceral centers, providing the basis for multisensory integration, resulting in feeding-related and odor-guided behaviors [5]. A functional imaging study demonstrated that regions of the OFC are related to olfactory sensory-specific satiety [9]. The activation of some regions within the OFC produced by the odor of a food eaten to satiety decreased, whereas there was no similar decrease for the odor of food which was not eaten in the meal.

### *Other Brain Areas Involved in Olfactory Processing*

►Cingulate: Although there are connections between the cingulate gyrus and frontal areas involved in olfaction, the cingulate gyrus has not typically been considered as a part of the olfactory system. The cingulate gyrus is involved in processing of information of various kinds. More specifically, the anterior cingulate is frequently involved in tasks requiring attention to sensory features in the environment. In olfactory studies, activations have been reported in anterior as well as in posterior parts of the cingulum. Interestingly, the cingulate gyrus has also been reported to be of critical importance in the processing of painful sensations. Thus, one might speculate that emotions induced by either odors or pain relate to a similar pattern of brain activation in the cingulate gyrus [2].

►Cerebellum: In several studies, cerebellar activation following olfactory stimulation has been reported. Yet, the functional significance of these findings remains unclear. In a functional imaging study the effects of smelling versus sniffing an odor on cerebellar activation were compared and it was hypothesized that the cerebellum maintains a feedback mechanism that regulates sniff volume in relation to odor concentration [10].

In conclusion, functional imaging data support a model of hierarchical organization of olfactory processing. From the ORs and olfactory bulbs (primary olfactory cortex), information are projected to the secondary olfactory cortex. The piriform cortex is the most prominent part of the secondary olfactory cortex in man. Neuroimaging as well as neuroanatomical data suggest that this area is at least minimally engaged during all olfactory tasks. A variety of tertiary regions have been shown to receive projections from the secondary olfactory cortex, among which the OFC seems to be engaged in most tasks of olfactory processing. Thus, core areas within the olfactory system may play a mandatory initial role. However, the involvement of tertiary regions seems to vary with specific task demands, e.g., whether odor processing is related to recognition or emotional response. Finally, another level of organization appears to involve brain areas that fall outside of the typically defined olfactory system, which become engaged during specific types of processing. Examples of these areas are the activation of the cingulate cortex as a multimodal sensory processing area or involvement of the cerebellum which is involved in the adjustment of sniff volume in regard to odor concentration. The ipsilateral nature of olfactory projections, the absence of the thalamic relay during information transmission to the cortex, and the overlap with limbic brain areas are properties of the olfactory system, which sharply distinguish olfaction from other sensory modalities. In summary, odor processing seems to comprise a serial processing of information from primary to secondary and tertiary regions, and also a parallel, distributed processing engaging a complex and distributed network of brain regions whose pattern of activation varies depending on the specific requirements of the task.

## Definition

Olfactory ►perception is a process that starts in the nose with the stimulation of olfactory sensory neurons and terminates in higher cerebral centers which, when activated, make us consciously aware of an odor. In humans this awareness is generally confirmed by verbal reports while in animal studies some sort of odor detection or discrimination task is used. In mammals, olfactory stimuli are received and processed by multiple systems (the main olfactory system, vomeronasal, and the ►septal organ system). Activation (particularly by irritants) of trigeminal, ►vagal and glossopharyngeal receptors in the respiratory tract may contribute to the perceptual experience. However, most research has concentrated on the main olfactory system which also appears to be the only functional olfactory system in humans.

Among the more remarkable aspects of olfactory perception are a seemingly infinite number of odors and odor combinations that can be discriminated, that for humans, most odors generate an emotional response that can range from extreme disgust to extreme pleasantness, and that, in many species, odor exposure can exert profound influence on social, including reproductive, behavior. The neuroscience of olfactory perception has been driven largely by these and related behavioral outcomes and may be viewed as attempts to understand their neurobiological basis.

## Characteristics

### The Biological Basis of Odor Perception

Molecular biological studies identifying the large family of odorant receptor genes have revealed principles in the organization of sensory neurons and their pattern of projection to the olfactory bulb. Each sensory neuron expresses one of a large number of receptor proteins (about 1,000 in rodents) and the axons of neurons that express the same receptor converge to terminate in the same glomerular areas in the olfactory bulb. While receptor–ligand interactions define which odorant molecules will activate a sensory neuron, the stimulus spectrum (range of sensitivity) of any one sensory neuron appears broadly rather than narrowly tuned. Consequently, each class of neurons may respond to a wide variety of odorants, more strongly to some, more weakly to others (depending on structural interactions of ligand–receptor binding). As a result, many and perhaps hundreds, of different classes of sensory neurons may respond more or less strongly to even simple (monomolecular) odorants [1,2].

The inputs to the bulb from sensory neurons are relayed to more central brain areas by second order (mitral and tufted) cells whose axons converge to form the lateral olfactory tract, the primary projection pathway from the bulb to the brain. Although the olfactory cortex (piriform and lateral entorhinal cortices) is the primary termination for these outputs, there are fairly direct projections to four other target areas: prefrontal orbital cortex (via the dorsal medial thalamic nucleus), hippocampus (via the lateral entorhinal cortex), the corticomedial division of the amygdala, and the hypothalamus [3]. As described below, it is tempting to associate each of these projection targets with different known olfactory functions: analysis of complex olfactory signals (primary olfactory cortex), acquisition of cognitive based olfactory tasks and, perhaps, conscious awareness of an odor (the medial dorsal thalamic-orbital frontal cortex system), excellent olfactory memory (the entorhinal–hippocampal system), emotional component of odors (amygdala, limlaic system), and olfactory influenced neuroendocrine changes (projections to hypothalamus).

### Odor Quality Perception

Perhaps the most active area of research relevant to olfactory perception concerns the neural mechanisms that code for odor discrimination and odor quality. Work here has concentrated largely on the olfactory bulb because the functional organization of its inputs is now well understood and because bulbar activity in response to odor stimulation can be visualized using a variety of methods including functional magnetic resonance imaging (fMRI), optical imaging of intrinsic signals, indexing increases in metabolic activity using 2-deoxyglucose (2-DG) and expression of molecular activity markers such as c-FOS [2].

The so-called "combinatorial" view of odor coding is the most widely accepted explanation for the physiological basis of odor quality perception. The convergence of inputs from sensory neurons expressing the same type of receptor plus the many different types of sensory neurons that respond to any one odor results in activation of multiple discrete regions in the olfactory bulb upon odor stimulation. Although structurally similar odors may activate similar or overlapping areas in the olfactory bulb, in all cases examined, each odor produced a unique pattern of glomerular activation.

This "odotopy" or odotopic map representation of different odors at the level of the olfactory bulb provides the primary evidence for the generally accepted "combinatorial" view of odor coding.

While the details of this scheme are topics in other chapters of this volume, its potential significance for understanding odor perception is clear: according to this view, the pattern of inputs from the sensory epithelium to the olfactory bulb provides the neural basis for odor discrimination and, hence, largely determines the perceived quality of an odor. In general, this combinatorial hypothesis has considerable face validity; it provides a reasonably parsimonious account of odor coding, and is solidly grounded in both the molecular biological studies on the organization of inputs to the olfactory bulb and the results of numerous mapping studies. Nevertheless, this view has been challenged by results obtained using fast imaging methods, by studies using awake, behaving animals, and by recent work suggesting that the organization of olfactory cortex may be more suitable for coding complex odor signals.

## Temporal Parameters and Early Events in the Olfactory Bulb

The minimum time required to identify a stimulus helps define the temporal period during which neural coding occurs. Both human and animal subjects can identify an odor after only a few hundred milliseconds of exposure (i.e., after one or two sniffs). What neural events occur during this brief period? Fast imaging methods demonstrate that, within the first few hundred milliseconds of odor exposure, activity across the glomerular layer of the olfactory bulb evolves, is temporally complex and that responses to different odors vary in many parameters including latency of onset, rise time, amplitude, modulation by respiration cycle, temporal dynamics of activation, sniff rate, and the extent to which rise time and amplitude are correlated [4]. The important point is that within the brief time needed to identify an odor, numerous neural events are potential candidates for odor coding. Because odotopic maps of the olfactory bulb are based on averaging activity over many seconds or minutes of odor exposure, it remains unclear whether such maps represent the temporally dynamic changes that occur during the first few sniffs of an odor [2].

## Disruption of Bulbar Inputs

One method for examining the functional significance of odor maps is to assess odor detection and discrimination after surgical or toxicant destruction of bulbar sites activated by a target odor. Surprisingly, even extensive disruption in the patterns of bulbar inputs in rats fails to produce a specific anosmia or hyposmia, or to significantly disrupt ability to discriminate between odors [5]. In related behavioral studies only mixed results have been obtained in attempts to assess other predictions based on the proposed odotopic view of odor coding (e.g., that similarity in patterns of bulbar activation should predict perceived similarity or difficulty in discriminating between odors).

## Perception of Complex Odors and the Olfactory Cortex

The question of whether we experience the individual components of odorant mixtures (i.e., analytic perception) or as a single odor (i.e., synthetically) is complex because, in mixtures, odorants having different vapor pressures and solubilities may produce complex outcomes, and the resulting molecules probably compete for sites on olfactory sensory neurons. Nevertheless, except in the laboratory, most odors encountered represent complex mixtures of vapors. Behaviorally, the issue has been largely resolved by a variety of studies in which human subjects are asked to identify the number of or components of different odors in mixtures. Even with training, subjects are rarely able to identify individual components or accurately identify the number of components in mixtures of three or more odorants.

The evidence from these and related studies strongly supports the view that olfaction is synthetic and that complex mixtures, such as the many volatile molecules that contribute to the odor of urine or coffee, are perceived as single odor "objects." It follows then that analytic or feature detection functions that occur at the level of the olfactory bulb may be early events in further signal processing that result in mixtures being perceived as a single identifiable odor. Where might such synthesis occur? The organization of inputs from olfactory epithelium to the olfactory bulb effects a relatively simple transformation in which signals from sensory neurons expressing the same membrane receptor are represented in spatially discrete areas of the bulb. In contrast, bulbar output neurons are subject to numerous synaptic interactions within the bulb as well as feedback from ►centrifugal projections originating in deeper brain structures and have extensive connections within olfactory cortex. These provide the opportunity for more complex modification in the representation in olfactory cortex of the initial sensory signals. For example, whereas mitral/tufted cells in the olfactory bulb receive input from just a single type of odor receptor, each neuron in the olfactory cortex appears to receive information from multiple bulbar output neurons and some neurons are activated only if two different odor receptor signals are received. Further, responses in olfactory cortex may have considerable plasticity: unit responses to components of odor mixtures are readily modified by exposure to the mixture and, in trained animals, modified as a function of whether the odor was associated with a reward [6].

In brief, our understanding of the biological basis of odor quality perception is incomplete. The results of behavioral studies with rodents, the enumeration of neural events during odor sampling and initial studies on olfactory cortex provide important data but not, as yet, an alternative scheme of odor coding.

## Perceptual Subqualities

Can odors be classified into types or subqualities? For other modalities stimulation produces only a limited number of qualitative differences or subqualities such as the basic types of tastes, skin sensation, colors or tonal frequencies that can be discriminated. For olfaction, literally thousands of monomolecular odorants may each produce a qualitatively different perception, and combinations of odorants may produce additional unique qualitative experiences. A number of odor classificatory schemes have been proposed, some of which are based on multivariate analyses of odor judgments by a panel of subjects sampling a wide variety of odors. None, however, are able to accommodate the full range of perceptual experience generated by monomolecular odors or have strong predictive value for how a novel odorant or a mixture of odorants would be judged. Nevertheless, there appears to be reasonably broad agreement for a limited number of descriptors (such as camphor, musk, floral, peppermint, ether, pungent and putrid, the seven primary odors suggested by Amoore) and such schemes have heuristic value. However, odorants within any such class often have diverse physiochemical properties and, with few exceptions, it has not proven possible to reliably predict odor quality from the molecular structure of an odorant.

## Affective Responses to Odors

Few olfactory stimuli are judged as hedonically neutral; most elicit a clear like or dislike reaction on the part of the perceiver. The ubiquitous use of odorants in cosmetics and foods attests to the fact that many odors are pleasing and can influence mood and appetite. In humans, the hedonic valence of an odor is largely learned and the experience associated with an odor probably determines its hedonic valence. There are obvious cultural differences in odor preference: for example the odor of the durian fruit is judged generally as fetid by Westerners but is described as heavenly by natives in South East Asia.

►Trigeminal, ►glossopharyngeal and vagus nerves in the respiratory tract respond to airborne irritants and their activation together with olfactory sensory neurons may contribute to perceived intensity and unpleasantness of some odors. Except for fear or aversive responses shown by some animals to the odor of predators, it has proven difficult to assess odor preferences in laboratory animals. Human fMRI studies demonstrate arousal of the amygdala by both pleasant and unpleasant odors but, interestingly, not by more neutral odors. These outcomes are in agreement with the more general findings that the amygdala plays an important role in emotional arousal.

## Odor Memory

The "Proust effect" provides a popular example of long-term odor memory, and déjà vu phenomena are often triggered by odors. Clearly, odors, particularly those associated with an emotion arousing event, are remembered for years if not the lifetime of an individual. Studies with rodents demonstrate near perfect retention of odor discrimination tasks even after a brief exposure to the conditioning odor or after manipulations specifically designed to maximize proactive and retroactive interference with odor memory [7]. Where such long-term memories are stored is uncertain; in rats, neither surgical disruption of the olfactory thalamic-orbital prefrontal cortex or projections to the amygdala disrupt odor memory. In humans, fMRI studies reveal activation of many brain areas during the encoding of odor stimuli but more restricted areas and especially olfactory cortex and orbital prefrontal areas in recall or identification of familiar odors.

## Cognitive Function

In humans, olfaction is generally not viewed as an essential sensory modality and does not appear to play an important role in cognitive or higher mental processes (i.e., we don't "think with our noses"). In contrast, rats, whose behavior is largely guided by and dependent on odors, become quite competent in performing complex, cognitive based tasks when odors are provided as discriminative cues. Thus, rats quickly acquire strategies for nearly errorless solutions for a series of simple discrimination tasks and more difficult matching to sample problems (i.e., they acquire a "learning set"), demonstrate paired associate learning, and even solve problems requiring a form of transitive inference. It is unlikely that other sensory cues could support such learning and, indeed, rats perform more poorly or fail when trained on learning set or matching to sample tasks if visual or auditory cues are used. These cognitive abilities appear to be dependent on thalamic-orbital frontal cortical projections: lesions of this system, including those confined largely to the olfactory component of the medial dorsal thalamic nucleus, have little or no effect on simple odor discrimination problems but disrupt acquisition of complex olfactory tasks [7].

## Odors, Reproduction and Unconscious Perception

Olfaction is a critically important sensory modality for most mammals and is used in a variety of behaviors from homing to identifying sources of food and the social status of conspecifics. The demonstration that exposure of gravid female mice to the odor of males from a different strain can disrupt pregnancy (the

"Bruce Effect") led to studies demonstrating clearly the influence of conspecific odors on neuroendocrine changes involved in sexual maturity, mate selection and other aspects of reproduction and social interactions in rodents and, to some extent, in primates. Whether odors play a similar role in humans remains a continuing topic of interest. In humans, exposure to steroidal and other odors from exocrine glands appears to have subtle and gender-specific effects on a number of physiological indices and may alter mood [8,9]. Of particular interest is the evidence that such changes may occur without the subject's conscious awareness of the odor stimulus. It is unclear whether this "unconscious perception" is mediated by neural pathways that bypass olfactory cortex. Such pathways exist in mammals with well developed vomeronasal/accessory olfactory bulb structures but there is scant evidence for the existence of a similar accessory olfactory system in humans.

### Olfaction, Schizophrenia and Neurodegenerative Disease

Deficits in odor identification together with signs of degeneration in central olfactory structures are a pervasive concomitant of schizophrenia, Wilson's, Parkinson's disease (PD) and Alzheimer-type dementia (AD). Patients diagnosed as schizophrenic perform poorly on an odor identification task despite having reasonably normal odor detection thresholds. Indeed, olfactory dysfunction may be near universal in neurodegenerative diseases and occurs even in those with cerebellar ataxia; its onset may predate the first clinical signs of the disease and, thus, be diagnostic, particularly for patients at risk for psychosis or AD (e.g., those with an ApoE4 allele).

Other sensory systems do not exhibit the extensive degenerative changes that occur in the olfactory system in PD and AD and it is unclear why a progressive loss of smell function should be characteristic of and even predate movement and cognitive disorders [10].

In brain imaging studies, identification deficits appear to be more closely associated with changes in olfactory cortex or the temporal lobe than with the frontal lobe. Interestingly, olfactory auras often precede the onset of temporal lobe psychomotor epilepsy. The temporal lobe may also be involved in other olfactory disorders including olfactory hallucinations (phantosmia) and altered or distorted perception of odors (parosmia).

# Olfactory Perceptual Learning

Donald A. Wilson, Heather Bell, Chien-Fu Chen
Department of Zoology, University of Oklahoma, Norman, OK, USA

### Synonyms

Odor memory; Odor familiarity; Odor expertise

### Definition

Perceptual learning is an improvement through experience in the ability or potential ability to detect and/or discriminate sensory stimuli. Perceptual learning can be demonstrated in nearly all sensory systems, for example through the enhanced ability of musicians to identify or discriminate musical notes, or of visual artists to identify similar colors. In the sense of smell, most ►odors experienced in nature or everyday life are complex mixtures of many different ►odorant molecules. Being able to discriminate these different mixtures from each other is one of the main functions of the olfactory system. In mammals, recognition and discrimination of such odors appears to involve an initial analysis of the inhaled stimulus into its component molecular and submolecular features, and a subsequent merging of those features into a unitary odor object, such as "coffee" or "rose." As odors become more familiar, both the encoding of the features and their synthesis into objects are enhanced, leading to improvements in fine

sensory discrimination. Experience-dependent changes within the nervous system underlying this olfactory perceptual learning occur throughout the olfactory sensory pathway.

## Characteristics

Sensory discrimination - the ability to determine whether two stimuli are the same or not - can improve with experience. Slight differences between two stimuli that originally went undetectable, can become detectable with experience and training. This experience-dependent improvement is called perceptual learning, and generally regarded as a form of ►implicit learning, not requiring conscious awareness. Typical examples of perceptual learning include improvements in visual vernier acuity, where the ability to determine whether two vertical lines are either exactly in line or slightly horizontally displaced from each other can be improved through training. Similar examples have been described for auditory pitch perception and haptic (sense of touch) texture discrimination. One common characteristic of perceptual learning is that the effect is largely limited to the familiar stimulus set. Thus, improvements in vernier acuity for vertical lines does not transfer to acuity for horizontal lines.

The improvement in sensory discrimination with experience implies a change in the underlying sensory system which encodes the stimuli. Sensory systems generally encode stimuli in the external world by having populations of neurons tuned to slightly different aspects of those stimuli. Thus, peripheral receptors, transducing sensory input into neural activity, may only respond to a narrow range of energy – a certain wavelength or location of light in vision, a certain frequency of sound in audition, or a certain molecular shape or charge in olfaction. Through the cooperative action of large ensembles of such neurons, information about the identity of the original stimulus emerges, which can then guide perception and behavioral responses.

This basic sensory system function leads to several potential mechanisms through which perceptual learning may arise. Experience with a specific range of sensory inputs could lead to changes in peripheral receptor number or relative tuning distribution, tuning of neurons within the central nervous system, and/or local circuit interactions within the large ensembles. There is evidence for all of these experience-dependent changes occurring in the olfactory system associated with perceptual learning.

## Behavioral Evidence of Olfactory Perceptual Learning

In humans, experience with specific odors enhances subsequent discrimination and identification of those odors. Thus, familiar odorants are more easily discriminated than unfamiliar odorants [1]. This experience-dependent improvement can be induced either through specific exposure or training, or emerge over a lifetime of experience. This latter process may contribute to strong cultural differences in perception and categorization of odors.

In animal models, as in humans, odor experience enhances discriminability of familiar odors [2,3]. Naïve rodents, for example, fail to respond differentially to many monomolecular odorants differing by a single hydrocarbon in their molecular structure. This can be tested in a habituation/cross-habituation paradigm, where one odorant is repeatedly presented until some behavioral response habituates. Then, a second odorant is presented. If the animal discriminates between the odorants, the new odorant evokes a behavioral response. If the animal does not discriminate between the odorants, the response to the new odorant is comparable to the habituated odorant. Using such a paradigm, naïve animals that were habituated to, for example the four carbon odorant molecule ethyl butyrate, showed cross-habituation to the five carbon odorant molecule ethyl valerate, suggesting they cannot discriminate between these odorants (i.e., the odors are similar). However, if given prior experience with these odorants, they subsequently do show differential responses to the two odorants. These experience-induced changes appear selective to the familiar odorants and do not create a general enhancement for discrimination of all odorants.

In addition to experience-induced enhancement of odorant discrimination, perceptual learning can also improve identification of components within odorant mixtures [4]. With simple mixtures of pure odorants, the intensity of individual components plays a major role in the ability to identify those components. Thus, as might be expected, as one component within a binary mixture becomes more intense (higher relative concentration) than the other, that component comes to dominate the perception of the mixture. However, familiarity of the components produces a similar effect. Familiar components are more easily identified within a mixture than unfamiliar components. This consequence of perceptual learning may underlie the ability of professional flavorists and perfumers to identify components with mixtures, although human psychophysical data suggest even professionals have only a limited ability to analyze complex mixtures that include greater than 3–4 components into their constituent parts.

Finally, in addition to experience-induced enhancement of discriminability, odorant exposure may also enhance detectability of odorants [5]. Perhaps the best example of this is perception of the odorant androstenone, though other odorants show similar effects. Androstenone is a component of human sweat, and is more concentrated in males than females. Many individuals appear to have very high thresholds for detecting androstenone, or are even ►anosmic to it. However, repeated exposure over multiple days can significantly improve detection in these individuals, dramatically lowering detection thresholds. There is some evidence

that females may acquire this experience-dependent sensitivity faster than males.

## Neurobiology of Olfactory Perceptual Learning

At the neurobiological level, memory for odors and their associations is distributed throughout the sensory pathway, with evidence for changes from the receptor sheet all the way to the primary olfactory cortex [2,6]. The olfactory systems of all vertebrates and many invertebrates share several basic structural features. Peripheral olfactory receptor neurons express one or a few olfactory receptor genes which code for proteins that bind to odorant molecules sharing a particular structure. These receptor neurons then project to the second order neurons within a central nervous system structure called the olfactory bulb (vertebrates) or antennal lobe (invertebrates). The connections between receptor and second order neurons occurs within structures called glomeruli, which receive input from receptor neurons all expressing the same olfactory receptor genes. Thus, stimulation with a particular odorant activates a unique combination of glomeruli based on which receptors that odorant molecule binds. The response of second order neurons reflects the homogeneous receptor input, as well as local circuit interactions. The second order neurons then project to the olfactory cortex (mammals) or mushroom bodies (invertebrates), where convergence of the different molecular features extracted by the periphery occurs on individual third order neurons. In different behavioral paradigms and different species, olfactory experience has been found to change the response patterns of receptor neurons and glomeruli, and both single cell and ensemble activity of second and third order neurons.

Experience-induced responsiveness to odorants, such as androstenone, may involve both peripheral and central changes. Evidence in humans and rodents suggests that repeated or prolonged exposure to an odorant such as androstenone produces enhanced olfactory receptor sheet responses as measured with electro-olfactogram [7]. The electro-olfactogram is a measurement of summed receptor sheet activity, much as the electroencephalogram measures summed cortical activity. The specific mechanism of enhanced receptor sheet responsiveness to exposed odors in currently unknown. In addition to these peripheral changes, there is some evidence for central sensitization [5]. Humans exposed unilaterally to androstenone will become able to smell it through either nostril, despite the lack of a direct connection between the two receptor sheets. This suggest that central neurons, that receive convergent information from the two airways, may partially mediate the exposure-induced sensitization.

Experience-induced enhancements in discrimination appear to rely on changes within the central nervous system. Exposure to an odor for as little a few minutes can produce a long-lasting shift in the tuning of second order neurons, such as olfactory bulb mitral cells [3]. These shifts enhance the number of second order neurons encoding familiar odorant features. These changes in individual neuron activity are accompanied by large scale neural ensemble changes, as evidenced by changes in odorant-evoked local field potentials within the olfactory bulb. At least two mechanisms may contribute to these changes in stimulus-evoked activity. First, connectivity between existing neurons may be altered during perceptual learning through synaptic plasticity. Plasticity of synapses within glomerular and/or between second order neurons and local interneurons could affect feedback, feedforward and lateral inhibition. These changes in inhibition could influence both responses of single neurons to familiar stimuli and timing of evoked activity. A change in odorant-evoked spike timing, for example increased synchrony, is hypothesized to enhance the salience of familiar stimulus features to downstream neurons, thus facilitating their identification and discrimination.

A second mechanism of perceptual learning associated change within the olfactory bulb is anatomical restructuring of local circuits. A major class of local interneurons in the mammalian olfactory bulb, granule cells, undergo continual neurogenesis throughout life in many animals. Survival and incorporation of granule cells into local circuits is dependent on odor experience. Given the precise projections of olfactory receptor neurons to olfactory bulb glomeruli, different stimuli evoke different spatial patterns of activity across the olfactory bulb, with activation of a given glomerulus associated with activity of a local, spatially defined column of second order neurons and interneurons such as granule cells. Repeated stimulation of a given glomerulus over several weeks by exposure to a particular odorant, enhances survival of granule cells near that glomerular column, while sensory deprivation reduces granule cell survival [8]. Granule cells not only control excitability of second order neurons, but are also the target of cortical feedback to the olfactory bulb. Thus, they may play an important role in familiarity induced effects on olfactory bulb odor encoding.

Finally, olfactory perceptual learning is associated with changes within mushroom bodies of invertebrates and olfactory cortex of mammals [2,9]. As noted above, the olfactory cortex is hypothesized to synthesize disparate, co-occurring odorant features into perceptual wholes, or odor objects. As this synthesis occurs, a template is formed in cortical circuits, allowing a rapid match of subsequent input to that stored template and enhanced discrimination and recognition. This cortical learning may also contribute to perceptual stability of complex odors, even in the face of slight alterations in intensity or presence of some components [6]. Olfactory perceptual learning may involve changes in both the anterior and posterior piriform cortices, as well as the orbitofrontal cortex. In both humans [9] and rodents

[10], the anterior piriform cortex appears to encode stimulus identity, with experience creating a unique encoding of a mixture stimulus distinct from that of its components. In contrast, the posterior piriform cortex appears to encode information about odor quality (e.g., fruitiness) or categorical information, a process again enhanced by experience and odor familiarity.

The types of modifications in neural coding and perception described here associated with olfactory perceptual learning most likely occur in all cases when odors become familiar or are actively learned. The result is that our perception of familiar odors is different than our perception of novel odors, allowing enhanced discrimination and identification of the familiar.

# Olfactory Plasticity

J. C. Sandoz
Research Center for Animal Cognition, CNRS UMR 5169, Paul Sabatier University, Toulouse Cedex, France

## Synonyms

Olfactory learning; Odor-exposure learning; Olfactory priming

## Definition

Olfactory plasticity is a general term referring to all types of changes in odor-evoked responses resulting from individual experience. These changes, usually monitored behaviorally, rely on short- or longer-lived structural and/or functional modifications at different levels of the olfactory circuits. Olfactory plasticity is therefore a form of ►neural plasticity.

## Characteristics

A general rule of sensory systems is that they constantly adapt to environmental conditions, inducing modifications of the way they process sensory stimuli. Such modifications can be very short (in the range of seconds, for instance receptor desensitization) or very long (in the range of years, plasticity of central representations), depending on the type of experience and of the species considered. Due to obvious differences in lifespan, modifications that are considered to correspond to a medium-term range in a given species may be assigned to the long-term range in a different species.

Olfactory plasticity is found in a wide range of species, from nematodes (*C. elegans*) to humans, with prominent examples in insects (fruit flies, bees, etc.) and mammals (rabbits, rats, mice, humans, etc.). These changes can affect all levels of the olfactory circuits, from the most peripheral (olfactory receptors) to the most central ones (cortical representation). Olfactory plasticity can be demonstrated in behavioral experiments, and its neural basis is usually the subject of neurophysiological and/or neuroanatomical experiments. We will first provide a brief description of a generalized olfactory system (for details, see essays on ►olfactory perception, or ►odor coding). We will then detail the types of sensory/associative experiences that induce olfactory plasticity at the behavioral level. To finish, we will present the current view of the neural basis of olfactory plasticity.

### The Olfactory System

The anatomical organization of the olfactory system of vertebrates and of invertebrates, like insects, shows many fundamental similarities. Odors are detected at the periphery (olfactory mucosa within the nose *or* antenna) by olfactory sensory neurons (OSN), which each express a given type of olfactory ►G-protein-coupled receptor. These neurons relay odor information to a first olfactory centre, the olfactory bulb (OB) in vertebrates or its equivalent in insects, the antennal lobe (AL). Both structures are organized in a similar modular way: each of their subunits, the glomeruli, receives input from OSNs expressing the same olfactory receptor type. Glomeruli are sites of intensive synaptic contacts between several neuron types, in particular inhibitory neurons providing local inter-glomerular computation (periglomerular cells/local interneurons), and second-order neurons (mitral cells/projection neurons) that relay processed

information to higher brain centers. Between mitral cells, granule cells provide additional lateral inhibition in vertebrates. The complex ►neural network of the AL/OB is considered to be a major site for olfactory plasticity. It performs computations which are thought to mediate better discrimination between similar olfactory inputs, allowing more segregated spatio-temporal odor representations to be conveyed to higher brain centers such as the piriform cortex, the entorhinal cortex and the peri-amygdaloid cortex in mammals, or the mushroom bodies and the lateral protocerebral lobe in insects (see essay on ►odor coding). These structures are thought to be involved in higher-order processing of odor information, like providing the synthetic part of mixture representation, but also in associative learning and memory of odors, and, at least in mammals, providing emotional and hedonic values to odors. As we will see, olfactory plasticity can take place at all levels of the olfactory system.

## Sensory and Associative Experience Inducing Olfactory Plasticity

Experimentally, olfactory plasticity is often demonstrated by the result of behavioral experiments, during which a particular olfactory experience induces changes in the way animals or subjects respond to odors. We will review these types of experiences from simple olfactory exposures to much more complex forms of associative learning between particular odors and different outcomes.

### *Olfactory Exposure*

Simple odor exposure, even a very short one, can have consequences on the way the olfactory system will respond to subsequent odor presentations. The most peripheral of these phenomena is called ►olfactory adaptation [1], during which exposure to an odor (from very short pulses to stimulations of a few seconds) decreases reversibly the sensitivity of olfactory receptor neurons (usually in the range of seconds to a few minutes). Functionally, this is believed to allow an animal to constantly adapt its olfactory system to environmental odors, avoiding saturation of the cellular transduction machinery and thereby keeping the ability for the animal to detect more relevant short-lasting odors. Different forms of odor adaptation have been described, depending on the length of the odor stimulation inducing it (short or long puff) and the length of the adaptation (short or long-lived). These different forms are thought to depend on slightly different but interconnected cellular feedback loops within olfactory sensory neurons. Odor adaptation is considered to be reversible. Experimentally, it has provided previous researchers an interesting way of testing whether two odorants are detected by different or overlapping sets of olfactory receptor neurons, in so-called cross-adaptation experiments: animals are first exposed to a mono-molecular odorant A until they adapt to it. Then a second odorant B is presented. If response to B is affected by the former presentation of A, it suggests that detection of B depends on receptors used for the detection of A.

Simple odor exposures do not only affect the periphery, and the changes that they induce at the central level are then considered forms of ►perceptual learning . On a quantitative level, repeated presentations of an odor can have two kinds of effects. On the one hand, the probability of a behavioral response provided by an animal to the presentation of the odor (for instance, a startle or a sniffing response) will tend to decrease through repeated presentations of this odor. This effect is termed ►odor habituation . In some cases, even if a decrease of an odor-evoked response is observed, this effect can be more related to a reduction of the animal's attention or of its overall responsiveness than to a decrease of odor detection ability or changes in odor processing. In fact, repeated experience with an odor can have the opposite effect, reducing the olfactory detection threshold (odors are detected at lower concentration) and can even allow odor detection by seemingly anosmic subjects. On a more qualitative level, repeated experience with a range of different odors can greatly improve the discrimination ability of subjects among these, but also novel, odorants. Furthermore, experience with an olfactory mixture can strongly modify the way the individual components of the mixture are perceived. For instance, a given odor presented to a subject together with a "smoky" odor will tend to be perceived afterwards as smoky, while the same odor would smell cherry-like after being presented together with a "cherry" odor. Such effects are usually interpreted as forms of ►implicit memory and are thought to rely on neural plasticity at different levels of central areas, from the OB where it would modify the receptive range of mitral/tufted cells to the piriform cortex and the orbito-frontal cortex where the synthetic representation of odors may change. These olfactory forms of perceptual learning can take place rapidly, but are usually long-lasting.

### *Associative Learning*

The most prominent forms of olfactory plasticity relate to associative conditioning, during which animals learn to associate odors with particular outcomes or behaviors, which have a positive or negative significance for the animal. It is generally accepted that most of our hedonic relationship to odors is not innate, but rather acquired throughout our lifetime by associations between these

odors and particular events or contexts. Odor learning starts even before birth from the mother's amniotic fluid, as the olfactory system is already functional in utero by 12 weeks of gestation. For instance, children of mothers who consume particular odors (garlic, cumin, etc.) and were therefore exposed to these odors during gestation and/or breast-feeding show specific preferences for these odors afterwards. Throughout young age, children learn to associate particular scents or tastes with edibility and/or positive and negative events, and it is generally accepted that by the age of 8, most of our adult olfactory preferences are acquired, although adult experience certainly continues to shape olfactory preference [2]; see also learning during a sensitive period, below].

Experimental psychology distinguishes two main forms of associative learning which both are very prominent in the olfactory domain:

1. In ►classical (Pavlovian) ►conditioning , an animal learns to associate an originally neutral, ►conditioned stimulus (CS – here an odor) with a biologically relevant, ►unconditioned stimulus (US). For instance, honeybees learn to associate odors with sucrose solution in the paradigm of the proboscis extension response (PER) conditioning. In a hungry bee, sucrose solution triggers the reflex extension of the mouthparts (the PER), allowing the insect to drink. Prior to conditioning, odors are ineffective. However, after a single CS/US association, the odor can now elicit the PER and after a few such associations an odor-sucrose memory is formed that can last for the bee's lifespan.
2. In ►operant (instrumental) ►conditioning , the animal learns to associate a behavioral action to a ►reinforcement , and a ►discriminative stimulus (e.g., an odor) can function as a signal for producing the learned behavior. For instance, an odor may act as the signal for a rat to poke its nose in a particular box in order to receive a food reward. Although conditioning creates an association between nose poking and the food reward, odor-food and odor-poking associations are also built and will drive the rat's choice.

In both learning paradigms, odor-outcome (US or reinforcement) associations are established, which can be either ►appetitive or ►aversive.

More complex olfactory learning tasks can be conceived, either in a classical or an operant framework, establishing multiple associations between different odors and multiple outcomes. A simple example of such tasks is differential conditioning (A+, B−), in which an odor A is associated with a US/►reinforcer and another odor B is left without consequence. Experimentally, such conditioning has often been used in the study of neural olfactory plasticity [3–4], because it provides the experimenter with a within-animal control as the same animal has to learn to respond to odor A but not to odor B: usually, specific changes in neural responses are found for A but not for B. In some cases, learning can induce a decorrelation of the neural representations of A and B, making them more discernible for the olfactory system. More complex forms involve ambiguities between odors and outcomes, and give a special meaning to the concomitant presentation of two or more odors: for instance, in biconditional discrimination (AB+, CD+, AC−, BD−), each odor is as often reinforced as not, and the right behavioral response can only be found after linking different odor representations (here the animal should respond to odor A when it is presented together with B but not when A is presented together with C). All these different forms of olfactory learning are based on increasingly complex associations, and pose each different constraints to the olfactory system. In this case, one expects a decorrelation of the representations of odor combinations with different outcome, irrespective of the common presence of a given odor (e.g., AB+ vs. BD−).

### *Olfactory Plasticity During a Sensitive Period*

The olfactory plasticity phenomena detailed above can take place at any moment in an animal's life. There are, however, instances of olfactory plasticity that can only happen during sensitive periods such as after mating or short after birth. Thus, newly-mated female mice learn the specific odor of the mating male, and any encounter with a different male will provoke pregnancy failure [5]. Another prominent example is neonatal learning in rabbit pups, which learn extremely fast – during the first three days after birth, odors that are present on the doe's belly. Recently, a mammary pheromone was found, which alone triggers stereotyped orocephalic movements of nipple search in young rabbit pups. Normally, odors do not elicit this response. However, a single simultaneous presentation of an odor together with the pheromone dramatically changes the pups' behavior, such that it will now respond to the odor presented alone [6]. This form of classical olfactory conditioning is particular, not only for the existence of a strict sensitive period, but also for the fact that an odor, the mammary pheromone, acts as a reinforcer.

## Neural Basis of Olfactory Plasticity

Changes in odor-evoked behavioral responses can rely on neural plasticity at all levels of the olfactory circuits, from the most peripheral during olfactory adaptation to the more central, OB/AL and/or higher brain centers for perceptual and associative conditioning. Olfactory plasticity is manifested at the neuron level through both structural and functional neuronal changes.

On a structural level, the number and/or repartition of synaptic contacts between olfactory neuronal populations can be modified. For instance, differential olfactory conditioning is accompanied in ►pyramidal neurons of the piriform cortex by an increased density of ►dendritic spines linked to intra-cortex connections, but also to pruning (reduction) of spines linked to afferent input from the olfactory bulb, suggesting intense rearrangements of olfactory connectivity through learning [7]. Such structural changes can sometimes be correlated with a change in the volume or shape of neuronal structures like the glomeruli. In the particular case of the olfactory bulb, neural olfactory plasticity can take the form of the genesis and preferential survival of novel neurons that will integrate the neural network, specifically as inhibitory interneurons (periglomerular and granule cells). It could be shown that this process is increased after differential olfactory learning [3] and that the novel production (or the loss) of such interneurons has important consequences for OB activity. Structural plasticity is usually related to long-term forms of olfactory plasticity, as they need time to take place.

On a functional level, the strength and efficacy of synaptic transmission can be modified. This can imply many changes at the level of neurotransmitter release, receptor equipment, intra-cellular cascades, second messengers and for long-term forms, it relies on novel protein synthesis. Most functional work on olfactory plasticity has concentrated on describing changes observed in odor-evoked responses within olfactory structures. Depending on the recording technique, modifications are observed on the amplitude, frequency or synchronisation of electrophysiological responses [8,9], on the intensity or repartition of optically-monitored activity [4], on the pattern of production of synaptic proteins etc. In some experiments, plasticity is assessed on whole brain structures with awake and behaving animals. For instance, olfactory bulb field potential activity can be monitored from freely-behaving rats. Odor stimuli usually produce a frequency change in the ►field potential, with a power decrease in the γ frequency range (60–90 Hz) associated with a power increase in the β range (15–40 Hz). This pattern of response was found to be strongly amplified in animals trained in an olfactory learning task, precisely at the moment when they started mastering the task [9]. In such cases, it is difficult to determine precisely the location of this plasticity, which can reveal synaptic efficacy changes over a whole olfactory network. In other approaches, particular neuron populations can be monitored, usually in fixed animals. Thus, in rats, it could be shown in electrophysiological recordings of mitral cell activity that an olfactory exposure can modify their receptive range, so that they would respond to a wider range of odors after olfactory exposure than before [8]. In fruitflies, associative aversive conditioning based on odor-electric shock associations can be applied on a fixed fly under the microscope. Optical imaging experiments coupled to the genetic expression of a reporter of synaptic activity (synapto-PHluorin) in particular antennal lobe populations showed that projection neurons that were initially not activated by an odor prior to conditioning could be recruited shortly after differential aversive conditioning. Recordings from sensory neuron or inhibitory local interneuron populations did not show any change, demonstrating that plasticity took place at the level of second order neurons [10].

Until now, most available data on neural plasticity underlying olfactory learning was obtained from primary olfactory centers (OB/AL) that are easier to access. However, research on higher-order structures is growing. Thus, experiments have already shown that electrophysiological responses of neurons in the olfactory cortex are strongly influenced by previous odor stimulations, and are certainly involved in perceptual learning. But the kind of activity changes appearing at this level, in contrast to those found within the primary centers, correspond to higher-order computations allowing, for instance, the discrimination between a mixture and its components, a task deemed as one of the most critical for odor perception. Moreover, such higher-order structures are good candidates for harboring associative olfactory memories. In fruitflies, Kenyon cells (third order neurons) within the mushroom bodies displayed dramatic increases of calcium responses to the learned odor several hours after a differential aversive conditioning task, with even a localization of changes within specific branches of these neurons [10]. In fact, as only a few third order neurons are activated by a given odor, as opposed to many second-order neurons, neurons in more central areas constitute an ideal substrate for the associative memory trace, giving a particular odor a particular meaning.

## Conclusion: Odor Processing Plasticity or Odor-Reinforcement Memory?

As detailed above, many electrophysiological, functional imaging or neuroanatomical studies find strong neural plasticity within olfactory circuits, especially after associative conditioning. However, it is often difficult to relate such neural plasticity to its exact function. Are the observed changes related to modifications of odor processing, modulating for instance the neural representation of the learned odors so that it can be better distinguished from environmental background? Or are they related to an olfactory ►engram,

revealing the storage of odor-reinforcement associations in the brain? The picture emerging from the studies carried out so far suggests that primary olfactory centers (OB/antennal lobe) may be responsible for the former, and higher olfactory centers for the latter, but considerable work is still needed to confirm this hypothesis. Future neurobiological studies of olfactory plasticity will have to answer these questions, using a combination of approaches, asking in particular whether the observed cells (and their plasticity) are necessary and sufficient for the expression of olfactory plasticity at the behavioral level.

# Olfactory Receptor

## Definition

Olfactory receptors are members of the seven transmembrane domain G-protein coupled family of receptor proteins. The binding of an odorant molecule to an olfactory receptor initiates a conformational change that activates the G-protein and leads to an electrical response in the olfactory sensory neuron that can be transmitted to the brain. Around 1,000 genes encoding functional olfactory receptor proteins have been identified in the mouse genome, with around 350 functional olfactory receptors identified in the human genome. Individual receptor types are typically activated by small and partially overlapping ranges of odorants. The identity of an odorant is therefore conveyed by the pattern of different odorant receptor types that it activates, i.e. an across-fiber pattern code.

# Olfactory Receptor Neuron (ORN)

## Definition

Olfactory receptor neurons are cells in the olfactory epithelium in the nasal cavity. They are bipolar neurons with an apical dendrite with cilia facing the interior space of the nasal cavity and a basal axon that via the first cranial (olfactory) nerve passes through the cribriform plate and enters the olfactory bulb. Each olfactory receptor neuron probably expresses a single type of olfactory receptor protein, and neurons with the same receptors are scattered through one of four zones in the epithelium. Olfactory sensory neurons are also sometimes called “olfactory receptors,” although this term can be confused with the odorant receptor proteins themselves. It should be noted that the olfactory epithelium is also innervated by the trigeminal nerve,

which is responsible for mechanical sensations (touch and pressure), as well as pain and temperature. Trigeminal fibers also respond to chemicals found in onions, mustard and chile powder.

## Olfactory Recognition

### Definition

Olfactory recognition, first and foremost, refers to the process by which an odor molecule is sensed and detected by an olfactory receptor. This process is not yet well understood, mainly because of the fact that the protein structure and function of many G-protein coupled receptors (GPCRs) is still under investigation. In contrast to most other GPCRs that recognize their ligands through ionic or hydrogen bond interactions, it appears that olfactory receptors recognize odorants primarily by weak hydrophobic and van der Waals interactions, which allow the observed broad but selective odor ligand binding of olfactory receptors.

## Olfactory Sense

Hanns Hatt
Department of Cell Physiology, Ruhr-University Bochum, Bochum, Germany

### Synonyms

Sense of smell; Chemosensation; Odor perception

### Definition

The olfactory system enables most animals to continuously monitor their chemical environment. The sensitivity and range of olfactory systems is remarkable, enabling organisms to detect and discriminate between thousands of low molecular mass, mostly organic compounds which we commonly call odors. The task is accomplished by specialized olfactory sensory neurons which encode the strength, duration and quality of odorant stimuli into distinct patterns of afferent neuronal signals. Thus, the molecular structure of an odorant molecule is converted into a pattern of electrical activity, which intern is processed in the olfactory bulb and higher brain centres and ultimately perceived as a characteristic odor quality. Odor perception is a result of complex biochemical and electrophysiological reaction mechanisms.

### Characteristics

Measurable characteristics of olfaction are:

1. Anatomical organization
2. Signal transduction pathway (molecular basis of sensitivity and specificity)
3. Odorant information processing
4. Olfactory receptors outside the nose

The human nose is often considered something of a luxury. However, even if we have lost faith in our noses, we are still strongly influenced by smells even if only subconsciously. Smells can evoke memories and

emotions, influence our mood and are important for our enjoyment when eating. All the delicate nuances of an excellent cuisine or of a noble glass of wine are, in the final analysis, savored through our sense of smell. In addition, before the spirit and beauty of a person can fascinate us, our nose must become infatuated. The olfactory systems have developed, the main olfactory system (described here in detail) and the accessory system, known as the ►vomeronasal system (►Vomeronasal Organ (system)), which is specialized for chemical communication between one another (see glossary). An indication of the importance of the olfactory system in humans is the significant proportion – more than one percent – of the genome is devoted to encoding the proteins of smell. Let us follow the odor trail from molecule to perception.

## Atomical Organization

A flower or any odorous subject has to release molecules according to their vapor pressure into the air. During inhalation they can reach our nasal cavity. There is a series of conchal formations, called turbinates. In the most upper one the olfactory epithelium is located, which consists of three mature cell types: bipolar primary sensory olfactory neurons, supporting (sustentacular) cells and basal cells (adult stem cells) which generate olfactory receptor neurons and sustentacular cells throughout our whole life (Fig. 1a). The turnover of the about 20 million olfactory neurons in less than one month. At the apical pole of the cell body of an olfactory sensory neuron (OSN) is a single dendrite that reaches up to the surface of the tissue and ends in a knob like swelling from which project some 20–25 very fine cilia. These cilia, which actually lie in the thin layer of mucus covering the tissue, contain all the molecular components necessary to convert the chemical odor stimulus into an electrical cell signal [1]. On the proximal pole the cell body of OSN narrows into an axon that joins with other axons to form small nerve bundles that then project into a region of the brain, known as the olfactory bulb. Molecular genetic studies have shown that all the neurons, expressing a particular olfactory receptor protein terminate within a single target in the olfactory bulb, called glomerulus: Spherical conglomerates of neuropil some 50–100 µm in diameter that consist of the incoming axons of OSN and the dendrites of the main projection cells in the bulb, the mitral cells. In human, as in other vertebrates, the number of glomeruli correlates with the number of different types of OSN (about 350).

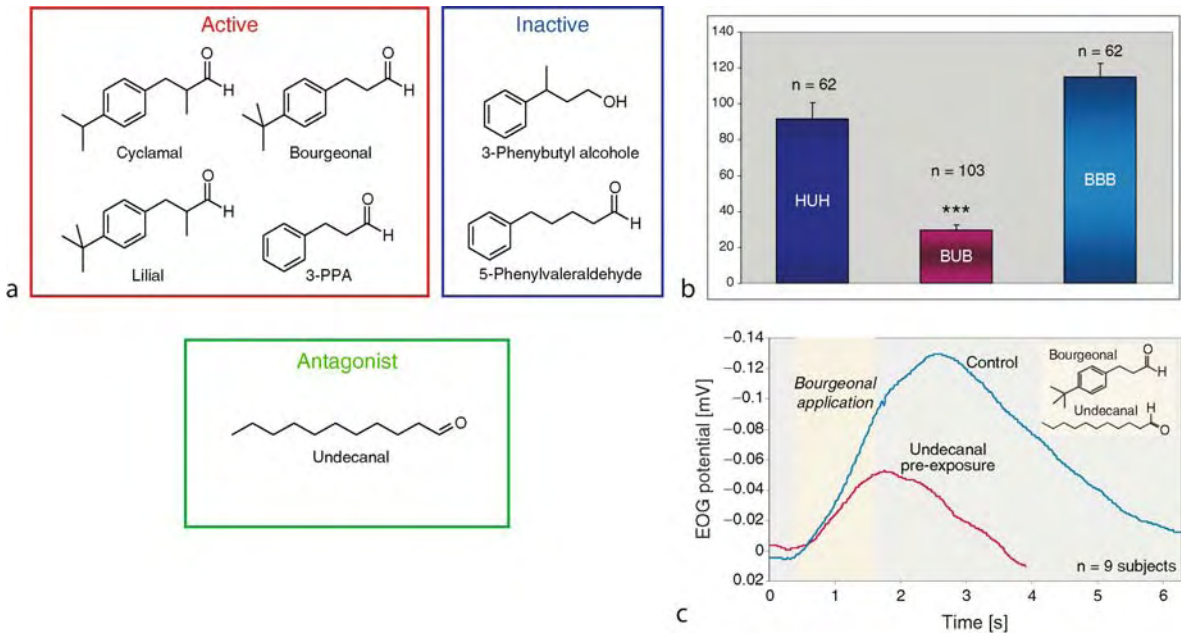
(b) Molecular processes during transduction of odor stimuli in an electrical cell response. (c) Molecular structure of a human olfactory receptor protein. The amino acid chain passes through the cell membrane seven times.

## Signal Transduction Pathway

Recent advances of electrophysiological and molecular biological methods have provided new insights into the mechanisms of chemosensory signal transduction. The transduction process begins when odorants are dissolved in the mucus. Here the discovery of small, water soluble proteins in the mucus fluid, which are produced by glands of the nasal cavity, has led to the concept that these so-called odorant binding proteins (OBP) may accommodate hydrophobic odor molecules in an aqueous environment and enhance their access to the receptor sides. Several distinct OBP-subtypes have been identified and each subtype appears to have an unique ligand binding profile suggesting a more specific role of these proteins [1]. Meanwhile, it is generally accepted that the interaction of odor molecules with the receptor protein leads to the activation of a so-called ►$G_{olf}$-protein as mediator to activate the enzyme adenylate cyclase which produces large amounts of cyclic adenosine monophosphate (cAMP) as second messenger. The cAMP molecules now act directly within the cell membrane to change the structure (conformation) of a channel protein (cyclic nucleotide gate channel, CNG) in its open state (Fig. 1b), enabling it to conduct specific cations ($Na^+$, $Ca^{2+}$) from the nasal mucosa into the cell [2]. As a result, the negative membrane potential (about −70 mV at rest) is shifted to more positive values, called depolarization or cell excitation. Above a certain threshold (−50 mV) this analog sensor potential is converted into a digital action potential frequency near the axon hill of the soma of the OSN. The action potentials are conducted along the neurites into the olfactory bulb. This signal transduction cascade provides amplification and integration of odorant binding events. One olfactory receptor protein activated by an odor molecule can produce about a thousand molecules of a second messenger (cAMP) per second. The calcium ions entering through the CNG channel have a double function. First, they are able to activate another ion channel that is permeable to the negatively charged chloride ion [2]. Because OSN maintain an unusual high intracellular chloride concentration such that there is a chloride efflux when these channels are activated. Thus, it further depolarizes the cells and adding to the excitatory response magnitude. However, calcium ions entering the CNG-channels are also important in response adaptation through a negative feedback pathway. Calcium acts probably via a ►calmodulin dependent mechanism to decrease the affinity of the channel for cAMP and therefore making the channel after a longer period of opening more and more insensitive. This is one of several mechanisms for adaptation. Others include phosphorylation of olfactory receptor proteins sending them into ►internalization, and of fast sodium channels leading to inhibit of action potentials.

The initial step in the recognition of an odorant is its binding to the olfactory receptor protein. The discovery of a large family of genes which encode heptahelical transmembrane proteins (Fig. 1c) and are expressed exclusively in the olfactory epithelium by Linda Buck and Richard Axel (1991) was the ground-breaking work which opened new avenues of research for better understanding of odorant recognition [3]. The odorant receptor proteins are classical G-protein coupled receptors and the about 320 amino acids are highly homologous and Southern blots of genomic libraries suggested that the gene family consists in mice of at least 1,300 putative members. In the human genome about 900 olfactory receptor genes were identified, but two third of these turned out to be non-functional or "pseudogenes" which have lost their function during evolution. A total of 347 putative functional olfactory receptor genes in man was determined [4]. It is still the largest gene family in the human genome. The high proportion of pseudogenes indicate a variable repertoire of functional olfactory receptor genes in the human population. Many specific anosmia, e.g., the inability to smell particular odors, could be due to hereditary defects of OR genes. Interestingly, out of the 347 functional OR genes, each olfactory sensory cell expresses only one type which implies a sophisticated mechanism of olfactory gene choice. The members of the olfactory receptor gene family are distributed on nearly every human chromosome except 20 and Y, often found in large clusters. Chromosome 11 is particularly notable in that it contains nearly half of all olfactory receptor genes including the two largest olfactory receptor gene clusters [4].

In 1998, six years after its identification, it could be shown by functional expression and characterization of olfactory receptor genes that they encode for odorant receptors [5]. One year later the first human olfactory receptor was deorphanized. The receptor hOR17–40 reacts specifically to Helional and structurally related substances [6]. The functionality of the protein was demonstrated by a recombinant expression of the receptor in HEK 293 cells and calcium imaging measurement to demonstrate the cell response after odor application. Unfortunately, it has not been possible to get a functional expression and activation of many of the human olfactory receptors so far. The ability of olfactory sensory neurons to express cloned receptors while other cells could not is further evidence for the involvement of some olfactory specific ►chaperone or cofactor necessary for functional receptor expression. So only a few other human olfactory receptors have been successfully expressed and characterized. Most data existing from the receptor hOR17–4 which is activated by odorants like Bourgeonal, Cyclamal and Lilial (smelling like Lilly of the Valley). A detailed molecular receptive field (Fig. 2a) could be described [7]. From these data it was suggested that the receptor

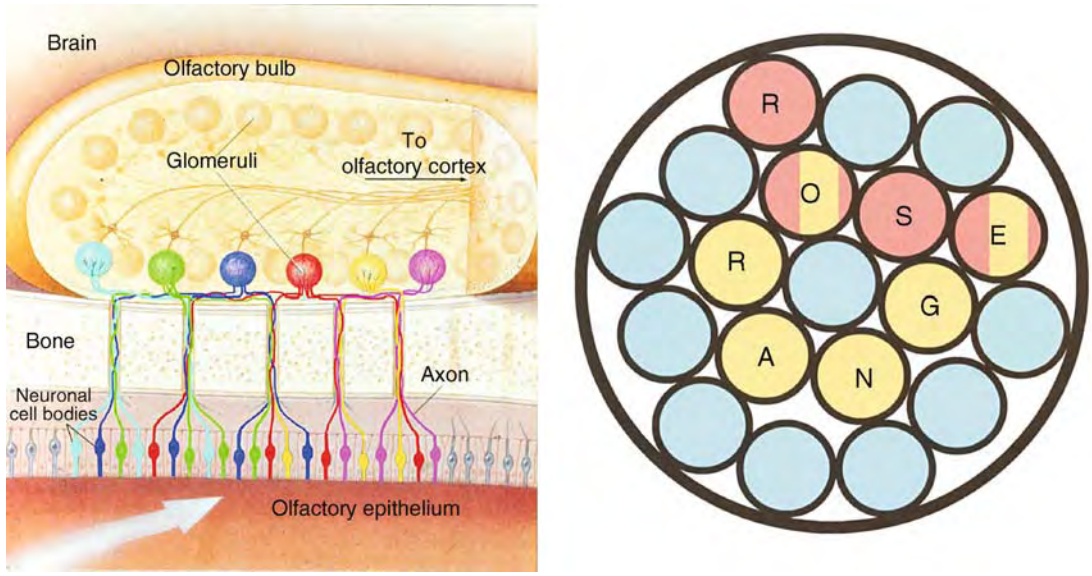


**Olfactory Sense. Figure 2** (a) Effective versus ineffective agonists and antagonists towards hOR17–4. (b, c) In psychometric measurements and electro-olfactogram recordings Undecanal was identified as ►competitive antagonist for hOR17–4.

recognizes a particular feature of different ligands, in analogy to a ►pharmacophore in medical chemistry. In addition another analogy to pharmacology, the existence and the effectiveness of antagonists, could be shown. It was speculated for many years that it should be possible to construct antagonists for olfactory receptors in a similar way as in the case of the medically used blockers of adrenergic or dopaminergic receptors. Interestingly, under the many substances tested, Undecanal showed a clear competitive antagonistic effect highly specific for the receptor hOR17–4 [8]. Variations of agonist/antagonist concentrations ratios indicate competition of both compounds for the receptors ligand binding pocket (Fig. 2b, c). Most odor molecules are recognized by more than one receptor and most receptors recognize several odor molecules, related by chemical properties. Thus, the recognition of an odorant molecule depends on which receptors are activated and to what extent. For each odorant there are best receptors, but also others that are able to recognize the odorant only in a higher concentration and will participate in the discrimination of that compound. Thus, all data indicate that the nose uses a combinatory coding scheme to discriminate the waist number of different smells [4].

## Odorant Information Process

To inform the brain, olfactory sensory neurons extend axons from the olfactory epithelium to the olfactory bulb. There is a considerable amount of data demonstrating that all neurons expressing the same receptor type convert their axons into the same glomerulus: usually two glomeruli which are located on the lateral and medial hemisphere of the bulb, respectively [4]. These findings indicate that an individual glomerulus is dedicated to receiving input from a single receptor type and so serves as a functional unit in the coding of olfactory information. The wiring process is still largely unknown. The basic olfactory map is probably established by a developmental hardwired strategy. The convergence of signals from thousands of neurons expressing the same olfactory receptor protein onto a few glomeruli by optimize the sensitivity to low concentrations of odorants by allowing the integration of weak signals from many olfactory epithelium neurons. The invariant pattern of inputs might have a different advantage, ensuring that the neuronal representation (code) from odorant remains constant over time, even though olfactory epithelium neurons are short lived cells that are continuously replaced. Many natural odors such as flowers, scents and perfumes consist of hundreds of individual chemical compounds. When such a complex mixture reaching our nasal cavity, out of the about 350 different types of olfactory sensory cells, only those are activated which bearing receptors for one of the chemicals in the mixture. Having in mind that all the sensory cells have the same receptor proteins, wherever they may be located in the olfactory epithelium (Fig. 3), all send their neuronal processes to one and the same glomerulus in the olfactory bulb, thus producing a

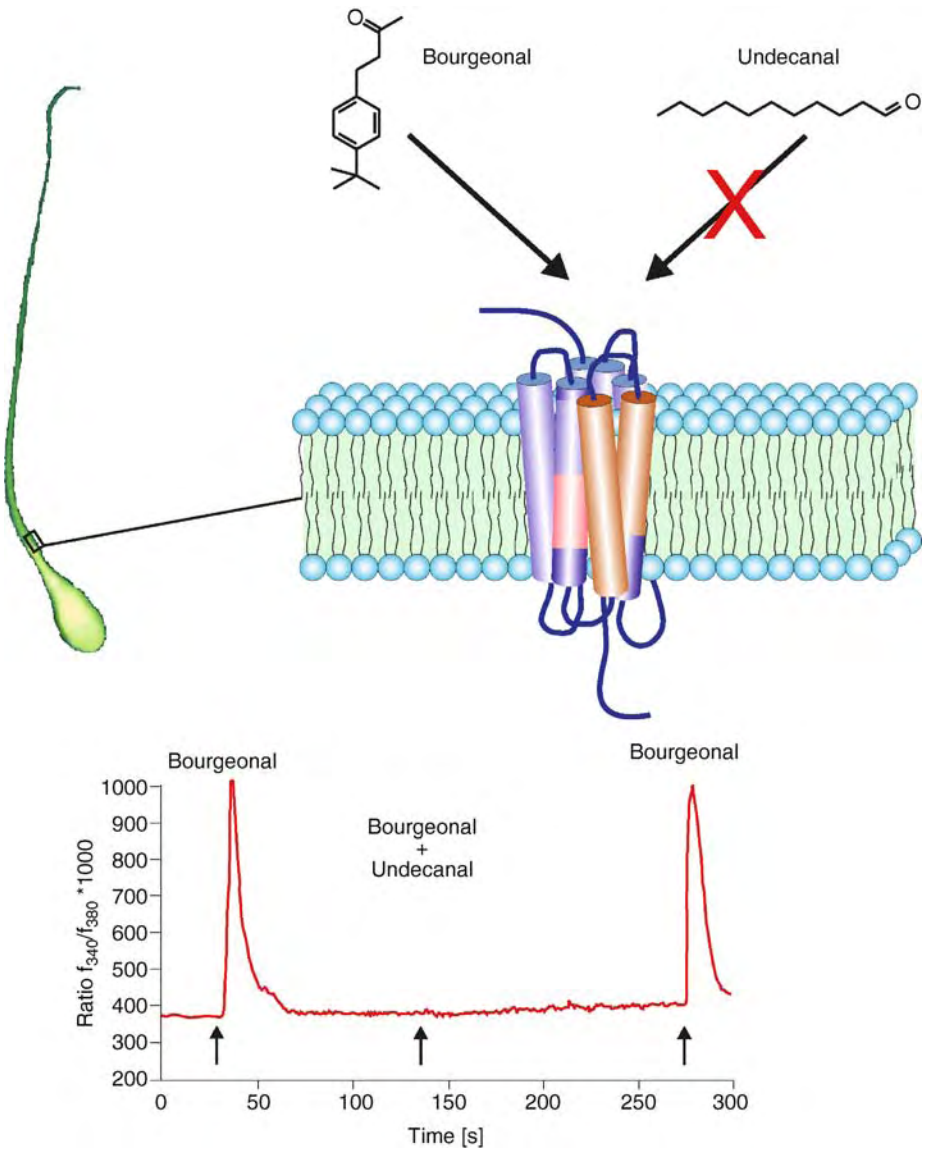


**Olfactory Sense. Figure 3** (a) Olfactory receptor neurons expressing the same olfactory receptor protein project to a specific glomerulus in the olfactory bulb. (b) Schematic activation model of the glomeruli after stimulation with the scent of rose or orange.

constant activation pattern. For instance, when we smell the odor of a rose, the complex odorant mixture in a rose essential oil activates about hundred different receptor types and a similar number of glomeruli. The result is a reproducible, but complex pattern of glomerular activation, from which it is possible to interfere by reverse logic which odor mixture has been smelt [9]. The rose scent activation pattern is clearly distinct from e.g., an orange-scent pattern (Fig. 3). Although individual chemical components are present in both odor mixtures, the patterns in activated glomeruli can overlap but are clearly discriminable. In psychology, this representation by a particular shape could be described with the terms "Odor Gestalt" or "Gestalt Recognition." Once we have learned an odor, we can recognize it again, even though some of the information it normally contains may be missing. Many artificial rose or orange scents that are industrially produced take advantage of this knowledge.

## Olfactory Receptors Outside the Nose

Recently it could be shown that olfactory receptors also exist and play an important functional role outside the olfactory epithelium: in human sperm cells. The latter possess olfactory receptor proteins as well as all the other members of the second messenger cascade, the G-protein, adenylate cyclase (Type III) and cyclic nucleotide gated channels [7,10]. Oversimplifying one could say that a sperm cell is nothing more than an olfactory neuron with a tail. Using molecular biological techniques (►Polymerase Chain Reaction (PCR)), biochemical methods (antibodies) and proteome analysis, it was clearly demonstrated that the receptor hOR17–4 is functionally expressed in human spermatozoa. By calcium imaging experiments it was shown that sperm cells indeed get activated by odorants like Bourgeonal or Cyclamal in a concentration dependent manner (Fig. 4). The threshold was in the micromolar range. Sperm react exactly to the same profile of active and inactive substances of the hOR17–4 as the recombinantly expressed receptor. Interestingly, the activation of hOR17–4 is completely inhibited by simultaneous presentation of the competitive inhibitor Undecanal [7]. These studies on the pharmacology of the sperm odorant receptor were then extended to the physiology of spermatozoa: Human sperm cells showed a concentration dependent positive chemotactic behavior to stimulating odorants (Bourgeonal, Cyclamal) and doubled their speed in presence of the odor. When the antagonist was applied, the effects of Bourgeonal on sperm navigation and swim speed were strongly inhibited. These data suggest that hOR17–4 signaling potentially governs chemical communication between sperm and egg cell. Additional studies made the important finding that this sperm receptor is in fact also expressed in human olfactory receptor neurons. Careful analysis of human tissue revealed bonafide expression of hOR17–4 in nasal epithelium [8]. The nose smells what sperm attracts. These data could potentially be used to manipulate fertilization with important consequences for contraception and procreation, but also to develop sniffing tests for identification of patients with fertilization problems based on functional olfactory receptors.



**Olfactory Sense. Figure 4** Bourgeonal works as a potent receptor agonist of hOR17–4 in human spermatozoa, whereas Undecanal inhibits this effect.

►Olfactory Peduncle

## Olfactory Tubercle

### Definition

From the olfactory trigone, the intermediate olfactory stria continues onto the anterior perforated substance. On top of the anterior perforated substance, there is a layer of gray matter, which is called the olfactory tubercle. In most mammals, the olfactory tubercle is a prominent bulge on the ventral surface of the frontal lobe situated caudally to the olfactory peduncle and medially to the lateral olfactory tract of mammals. It receives afferent input from the lateral olfactory tract. The olfactory tubercle differs from the piriform cortex in that it does not send output projections to the olfactory bulb or to any other secondary olfactory structure. The outputs of the olfactory tubercle are directed towards the thalamus, ventral pallidum, nucleus accumbens and, in monkeys, the orbitofrontal cortex. The inputs and projections to and from olfactory tubercle can vary substantially among species. The olfactory tubercle resembles the underlying corpus striatum and thus is often combined with the nucleus accumbens to the ventral striatum. In humans the olfactory tubercle is poorly developed resulting in a difficult visualization using functional imaging techniques.

## Oligoclonal Bands (OCBs)

### Definition

OCBs are distinct bands of IgG seen in electrophoretic analysis of CSF in MS patients. A few antibody-producing plasma cell clones produce the IgG within the CNS. This pattern is not normally seen since most IgG in CSF is derived from serum and appears as diffuse broad bands in CSF as well as in serum. In MS, two or more bands must be seen in CSF and be absent in serum indicating intrathecal synthesis of IgG. Though approximately 90% of CDMS patients have OCBs, they may also be found in patients with other CNS inflammatory or infectious diseases.

►Multiple Sclerosis

## Oligodendrocyte

### Definition

Oligodendrocytes are a type of glial cell in the CNS. The cytoplasmic extensions of these cells form myelin, which wraps around large axons. One oligodendrocyte can myelinate up to 30 axons. Oligodendrocytes are found predominantly in the white matter of the CNS. Diseases of oligodendrocytes include demyelinating diseases such as multiple sclerosis, leukodystrophies and tumors named as oligodendrogliomas.

## Omnipause Neuron Area

### Definition
A small region on the midline of the brainstem near the boundary of the pons and medulla. Neurons in this structure discharge at high tonic rates whenever an animal is fixating, but then turn off sharply and completely for saccades in all directions. These cells function as an inhibitory brake on other saccade-related cells in the saccadic system during fixation and help to prevent unwanted saccades from occurring.

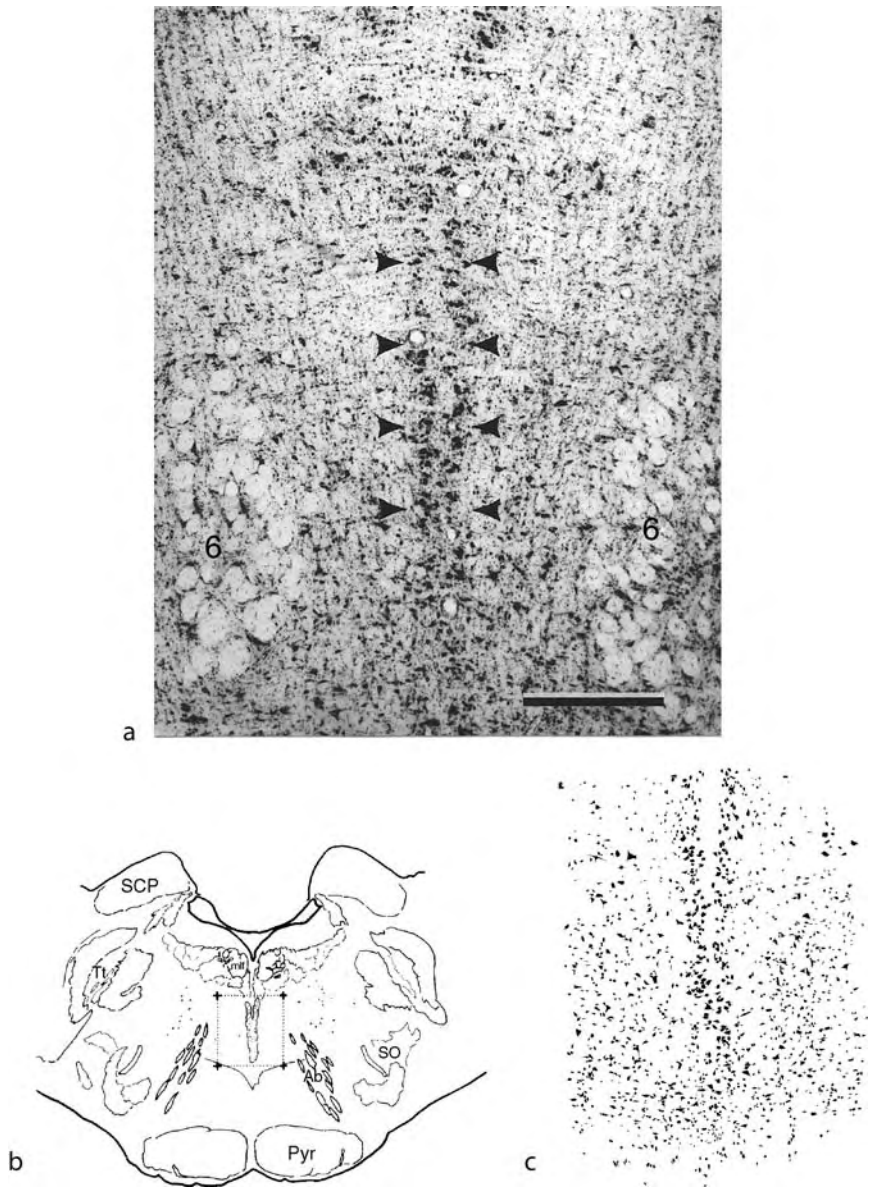
►Omnipause Neuron
►Saccade, Saccadic Eye Movements

## Omnipause Neurons

Chris R. S. Kaneko
Department of Physiology and Biophysics, Washington National Primate Research Center, University of Washington, Seattle, WA, USA

### Synonyms
Pause neurons (pns); OPNs

### Definition
Omnipause neurons (OPNs) are the neurons that control saccadic eye movements by inhibiting the activity of all burst neurons. Burst neurons, in turn, directly drive the saccadic burst in motoneurons that produces the saccade. These neurons are located in the medial pons between the rootlets of the abducens nerves as they leave the brainstem ([4], Fig. 1). They are normally tonically active and discharge at a constant high rate (up to 200 ►spikes/s in ►rhesus monkey) that is unrelated to eye position (rasters and histogram, Fig. 2 bottom two traces in each panel). They cease firing (pause) before and during all saccades (Fig. 2). Their



**Omnipause Neurons. Figure 1** OPN Anatomy. (a) Photomicrograph of the nucleus raphe interpositus (rip; arrowheads). OPNs are co-extensive with the rip and form a bilaminate columnar nucleus that straddles the midline between the rootlets of the abducens nerve [1]. (b) Tracing of the frontal section for orientation. The photomicrograph in (a) was taken from this section (dotted box). (c) Drawing of every neuron in (a) to show the distinct appearance of the OPNs is not due to poorly stained neurons, that the OPNs are larger than neighboring neurons, and are further distinguished by their isolated position between the longitudinal fiber tracks. pause begins just before (~15 ms) the onset (Fig. 2, thin vertical lines) of the movement and a few ms before the burst in medium lead burst neurons (mlbns). The duration of the pause is highly linearly correlated with saccade duration (Fig. 2b, middle). Anatomical studies have shown that OPNs project directly to both horizontal and vertical burst neuron regions. Physiological studies confirm that OPNs monosynaptically inhibit burst neurons. Based on their discharge and their connections, there is no doubt that OPNs control saccades by gating the activity of burst neurons.

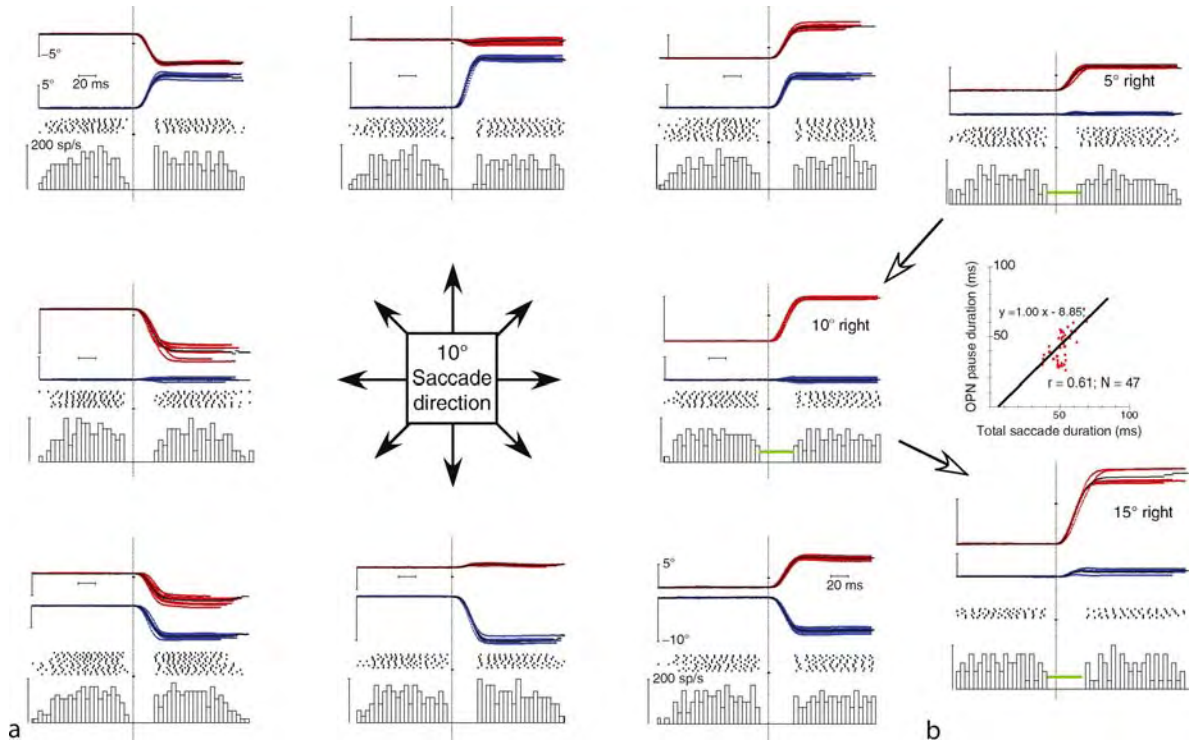
OPNs are perhaps the most studied of the neurons that comprise the saccadic ▶burst generator, and saccades may be the best characterized motor system, so we know quite a bit about OPN anatomy and physiology. In 1972, Luschei and Fuchs [1] and Cohen



**Omnipause Neurons. Figure 2** Discharge of OPNs. and Henn [2] reported recording eye movement related neurons in the pontine and medullary ►reticular formation of alert monkeys. One class, the OPNs, discharged at a high tonic rate (Fig. 2, rasters and histograms) but ceased firing in association with saccades or ►quick phases in any direction (Fig. 2a). Shortly thereafter, Keller [3] showed that electrical microstimulation of OPNs prohibited saccades and quick phases of ►nystagmus. This result immediately suggested their function was to control saccades by discharging at a high tonic rate in order to tonically inhibit burst neurons. These early results led to Robinson's model of saccadic control [4] that posited the role of OPNs was to prevent the discharge of the high gain, burst neurons that might otherwise cause instabilities in the system and thus, unwanted eye movements. He further suggested that saccades were initiated by a trigger signal of unknown origin mediated by an inhibitory interneuron and originating from more central structures like the superior colliculus. A final element was that the OPNs were modeled as being actively inhibited during the saccade to prevent unwanted interruptions of the saccade by means of a latch circuit comprised of burst neuron feedback to OPNs via another inhibitory interneuron.

While the basic circuit has been confirmed thoroughly in both cats and monkeys, some of the other details of the Robinson model [4] have garnered only rudimentary support. Anatomical tracing studies (e.g. [5]) showed that OPNs projected to each of the areas that contained saccadic burst neurons (see ►HMLBs (horizontal medium lead burst neurons), ►PPLLBs (ponto-pontine LLBs), ►PCbLLBs (precerebellar LLBs), and ►RSLLBs (reticulospinal LLBs)). Later, intracellular staining and modern tracing studies using transneuronal labeling have unequivocally demonstrated the projection from OPNs to burst neurons. Electrophysiological studies in cats have shown that this monosynaptic connection is inhibitory in all cases. Recent immunolabeling suggests that OPNs use glycine to inhibit burst neurons. Recordings from alert cats and monkeys and anatomical studies of their afferents has shown that the high rate of tonic discharge is probably due to a multiplicity of afferent input from all sensory modalities

[6]. This surmise is corroborated by the fact that OPNs are silent when animals go to sleep, and that a burst of OPN activity can be recorded if an afferent volley is synchronized by, for example, a click of sound. On the other hand, a neural basis for the trigger and the latch is yet to be established. Intracellular recording from identified cat OPNs has shown that they are inhibited during saccades. The inhibitory ►postsynaptic potentials (ipsps) are characterized by an initial abrupt hyperpolarization that decays back to resting, with a time course that is well correlated with saccadic eye velocity, consistent with them receiving both trigger and latch inputs. The ipsp decay is expected if it is caused by burst neuron input whose discharge is also highly correlated with eye velocity. Electrical microstimulation amongst long-lead burst neurons (LLBs) suggests some of them may be appropriate inhibitory interneurons to provide some of that input, but the juxtaposition of these elements has made it difficult technically to affect each element independently and thereby produce more substantive proof.

OPNs receive their major saccadic input from the contralateral superior colliculus. The input appears to be heavier from the caudal than the rostral portions of the colliculus and more concentrated from the lateral portions than the medial. The input is both monosynaptic (excitatory) and disynaptic (inhibitory), and it is assumed that the inhibitory input is relayed via an inhibitory interneuron and acts as a trigger for saccade generation. As mentioned, their high tonic rate is maintained by multiple afferent sources that use gamma-aminobutyric acid, glycine and glutamate but not monoamines as transmitters [7].

OPNs have been identified in man by immunohistochemistry and damage to OPNs has been invoked to explain a variety of eye movement pathologies, like square wave jerks, that result in oscillopsia. However, either transient or permanent inactivation of OPNs in monkeys leads to slower saccades (longer durations and lower peak velocities), possibly due to inactivation of ►post-inhibitory rebound in the EBNs that they innervate.

## Characteristics

### Higher Order Structures

There are three higher order structures that influence OPNs directly. OPNs receive input from the contralateral superior colliculus. Whether they also receive an ipsilateral input remains controversial. There also may be inputs from the frontal eye fields. One that projects directly to the pons, but this is still uncertain, and another that is indirect via the superior colliculus. Based on anatomical evidence, OPNs may also receive direct input from the caudal fastigial nucleus of the cerebellum that is presumably excitatory. The fastigial input may play a role in adaptive plasticity of saccade amplitude and/or saccadic error correction during on-going saccades by allowing fastigial output to terminate the saccade.

### Parts of This Structure

OPNs have been studied extensively in cat and monkey and there are a number of differences between the species. The somata of the majority of OPNs (Fig. 1) are located in the nucleus raphe interpositus (rip) [8] in the monkey and in the nucleus raphe pontis in the cat [5]. In both species, occasional OPNs can be found in the surrounding reticular formation; specifically the caudal nucleus reticularis tegmenti pontis in the monkey [5] and the superior central nucleus in the cat. In the monkey, it appears that virtually all neurons in the rip are OPNs [5]. They are medium-sized (~35 μm diameter), multipolar neurons in monkey (Fig. 1a). In cat, their shape ranges from spindle shaped to spheroid and they are slightly larger (~46 μm, [9]). In monkey, OPNs send long horizontal dendrites in both directions, and the contralateral branches extend across the midline and into the longitudinal fiber tracts that traverse this portion of the pons in the ventral portion of, and below the medial longitudinal fasciculus. In contrast, cat OPN dendritic fields are ellipsoidal and only a minority have dendrites that cross the midline. Axons arise from the soma and bifurcate either ipsilaterally, or more usually, contralaterally after crossing the midline. In the cat, the stem axons are about 4 μm in diameter and the branch axons are about 3 μm in diameter. In the cases, from cat, where axons could be traced to terminal boutons, all were found in burst neuron regions and were either en passage or terminaux endings. The former were 2.6 μm in diameter and the latter 2.8 μm. Detailed intracellular fills are not available for monkey OPNs.

### Function of This Structure

OPNs provide tonic inhibition to the saccadic burst neurons to prohibit saccades except when they are silenced. In addition, clinical and inactivation evidence suggests that the inhibition, when interrupted, contributes to activation of a post-inhibitory rebound in burst neurons that potentiates the very high-frequency discharge of burst neurons. Besides this permissive role in saccades, the OPNs also serve to coordinate various types of eye movements. The horizontal and vertical components of oblique saccades are mediated via separate horizontal and vertical burst neuron groups and are coordinated via OPN disinhibition. Thus, the OPNs serve to cross couple the burst neurons and control oblique saccade duration. This function is featured prominently in models of saccade generation that include both horizontal and vertical burst generators. The coordinating function seems to extend to other types of eye movements because OPNs are silenced during combined eye and head movements, combined ►vergence and ►version movements, as

well as during blinks. They may also have a role in slow pursuit eye movements, but the exact nature of that role is uncertain. Thus, OPNs seem to assist in the timing of coordinated eye movements in general.

### Higher Order Function

OPNS are low-level premotor neurons with no higher order (e.g., cognitive) functions yet indicated. The function of the potential direct, cortical inputs is not clear, but all of the OPN inputs seem to share at least a portion of the responsibility for triggering saccades. Although still somewhat controversial, there don't appear to be any OPNs that are specialized either for head or coordinated eye and head movements, even though some LLBs are so specialized. As mentioned, their connectivity mediates the co-ordination of oblique saccades (►Hering's Law of equal innervation), and the push-pull organization of EBNs and IBNs results in relaxation of antagonist during agonist activation (►Sherrington's Law of reciprocal innervation). There is also emerging evidence that OPNs may play a role in the coordination of smooth pursuit and saccadic eye movements in both cats and monkeys, but the nature of that role has not yet been elucidated.

### Quantitative Measure for This Structure

Just as for other elements of the saccadic burst generator, the number of OPNs is not clear because of technical limitations in marking all of them so that they may be counted. Perhaps transneuronal retrograde labeling techniques will allow an estimate in the near future. Likewise, virtually nothing is known about the unitary ipsps OPN output to burst neurons or the membrane biophysics of OPNs.

## Ontology

### Definition

Ontology is the study of being or of what there is. Typically, ontologies of philosophers might comprise concrete objects like chairs or electrons, abstract objects like numbers or ►propositions, properties like the property of being a chair, facts like the fact that Paris is west of Warsaw, or events like the 2004 World Series.

►Epiphenomenalism

## Opacity

### Definition

Primarily a feature of certain sentences, e.g., of many ascriptions of propositional attitudes. The truth of such ascriptions does not systematically depend on the truth or falsity of the proposition involved. Consider the following two belief-ascriptions: "Mary believes that 1 + 1 = 2" and "Mary believes that 2756 + 488 = 3244." Even though both propositions ("1 + 1 = 2" and "2756 + 488 = 3244") are true, the two beliefascriptions can differ in truth-value. Whether it is true that Mary believes that 2756 + 488 = 3244 therefore does not systematically depend on the truth of "2756 + 488 = 3244."

## Open Loop Behavior

### Definition

Behavior that is executed without feedback control. This may, in nature, be due to completing a task before feedback is possible.

## Open Reading Frame

### Definition

The region of the gene between the start and stop codon that encodes for the protein.

## Operant

### Definition

Control by the consequences, i.e. by positive or negative reinforcement (=punishment) that is the result of a particular behavior and that shapes the future expression of that behavior.

## Operant Conditioning

Björn Brembs
Freie Universität Berlin Fachbereich Biologie, Chemie, Pharmazie, Institut für Biologie – Neurobiologie, Berlin, Germany

### Synonyms

Instrumental conditioning

### Definition

Operant conditioning describes a class of experiments in which an animal (including humans) learns about the consequences of its behavior and uses this knowledge to control its environment.

### Characteristics

Our life consists of a series of experiences in which we learn about our environment and how to handle it. Learning about the environment ("the plate is hot") and learning the skills to control it ("riding a bike") have been experimentally conceptualized as classical and operant conditioning, respectively. The two are so intertwined that a treatment of operant conditioning is impossible without reference to classical conditioning.

### Operant Conditioning

Operant (instrumental) conditioning [1] is the process by which we learn about the consequences of our actions, e.g., not to touch a hot plate. The most famous

operant conditioning experiment involves the "Skinner-Box" in which the psychologist B.F. Skinner trained rats to press a lever for a food reward. The animals were placed in the box and after some exploring would also press the lever, which would lead to food pellets being dispensed into the box. The animals quickly learned that they could control food delivery by pressing the lever. However, operant conditioning is not as simple as it first seems. For instance, when we touch a hot plate (or the rat the lever), we learn more about the hot plate than about our touch: we avoid contact of any body part with the plate, not only the hand that initially touched it. Obviously, we learned that the hot plate burns us. It is not only confusing that this type of environmental learning is usually called classical conditioning, we cannot even be sure that it is the only process taking place during conditioning.

## Classical Conditioning

Classical (Pavlovian) conditioning [2] is the process by which we learn the relationship between events in our environment, e.g., that lightning always precedes thunder. The most famous classical conditioning experiment involves "Pavlov's dog": The physiologist I.P. Pavlov trained dogs to salivate in anticipation of food by repeatedly ringing a bell (conditioned stimulus, CS) before giving the animals food (unconditioned stimulus, US). Dogs naturally salivate to food. After a number of such presentations, the animals would salivate to the tone alone, indicating that they were expecting the food. The dog learns that the bell means food much as we learn that the plate is hot in the operant example above. Therefore, it is legitimate to ask if operant conditioning is in essence a classical process. Both operant and classical conditioning serve to be able to predict the occurrence of important events (such as food or danger). However, one of a number of important differences in particular suggests that completely different brain functions underlie the two processes. In classical conditioning, external stimuli control the behavior by triggering certain responses. In operant conditioning, the behavior controls the external events.

## The Relationship Between Operant and Classical Conditioning

Ever since operant and classical conditioning were distinguished in 1928, their relationship has been under intense debate. The discussion has shifted among singular stimulus-response concepts, multiprocess views, and a variety of unified theories. Today, modern neuroscience distinguishes between procedural memories (skills and habits) and declarative memories (facts or events). The intensity and duration of the debate can in part be explained by the fact that most learning situations comprise operant and classical components to some extent: one or more initially neutral stimuli (CS), the animal's behavior (BH), and the ►reinforcer (US). The example above of learning to avoid touching a hot plate is very instructive. Extending the hand (BH) toward the round hotplate (CS) leads to the painful burn (US). In principle, our brain may store the situation as memory of the pain associated both with the hotplate (classical conditioning, CS-US) and with the extension of the hand (operant conditioning, BH-US) to predict the consequences of touching the plate at future encounters.

## Habit Formation

A phenomenon called habit formation [3] confirms the tight interaction between operant and classical components in operant conditioning. In the early stages of an operant conditioning experiment (e.g., a rat pressing a lever for food in a Skinner box), the animal performs the lever presses spontaneously with the aim of obtaining the food (goal-directed actions). This can be shown by feeding the animals to satiety after training: they now press the lever less often when they are placed back in the box, because they are not hungry anymore. However, the same treatment fails to reduce lever pressing after the animals have been trained for an extended period. The behavior has now become habitual or compulsive; whenever the animals are placed now in the box, they frantically press the lever even if they are not hungry (or even if the food will make them sick). Although in the early stage of operant conditioning the behavior controls the environment (lever pressing to obtain food), habit formation effectively reverses the situation such that now the environment (box, lever) controls the behavior (lever pressing). One could say that overtraining an operant situation leads to a situation very similar to a classical one. Thus, operant conditioning consists not only of two components (operant and classical) but also of two phases (goal-directed and habitual behavior), with the relationship of the components changing with the progression from one phase to the next. Despite many decades of research filling bookshelves with psychological literature, our neurobiological understanding of the mechanisms underlying these processes is rather vague. What little is known comes from a number of different vertebrate and invertebrate model systems on various levels of operant conditioning. This essay is an attempt to integrate the neuroscience gained from many such disparate sources.

## Neuroscientific Principles in Operant Conditioning

If there is a consensus for a critical early-stage process in operant conditioning, it is that of reafference. To detect the consequences of behavior, the brain has to compare its behavioral output with the incoming sensory stream and search for coincidences. The

neurobiological concept behind this process is that of corollary discharges (or efference copies). These efference copies are "copies" of the motor command sent to sensory processing stages for comparison. Thus, neurobiologically, any convergence site of operant behavior and the US is very interesting with regard to potential plasticity mechanisms in operant conditioning. The efference copies serve to distinguish incoming sensory signals into self-caused (reafferent) and other, ex-afferent signals [4]. Modern theories of operant conditioning incorporate and expand this reafference principle into two modules: one is concerned with generating variable behavior and another predicts and evaluates the consequences of this behavior and feeds back onto the initiation stage [5]. Some evidence exists that the circuits mediating these functions are contained within the dorsal and ventral striatum of the vertebrate brain. We have only very poor mechanistic knowledge about the first module. Behavioral variability could be generated actively by dedicated circuits in the brain or simply arise as a by-product of accumulated errors in an imperfectly wired brain (neural noise). Despite recent evidence supporting the neural control of behavioral variability, the question remains controversial. Only little more is known about the neurobiology of the second module. Promising potential mechanisms have been reported recently from humans, rats, crickets, and the marine snail *Aplysia*. These studies describe conceptually similar neural pathways for reafferent evaluation of behavioral output (via efference copies) and potential cellular mechanisms for the storage of the results of such evaluations at the convergence site of operant behavior and US. However, to this date, a general unifying principle such as that of synaptic plasticity in classical conditioning is still lacking.

From a larger perspective, there is evidence suggesting that the traditional distinction of entire learning experiments into either operant or classical conditioning needs to be reconsidered. Rather, it appears that an experimental separation of classical and operant components is essential for the study of associative learning. As outlined above, most associative learning situations comprise components of both behavioral (operant) and sensory (classical) predictors. Vertebrate research had already shown that operant and classical processes are probably mediated by different brain areas. Research primarily from the fruit fly *Drosophila* and *Aplysia* has succeeded in eliminating much if not all of the classical components in "pure" operant conditioning experiments, a feat which has so far proven difficult to accomplish in any modern vertebrate preparation. This type of operant conditioning appears more akin to habit formation and lacks an extended goal-directed phase. These paradigms successfully reduce the complexity of operant conditioning by isolating its components and as such are vital for the progress in this research area. The new invertebrate studies revealed that pure operant conditioning differs from classical conditioning not only on the neural, but also on the molecular level. Apparently, the acquisition of skills and habits, such as writing, driving a car, tying laces, or our going to bed rituals is not only processed by different brain structures than our explicit memories, but also the neurons use different biochemical processes to store these memories.

The realization that most learning situations consist of separable skill-learning and fact-learning components opens the possibility to observe the interactions between them during operant conditioning. For instance, the early, goal-directed phase is dominated by fact learning, which is facilitated by allowing a behavior to control the stimuli about which the animal learns. Skill learning in this phase is suppressed by the fact-learning mechanism. This insight supports early hypotheses about dominant classical components in operant conditioning [6], but only for the early, goal-directed phase. If training is extended, this suppression can be overcome and a habit can be formed. Organizing these processes in such a hierarchical way safeguards the organism against premature stereotypization of its behavioral repertoire and allows such behavioral stereotypes only if they provide a significant advantage. These results have drastic implications for all learning experiments: as soon as the behavior of the experimental subject has an effect on its subsequent stimulus situation, different processes seem to be at work than in experiments where the animal's behavior has no such consequences, even if the subject in both cases is required to learn only about external stimuli. Conversely, apparently similar procedural tasks that differ only in the degree of predictive stimuli present may actually rely on completely different molecular pathways. The hierarchical organization of classical and operant processes also explains why we sometimes have to train so hard to master certain skills and why it sometimes helps to shut out dominant visual stimuli by closing our eyes when we learn them.

## Operant Conditioning

### Definition

A Definition of operant conditioning, also called instrumental conditioning, requires a distinction between elicited and emitted behavior. Elicited behavior is a response that is associated with a biologically relevant stimulus. Pavlovian or classical conditioning is an example of elicited behavior since there is always a formal, temporal relationship between the conditional stimulus (for example, a bell) and the unconditional stimulus (for example, meat powder to the tongue which elicits salivation). After a number of pairings, the conditional signal is seen to elicit a response that is similar to that elicited by the unconditional stimulus. Emitted behavior is behavior, which is produced by the subject in order to obtain a desirable outcome (commonly called a reinforcer): such behavior is said to operate upon the environment to produce reinforcement. In typical studies of operant conditioning, the availability of the reinforcer is signaled by a cue of some sort. Thus, the relationship between elicited and emitted behavior is complex. However, any discussion of this issue goes well beyond the subject matter of this essay.

## Operational Closure

### Definition

Operational (or organizational) closure means that certain relations and processes define a system as a unity, in determining the dynamics of interaction and transformations that the system may undergo as such a unity (Maturana/Varela). Operationally closed systems are not causally closed, i.e. they may interact causally with the environment.

## Opsonin

### Definition

A terminology derived from the Greek and meaning, sauce or seasoning, in other words making the target cells such as pathogen more palatable to the phagocyte and more easily eaten. For example, C3b is an opsonin bound to target cells following complement activation and promoting phagocytosis by macrophages expressing C3 receptors.

►Neurodegeneration and Neuroprotection – Innate Immune Response

## Optic Ataxia

### Definition

Specific impairment of the visual control of limb movements observed in patients with lesion of the posterior parietal cortex. This deficit is expressed as errors both in final limb position in reaching/pointing tasks and in the shaping of hand aperture in grasping tasks. These deficits are exacerbated when the movements are programmed and executed under peripheral vision by asking the patient to keep gaze on a fixation point. Pure forms of optic ataxia, without sensory or motor deficits, indicate a role of the posterior parietal cortex in visuo-motor transformations for limb movement control.

## Optic Axis

### Definition

Where we look, i.e., roughly coincidental with the line of sight.

## Optic Chiasm

### Definition

The optic chiasm is a landmark between the optic nerve and optic tract in the pathway between the retina and lateral geniculate nucleus of the thalamus. It contains the crossing of fibers of the so-called optic nerve to form its continuation, the optic tract of the opposite side. The fibers arise from ganglion cells in the retina. The crossing fibers in the optic chiasm contain information from the temporal visual fields (retinal nasal fields) of both eyes. Uncrossed fibers in the optic chiasm contain information from the nasal visual fields (temporal retinal fields) of both eyes. The chiasm is located on the ventral surface of the brain at the level of the anterior hypothalamus.

## Optic Flow

Markus Lappe
Psychologisches Institut II, Westf. Wilhelms-Universität, Fliednerstrasse, Münster, Germany

### Synonyms

Optical flow; (optic) Flow field; Retinal flow

### Definition

Optic flow is the pattern of motion induced on the retina of a moving observer.

### Characteristics

#### Mathematical Properties

Optic flow arises from the movement of an observer through a static visual scene. The movement of the observer creates relative movement between the visual objects in the scene and the eye of the observer. The projection of the relative movement of the scene objects

onto the ►visual field of the observer creates ►visual motion. The collection of all the visual motions from throughout the visual field forms the optic flow. Since the motion in the visual field is first sensed by its projection on the retina, retinal flow is the collection of all image motion on the retina that arises from observer movement.

The retinal projection of the relative movement of a point in the scene can be described as a motion *vector*, i.e., by noting the motion direction and speed on the retina. The direction depends on the particular self-motion that the observer performs. When the observer moves to the left, all image motion is directed to the right. When the observer moves straight forward, all image motion is directed radially away from a point in the movement direction of the observer. This point is known as the ►focus of expansion. The speed of a particular motion vector in the optic flow depends on the distance of the point from the eye of the observer. Points near to the observer move faster in the retinal projection than points further away. The difference in the speeds of two points in the same visual direction but in different distances from the observer is known as ►motion parallax.

Optic flow not only arises from linear translations of the observer, such as sideward or forward movement, but also from rotations. Such rotations can occur either from moving along a curve or from eye movements of the observer. For example, when the observer performs an eye movement from right to left then rightward visual motion is induced on the retina. However, unlike in the case of leftward linear translation, the speeds of the motion vectors induced by eye rotation do not depend on the distance of the respective scene points from the observer. All points move with the same speed which is exactly opposite to the speed of the eye movement.

Thus, a single optic flow vector $\theta$ of a point R in the scene is mathematically a function of the translation T and rotation $\Omega$ of the eye of the observer and the distance Z of the point from the eye: $\theta = f(T, \Omega, Z)$. The precise equation is derived from perspective geometry [1]. Important for many aspect of flow analysis is the fact that in this equation the observer speed T and the depth Z are coupled such that the flow depends only on the quotient T/Z, not on Z directly.

The simplest optic flow is that of the radial outward movement obtained from linear forward movement. However, this is only a special case and the combination of translation, rotation, and scene distances can give rise to very different optic flow patterns. Since observer movement naturally triggers gaze stabilization reflexes such as the ►vestibulo-ocular reflex or the ►optokinetic reflex the optic flow observed under natural conditions will often result from a combination of translation and eye rotation.

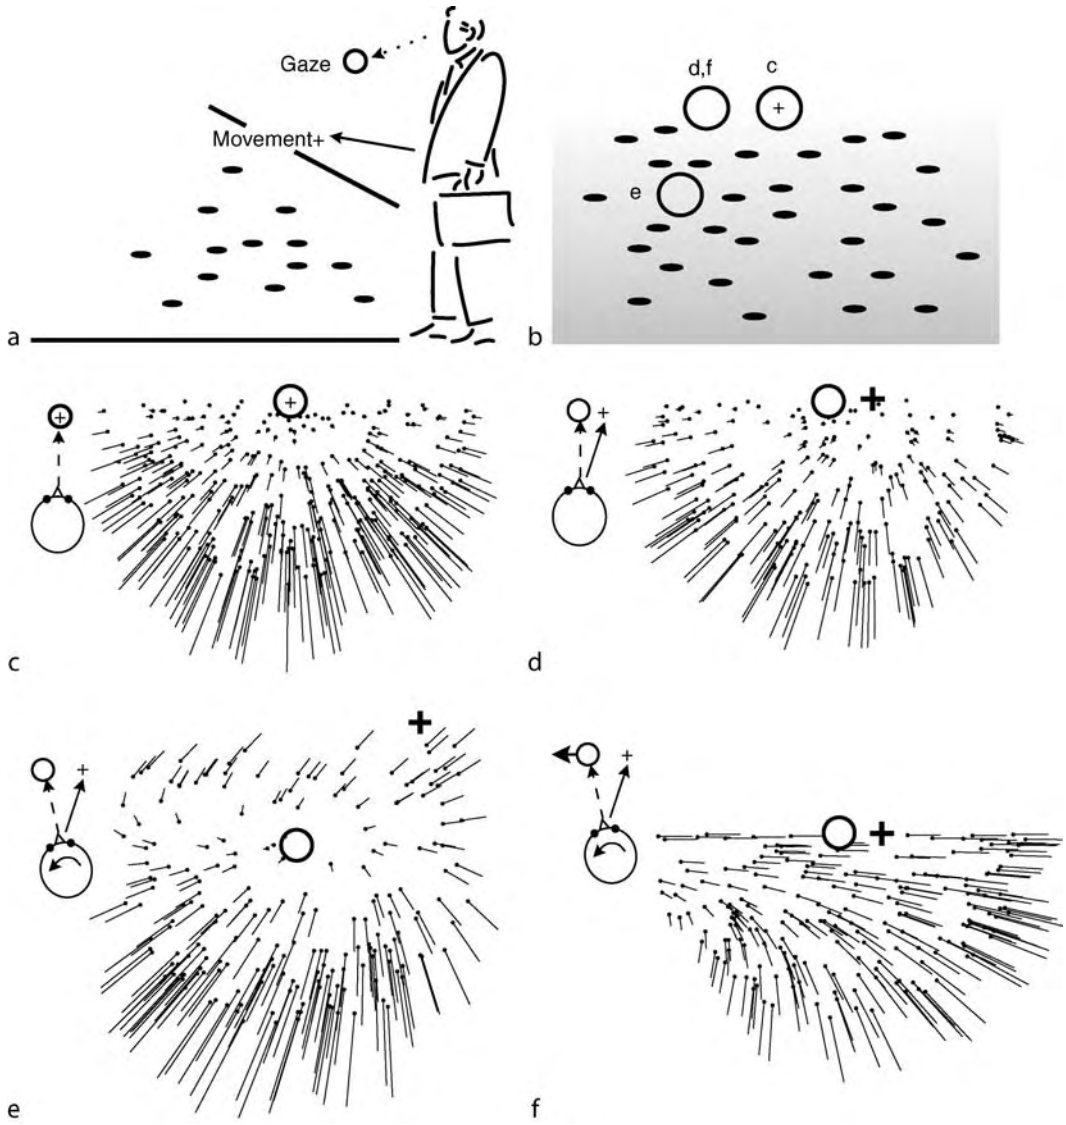
Figure 1 shows a few characteristic examples. The observer moves across a ground plane. Heading is marked by a cross, gaze direction by a circle. Panels c to f show cases where the same heading is combined with different gaze directions. These gaze directions are shown in panel b. Panel c shows the retinal flow when gaze coincides with heading, i.e., when the observer looks straight into the direction of movement. In this case a focus of expansion is centered on the retina. In panel d, the observer looks off to the side. Gazing at some fixed point on the horizon allows him to keep his eyes stationary, i.e., no eye movements occur. A focus of expansion identifies heading, but now it is displaced from the center of the visual field. In panel e, the observer's gaze is directed at some element of the ground located in front of him and to the right. Because gaze is directed downward the horizon is in the upper visual field. Moreover, since the observer now looks at a point that is moving relative to himself, an eye movement is induced to stabilize gaze on this point. The resulting retinal flow field, a combination of translational and rotational flow, resembles a distorted spiraling motion around the fovea. There is no focus of expansion in the direction of heading (+). In panel f the observer looks at the same point as in panel d, but now he tracks an object that moves leftward along the horizon (for instance a car). This leftward pursuit induces rightward retinal image motion. The combination with the forward movement results in a motion pattern that resembles a curved movement and does not contain a focus of expansion.

## Behavioral Aspects

From its conception by Gibson in the 1950s [3] optic flow has been assumed to play a role in the control of self-motion. Since then, experimental studies have shown that optic flow is involved in many behavioral tasks:

*Control of Stance*. Direction and speed of the optic flow are used as feedback signals for postural stability. When standing observers are exposed to a large flow field that periodically expands and contracts they sway in phase with the flow field [4]. The coupling between optic flow and posture maintenance is particularly strong in children and decreases in strength with age as the influence of ►vestibular and somatosensory contributions to postural stability increases.

*Control of Speed*. Walking observers use the speed of the optic flow as a control signal for walking speed. Normally, a particular forward movement leads to a particular optic flow speed. If the flow speed is artificially increased, as has been done for observers walking on a treadmill in front of a projection screen on which a flow pattern was presented, walking speed increased proportionally [5]. Similar effects are seen for bicycling and car driving. When a mismatch between flow speed and walking speed is maintained for a



**Optic Flow. Figure 1** Examples of optic flow fields induced by combinations of forward movement and eye movement. Taken with modifications from [2]. See text for detailed explanation. (a) Observer moves towards the cross while lookins at the circle. (b) different directions of gaze used in panels c to f. (c) Optic flow for straight translation int the direction of gaze. (d) Optic flow when directon of motion differs from direction of gaze. (e) Optic flow when direction of motion differs from direction of gaze and gaze stabilizing eye movement reflexes are taken into account. (f) Optic flow when direction of motion differs from direction of gaze and the observer tracks a moving object.

several minutes, for example when the flow speed is constantly lower than normal for a runner on a treadmill, an after effect is observed in which the walker inadvertently advances when attempting to run in place on solid ground with eyes closed.

*3D Scene Perception*. Because of motion parallax the optic flow contains information about the distances of the points of the scene. This information can be extracted to estimate the relative distances between objects in the scene and to recover surface layout [1]. Absolute distances cannot be retrieved from the optic flow because flow magnitude depends on the quotient of observer speed (T) and point distance (Z). For example, in an airplane flying high above the ground optic flow speed is very low even for very high forward speed of the plane. Thus, distance can only be calculated when the observer speed is known, which is usually not the case.

►*Time-to-Contact*. Information in the optic flow allows to estimate the time-to-contact or the time-to-passage with an obstacle during forward motion. By itself, the speed of an optic flow vector of a particular

object is insufficient for the estimation of distance to the object (because it depends on T/Z) but a combination of speed with object size or of speed with the object's visual angle allows a direct calculation of time-to-contact. This information may be used to control braking or catching and to control running speed and direction for the intersection with a target object (for instance in ball sports). An overview can be found in [6].

►*Path Integration*. By integrating the speed of the optic flow over time an estimate of the travel distance or path length of an extended movement can be obtained. This estimate is subject to a scale factor since the speed of the flow depends on both the speed of the self-movement and the distance to the objects in the environment, but in many natural circumstances the height of the observer above the ground can provide the required scale. The estimation of travel distance from optic flow is based on an the integration of an estimate of observer velocity that is derived from the optic flow [7].

*Heading*. Heading refers to the direction of the movement of the observer. Gibson's original proposal for the use of optic flow was the identification of the heading (for example when landing an aircraft) by locating the focus of expansion in the flow field. Most optic flow research since then has centered on heading perception (overviews in [8] and [9]). Indeed, human observers are quite accurate in finding the focus of expansion in an expanding flow field. However, the situation is much more complicated because in most natural situations the optic flow on the retina is influenced by rotations and the flow field does not contain a focus of expansion (cf. Fig. 1). Yet, geometric calculations prove that the optic flow in these cases also contains sufficient information to separate the translational and rotational contributions if several flow vectors are available [1]. Many computational algorithms have been developed for this task, among them a few that are formulated as biologically plausible neurocomputational models (overview in [2]). Human observers can indeed estimate heading from flow fields of translation and rotation with reasonable accuracy (a few degrees of visual angle). An important finding was that heading estimation can be performed solely from the information in the flow field, i.e., from the direction and speed of the flow vectors, without any other sensory signals necessary. However, in natural situations eye movements that influence the structure of the retinal flow are accompanied by extra-retinal eye movement signals such as the ►efference copy signal or eye muscle ►proprioception. These signals are also used in optic flow analysis and increase the accuracy of the heading estimate. Rotational contributions to the retinal flow may also arise from movements on a curved path, in addition to, or instead of eye movements. Therefore, a separation of translational and rotational contributions may only provide the momentary or instantaneous heading but not the full information about the future path of the observer, since the rotational contributions are ambiguous. Estimations of path curvature, which are required for steering for instance, can be derived from successive independent heading estimates or from a combination of optic flow and extraretinal eye movement signals. Alternatively, specialized behavioral strategies, such as fixating a specific point in the flow field, may allow the estimation of steering-relevant information directly from the retinal velocities.

Although the above descriptions refer to human observers, optic flow is used for such behavioral tasks throughout the animal kingdom (see [2] for several examples). The use of optic flow for the control of speed, distance, time-to-contact, and course control has been shown in insects, birds, and mammals, exemplifying the ecological importance of optic flow. Moreover, the above descriptions show that optic flow is often part of multi-modal mechanisms for behavioral control, interacting with ►proprioceptive, vestibular, and internal feedback signals. Exposure to optic flow is also known to induce ►vection, the subjective feeling of self-movement in a physically static observer.

## Neurophysiological Processing

In the visual system of primates visual motion information is routed via V1 and V2 to the ►middle temporal (MT) and subsequently to the ►medial superior temporal area (area MST) and other visual areas in the parietal lobe. Most clearly related to optic flow is area MST (detailed reviews in [2]). Many neurons in area MST respond selectively to entire optic flow patterns and not just to an individual motion vector in a particular flow field. A neuron might respond selectively to a particular flow pattern, such as an expansion as in Fig. 1c, but when tested with small stimuli the selectivities in subfields of the ►receptive field do not match one-to-one the pattern of the preferred large flow field. Thus, MST neurons are genuinely selective for optic flow. Their selectivity arises from complex interactions between selectivities in local subfields. Functional ►brain imaging in humans has confirmed an area selective for optic flow which is part of the human ►MT± complex.

When tested with multiple different flow patterns such as visual expansions, rotations and translations, MST reveals a continuum of response selectivities. Some neurons respond to several different patterns or to flow fields that combine translational and rotational contributions. Instead of classifying the selectivity of MST neurons by the preferred pattern of flow it is also possible to describe their selectivity in terms of heading. Indeed, it is possible to calculate heading from the firing rates of the neuronal population in MST. Next to visual motion signals, area MST also receives extra-retinal eye movement information. This information is used to counteract the effects of eye movements on the retinal

flow and maintain selectivity for heading in the presence of eye movements. There are also interactions with vestibular signals during self-motion.

Other areas of the parietal lobe, the ►ventral intraparietal area (VIP) and area 7A, as well as the ►fundus of the superior temporal sulcus (FST) also respond to optic flow. Neurons in area MT, the major input to area MST, respond to optic flow but their responses can be explained by their selectivity to local image motion within their receptive field. However, some global properties of the visual field map in MT seem related to optic flow analysis. Preferred speeds increase with eccentricity similar to the increase of speed with eccentricity in typical flow fields. The distribution of preferred directions for neurons with peripheral receptive fields is biased towards centrifugal motion similar to the radial motion directions in a typical optic flow. The increase of the receptive field sizes with eccentricity is well adapted to the size of image patches over which neighboring flow signals are uniform. These patches are small in the center of the visual field, where optic flow vectors point in different directions, and large in the peripheral visual field where neighboring flow vectors are usually very similar. Computational modeling shows that this adaptation of receptive field sizes leads to significant noise reduction in the optic flow representation in area MT.

As mentioned above, optic flow is used by many animals. A brief description of the neuronal pathways of optic flow analysis in birds can be found in the essay on *visual-vestibular interactions*. In flies, optic flow is analyzed by a small number of neurons of the horizontal (HS) and the vertical (VS) system in the lobula plate (Krapp in [2]). Unlike neurons of primate MST, which show no simple correlation between local motion selectivities and flow patterns selectivity, the flow selectivity of these neurons in the fly is matched by the sensitivity to local motion in subfields of their very large receptive fields. These neurons seem to form matched filters for particular flow patterns. Like in primate MST, information about the translation and rotation of the animal can be decoded from the population activity.

## Optic Tract

### Definition
The optic tract is the portion of the visual pathway between the retina and lateral geniculate nucleus of the thalamus that lies caudal to the optic chiasm. The portion that is rostral to the optic chiasm is the optic tract. The cell body of origin for this pathway is the ganglion cell in the retina.

## Optic Tract Nucleus

### Synonyms
►Nucl. tractus optici; ►Nucleus of optic tract

### Definition
The optic tract nucleus lies in the Myelencephalon near the superior colliculus. The nucleus is fused with the dorsal terminal nucleus and is an important center of the subcortical pathway which mediates horizontal optokinetic nystag

►Diencephalon

## Optical Coherence Tomography (OCT)

### Definition
OCT is an emerging ocular imaging technique to measure optic structures with micrometer resolution. It is useful in the measurement of retinal nerve fiber layer (RNFL) thickness and total macular volume corresponding to the ganglion cell body layer. The thickness of these unmyelinated nerve fiber layers may reflect axonal integrity, and function (vision) may be directly correlated with structure. Though RNFL thickness may be significantly decreased in multiple scerosis (MS) patients with optic neuritis compared to healthy controls, even in MS patients with no history of optic neuritis, RNFL may still be decreased in thickness consistent with a neurodegenerative disease model of MS.

## Optimal Muscle Length

### Definition
The optimal length of a muscle is defined as the length at which a muscle can exert its maximal isometric steady-state force.

►Force Depression/Enhancement in Skeletal Muscles
►Length-tension

## Optimization

### Definition
An algorithm to achieve a particular goal while minimizing one, or a set of criteria. Mathematical optimization is defined by minimizing, maximizing, or optimizing a specific function (typically called the objective or cost function) while simultaneously satisfying any equality and/or inequality constraints. Mathematical Optimization has been the preferred approach to solve the distribution problem in biomechanics.

►Distribution Problem in Biomechanics
►Motor Control Models

## Optimization Model for Motor Control and Learning

### Definition
Computational models based on the idea that motor control and learning are planned and executed so as to achieve a behavioral goal, namely a tradeoff between task performance, body stability, and energy consumption. These models explain invariant movement features as a result of optimality and motor learning as a relaxation process toward a global minimum of a behavioral goal. Voluntary arm reaching, for example, has been modeled as smoothness or accuracy maximization, and locomotion as gait optimization in such a way as to maximize traveling distance using minimal muscle work.

## Optokinetic After-Nystagmus (OKAN)

### Definition
When subjects are placed in darkness following optokinetic nystagmus, the nystagmus continues and

the slow phase velocity has characteristics similar to Per- and Post-Rotatory Nystagmus. The presence of OKAN can be directly related to activation of velocity storage.

►Optokinetic Nystagmus
►Per-rotatory Vestbular Nystagmus
►Velocity Storage

## Optokinetic Nystagmus (OKN)

### Definition

A physiological nystagmus that occurs when a large part of the image moves uniformly over the retina, such as when viewing objects from a moving train or turning around. It consists of two components of eye movements: slow phase, which moves the eyes to follow the visual scene motion (called optokinetic response), and quick phase, which rapidly reset the eye position deviation by slow phase.

►Nystagmus
►Optokinetic Response

## Optokinetic Reflex

### Definition

►Optokinetic Nystagmus (OKN)

## Optokinetic Response

### Definition

Compensatory head, eye and body movements in response to motion of the entire visual world. They function to control gaze, posture and locomotion (alternatively known as optomotor responses).

►Visual-Vestibular Interaction

## Optokinetic Response Adaptation

Charles A. Scudder
Portland, OR, USA

### Definition

Optokinetic response (OKR) adaptation is a behavioral change and underlying neural process that increases the ability of the optokinetic system to move the eyes and track moving large-field visual stimuli (see ►Optokinetic nystagmus). The adaptation is stimulated by motion of the visual image across the retina (►Retinal slip), and is prominent in species where the performance of the optokinetic system is normally low, such as rodents and fish. The increased efficacy of the OKR acts to reduce image motion across the retina and thereby improve visual acuity.

### Methods to Produce and Measure Adaptation

Methods to produce and measure OKR adaptation are an extension of those used to produce and measure OKR itself. Subjects typically sit at the center of a large cylindrical drum with a visual pattern on the inside that takes up most of the subject's visual field (Fig. 1).

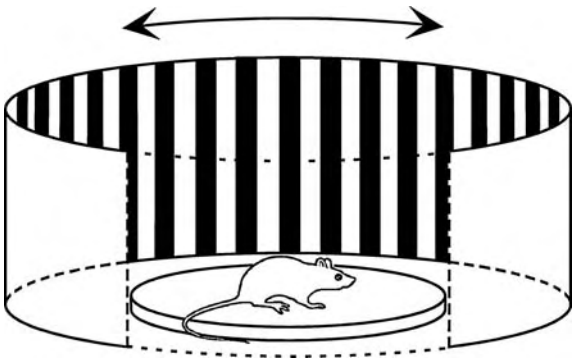
Oscillation of the "optokinetic drum," usually in a horizontal plane, evokes eye-movements that tend to track the motion of the drum (see Optokinetic eye movements). The ability of the eye-movements to track drum motion is often measured as gain, which is the ratio of eye angular velocity to drum angular velocity. Perfect tracking would produce equal eye and drum velocities and a gain of 1.0. Actual gains are always less than one, and cannot exceed one.

Whereas measurement of OKR gain requires only a few minutes, continued drum motion is used to produce adaptation. Adaptation takes place anytime there is retinal slip, but a measurable change in OKR gain requires an hour or so of drum oscillation. Figure 2 illustrates adaptation in a rabbit. OKR gain at the start of adaptation is about 0.5 (eye movement only compensates half of the drum motion). After an hour, OKR efficacy has increased to 0.74, and an additional two hours of adaptation increases gain only slightly more to 0.78.

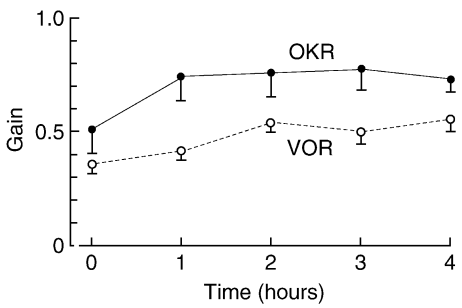
### Characteristics

#### Species Dependencies

OKR adaptation has mainly been observed in rodents [1–3] and goldfish [4] where the gain of the OKR is typically well below 1.0 except at very low drum velocities. This is in part because gains less than one allow adequate retinal slip to produce adaptation in a suitable paradigm, and there is sufficient room below the maximum gain of one for the increased OKR efficacy to



**Optokinetic Response Adaptation. Figure 1** Illustration of the apparatus used to generate and adapt the optokinetic response. A mouse sits on a stationary platform surrounded by an optokinetic drum which oscillates back and forth about a vertical axis. The mouse would be restrained in an actual experiment. The drum is illustrated as being lined on the inside with vertical black and white stripes, but other high contrast patterns have been used. Vestibular responses can be produced by rotating the platform on which the mouse sits. To induce the vestibuloocular reflex (VOR), rotation takes place in the dark, but various VOR adaptation paradigms combine rotation of the mouse with motion of the optokinetic drum in the light.



**Optokinetic Response Adaptation. Figure 2** Plot of the gain of the optokinetic response (OKR – solid line) as a function of the duration of OKR adaptation. OKR gain increases rapidly in the first hour and then plateaus. The paradigm for increasing OKR gain also has the effect of increasing the gain of the vestibuloocular reflex (VOR – dotted line) in rodents. Figure adapted from Nagao et al. [6].

be observed. In one case where OKR gain was close to one at low drum velocities, the effect of OKR adaptation could still be observed at higher drum velocities where OKR gain normally drops well below one [2].

OKR adaptation has not been reported in primates, but neither has it been systematically tested. The excellent tracking of optokinetic targets at velocities less than 60°/s leaves little opportunity for adaptation to occur or to be observed. Moreover, differences between primate and rodent physiology argue that OKR adaptation is less likely in primates. Primates lack the directionally selective retinal ganglion cells that participate in rodent OKR, they have a fovea instead of a visual streak, and ►smooth pursuit rather than OKR dominates primate responses to motion in the visual field.

## Velocity Dependence

OKR adaptation has been produced using optokinetic drum velocities past the limit at which the eyes reliably track the drum. In rodents, this is at low stimulus frequencies (0.1–0.4 Hz) and at peak drum velocities of 3°/s–10°/s. Retinal slip velocities are then between 2°/s and 8°/s. It has been reported that low retinal-slip velocities (<1°/s) do not produce adaptation [3], but this has not been extensively tested.

## OKR Adaptation and Head Movement

The vestibulo-ocular reflex (VOR), which is not a visual-following reflex, acts to counter-rotate the eyes in the head whenever the head moves with the goal of stabilizing the visual scene on the retina (see ►VOR). Adaptation of the VOR occurs when this ocular compensation is imperfect, or in other words, when movement of the head produces retinal slip (see ►VOR adaptation). This retinal slip might be expected to produce OKR adaptation as a byproduct, and indeed it does [1,2]. This is best demonstrated by using different combinations of forced head motion and drum motion in order to create retinal slip velocities that are either in the same or opposite direction as eye motion. For instance, when the drum motion is in the opposite direction as head motion (a paradigm that increases VOR gain), slip velocity is in the same direction as eye velocity. However, when drum motion is in the same direction as the head motion (a paradigm that decreases VOR gain), slip velocity is in the opposite direction as eye velocity. In rodents, both paradigms produce OKR adaptation and the effect of both is to increase OKR gain [1,2]. Apparently retinal slip of any kind augments OKR gain in these animals.

However in monkeys and cats, the situation is different [5]. Paradigms that increase VOR gain also increase OKR gain, and those that decrease VOR gain also decrease OKR gain. In each case, the result is to improve the VOR in the sense that there is less retinal slip during head rotation at the end of the particular paradigm, but the concomitant reduction of OKR gain is maladaptive. This has been interpreted to mean that the primary function of the adaptive mechanisms is to adjust VOR gain, but that the VOR and OKR pathways share a common structure that changes the gain of both systems simultaneously.

Finally, there is the possibility that the OKR-adaptation paradigm (drum motion with no head motion) could

alter the VOR because of the retinal slip. In rodents and goldfish, this paradigm does increase the gain of the VOR [1,4,6] (Fig. 2). However in monkeys, the effect is negligible [7]. The above differences between rodents and primates reinforce the idea that primates are not the same as rodents and goldfish regarding the existence of OKR adaptation.

### Upstream Conditions

As noted above, the existence of retinal slip of adequate velocity is required for OKR adaptation to occur.

### Involved Structures

Adaptation of the OKR presumably involves plasticity at synapses that are part of the normal OKR pathway (see ►Optokinetic eye movements). In most species, this involves indirect projections of from the accessory optic system to the floccular lobe of the cerebellum and then to the vestibular nuclei. Rodents may have an additional pathway that has not been found in primates from the pretectum directly to the vestibular nuclei.

Experimental interventions that diminish or abolish OKR adaptation precisely parallel those that diminish or abolish adaptation of the VOR (see VOR adaptation and ►Flocculus hypothesis). Among these interventions are those known to disrupt long-term depression (LTD) at the cerebellar parallel-fiber to Purkinje-cell synapse. They include destruction or inactivation of the flocculus [6], destruction of the climbing-fiber afferent pathway to the cerebellum [3], disruption of metabotropic glutamate receptors either by direct blockage or by elimination in mutant mice [8], blockage of nitric oxide synthase [9], and disruption of phosphokinase C. The first two appear to implicate the flocculus in OKR adaptation, but the latter four are not necessarily specific. Measurements of Purkinje-cell activity during adaptation show that changes do occur within the flocculus, and that the changes probably produce the changes in OKR gain rather than reflect feedback from the altered eye velocity [6]. In different experiments, physiological changes have also been observed in synapses the vestibular nuclei [10]. Shutoh et al. [10] argue that short-term plastic changes (about a day) reside in the flocculus while long term plastic changes reside in the vestibular nuclei. As has been strongly indicated for the VOR, it seems likely that plastic changes of some sort occur in both the flocculus and the vestibular nuclei.

Orbital tissues are the fat and connective tissues that surround the eyeball in the bony orbit.

►Eye Orbital Mechanics

## Orbitofrontal Cortex

### Definition
The orbitofrontal cortex is a region situated at the ventral surface of the frontal part of the brain. It is the subpart of the prefrontal cortex that receives projections from the magnocellular medial nucleus of the mediodorsal thalamus. The orbitofrontal cortex is an important brain region for the processing of rewards and punishments. The medial orbitofrontal cortex activity is related to monitoring the reward value of many different reinforcers, whereas lateral orbitofrontal cortex activity is related to the evaluation of punishers, which may lead to a change in ongoing behavior. The subjective hedonic experience is mediated by mid-anterior orbitofrontal cortex.

## Orexigenic

### Definition
Orexigenic means possessing activity that stimulates food intake. [Anorexigenic: opposite of orexigenic.]

►Neuropeptides

## Orexin/Hypocretin

### Definition
Orexins (OxA and OxB) are two neuroexcitatory peptides derived from the same precursor produced in a few thousand neurons restricted to the perifornical area of the hypothalamus. The orexins bind to two receptors (Ox1 and Ox2). Orexin is a synonym of hypocretin, and was given its name (orexi, appetite in Greek) because of initial studies showing increase in food intake following infusion of pharmacological doses of the peptides in the brain. The orexin/hypocretin system stabilizes wakefulness and sets the arousal threshold, enhances catabolism and is a gate to drug reinstatement. Dysfunctional orexin may be associated with the sleep disorder narcolepsy.

## Organizational Hormonal Effects

### Definition

Hormone-induced alterations occurring during the early development of an organism that give rise to chronic changes in structure and/or function of particular anatomic systems. For example, manipulating the gonadal hormonal milieu of neonate rodents can produce durable effects on the developing nervous system resulting in lifelong changes in nociception and antinociception.

►Gender/sex Differences in Pain

## Organizer

### Definition

Area, tissue or cell group of an embryo able to produce signals (or signaling proteins) that have an effect at a distance on the fate of adjacent tissue, in a concentration dependent manner (this requires the expression of specific receptors in the tissue). Examples of organizers are the node and the notochord, which produce signals that have an effect either on the ectoderm (node signals related to neural induction) or on the ventral neural plate/tube (notochord signals related to dorsoventral patterning). These are cases of organizers acting early in development and are many times referred to as "primary organizers." Later in development, there are "local organizers" inside the neural tube having an effect on patterning and specification of adjacent areas (for example, the isthmic organizer or the zona limitans intrathalamica). These local organizers of the neural tube that appear later in development are called "secondary organizers."

## Orientation Behavior

### Definition

Ability to move in space either with respect to an external reference system (passive) or by actively generating spatial information (like in echo location).

## Orientation Selectivity in Vision

### Definition

Neurons in the retina and lateral geniculate nucleus of the thalamus are sensitive to local changes in light

levels, much like sensors in a digital camera. But these cells are not able to resolve higher order features of the visual scene. By contrast, cortical cells respond best to elongated contours, or edges, formed by extended boundaries between relatively dark and bright regions of the image – contrast borders. Importantly, almost all cortical neurons are orientation selective: individual cells are strongly excited by contours that share a common spatial orientation but respond weakly if at all to stimuli tilted perpendicular to the optimal angle. Different neurons prefer different stimulus orientations. Also, some neurons are tuned to a narrow range of stimulus angles while others are less selective. Orientation selectivity is the most widely studied aspect of visual cortical function; its origin in different species and its role in visual processing remain a subject of great interest.

►Visual Cortical and Subcortical Receptive Fields

## Orientation Sensitivity in Cutaneous Mechanosensation

### Definition

Subjects can discriminate a 10% angular difference in the orientation of a cylinder indented into the fingertip. Discriminating the orientation of a grating (usually vertical vs. horizontal) is also used to assess spatial resolution. Orthogonal gratings can be discriminated for groove widths around 1 mm at the fingertips and around 4 mm at the more proximal regions of the fingerpad.

►Processing of Tactile Stimuli

## Orienting Linear Vestibulo-ocular Reflex (IVOR)

### Definition

The reflex that responds to low frequency linear accelerations of the head in space to produce eye movements that tend to align the coordinate frame of the eyes with the net direction of the linear or equivalent linear acceleration of the head. This has also been referred to as the tilt response.

►Vestibuloocular Reflexes

## Orienting Movement

### Definition

►Orienting Reflex

## Orienting Reflex

### Definition

Also known as orienting response(s). In a general sense, it is the complex behavioral pattern aimed at optimizing the perception of biologically significant events in the environment and to make rapid and efficient choice of an appropriate motor response. Orienting is truly "reflexive" toward particularly intense or previously unexperienced, novel sensory stimuli. Accordingly, the Pavlovian school used the term "what happens?-reflex." Its earliest manifestation is the generalized alerting. Sensory events signaling a potential danger or a positive reinforcement, such as prey for a predator or food delivery for an operantly conditioned animal, are also highly efficient to induce orienting. Motor responses to such stimuli are, respectively, either avoidance or approach. To make the choice between these strategies, the source of the stimulus must be rapidly identified. Alignment of the line of sight on the stimulus (gaze shifting) is the most important motor component of orienting reflex in animals whose behavior is dominated by vision and, in particular, in those having a small central region of the retina specialized for fine-grain visual discrimination (e.g., fovea in primates, area centralis in felines).

## Definition

Learning induces neural assemblies formation detectable in the network through modulation of oscillatory activities.

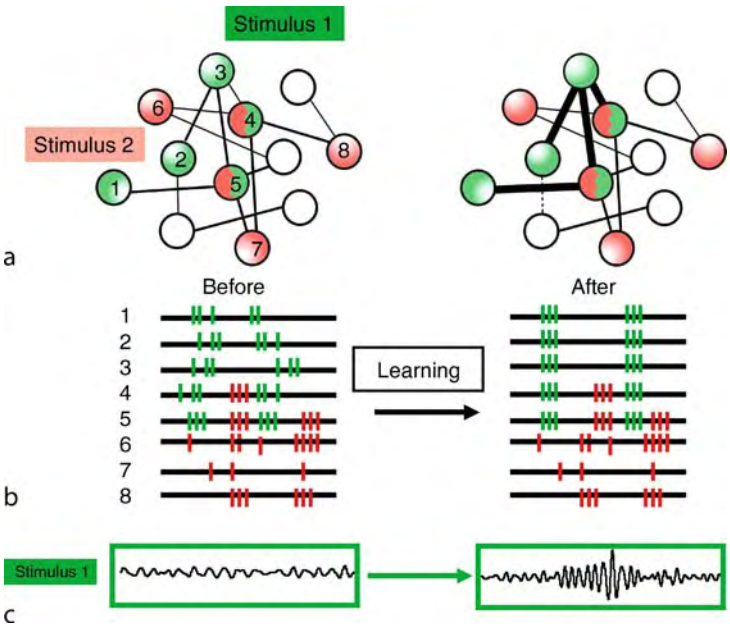
## Characteristics

### The Concept of Neural Assemblies

Current theories put forward that information storage in the brain relies on changes in functional interactions within widely distributed neural areas. This concept of distributed memory suggests in turn the idea that stimuli representations could be achieved through assemblies of simultaneously active neurons. Such assemblies could be found within a given structure or between distinct neural areas. As a consequence, memory should be considered as a dynamical process involving spatio-temporal patterns of reactivation of previously reinforced neural ensembles within and across different brain areas. These assemblies involve both sensory and limbic areas.

If we accept this concept of distributed representations one have to face the problem, commonly addressed as the "binding problem" of how such distributed activities could be put back together to elicit stable and unambiguous representations of objects in the brain. Indeed, according to this theory a given neuron would be able at different time to take part to different stimuli representations. As a consequence, neuronal elements belonging to the same assembly must be identifiable and differentiated from members of other assemblies (see Fig. 1). Twenty years ago, von der Malsburg proposed that neurons joining into an assembly should establish temporal synchronization on a millisecond time scale. This temporal tagging has two major advantages: Synchronization of neuronal activities facilitates signal transmission to target structures because temporal coincidence of action potential volleys on post-synaptic higher areas increases probability of eliciting action potentials. In addition, this coincidence is very important in voltage-dependent processes like NMDA-receptor-gated conductance which are of prime importance in induction of synaptic plasticity.

Synchronous activities in assemblies often occur in a repetitive way and give rise to well-known brain rhythms also called oscillations. They can be recorded with macro electrodes either directly from the scalp (electroencephalogram, EEG) or from intracerebral inserted electrodes (►local field potentials, LFPs). They have been observed in many different brain areas especially those showing a laminar organization like cortices. These oscillations of LFPs exhibit a large variety of frequencies from 1 to 100 Hz depending on the vigilance state (arousal, attentiveness, sleep, etc.) or the presence of a sensory stimulation or the necessity to control a motor behavior. The origin of oscillations is still a matter of debate but one major hypothesis is that they could be an emergent property of a given network resulting from inhibitory interneurons and reciprocal connections. In relay neurons of any cortical area, these oscillations likely reflect current source generated by neuronal synaptic input in the dendritic tree and action potentials generated at the cell body level. LFP activities are a good indicator of how and when a large set of neurons synchronize and desynchronize during information processing. This review will illustrate how the study of the mammalian olfactory system brings information on the functional significance of neural oscillations in sensory processing and memory.



**Oscillations and Plasticity in the Olfactory System. Figure 1** Illustration of the concept of neural assemblies. (a). As symbolized by the colour code, each stimulus co activates a specific ensemble of neurons. However, some neural elements (4 and 5) could be co activated by both stimuli. Learning of stimulus 1 is associated with reinforcement of synaptic contacts between neurons previously co activated by this stimulus (*thick lines*). (b). Temporal organization of the discharge of each neuron clearly differentiates two neural assemblies (in green for stimulus 1 and red for stimulus 2). Neurons 4 and 5 could take part to both representations depending on their discharge timing. Before learning, units taking part to the same assembly are simply co-activated. Repeated presentation of stimulus 1 refines of neural discharge synchronization. As a consequence, the amplitude of ►local field potential oscillatory activity is increased and the dominant frequency corresponds to the periodicity of the synchronization.

## Oscillatory Activities in the Olfactory System

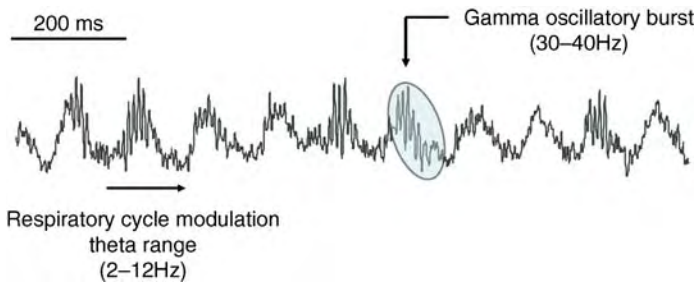
In the mammalian olfactory system, Adrian in the 50's initially described prominent oscillations in field potential activities. In ►awake animals, in the absence of any olfactory stimulation, the signal derived from the first relay of olfactory processing, the olfactory bulb, exhibits a well structured activity as shown on Fig. 2.

Slow modulations of LFP associated with inhalation are easy to observe. These high amplitude oscillations are in the theta range (2–12 Hz). They have been shown to follow the respiratory activity and hence might vary in frequency. Moreover, during period of exploration associated with active sniffing, the respiratory modulation has a frequency range which overlaps with the theta activity typically observed in limbic areas such as the hippocampus (4–12 Hz).

Recordings also show regular spindle bursts of oscillations during each inspiration phase of the respiratory cycle. This second type of oscillatory activity is in the gamma range (30–90 Hz). Interestingly, in a given animal, even in the absence of any olfactory stimulus, the distribution of amplitude of gamma bursts forms a stable map at the surface of the OB. Presentation of an odor in a specific experimental context modifies this distribution. However, this new map is more related to the behavioral meaning of the stimulus than to its chemical quality. Indeed, if the same odor is presented in another context, a different map is obtained [1]. Recently, Kay [2] proposed to distinguish two types of gamma activity, type 1 (65–90 Hz) corresponding to the bursts associated to the peak of inhalation and type 2 (35–65 Hz), lower in frequency. These rhythms seem to be associated with different behavioral features and are likely to be produced by different synaptic interactions within the olfactory bulb.

Whereas gamma and theta activities have been studied for a long time, at first, little attention was paid to an intermediate type of periodic activity in the beta range (15–35 Hz).

This activity has now been reported by several authors to be selectively associated with ►odor sampling not only in the olfactory bulb, but also at higher level of olfactory processing like the piriform cortex and lateral entorhinal cortex. These studies pointed out to a more or less prominent increase in the amplitude of this oscillatory activity in response to behaviorally relevant odors [3,4] or odors experimentally associated with a reward [5–8].



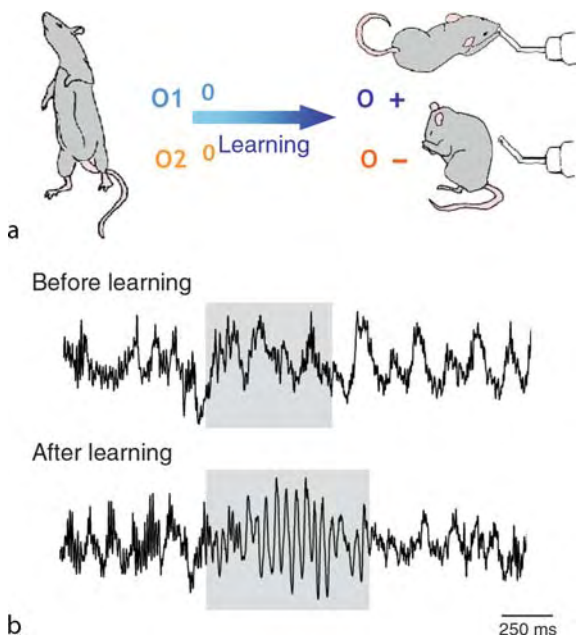
**Oscillations and Plasticity in the Olfactory System. Figure 2** Spontaneous activity recorded in the olfactory bulb in ►awake animal.

Thus, both gamma and beta oscillatory activities were associated to perception and cognitive processing of olfactory stimulus. In awake animals, gamma oscillatory activity is prominent in the absence of odor and seems more related to attention toward an expected stimulus or a given experimental context. Beta oscillatory activity has never been reported in the absence of odor. This activity emerges during odor sampling and is modulated both by the chemical nature of the odor and its behavioral significance.

## Oscillations and Construction of Odor Representations

According to the concept of neural assemblies proposed above, synchrony in a given neural network favors both signal transmission and synaptic plasticity. Hence, if this view is correct one could predict that olfactory learning should induce reinforcement of excitatory transmission between cells responding to the odor to be learned. As a consequence, learning should modify oscillatory regimes associated with the processing of learned odors. A first step toward the experimental demonstration of this hypothesis has been made by a few studies in which multisite neural recordings were performed in animals engaged in two different olfactory discrimination learning paradigms [7–9].

In the first paradigm (see Fig. 3), two odors without any a priori ►behavioral signification (►odor with behavioral signification) were assigned with two different values by pairing their presentation either with a sweet (O+) or a bitter (O−) solution. At the beginning of the experiment, the two odors induced the same behavioral response but after a few experimental sessions, thirsty rats exhibited a differential response to each odorant. Indeed, they learnt to run promptly to drink when O+ was delivered and avoid drinking when O− was presented. In parallel to this behavioral response modification, a clear oscillatory activity in the beta band (near 27 Hz) emerged in the olfactory bulb in response to odors used in the learning paradigm. In respect to a potential role in olfactory coding, we found that this activity exhibited different characteristics in amplitude and latency according to the recorded region



**Oscillations and Plasticity in the Olfactory System. Figure 3** Learning-induced modulation of beta oscillatory activity. (a). Experimental protocol. Two odors without any a priori behavioral signification (O1 and O2) are assigned with two different values by pairing their presentation either with a sweet (O+) or a bitter (O−) solution. (b) Comparison of odor-induced activity in the olfactory bulb before and after O1 has acquired a positive value for the rat. The shaded zone corresponds to the odor sampling period. After learning, an oscillatory burst in the beta range (around 27 Hz) is clearly observed.

in the olfactory bulb (anterodorsal vs. posteroventral) and the chemical nature of the odorants. More interestingly, the large beta oscillatory activity emerged a few trials before the animal reached the criterion level. As a whole, results stressed out the possible role of the beta oscillatory activity in both odor representation and olfactory recognition. The same type of activity

was also found in other structures involved in odor stimulus processing like the piriform cortex. Moreover, a pharmacological inactivation of feedback connections from piriform cortex to olfactory bulb prevented in both structures the emergence of beta activity in response to learned odors suggesting that this oscillatory activity could be the signature of a neural network set up through learning and involving well-known reciprocal excitatory cortico-cortical connections between the olfactory bulb and the piriform cortex.

Recently, using a two-alternative choice odor discrimination, Beshel and colleagues [9] also showed a functional link between gamma range oscillatory activities in the OB and plasticity. In this paradigm, task demand was manipulated using either dissimilar or similar odorants ("coarse" vs. "fine" discrimination). Gamma oscillatory power progressively increased over the course of fine discrimination learning in contrast to coarse discrimination. This modulation was specific to gamma frequency range (65–85 Hz) and independent of changes in the theta or beta frequency range. It was also restricted to the OB despite gamma activity was also reported during spontaneous activity in the piriform cortex. This experimental result is in favor of a functional role of gamma oscillatory activity in pattern disambiguation. However, in mammals, data establishing a direct link between oscillatory activity disruption and behavioral performance alteration are still lacking.

Until now, the only demonstration that oscillatory synchronization might play a determinant role in fine stimulus encoding and odor recognition was brought by a work on honeybees [10]. In this animal model, odors evoke oscillatory synchronizations of groups of neurons in the antennal lobe, a structure functionally equivalent to the vertebrate olfactory bulb. These oscillations, in the beta range (around 30 Hz) could be selectively disrupted with picrotoxin, a pharmacological antagonist of $GABA_A$ receptors without affecting neural response and selectivity to odors. Behavioral experiments combining pharmacological disruption of odor-evoked oscillatory activity and evaluation of olfactory discrimination performance showed that picrotoxin-treated animals failed to discriminate between similar odorants although they were unimpaired for coarse discrimination. These observations were the first real argument for a role of neural synchronization in separation of spatially overlapping neural networks. It is of course tempting to speculate that neural oscillatory synchronization might play a similar role in other animal models.

In conclusion, one can point out that the detailed investigation of neural rhythms through LFPs recordings in behaving animals brings important insight on neural correlates of sensory discrimination and recognition. One of the main advantages of this approach is the relative ease with which one can obtain signal from several recording sites simultaneously and over the course of training (several days). This allows investigation of some neural correlates which sustain learning and memory in a time scale which characterized many forms of knowledge acquisition.

# Oscillations in the Brain

## Definition

Oscillation is the variation, typically in time, between two boundary values of some measure. In the brain, oscillatory activities have been widely observed. At the level of the neurons and networks of neurons, it has been shown that intrinsic (mainly due to ion channel) and networks properties (connectivity, inhibition and excitation), endowed the neuron and the network with

dynamical properties, including abilities to oscillate at multiple frequencies. Oscillations are groups into category that depend on their frequency and their relation with particular behaviors. Among other one can distinguished oscillations in the gamma band (30–90 Hz) that have been involved in perception, problem solving, fear and other higher brain function.

►Network Oscillations
►Network Oscillations in Olfactory Bulb

## Oscillator

### Definition

A device that generates a periodic signal.

►Signals and Systems

## Oscillator for Circadian Rhythm

### Definition

A system that produces rhythmic output or whose state varies in a periodic fashion in the absence of external stimuli. A circadian oscillator produces a rhythm whose period is approximately 24 h when the organism is maintained in constant conditions. This may be detected in the cycle of activity and rest, in gene expression as reflected by mRNA abundance or protein concentration, etc. Negative feedback loops involving regulation of transcription by translational products have been found to generate such circadian oscillations in a number of organisms. Circadian oscillators are typically entrainable by environmental cues within a range of periods close to 24 h, and often vary little in period over a range of temperatures.

## Oscillator Versus Hourglass Timers

### Definition

Time-measurement can be achieved by different types of mechanisms that change state in a predictable way before returning to the starting point. Once started, an oscillator may continue to generate cycles (have an endogenous rhythm) indefinitely, or it may damp out. In contrast, an hourglass measures a fixed interval and then must be restarted (by some external stimulus) in order to measure a second interval. Whether a biological system acts as an oscillator or as an hourglass can be a function of its environment; changes in parameters may alter the behavior of an oscillator so that it damps rapidly and thus functions as an hourglass.

## Osmolality

### Definition

Osmolality refers to the total concentration of all particles that are free in a solution. Thus, glucose contributes one particle, whereas fully dissociated NaCl contributes two. In all body fluid compartments, humans have an osmolality – expressed as the number of osmotically active particles per kilogram of water – of approximately 290 mOsmoles/kg water (290 mOsm).

## Osmotic Energy

### Definition

The energy associated with a concentration gradient.

## Other Minds Problem

### Definition

The other minds problem is the problem of how we know (or are justified in believing) that other human beings exemplify mental properties similar to the ones we exemplify, given that their conscious mental life is not accessible from our third person point of view. The existence of other minds is typically justified by an argument from analogy, stated in its classic form by John Stuart Mill and Bertrand Russell, according to which one's own body and outward behavior are observably similar to the body and the behavior of others, so that one is justified by analogy in believing that they also exemplify similar mental properties.

## Outer Plexiform Layer

**Definition**
Synaptic layer in the outer (distal) retina where photoreceptors make synapses with horizontal and bipolar cells.

►Inherited Retinal Degenerations

## Output Unit

### Definition
A model network neuron that provides the network response to activity propagated through hidden units due to signals received by input units.

►Neural Networks

## Ovariectomize

### Definition
Surgical removal of the ovaries.

## Overdetermined System

### Definition
A mathematical system is called overdetermined if it has more system equations than unknowns. Overdetermined systems typically do not have a solution.

►Distribution Problem in Biomechanics

## Overfitting

### Definition
Overfitting refers to a problem that can arise during the training of artificial neural networks (or other statistical learning systems). During training the network learns a mapping from the input domain to the desired output. The target of this process is to capture the underlying regularities in the data that are to be modelled. However, since there are, in general, limited amounts of training data, the network may learn to approximate these correctly, while failing to process new data appropriately. This is referred to as overfitting: the network has learned a function that is too complex, modelling not only the regularities of the dataset, but also its noise.

►Connectionism

## Overhang (DNA)

### Definition
When a restriction cleaves DNA asymmetrically a stretch of single stranded nucleotides is left. If the single stranded bases end in a 3' hydroxyl a 3' overhang remains. Similarly, a 5' overhang remains when the single stranded bases end in a 5' phosphate. Overhangs are often generated in molecular biology by use of DNA endonucleases. Larger overhangs of several nucleotides, such as those created by restriction endonucleases, are often called "sticky-ends" since a DNA molecule with complimentary sequence in the overhang region can anneal to each other. This phenomenon is used in molecular biology to piece together DNA molecules from different sources which are then covalently linked with DNA ligase.

►Serial Analysis of Gene Expression

## Overlap Zone in Skeletal Muscle

### Definition
The overlap zone in skeletal muscle designates the area of overlap between the contractile proteins actin and myosin. At short muscle length, the overlap zone is big, and for increasing muscle length, the overlap zone becomes smaller. When there is no overlap between actin and myosin (i.e. the overlap zone has vanished), active force production is not possible anymore.

►Actin
►Force Depression/Enhancement in Skeletal Muscles
►Myosin
►Sarcomere Structural Proteins

## Overshadowing

### Definition
The ability of a conditioned stimulus (CS) to elicit a conditioned response (CR) is reduced when its pairings

with the unconditioned stimulus (US) take place in the presence of another neutral stimulus. Assessment of the magnitude of overshadowing is made through comparison with a control group that receives only pairings of the CS and the US. This is one of several examples of cue competition or stimulus selection effects that prompted development of predictive-driven learning models.

## Overshoot (of Action Potential)

### Definition

Reversal of membrane potential during the action potential peak.

►Action Potential

## Overtraining Syndrome (OTS)

### Definition

When prolonged, excessive training stress are applied concurrent with inadequate recovery, many of the positive physiological changes associated with physical training are reversed with overtraining. Chronic physiological maladaptations and performance decrements occur. Throughout the twentieth century, many names have been given to this chronic maladaptive state (e.g., underperformance syndrome, sports fatigue syndrome), but presently the term overtraining syndrome (OTS) is used. A large number of symptoms associated with overtraining have been reported in the literature and categorized according to physiological performance, psychological/information processing, immunological, and biochemical parameters. It is also probable that other signs/symptoms typically associated with overtraining are evident before a deterioration in performance. These might include generalized fatigue, depression, muscle and joint pain, and loss of appetite. However, it is the decline in performance frequently associated with an increased volume or load of training that captures the attention of the athlete and coach.

P element – transposable elements are a heterogeneous class of genetic elements that can move and insert at new locations on a chromosome. P elements contain terminal inverted repeat sequences and encode the protein transposes to allow for integration into the genome.

►GAL4/UAS

## p38 MAPK

### Definition
p38 MAPK is a member of mitogen-activated protein kinase (MAPK) family. The name MAPK was given,

because another member of the family extracellular signal-regulated kinase (ERK) was first recovered as a kinase activity in the cytosol of EGFtreated cells. Later, MAPK has been found to operate in three pathways: ERK, p38, and c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK). p38 MAPK is a kinase of 38 kDa that responds to stress condition such as tumor necrosis factor-alpha (TNFα), UV, and $H_2O_2$.

## PACAP

### Definition

Pituitary adenylyl cyclase activating peptide; a neuropeptide expressed in nervous system where it functions to regulate cellular communication. PACAP has emerged as a likely retinal messenger to the suprachiasmatic nucleus (SCN), acting in concert with glutamate to communicate photic information to the circadian system. PACAP-like immunoreactivity is found in terminals of retinal ganglion cells (RGCs) innervating the SCN and two of the receptors sensitive to PACAP (PAC1 and VPAC2) are expressed in the SCN. To date, all of the available evidence indicates that the PAC1 receptor is responsible for mediating the effects of PACAP on SCN neurons.

Mechanistically, PACAP pre-synaptically enhances the release of glutamate onto SCN neurons and postsynaptically enhances the magnitude of the response to glutamate within the SCN. PACAP can also increase calcium in SCN neurons by causing a release from intracellular stores as well as an enhancement of voltage-dependent calcium currents. Increasing calcium has the consequence of activating the mitogen-activated protein kinase (MAPK) signaling cascade and increasing transcription. At a systems level, application of PACAP can shift the phase, or alter the magnitude of glutamate-induced phase shifts, in the circadian rhythm of SCN neuronal firing in a brain slice preparation. Similarly, microinjections of PACAP into the SCN region in vivo can cause phase shifts. Administration of a PACAP receptor antagonist or an antibody against PACAP attenuates light-induced phase delays. The circadian system of mice deficient in PACAP or the PAC1 receptor exhibit altered behavioral responses to light. Overall, these studies point to a role for PACAP in increasing the functional coupling between the melanopsin-containing RGCs and the retino-recipient subpopulation of SCN neurons.

## Pacemaker

### Definition

In a rhythmically active neuronal network, the neuron or neurons that have the major role in generating the rhythm. These may exhibit spontaneous oscillations of their membrane potential leading to action potentials that are very nearly equally spaced (endogenous bursting neurons), or a mutually excitatory set of neurons. An oscillator in a multi-oscillatory system entrains the other oscillators in the system, and so sets their phase relative to the pacemaker's phase, as well as forcing each oscillator's period to equal that of the pacemaker. An entrained oscillator's phase may lead or lag (occur either earlier or later than) that of the pacemaker, depending on the type of coupling (inhibitory or excitatory) and the relative periods of the oscillators in the system. Experimental proof that an oscillator can behave as a pacemaker in a physiological system is provided when transplantation confers the period or phase of the donor to the reconstituted system.

[2]Department of Occupational Therapy, Aino University Faculty of Nursing and Rehabilitation, Shigashiohta 4-5-4, Ibaragi City, Osaka, Japan

### Synonyms

Vater-Pacini corpuscle; Vater-Pacini's corpuscle; Pacini corpuscle; Pacini's corpuscle; Pacinian corpuscle; Corpusculum lamellosum

### Definition

The Pacinian corpuscle is the largest ellipsoidal sensory corpuscle functioning as a very rapidly adapting mechanoreceptor. It consists of one straight axon terminal extending at the center of the corpuscle along its long axis, the inner core surrounding the axon terminal, and the outer core occupying the outermost part of the corpuscle.

### Characteristics

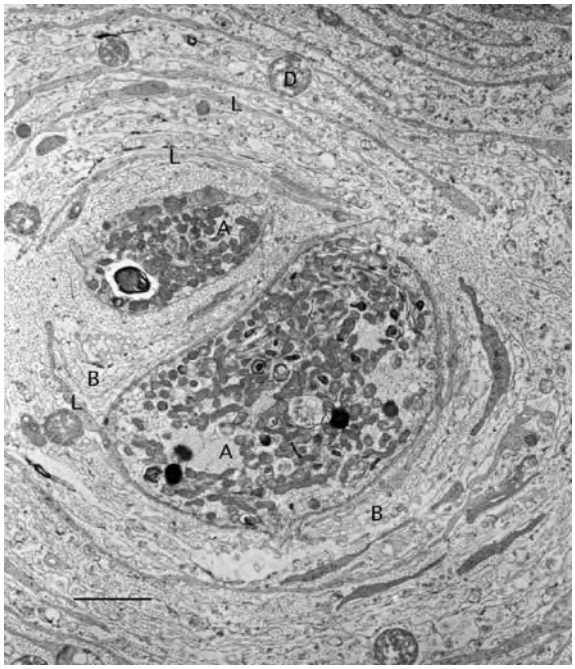
#### Structure

The Pacinian corpuscle is ellipsoidal in shape, measuring 0.2–1 mm at the long axis, and can be seen by the naked eye in dissection. It is found in connective tissues of the subcutaneous layer, joint capsule and periosteum. The corpuscle is innervated by a single thick myelinated axon that ends as a straight axon terminal in the center. The axon terminal is sandwiched by hemicircular inner cores, so that the axon terminal is oval in cross section [1]. The inner core consists of stacks of numerous thin cytoplasmic processes of specialized Schwann cells. The outer core is composed of loose lamellae of modified perineurial cells. The inner core cells express p75 and TrkB, while the outer core cells express only p75 [2]. Small axoplasmic protrusions are formed at the oval edges as well as at the extreme end of the axon terminal. These protrusions are considered to be the site of mechano-electric transduction [3].

#### Regeneration

Following denervation, the axon terminal disappears, and the inner core becomes somewhat atrophic but remains with the outer core for an extended period. Following re-innervation, an axon enters the corpuscle and the inner core lamellae become "active," as in the case of the Meissner corpuscle. After regeneration, most Pacinian corpuscles are innervated by a single axon, but there are a few that receive two axons, or remain non-innervated. Some corpuscles have multi-terminals associated with inner cores, resulting partly from the branching of regenerating axon terminals [4]. Aberrant regenerating nerves other than sensory axons can enter Pacinian corpuscles [5].

Pacinian corpuscles can be regenerated even in the non-cellular environment; the connective tissue scaffolds of the Pacinian corpuscle remain after the cellular components have been degraded by local freeze-treatment. A regenerating axon enters such acellular scaffolds, accompanied by Schwann cells migrating from the proximal stump (Fig 1). Schwann cells develop into inner core cells associated with axon terminals. Perineurial cells develop into outer core cells within the scaffold of the original outer core region. Although atypical in its organization, the newly regenerated corpuscle possesses the three basic components including axon terminals, inner and outer cores [6]. This indicates



**Pacinian Corpuscle Regeneration. Figure 1** The periosteum of the tibia, in which numerous Pacinian corpuscles are located, was freeze-treated to kill cellular components of the corpuscle in the rat. The acellular matrix including basal laminae (B) of the corpuscle remained after the cellular components had been degraded. Regenerating axons accompanied by immature Schwann cells enter the matrix; the axon terminals (A) are situated at the center of the matrix and Schwann cells extend thin cytoplasmic lamellae (L) along the basal lamina scaffolds around axon terminals with a pattern similar to that of the normal corpuscle. New Pacinian corpuscles, although atypical in overall cellular structure, can develop in the acellular matrix of the old corpuscle. (D) cell debris. Scale bar: 2 μm.

that the acellular matrix of the Pacinian corpuscle has the ability to induce the innervating axons, Schwann cells and perineurial cells to develop into axon terminals, inner core cells, and outer core cells, respectively.

# Paedomorphosis

## Definition

The brains of amphibians appear to be much simpler than those of other vertebrates. Lissamphibians, i.e., living amphibians, have undergone secondary simplification, which arises from paedomorphosis, a form of heterochronic evolution. This process has affected the three amphibian orders differently: anurans appear to be least and salamanders most paedomorphic, while caecilians exhibit an intermediate degree of paedomorphosis.

It commonly involves different degrees of retardation, reduction or absence of traits in otherwise fully developed organisms when compared with phylogenetic outgroups. Thus, a mosaic of fully adult traits, weakly expressed traits, and missing characters appears in terminal ontogenetic stages. Accordingly, amphibian brains are expected to have fewer cells, a lower degree of morphological differentiation of cells, and reduced migration, but retain the plesiomorphic structural, functional and developmental organization found among other vertebrates.

## Introduction

Pain is appreciated to be a complex sensory experience, characterized by both discriminative and emotional/cognitive dimensions. Moreover, the peripheral and central nervous system components that comprise the pain "network" are highly plastic, meaning that neural and non-neural constituents undergo changes in behavior and excitability in painful conditions. Thus, tissue insult commonly leads to changes in either or both the quality and intensity of perceived stimuli, typically beginning at peripheral sites and including central components in persistent pain states.

Stimuli that evoke pain are termed noxious and the peripheral sensory receptors/transduction sites acted upon by ►noxious stimuli are termed ►nociceptors. Input from nociceptors is widely distributed throughout the central nervous system and can evoke simple ►nociceptive reflexes that are organized at the level of the spinal cord (e.g., ►nociceptive withdrawal reflexes), engage ►autonomic centers in the brainstem that increase heart rate and blood pressure, or lead to expression of emotional-affective responses that can be influenced by gender, age, previous experience, ►stress and mood (among other factors) (►Emotional/affective aspects of pain; ►Pain in older adults; ►Pain in children; ►Gender/sex difference in pain).

More than 100 years ago, Sherrington [1] advanced the operational definition of a noxious stimulus and anticipated by decades the discovery of sensory receptors (nociceptors) in skin that responded only to noxious intensities of stimulation. Sherrington's experimental work established that mechanical, thermal or chemical stimuli that damaged or threatened damage to skin were *adequate* for activation of nociceptors to cause pain. We know now that adequate noxious stimuli differ for skin, muscle, joints and internal organs, and also that some nociceptors can be activated by low-threshold stimuli, revealing the importance of encoding of stimulus intensity by peripheral sensory receptors (►Cutaneous pain, nociceptor and adequate stimuli). For example, cutting, crushing or burning stimuli, which reliably produce pain when applied to skin, are not reliable noxious stimuli when applied to internal organs. Pain arising from internal organs is more commonly produced by over-distension, traction on the mesenteries, ischemia or inflammation (e.g., appendicitis). Similarly, adequate noxious stimuli for muscle and joints, which also are not exposed to the external environment, include chemicals typically associated with inflammatory processes. In further distinction from skin, deep pain such as arises from muscle and viscera are relatively poorly localized and commonly referred to other sites, including overlying skin and muscle. The clinical presentation and characteristics of muscle pain (►Muscle pain including fibromyalgia), ►joint pain (►Joint pain, nociceptors and adequate stimuli) and ►visceral pain are discussed in detail in essays in this section of the Encyclopedia (see also ►incisional/post-op pain; ►Low back/spine pain).

As indicated above, tissue insult commonly alters either the quality and/or intensity of applied stimuli. Hyperalgesia (an increased response to a stimulus which is normally painful) and allodynia (pain due to a stimulus which does not normally provoke pain [►Hyperalgesia and allodynia]) represent increases in the excitability of nociceptors (hyperalgesia) and activation of low-threshold mechanoreceptors (allodynia – by mechanisms not fully understood), respectively. Increases in excitability of nociceptors have been documented to arise from changes in ►voltage-gated ion channels (e.g., ►$Ca^{2+}$ channels, ►$K^{+}$ channels and ►$Na^{+}$ channels [►Voltage-gated ion channels and pain]) and ►ligand-gated channels and receptors (e.g., transient receptor potential [TRP] channels (►TRP channels), purinergic receptors, including both P2X and P2Y, etc. [►G-protein coupled receptors (GPCRs) in sensory neuron function and pain]). Such changes can be initiated by a variety of peripheral mediators, including those associated with inflammation (e.g., ►prostaglandins, protons, etc. [►Inflammatory pain]), ►growth factors (►Growth factors and pain) and the ►immune system (►Immune system and pain). Typically, increased excitability of nociceptors (for example produced by inflammatory mediators) is relatively short-lived and reversible. However, these changes can persist, such as occurs in ►autoimmune diseases characterized by dysregulation of an immune response or following tissue insult early in life. ►Rheumatoid arthritis, ►multiple sclerosis and some viral infections can produce ►chronic pain that is difficult to manage.

After nociceptor neurogenesis and maturation (►Development of nociception) [2], tissue damage in the neonatal period can lead to increased pain

sensitivity [3] and exaggerated responses to noxious stimuli in adult non-human animals well after the early insult has fully recovered. For example, organ insult in neonatal animals [4,5], skin incisions/surgery as well as stressful events (e.g., maternal separation [6]; all have been shown to lead to increased sensitivity to noxious stimuli in adult life. This increased sensitivity is not always apparent when acute noxious stimuli are tested, but is clearly evident when tissue is re-inflamed or injured.

These peripheral events, whether introduced early in life or produced in adults, have far-reaching central consequences. ►Sensitization (increased excitability of nociceptors [7]; leads to changes in excitability of neurons in the spinal cord as well as sites rostral in the brain. By analogy to the periphery, increases in the excitability of spinal and supraspinal neurons is referred to as "central sensitization" [8]. The initial impetus for the increase in excitability of central neurons arises from the increased input from peripheral nociceptors, including ►silent nociceptors (►Nociceptors and characteristics) [9], and increased release of ►neurotransmitters from their central terminals. Central sensitization, either at the level of the spinal cord or at supraspinal sites, represents plasticity of central neurons, which apparently can be sustained well beyond recovery from the peripheral insult.

At the level of the spinal cord, because of similarities in neurotransmitters released from nociceptor terminals and characteristics of neuron response properties, central sensitization shares characteristics with learning (►Synaptic long-term potentiation (LTP) in pain pathway). At supraspinal sites, nociceptive input is widely distributed to sites important for the discriminative aspects of pain (e.g., location, duration and intensity) (►Ascending nociceptive pathways) and also to brain areas associated with emotion and cognition (►Pain imaging; Emotional/affective aspects of pain). This nociceptive input also influences sites in the brainstem important to descending control of spinal input (►Descending modulation of nociception). Descending influences from the midbrain and medulla were initially believed to be principally, if not exclusively, inhibitory in nature and selective for nociceptive input. We now know that descending influences can contribute to chronic pain states, either by reduced descending inhibition or active facilitation of spinal input and, moreover, and are not selective for spinal nociceptive input, but also modulate non-noxious (innocuous) spinal input. Indeed, it is now considered that chronic disorders such as functional gastrointestinal diseases, ►fibromyalgia, etc. may be contributed to by disordered descending modulation of spinal input.

It addition to the nociceptive component of the experience of pain (e.g., activation of nociceptors, spinal pathways, mechanisms of peripheral and central sensitization, etc.), nociceptive input at supraspinal sites also engages emotional, affective and cognitive dimensions of pain (Emotional/affective aspects of pain). That supraspinal influences can be potent is attested to by the ►placebo analgesic response, in which expectancy has been identified as the most relevant psychological mediator. Expectancy can be manipulated by verbal instruction or by conditioning. The discriminative dimension of pain is associated with ►thalamic and ►somatosensory cortex and ►motor cortex whereas the emotional/affective dimension of pain activates the amygdala, cingulate gyrus and ►prefrontal cortex (Pain imaging). Brain imaging has thus confirmed and extended our anatomical understanding of the discriminative and emotional/cognitive anatomical dimensions of the experience of pain. Interestingly, both the discriminative and emotional/cognitive dimensions of pain may be sexually dimorphic. A growing literature reveals differences between males and females with respect to sensitivity to noxious stimuli as well as to the ability to tolerate pain (►Gender/sex differences in pain). Women access physicians for pain-related problems far more frequently than do men, and while there may be many reasons why this is so, one contributing factor certainly relates to distinct differences in responses to noxious stimuli, likely contributed to by hormonal influences.

Despite our significantly increased knowledge about pain and pain mechanisms, there remain significant challenges in several areas. ►*Neuropathic pain*, including ►*central pain*, arises from damage to the nervous system, either in the periphery or centrally. Unlike *inflammatory pain*, damage to the nervous system results in pain commonly produced by normally innocuous stimuli (i.e., touch-evoked pain, or allodynia), which is difficult to manage. Pain in neonates (Development of nociception) and children (Pain in children), as well as pain in older adults, including those with ►dementia (Pain in older adults), similarly present challenges in terms of both pain assessment/measurement (►Pain psychophysics) and pain management. It was incorrectly assumed until relatively recently that the nociceptive system was undeveloped or underdeveloped in neonates and, accordingly, that they did not feel pain (Development of nociception; Pain in children) or require analgesia or anesthesia. This flawed thinking has fortunately been corrected and we now know that untreated, unattended pain in neonates and young children can lead to long-term changes in responses to noxious stimuli. Because young children and adults with dementia cannot effectively communicate their pain, they too tend to be under-treated.

In the United States, pain accounts for 20% of patient visits to physicians and 10% of prescription drug sales [10], figures likely comparable to those in many other countries (but not including those where governments restrict access to analgesic drugs, and unrelieved pain is

commonplace). Pain management can be daunting for health care providers, even with access to all available drugs and management strategies. As recounted in the essays in this section of the Encyclopedia, significant progress has been achieved in understanding mechanisms underlying painful disease conditions, with consequent improvement in pain management.

## Definition

Pain imaging is the capacity to identify functionally relevant neuronal activity within the central nervous system (brain and spinal cord) correlated with the subjective experience of pain. Imaging relates principally to studies in humans, but not exclusively. Different technologies provide this capability to image pain with varying degrees of invasiveness, spatial and temporal resolution.

## Characteristics

### Why Image Pain?

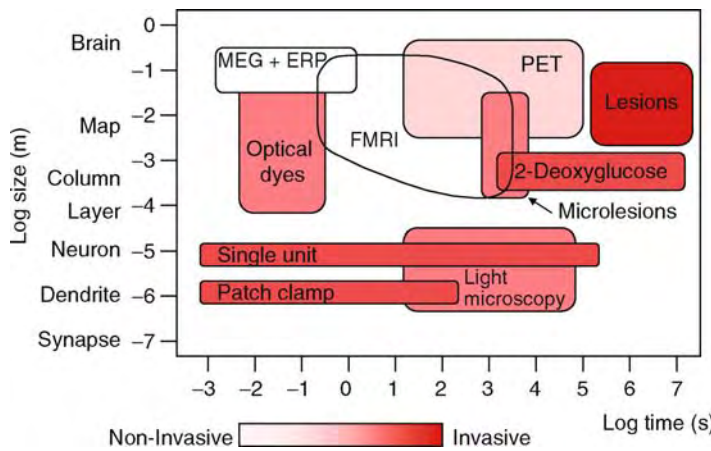
Most neuroimaging methods provide a non-invasive, systems-level understanding of the central mechanisms involved in pain processing. To date, the focus has been to dissect the physiological, psychological and cognitive factors that influence nociceptive inputs to alter pain perception in healthy subjects and patients suffering from chronic pain. Obtaining reliable objective information related to the individual's subjective pain experience provides a powerful means of understanding not only the central mechanisms contributing to the chronicity of pain states, but also potential diagnostic information. Identifying non-invasively where plasticity, sensitization and other amplification processes might occur along the pain neuraxis for an individual, and relating this to their specific pain experience or measure of pain relief, is of considerable interest to the clinical pain community and pharmaceutical industry. This is why imaging pain is useful.

### Imaging the Brain – Methods Available

Figure 1 illustrates the main imaging modalities in use today and what physiological correlate of brain activity they measure. There is a "cost" or balance between the spatial and temporal information achievable and how "invasive" you have to be if you want high resolution in both domains. Therefore, when choosing your imaging modality, pros and cons must be considered, dependent upon your hypothesis and goal. Other methods provide different sorts of information about the brain (i.e., structural or metabolic rather than functional), and these newer ways of examining the human brain are providing exciting and highly novel information about pain processing.

### Pain as a Perception

Pain is a conscious experience, an interpretation of nociceptive inputs influenced by memories, emotional,



**Pain Imaging. Figure 1** A schematic displaying the relationship between the spatial and temporal resolution, as they relate to non-invasiveness, for the main current imaging tools.

pathological, genetic and cognitive factors. Resultant pain is therefore not always related linearly to nociceptive drive or input, neither is it solely for vital protective functions; this is especially true in, chronic pain states. Furthermore, the behavioral response of a subject to a painful event is modified according to what is appropriate or possible in any particular situation. Pain is, therefore, a highly subjective experience. Figure 2 illustrates the mixture of physical, cognitive and emotional factors that influence nociceptive inputs to amplify, attenuate and color the pain experience.

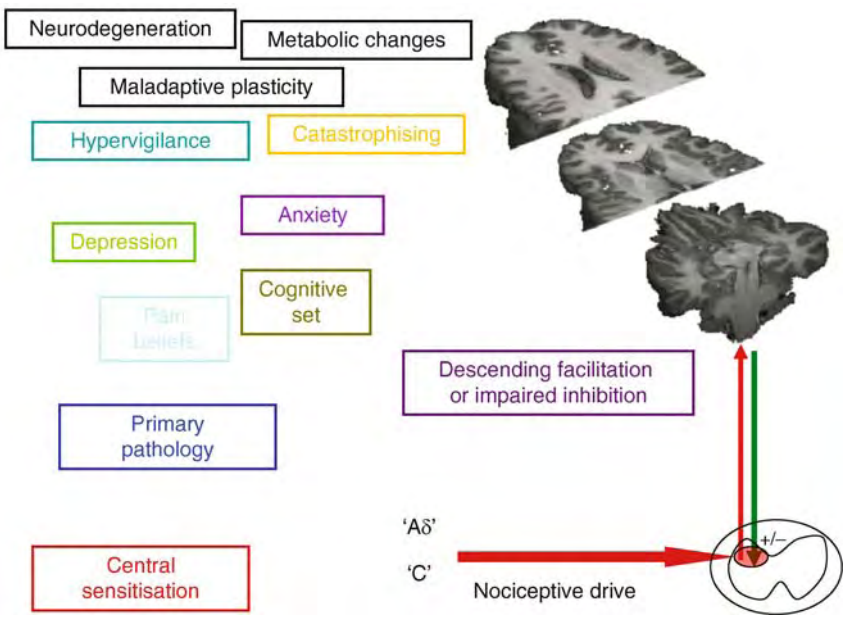
Clearly, the majority of factors influencing pain percepts are centrally mediated and our ability to unravel and dissect their contribution has only been feasible since neuroimaging allowed us non-invasive access to the human CNS. Determining the balance between peripheral versus central influences, and ascertaining which are due to pathological versus emotional or cognitive influences, will clearly aid decisions regarding the targeting of treatments (i.e., pharmacological, surgical, cognitive behavioral or physical rehabilitation). This is perhaps where imaging might provide its greatest contribution in the field of pain.

## The "Cerebral Signature" for Pain Perception

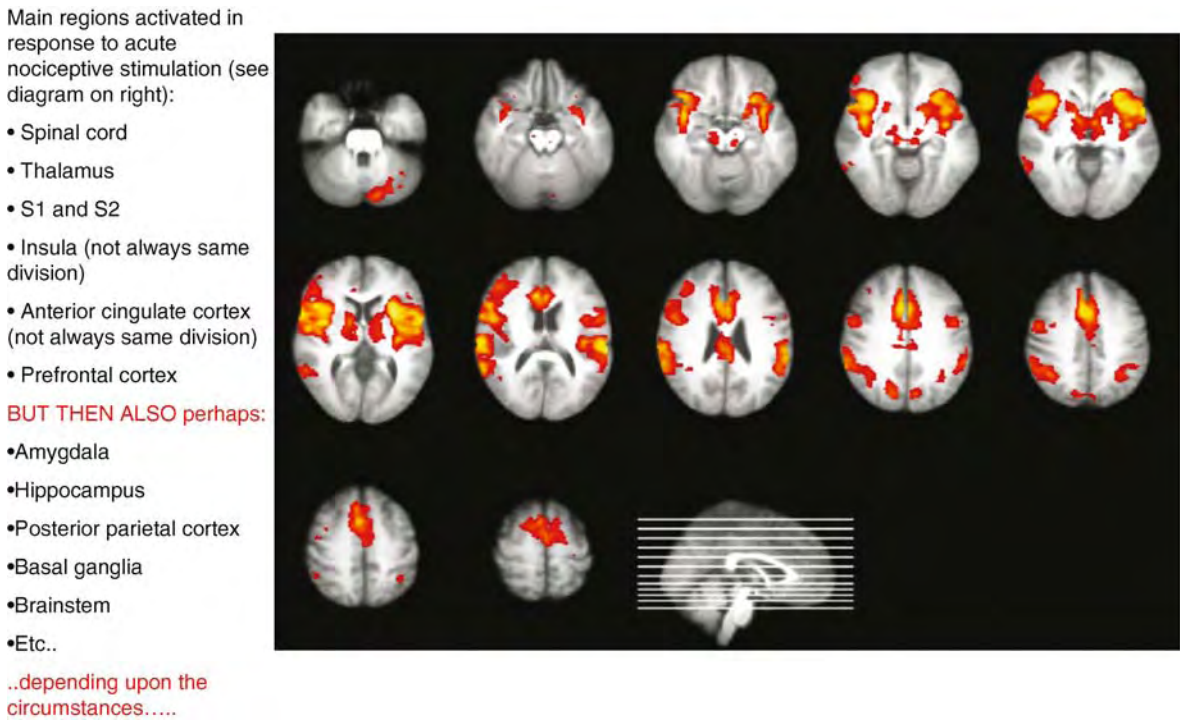
Because pain is a complex, multifactorial subjective experience, a large distributed brain network is accessed during nociceptive processing; this is often called the "pain matrix" and simplistically can be thought of as having lateral components (sensory–discriminatory, involving areas such as primary and secondary somatosensory cortices, thalamus and posterior parts of insula) and medial components [affective–cognitive-evaluative, involving areas like the anterior parts of insula, anterior cingulate cortex (ACC) and prefrontal cortices]. However, because different brain regions play a more or less active role depending upon the precise interplay of the factors involved in influencing pain perception (e.g., cognition, mood, injury, and so forth), the "pain matrix" is not a defined entity [1]. A recent meta-analysis of human data from different imaging studies provides clarity regarding the commonest regions found active during an acute pain experience as measured by PET and ▶FMRI [2] (See Fig. 3).

These areas include: primary and secondary somatosensory, insular, anterior cingulate, and prefrontal cortices as well as the thalamus. This is not to say these areas are the fundamental core network of human nociceptive processing (and if ablated would cure all pain), although studies investigating acute pharmacologically induced analgesia do show predominant effects on this core network, suggesting their overall importance on influencing pain perception. Other regions such as basal ganglia, cerebellum, amygdala, hippocampus, and areas within the parietal and temporal cortices can also be active dependent upon the particular set of circumstances for that individual (see Fig. 2). A "cerebral signature" for pain is perhaps how we should define the network that is necessarily unique for each individual.

To understand how nociceptive inputs are processed and altered to subsequently influence changes in the pain experienced, it is useful to separately examine the main factors listed in Fig. 2 that alter pain perception.



**Pain Imaging. Figure 2** Schematic illustrating the main factors that influence nociceptive inputs to alter pain perception.



**Pain Imaging. Figure 3** Neuroanatomy of pain processing. Main brain regions that activate during a painful experience are highlighted as bilaterally active but with more dominant activation on the contralateral hemisphere (more yellow).

*Genetics*: We cannot ignore the possibility that our genes influence both how nociceptive stimuli are processed and how the brain reacts to peripheral injury and increased nociceptive inputs. Similarly, we cannot ignore the central role that our life experiences have on both these processes. Imaging studies have investigated whether individuals claiming to be more "sensitive" to pain, compared with others, activate more brain regions involved in pain perception. Early work suggests that subjects who rated the pain highest exhibit more robust pain-induced activation of ►S1, ACC, and ►PFC compared with those who rated pain lowest. The key question is whether this increased pain report and correlated objective readout is nature or nurture driven. Studies are beginning to link genetic influences on human nociceptive processing with physical processes within the brain. Zubieta and colleagues examined the influence of a common functional genetic polymorphism affecting the metabolism of catecholamines on the modulation of responses to sustained pain in humans using psychophysical assessment and ►PET [3]. Individuals homozygous for the met158 allele of the catechol-*O*-methyltransferase (COMT) polymorphism (val158met) showed diminished regional μ-opioid system responses to pain (measured using PET) and higher sensory and affective ratings of pain compared with those homozygous for the valine polymorphism. This study and others are providing good evidence regarding how our genes influence nociceptive processing within the brain and consequently our pain experience.

## Attention

We know from experience that attention is very effective in modulating the sensory and affective aspects of pain. FMRI and neurophysiological studies showed attention- and distraction-related modulations of pain-evoked activations in many parts of the pain "matrix." From these studies, regions that appear critical during the attentional modulation of pain include the descending pain modulatory system as well as key elements of the pain "matrix."

## The descending pain modulatory system

This is a well characterized anatomical network that enables us to regulate nociceptive processing (largely within the dorsal horn) in various circumstances to produce either facilitation (pro-nociception) or inhibition (anti-nociception) [4] (see also ►Descending modulation of nociception). The pain-inhibiting circuitry, of which the periaqueductal grey (►PAG) is a part, is best known and contributes to environmental (e.g., during the fight or flight response) and opioid-mediated analgesia. There are descending pathways that facilitate pain transmission, however, and it is thought that sustained activation of these circuits may underlie some

states of chronic pain (see below). Recently, researchers have investigated whether alteration in people's attention influences brainstem activity and, therefore, nociceptive processing via cortical–brainstem influences. In an early study using high-resolution imaging of the human brainstem, we showed significantly increased activity within the PAG in subjects who were distracted compared to when they paid attention to their pain, with concomitant changes in pain ratings. Indeed, the change in pain rating between attending and distracting conditions correlated with the change in PAG activity across the group, suggesting a varying capacity to engage the descending inhibitory system in normal individuals. Further work by others has extended these observations and shown that the cingulo-frontal cortex exerts top–down influences on the PAG and posterior thalamus to gate pain modulation during distraction. These studies, and others, provide clear evidence for the involvement of brainstem structures in the attentional modulation of pain perception, and recent work using diffusion tractrography confirms that anatomical connections exist between cortical and brainstem regions in the human brain, thereby enabling such top-down influences.

## Placebo

Recent work in humans has helped provide a framework by which the placebo effect and subsequent analgesia is mediated (see ►Placebo analgesic response). Again, the brainstem is critically involved in mediating placebo analgesia. Descending influences from the diencephalon, hypothalamus, amygdala, ►ACC) insula and prefrontal cortex that elicit inhibition or facilitation of nociceptive transmission via brainstem structures are thought to occur during placebo analgesia. Using PET, it has been confirmed that both opioid and placebo analgesia are associated with increased activity in the rostral ACC, and that a covariation between the activity in the rostral ACC and the brainstem during both opioid and placebo analgesia, but not during pain alone, exists. Wager and colleagues extended these early observations to examine placebo expectation effects [5]. Using a conditioning design, they found that placebo analgesia was related to decreased brain activity in classic pain processing brain regions (e.g., thalamus, insula, and ACC), but was additionally associated with increased activity during anticipation of pain in the prefrontal cortex (PFC), an area involved in maintaining and updating internal representations of expectations. Stronger PFC activation during anticipation of pain was found to correlate with greater placebo-induced pain relief and reductions in neural activity within pain regions. Furthermore, placebo-increased activation of the PAG was found during anticipation, the activity within which correlated significantly with dorsolateral PFC (DLPFC) activity. This is consistent with the concept that prefrontal mechanisms can trigger opioid release within the brainstem and, thereby, influence the descending pain modulatory system to modulate pain perception during the placebo effect.

## Mood

For both chronic and acute pain sufferers, one's mood and emotional state has a significant impact on resultant pain perception and ability to cope. For example, it is a common clinical and experimental observation that anticipating and being anxious about pain can exacerbate the pain experienced. Anticipating pain is highly adaptive, but for the chronic pain patient it becomes maladaptive and can lead to fear of movement, avoidance, anxiety, and so forth. Studies aimed at understanding how anticipation and anxiety cause a heightened pain experience have been performed using imaging methods [6]. Critical regions involved in amplifying or exacerbating the pain experience include the entorhinal complex, amygdala, anterior insula and prefrontal cortices.

With regard to mood, depressive disorders often accompany persistent pain. Although the exact relationship between depression and pain is unknown, with debate regarding whether one condition leads to the other or if an underlying diathesis exists, studies have attempted to isolate brain regions that may mediate their interaction. Early studies indicated that activation in the amygdala and anterior insula appears to differentiate fibromyalgia patients with and without major depression. Another fibromyalgia study found that pain catastrophizing (defined as a set of negative emotional and cognitive processes), independent of the influence of depression, was significantly associated with increased activity in brain areas related to anticipation of pain (medial frontal cortex, cerebellum), attention to pain (dorsal ACC, dorsolateral PFC), emotional aspects of pain (claustrum, closely connected to amygdala) and motor control [7]. The construct of catastrophizing incorporates magnification of pain-related symptoms, rumination about pain, feelings of helplessness, and pessimism about pain-related outcomes. The results by Gracely and colleagues support the notion that catastrophizing influences pain perception through altering attention and anticipation, as well as heightening emotional responses to pain (see ►Emotional/affective aspects of pain).

## The prefrontal cortex and pain

It is clear from these few studies described above and others in the literature that pronounced PFC activation is consistently found across clinical pain conditions, irrespective of underlying pathology. We are only beginning to unravel the roles of specific PFC regions in pain perception; it is thought they reflect emotional,

cognitive and interoceptive components of pain conditions, as well as perhaps processing of negative emotions, response conflict and detection of unfavorable outcomes in relation to self. Interestingly, imaging studies attempting to capture the neural signature of the ongoing, spontaneous pain that patients commonly experience are finding increased medial PFC, including rostral ACC, activity during episodes of sustained high ongoing pain. These early data suggest a very different neural "signature" for the patient's ongoing pain, compared to the acute nociceptive network found active in response to provoked stimulation, as described above in most FMRI studies. A specific role for the lateral PFC as a "pain control center" has been put forward in a study of experimentally induced allodynia in healthy subjects [8]. In this study, increased lateral PFC activation was related to decreased pain affect, supposedly by inhibiting the functional connectivity between medial thalamus and midbrain, thereby driving endogenous pain-inhibitory mechanisms.

It is important to also note that the PFC (specifically the dorsolateral PFC) is one site of potential major neurodegeneration and cell death in chronic pain patients. These latest findings suggest that severe chronic pain could be considered a neurodegenerative disorder that especially affects this region. However, determining what the possible causal factors are that produce such neurodegeneration is difficult. Candidates include the chronic pain condition itself, the pharmacological agents prescribed for pain management or perhaps the physical lifestyle change subsequent to becoming a chronic pain patient. Carefully controlled longitudinal studies are needed.

## Pain without a nociceptive input

Recent imaging data display activity of the near entire "pain matrix" without any nociceptive input during empathy and hypnosis manipulations, suggesting it is time to reconsider how we define central pain processing with respect to the origin of the input and resultant perception and meaning. This is not to say that pain experienced without a nociceptive input (sometimes referred to as psychogenic pain) is any less real than "physically" defined pain; indeed, neuroimaging studies have highlighted the physiological reality of such experiences due to the extensive neural activation that occurs.

## Injury

Recently, changes within the descending pain modulatory network have been implicated in chronic pain (central sensitization) and in functional pain disorders [9] (see also ►Descending modulation of nociception). Changes are defined in terms of patients having either a dysfunctional descending inhibitory system or an activated and enhanced descending facilitatory system. There has been convincing evidence advanced regarding the differential involvement of the PAG, rostroventromedial medulla (►RVM), parabrachial nucleus (►PB), dorsal reticular nucleus and nucleus cuneiformis (►NCF) in the generation and maintenance of central sensitization states and hyperalgesia in both animal models and, for the first time, in a human model of secondary hyperalgesia [10]. Changes within the descending pain-modulatory network in chronic pain, in terms of patients having either a dysfunctional descending inhibitory system or an activated and enhanced descending facilitatory system, are clearly implicated in these and increasingly in other clinical studies.

Understanding which CNS areas are involved in engaging or disengaging this descending modulatory system has significant potential to not only further our understanding of how pain is perceived, but in developing mechanism-based therapies for treating different types of acute and chronic pain.

## Spinal cord imaging

Clearly, to determine the extent of changes present within the CNS we must develop methods that allow noninvasive access to the changes within the human spinal cord, and these are currently being successfully developed.

## Altered opioidergic and dopaminergic pathways

The availability of PET ligands for opioid and dopamine receptors has allowed the study of these receptor systems in several clinical pain states. Early opioid receptor ligand studies showed decreased binding in patients with chronic pain that normalized after reduction of their pain symptoms. Regional differences in ligand binding have recently been found in neuropathic pain studies with decreased binding in several key areas involved in pain perception. The dopaminergic pathways have also been implicated in pain processing in animal and patient studies. Early studies in fibromyalgia patients indicate reduced presynaptic dopaminergic activity in several brain regions in which dopamine plays a critical role in modulating nociceptive processes. Similar to the endogenous opioid system, the issue of cause and effect between a "functional hypodopaminergic state" and pain has yet to be resolved, making this an exciting area of current research.

## Conclusion

Knowledge regarding how pain is perceived at a central level in humans is growing. An extensive network is recruited that is highly modifiable depending upon genetics, the environment, mood and the particular injury sustained. Combined, these produce a unique cerebral signature that produces an individualized pain experience.

[2]Neuroscience and Mental Health Program, Research Institute at The Hospital for Sick Children; Department of Anaesthesia, The University of Toronto, Toronto, ON, Canada

## Synonyms

Pediatric pain; Adolescent pain

## Definition

The unique aspects of nociceptive processing and pain perception associated with a developing pain system and a maturing child, in contrast to those of a mature adult.

Children are not "little adults" with respect to nociceptive processing and pain perception. The ►developing nociceptive system responds differently to injury (i.e., increased excitability and sensitization) when compared to the mature adult system [1,2]. Moreover, a child's pain appears to have a greater degree of ►plasticity when compared to that of adults – more influenced by cognitive, behavioral, and emotional factors [3].

## Characteristics

### Children's Pain Problems

Like adults, children can experience many different types of pain throughout their lives – acute pain due to disease or trauma, recurrent episodes of headache, stomach ache, or limb pain unrelated to disease, and chronic pain due to injury, disease, psychological factors, or of unknown etiology. However, the prevalence of certain types of pain is different for adults and children. For example, chronic back pain is a major problem for adults but not for children. Recurrent pain syndromes (i.e., abdominal, headache, limb pains or "growing pains") are more common pain problems for children.

Pain prevalence increases with age and certain pain conditions vary with sex and age. For example, clinical referrals indicate that Complex Regional Pain Syndrome-Type 1 affects girls more than boys with a ratio of ~6–9:1 and affects children primarily in their pre- and early teen years. Complex idiopathic pain conditions and somatization disorders seem to predominantly affect older adolescents.

Although we lack precise data on the incidence and prevalence of many childhood pain conditions, an increasing number of epidemiological studies are focused on obtaining such data, identifying individual risk and prognostic factors and documenting the long term impact for children and their families.

### Developmental Considerations

Considerable neuronal plasticity is evident throughout the developing system from the periphery to the brain (for review, [1,2]) (see ►Development of nociception). Although basic nociceptive connections are formed before birth, these systems are immature and exhibit increased responsivity in comparison to the adult animal. The conduction velocity of afferent fibers, action potential shape, receptor transduction, firing frequencies and receptive field properties change substantially over the postnatal period. High threshold Aδ mechanoreceptors (which respond maximally to noxious mechanical stimuli) and low threshold Aβ mechanoreceptors (which respond maximally to innocuous stimuli) respond with lower firing frequencies than those in the adult animal. The receptive fields of dorsal horn cells are larger in the newborn. The larger receptive fields and dominant A-fiber input increases

the likelihood of central cells being excited by peripheral sensory stimulation and acts to increase the sensitivity of infant sensory reflexes. Some inhibitory mechanisms (►Inhibitory mechanisms in developing system) in the dorsal horn are immature at birth and descending inhibition is delayed. The lack of descending inhibition in the neonatal dorsal horn means that an important endogenous analgesic system that should attenuate noxious input as it enters the spinal cord is lacking, and thus the effects of the input may be more profound than in the adult [2].

Most studies in developmental neurobiology have been conducted on rat pups because they have comparable developmental timetables with respect to the anatomy, chemistry, and physiology of maturing human pain pathways. To study neural function in human infants, investigators have monitored behavioral and neurophysiologic responses, and revealed comparable findings of plasticity and increased excitability in the developing nervous system (for review, [1,4]). In comparison to adults, young infants have exaggerated reflex responses (i.e., lower thresholds and longer lasting muscle contractions) in response to certain types of trauma, such as needle insertion. Repeated mechanical stimulation at strong (but not pain-producing) intensities can cause sensitization in very young infants, while repeated painful procedures such as those required during intensive care can profoundly affect sensory processing in infants. Infants after surgery can develop a striking hypersensitivity to touch, as well as to pain.

While we do not know specifically how such injuries may affect the mature human pain system or influence adult pain perception, increasing attention is focused on the possible consequences of untreated pain, particularly in infants [5]. For example, circumcised newborn infants display a stronger pain response to subsequent routine immunizations at 4 and 6 months than uncircumcised infants, but application of lidocaine-prilocaine anesthetic cream at circumcision attenuates the pain response to the subsequent immunizations [6]. Studies of former premature infants who required intensive care have shown behavioral differences related to early pain experiences. The results of behavioral studies in infants, like those from neurobiological studies in animals, indicate increased responsivity to pain.

## Factors that Modify Children's Pain

A child's pain perception can be regarded as plastic from a psychological, as well as biological perspective. Tissue damage initiates a sequence of neural events that may lead to pain, but many developmental, social, and psychological factors can intervene to alter the sequence of nociceptive transmission and thereby modify a child's pain. Child characteristics, such as cognitive level, sex, gender, temperament, previous pain experience, family, and cultural background shape generally how children interpret and cope with pain (for review [7–9]).

In contrast, ►situational factors vary dynamically, depending on the specific circumstances in which a child experiences pain. For example, a child receiving treatment for cancer may have repeated injections, central venous port access and lumbar punctures – all of which can cause pain (depending on the analgesics, anesthetics, or sedatives used). Even though the tissue damage from these procedures is the same each time, the particular set of situational factors for each treatment is unique for a child. The expectations, behaviors and emotional state of the child, parent and health care provider all play a critical role. "What children and parents understand, what they (and health care staff) do, and how children and parents feel" can profoundly impact a child's pain experience. Certain situational factors can intensify pain and distress, while others can eventually trigger pain episodes, prolong pain related disability, or maintain the cycle of repeated pain episodes in recurrent pain syndrome [3]. Parents and health care providers can dramatically improve a child's pain experience and minimize their disability by modifying children's understanding of a situation, their focus of attention, perceived control, expectations for obtaining eventual recovery and pain relief, and the meaning or relevance of the pain.

Situational factors may affect children even more than adults. Adults typically have experienced a wide variety of pains (i.e., diverse etiology, intensity and quality), providing them with a broad base of knowledge and coping behaviors. When adults encounter new pains, they evaluate them primarily from the context of their cumulative life experience. In contrast, children with more limited pain experience must evaluate new pains primarily from the context of the immediate circumstances. Children's understanding of pain, pain coping strategies, and the impact of pain increase with age, but many questions remain about the interplay of maturation, cognitive development, and experience in mediating a child's pain.

## Pain Measures for Infants and Children

Pain assessment is an intrinsic component of pain management in infants and children. Clinicians need an objective measure of pain intensity and an understanding of the factors that cause or exacerbate pain for an individual child. More than 60 pain measures are now available for infants, children, and adolescents (for review, [10]). While no single pain measure is appropriate for all children and for all situations in which they experience pain, we should be able to evaluate pain for almost every child.

►Physiological parameters including heart rate, respiration rate, blood pressure, palmar sweating, blood cortisol and cortisone content, $O_2$ levels, vagal tone and

endorphin concentrations have been studied as potential pain measures. However, they reflect a complex and generalized stress response, rather than correlate with a particular pain level. As such, they may have more relevance as distress indices within a broader behavioral pain scale. Behavioral scales record the type and amount of pain-related behaviors children exhibit. Since a child's specific pain behaviors depend on the type of pain experienced, different scales are usually required for acute and persistent pain. Clinicians monitor children for a specified time period and then complete a checklist noting which distress behaviors (e.g., crying, grimacing, guarding) occur. Behavioral scales must be used for infants and children who are unable to communicate verbally. Recently, investigators are validating pain scales for children who are ►developmentally disabled. However, the resulting pain scores are indirect estimates of pain and do not always correlate with children's own pain ratings. Even though clinicians may use diaries rather than formal scales, prospective evaluation of a child's behavior is an essential component of pain management, providing information about medication use, compliance with treatment recommendations, and the extent of pain-related disability (i.e., school attendance, physical activities, and social activities with peers).

Psychological or self-report measures include a broad spectrum of projective techniques, interviews, questionnaires, qualitative descriptive scales, and quantitative rating scales designed to capture the subjective experience of a child's pain [11]. By the age of five, most children can differentiate a wide range of pain intensities, and many can use simple ratio and interval pain scales (e.g., visual analog scales, numerical scales, faces, verbal descriptor scales) to rate their pain intensity. Many scales have excellent psychometric properties, are convenient to administer, easy for children to understand, adaptable to many clinical situations, and help parents to monitor their child's pain at home. Interviews, usually conducted independently with a child and parents, are the cornerstone of assessment for children with persistent pain, enabling clinicians to identify relevant child, family, and situational factors that contribute to children's pain and disability problems.

## Child-centered Pain Management

Pain control is not merely "drug versus nondrug therapy," but rather an integrated approach to reduce or block nociceptive activity by attenuating responses in peripheral afferents and central pathways, activating endogenous pain inhibitory systems, and modifying situational factors that exacerbate pain. Adequate analgesic prescriptions, administered at regular dosing intervals, must be complemented by a practical cognitive-behavioral approach to ensure optimal pain relief. Pain control is achieved practically by adjusting both drug and nondrug therapies in a rational child-oriented manner based on the assessment process [12]. Analgesics include acetaminophen, non-steroidal anti-inflammatory drugs, and opioids. ►Adjuvant analgesics include a variety of drugs with analgesic properties, such as anticonvulsants and antidepressants that were initially developed to treat other health problems, but whose therapeutic uses have been expanded. The use of adjuvant analgesics has become a cornerstone of pain control for children with chronic pain, especially when pain has a neuropathic component. Children with severe pain may require progressively greater and more frequent opioid doses due to drug tolerance and should receive the doses they need to relieve their pain. The fear of opioid addiction in children has been greatly exaggerated. Neonates and infants require the same three categories of analgesic drugs as older children. However, premature and term newborns show reduced clearance of most opioids. The differences in pharmacokinetics and pharmacodynamics among neonates, preterm infants, and full-term infants, warrant special dosing considerations for infants and close monitoring when they receive opioids.

An extensive array of nondrug therapies is available to treat a child's pain including physical, psychological and complementary and alternative approaches. Counseling, attention and distraction, guided imagery, hypnosis, relaxation training, biofeedback, and behavioral management are used routinely to treat a child's procedural pain and chronic pain. Children seem more adept than adults at using psychological therapies, presumably because they are generally less biased than adults about their potential efficacy. Strong and consistent scientific evidence supports the efficacy of many psychological therapies for relieving children's procedural pain and for relieving childhood headache, but few rigorous evaluations have been conducted on their efficacy for relieving other types of chronic pain – even though they are considered an essential component of many treatment programs.

## Clinical and Research Challenges

As a result of extensive research, we have gained better insights about how the developing nociceptive system responds to tissue injury, how children perceive pain, how to assess pain in infants and children, and which drug and nondrug therapies will alleviate their pain. The emphasis has shifted gradually from an almost exclusive disease-centered focus – detecting and treating the putative source of tissue damage – to a more child-centered perspective, assessing the child with pain, identifying contributing psychological and contextual factors, and then targeting interventions accordingly. However, serious challenges remain from both research and clinical perspectives [13].

We have discovered much about the plasticity of the developing nociceptive system, but still have much to

learn about how signals from painful stimuli are processed, especially at higher levels (see ►Pain imaging). Although we need further developmental research in neurobiology, neurophysiology, and pharmacology, we now know that infants seem particularly vulnerable because of their heightened responsivity to tissue injury and we must devote particular attention to their pain management.

We need to apply the existing knowledge about pain assessment and pain management more consistently within our clinical practice. Regrettably, many hospitals still do not require consistent documentation of children's pain, preventing us from ensuring that children's pain is adequately controlled. Hospital administrators or accreditation organizations should establish children's pain control as a priority. In spite of established analgesic dosing guidelines for infants and children, the undertreatment of postoperative and chronic pain is a continuing problem in many centers.

Moreover, increasing responsibility for evidence-based practice dictates that health care providers adopt clear guidelines for determining when treatments are effective and for identifying children for whom they are most effective. We lack data from well-designed cohort studies and randomized controlled trials to validate the efficacy of many interventions (both drug and nondrug therapies) used extensively in clinical practice. Although cognitive-behavioral interventions are critical components of pain management programs for chronic pain, most of the data supporting their efficacy is derived from studies of childhood headache [14].

We critically need data on child-centered treatment efficacy – that is, when interventions are selected for the individual child with pain, based on an assessment of the specific cognitive, behavioral, and emotional factors contributing to their pain and disability. We need longitudinal studies to identify key risk factors that influence a child's vulnerability to chronic pain, in particular the apparent increased vulnerability in females. Future studies should use brain imaging technology and psychophysical measurement to evaluate the neural mechanisms underlying chronic pain and cognitive function in children. Our ultimate and continuing challenges are to better understand the experience of children's pain and to improve clinical practice, so that health care providers use the existing "state of the art" pain scales, interpret children's pain scores to guide therapeutic decisions, and document treatment effectiveness.

# Pain in Older Adults (Including Older Adults with Dementia)

Thomas Hadjistavropoulos
Centre on Aging and Health and Department of Psychology, University of Regina, Regina, SK, Canada

## Synonyms

Pain in the elderly; Pain among seniors; Pain in patients with dementia

## Definition

Most investigations focusing on pain among older adults (elderly persons) involve participants who are at least 60 or 65 years of age.

## Characteristics

### Prevalence

Although the prevalence of acute pain remains steady across the lifespan, there is an increased prevalence of chronic pain at least until the seventh decade of life [1]. Limited evidence also suggests a plateau or even a slight reduction in the frequency of pain complaints after age 80 [1].

Pain is a very common problem among older adults. Chronic pain affects at least 50% of seniors living in the community and approximately 80% of residents of long-term care facilities. Moreover, in a large scale Canadian investigation of nursing home residents, it was shown that conditions likely to cause pain occur with equal frequency in residents with and without dementia [2]. Despite the increasing prevalence of most pain problems with age, the study of pain among older adults had not received much literature attention until recently [1].

### Pain Perception, Thresholds and Tolerance

Age-related changes in peripheral, spinal and central nervous system ►nociceptive pathways would be expected to alter pain sensitivity and therefore the perception of noxious stimulation [3]. Indeed, evidence suggests that age can have an impact on the function of nociceptive pathways and mechanisms, including alterations in afferent transmission and descending modulation [1]. More specifically, for example, research on the perceptual experience that tends to accompany activations of nociceptive fibers has suggested the presence of a selective age-related impairment in A-fiber function and a greater reliance on C-fiber information in older adults. Considering that A-fibers subserve the epicritic, first warning aspects of pain, while C-fiber information is more diffuse, dull and prolonged, it might be reasonable to expect some changes in pain intensity and quality among elderly persons [3].

Research has also revealed evidence that temporal summation (i.e., the enhancement of pain sensation that is associated with repeated stimulation) is altered in older adults. Temporal summation is the result of transient, repetitive activation of dorsal horn neurons in the spinal cord and is believed to play a central role in the development of ►hyperalgesia and post-injury tenderness [3]. Based on the findings that are available in the literature, it is likely that post-injury tenderness and hyperalgesia may take longer to resolve among older adults [3]. An additional age-related change has been demonstrated by Washington, Gibson and Helme [4], who have shown that endogenous inhibitory pain control mechanisms that descend from the cortex and midbrain onto spinal cord neurons decline with advancing age. Such a decline could be expected to reduce the ability of older adults to cope with persistent pain states [3].

With respect to neurochemical and morphological age-related changes in the central nervous system, Gibson, Gorman and Helme [5] used the pain-related encephalographic response to index the central nervous system processing of noxious stimulation. These researchers found that that older adults tended to display a significant reduction in peak amplitude and an increase in response latency. They concluded that these findings were suggestive of a reduced cortical activation and slowing in the cognitive processing of noxious information. Nonetheless, it is important to remember that despite such limited laboratory evidence of reduced sensitivity to pain with advancing age, there is no evidence to suggest that seniors who report pain suffer any less than their younger counterparts [1].

Research has also examined the possible impact of dementia on pain responses. In general, the findings have shown no difference in the ►pain threshold of those with mild to moderate Alheimer's disease, despite an increase in ►pain tolerance when compared to age matched controls [6,7]. Nonetheless, Benedetti et al. [6] have demonstrated that whereas the sensory-discriminative components of pain are preserved even in advanced stages of Alzheimer's disease, the cognitive and affective functions, which are related to both anticipation and autonomic reactivity, are severely affected. This sensory-affective dissociation is well correlated with neuropathological findings in Alzheimer's disease. Moreover, Benedetti et al. [6,7] showed that pain tolerance among older adults with Alzheimer's disease is tightly related to the severity of the disease. That is, more severe cognitive impairment and more significant electroencephalogram (EEG) changes were associated with higher pain tolerance. Thus, despite the preservation of pain thresholds in the presence of dementia, there is an increase in pain tolerance with increased severity of the disease. It is noted, however, that clinical research has shown that the reflexive reactions that dementia patients show to painful stimulation (e.g., pain due to discomforting physiotherapy exercises) are comparable or more intense than the reactions of cognitively intact patients [8]. Such clinical findings underscore the importance of managing pain effectively regardless of patient cognitive status.

### Age Differences in Psychosocial Aspects of Pain

There is evidence of psychosocial differences in the mediators and context of pain. Although not perfectly consistent across studies, the evidence shows age-related differences in beliefs and attributions about pain as well as coping strategies [9]. There is, for

example, evidence of increased stoicism among older adults when it comes to the reporting of symptoms. This stoicism could lead to an underreporting of pain among older adults [9]. Moreover, the social context and stressors that affect seniors with pain differ from those of younger persons. For example, younger adults with chronic pain conditions are often concerned about issues relating to return to work whereas older persons are often retired, may be widowed and may be more concerned about loneliness and possible social isolation.

### The Assessment of Pain in the Older Adult

Given age-related differences in the social context and co-morbidities of chronic pain, research has focused increasingly on the validation of pain assessment tools among older adults [10]. Instruments that are specialized in the assessment of the older adult have also been developed [10].

The accurate assessment of pain in the older adult is especially challenging when it comes to persons with severe dementia who have limited ability to communicate. Because pain is a subjective phenomenon, clinicians tend to rely on self-report. Recently, there have been worthwhile efforts to develop and validate observational measures of pain that rely on the recording of pain-related behaviors such as facial expressions and paralinguistic vocalizations (such assessment tools have been reviewed elsewhere [8]).

### The Treatment of Pain in the Older Adult

Although the prevalence of chronic pain increases with age, pain is always the result of pathology and is never a natural part of being old. As such, it is always important to manage chronic pain. Recommended doses of drugs used for pain management in older adults are often lower than doses used in younger persons because of age-related physiological changes (e.g., age-related changes in fat to muscle ratio, slowing of metabolic rates, lower protein levels in the blood). Although numerous drugs have been shown to be effective in treating pain in older adults, more research concerning the ►pharmacokinetics, ►pharmacodynamics, efficacy and safety of medications in older persons is needed [9]. In addition, many of the painful conditions that elderly persons tend to suffer are responsive to physiotherapy, although special adaptations may be required for frail seniors [9]. Finally, initial evidence suggests that ►cognitive behavior therapy can be helpful in assisting older adults with pain management [9].

### Synonyms

Quantitative sensory testing QST

### Definition

The systematic evaluation of the quantitative relationship between physical stimuli and the pain they evoke.

### Characteristics

The discipline of ►psychophysics was developed in the German experimental psychology laboratories of the early nineteenth Century. It has been applied to every sensory system, including pain. The earliest published work in pain psychophysics recognized today is that of Ernst Weber [1] While most of Weber's work in psychophysics addresses tactile perception, a portion encompasses pain. The first major opus in pain psychophysics of the twentieth Century was that of James Hardy and colleagues at Cornell University. Over 200 papers from this group were distilled for the book "Pain sensations and reactions"[2]. This body of work was a principal reference for pain psychophysics for decades, despite a reliance on a narrow range of approaches that were not always found to generalize in subsequent studies.

The two essential components for psychophysical evaluation of any sensory system are (i) controlled stimuli and (ii) a valid method of quantifying sensory experience. For pain psychophysics, the development of reliable pain-evoking stimuli was complicated by the need to avoid tissue damage. The most commonly used stimulation techniques are cutaneous heating and mechanical pressure applied to cutaneous and/or deeper tissues. However, several other forms of stimulation are used for pain psychophysics, including cold, electrical, chemical, laser, and visceral distention [3].

### Pain Threshold

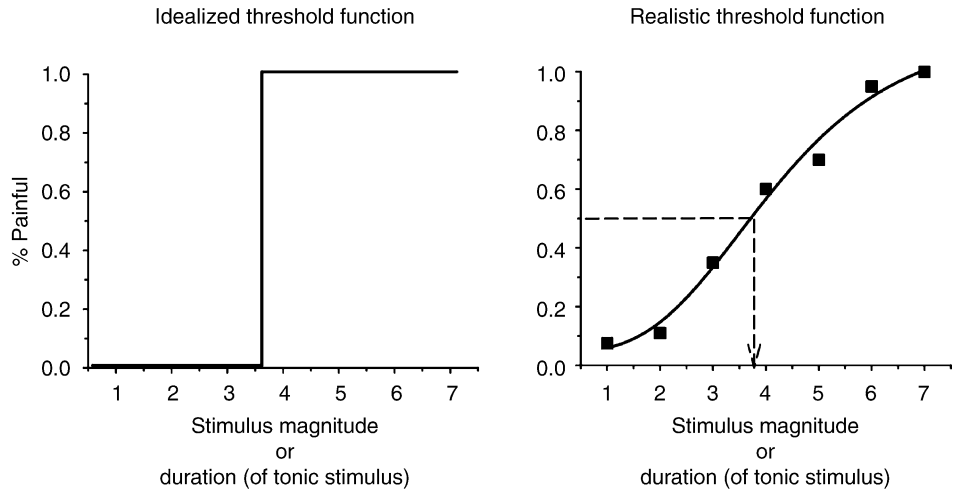
One principal psychophysical measure is ►threshold. Simply stated, threshold is the minimal level of stimulation needed to evoke a sensation. By extension pain threshold is the minimal level of stimulation needed to evoke a sensation of pain. Accordingly, thresholds are reported in terms of stimulus values, such as temperature (in °C) or mechanical forces (kg equivalent weight, or Newtons). An alternative measure is the time it takes a constant, sustained stimulus to be perceived as painful, thus measuring pain threshold in terms of seconds.

The assessment of pain threshold is more complicated than other sensory thresholds because of the nature of pain and people's concept of it. In other sensory modalities, threshold is recognized by the "step" between no sensation and sensation. Thus, the subject is attempting to distinguish between sensing nothing and something. For pain thresholds, the subject is instead distinguishing between two types of sensation – one considered painful and one non-painful. Thus, a critical element in pain threshold determination is the particular sensory experience an individual considers painful. This factor will be influenced by, among other things, the subject's pain experience history, and the instructions given by the experimenter. For instance, thresholds are likely to be different if a subject is instructed to indicate when he perceives "pain" versus when he perceives "a sharp or burning sensation" or "an uncomfortable sensation." It is also possible that a subject's criterion for judging what sensation is painful changes in the course of an evaluation session. Furthermore, the likelihood and extent of such changes can vary depending upon the range and number of stimuli applied [4]. Several other factors can influence pain threshold values, including features of the psychophysical protocol (e.g., the specific design, stimulus parameters, the range of stimuli, the threshold calculation procedure), which makes it questionable to compare threshold values across studies that vary with respect to these and any other protocol features.

Another important fact to recognize is that threshold is a statistical entity. While we are accustomed to representing thresholds as very precise values (i.e., heat pain thresholds expressed as temperature at a 0.1°C level of precision), it is not the case that weaker stimuli are necessarily painless, and stronger ones are always painful. Instead, there is a range of stimuli for which the lower values are less frequently painful and the higher values are more frequently painful. The threshold value, in principle, is the midpoint of that range (Fig. 1).

This concept applies whether one is considering data derived from a single person tested repeatedly, or from a group of people.

Heat pain threshold has been found to be fairly consistent across many body sites. However, heat pain thresholds are significantly higher on ►glabrous skin than on hairy skin of the extremities. This relative consistency across the body allows one to assess regional pain threshold abnormalities by comparing



**Pain Psychophysics. Figure 1** Ideally, pain threshold can be envisioned as the stimulus intensity that divides non-painful from painful intensities of stimulation (*left*). But, in reality, there is a range of stimulus intensities that are sometimes perceived as painful and sometimes as non-painful. Thus, pain threshold is typically regarded as the stimulus intensity that is painful 50% of the time (*right*).

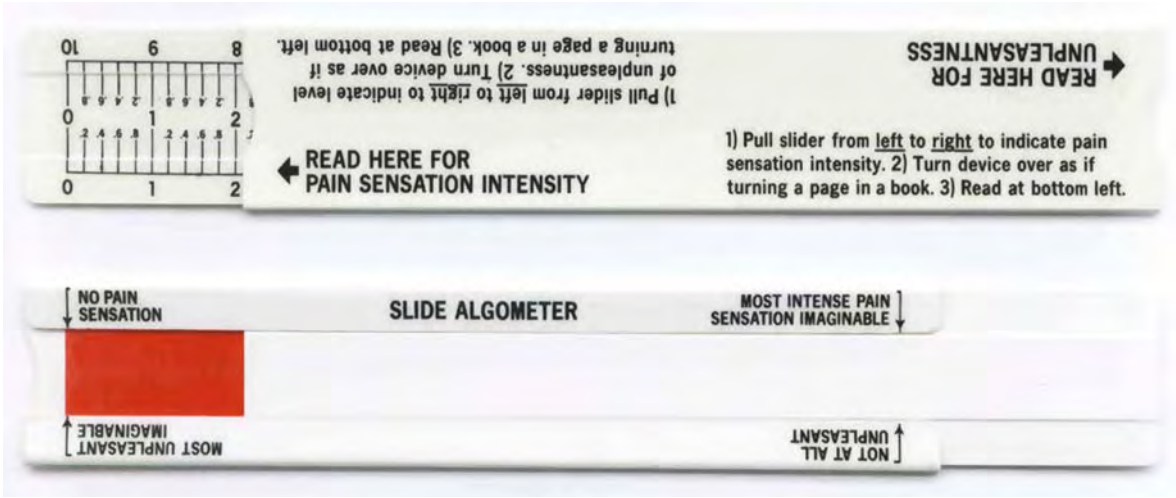
thresholds between two body sites, when one of them is accepted as a reference. This approach is often done by comparing thresholds between homolateral body sites in the cases of unilateral sensory abnormalities [5]. Despite this intra-personal consistency, there is considerable inter-personal variability in pain threshold. This feature has been demonstrated in studies that have evaluated a large number of subjects in attempts to develop a normative database of pain thresholds [6].

While the concept of psychophysical threshold has been used for almost two centuries, it has been criticized as a strict measure of sensory perception because it can be influenced by psychological states such as expectancy and anticipated rewards. In an attempt to account for these and other "non-sensory" factors that could influence threshold determination, the approach of ►signal detection theory (SDT) was adapted for psychophysics [7]. This approach allowed for the distinction between stimulus discriminability (d') and response bias (β), in which the former was the "bias-free" measure of sensory detection. Threshold measures cannot make this distinction. Approaches based on SDT have been applied to pain psychophysics; however, problems particular to pain psychophysics have been noted. Despite the advantage of SDT approaches in distinguishing stimulus discriminability from response bias in psychophysical assessments, the major drawback of this approach is the need for many more stimulus trials than are needed for most threshold protocols. In addition, SDT assumes a perceptual stability over the course of testing, which is not necessarily the case for pain. Another concern is that knowing how discriminable two (or more) stimuli are from one another is not the same information as how painful those stimuli are. Thus, the kind of information derived from STD-derived protocols are supplemental to, rather than replacements for, the type of information gathered using other psychophysical approaches to pain perception.

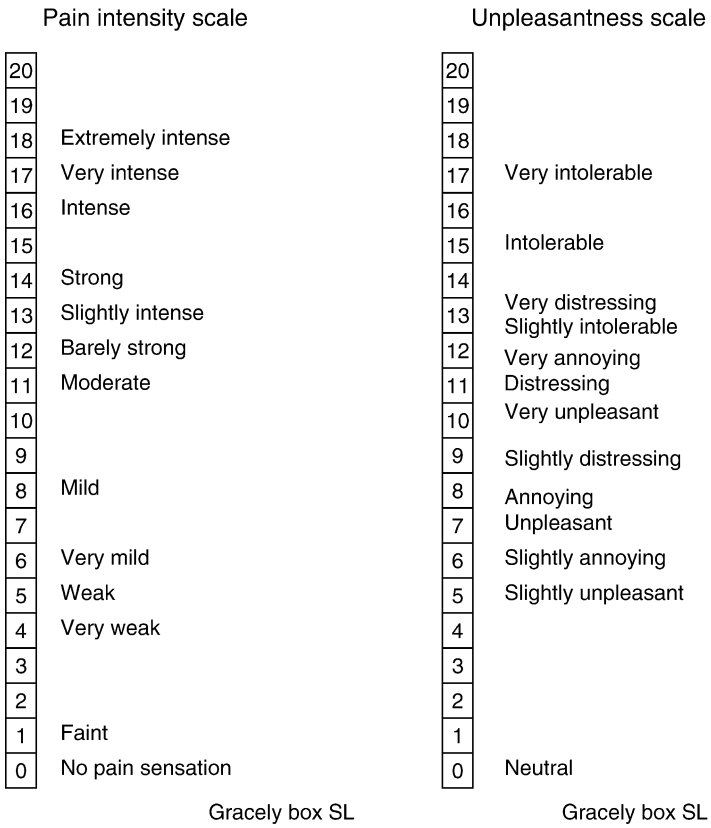
## Suprathreshold Pain Scaling

Another major psychophysical endpoint is evaluation of perception above threshold (suprathreshold perception). The principle is to have the subject represent the sensory experience on a quantitative continuum – often referred to as "scaling" perception. There are many ways to accomplish this, and protocols are based on either direct or indirect methods. Indirect scaling methods require the subject to use another continuum to match the perception under investigation. An example of this is to have the subject adjust the volume of a sound so that the loudness matches the intensity of another sensory dimension, such as pain. In this way, the pain intensity can be measured in terms of decibels of sound. Another approach is to have the subject draw a line length to represent the intensity of a sensation, allowing the sensation intensity to be measured in millimeters.

The direct scaling methods require the subject to choose a number that reflects perceptual intensity, and thus do not require an intermediate modality such as another sensory dimension or a motor task. These direct scaling methods have been more frequently employed for pain psychophysics over the last few decades. In most pain studies, subjects are provided a number



**Pain Psychophysics. Figure 2** A mechanical visual analog scale for pain rating developed by Dr. Donald D. Price and colleagues. *Bottom*: A sliding plastic piece moves to reveal a red bar. The subject adjusts the length of the red bar to match the perceived pain intensity (in the orientation shown), or the perceived unpleasantness (when rotated 180°). *Top*: The number at the edge of the adjusted plastic piece is the numerical value assigned either pain intensity or unpleasantness. Figure courtesy of Dr. Price.



**Pain Psychophysics. Figure 3** Pain rating scales with descriptors developed by Dr. Richard H. Gracely and colleagues. The subject reports the perceived pain intensity (a) or unpleasantness (b) by choosing a number between 0 and 20. Placement of descriptors along the length of the numeric scale, which serve to provide connotative meaning to the numbers, was based on psychometric procedures described in [9]. Figure courtesy of Dr. Gracely.

scale to use, which can be as limited as 0–5, or as large as 0–100, or even unbounded. In many instances, the numeric scale also includes descriptors at specific points to give the numeric scale a qualitative frame of reference. One of the most commonly used scales for pain ratings is a 0–100 visual analog scale (VAS) with descriptors at both ends of the scale (Fig. 2).

This scale has been validated and found to produce data with ratio scale properties suitable for parametric analysis [8]. Other pain scales have been developed with more descriptors, based on psychometrically determined associations among the descriptors (Fig. 3a) [9,10].

The principle of assigning descriptors along a numeric scale for the subject can be an advantage, but also potentially problematic. On one hand, descriptive anchors serve to give the numbers a consistent connotative meaning to the subjects, and thereby help to standardize the scale. On the other hand, if different people interpret the same term differently (Is your concept of "extremely intense" the same as mine?), the presence of these terms can introduce an idiosyncratic bias, rather than standardizing the numeric scale. Despite this possibility, and the inherent uncertainty of measuring a subjective phenomenon, these types of scales have been successfully used for many psychophysical studies of pain over the last few decades.

While the aforementioned scales are designed to measure pain intensity, a similar set of scales have been developed to measure pain affect or unpleasantness (Figs. 2 and 3b). In principle, any perceptual dimension could be measured with a similarly constructed scale.

### Pain Tolerance

Pain tolerance is less frequently used than pain threshold in scientific studies, and it has some significant disadvantages: (i) For some forms of stimulation, pain tolerance cannot be reached without risking tissue injury; (ii) Pain tolerance generally shows greater variability than threshold, both within and across subjects; (iii) It is more widely altered by subject bias or past experience than threshold. However, pain tolerance measures a qualitatively different aspect of the pain experience than does pain threshold. Arguably, pain tolerance is a measure more reflective of the affective and motivational aspects of the pain experience, while threshold is a measure of the discriminative aspect. One common form of this test is the "►cold pressor test," which involves submersion of a body part in ice water. Another test involves ischemic pain, produced by applying a pressure cuff on the subject's arm.

## Pain System

►Ascending Nociceptive Pathways

## Pain Threshold

### Definition

The International Association for the Study of Pain defines pain threshold as the least amount of pain that a person can recognize.

►Pain in Older Adults (Including Older Adults with Dementia)

## Pain Tolerance Level

### Definition

The International Association for the Study of Pain defines pain tolerance level as the greatest amount of pain that a person can tolerate.

►Pain in Older Adults (Including Older Adults with Dementia)

## Pain Unpleasantness

### Definition

The immediate, disagreeable aspect of pain, similar to feelings of thermal distress (too hot or cold), thirst, or hunger, that motivates behaviors to reduce this feeling state. This immediate state is in contrast to the emotional reactions and feeling states associated with thoughts about pain (pain emotion), such as anxiety, depression, fear, and despair. In the case of injury, the unpleasantness of pain usually motivates movements to escape or to minimize the injury (pain evoked movement). After the injury, during the healing phase, the unpleasantness of pain may inhibit movement to protect the injured area and promote healing (movement evoked pain).

## Palaeocerebellum

### Synonyms

►Paleocerebellum

### Definition

Phylogenetically, a very old part of the cerebellum. Corresponds to the vermis cerebelli with its surrounding intermediate part (paravermal part). The afferents of this region come from the spinal cord, hence this part is also called the spinocerebellum.

►Cerebellum

## Palaeomagnetism

### Definition

The study of remanent magnetization of rocks and sediments to unravel information of the ancient magnetic field.

►Geomagnetic Field

## Paleocortex

### Definition

The paleocortex (Greek for old cortex) is a phylogentically older type of cortex with less than the six layers seen in the neocortex, but more than the three layers seen in the archicortex (hippocampal formation). The parahippocampal gyrus has cortex of this type.

## Paleoencephalon

### Definition

The paleoencephalon describes phylogentically older parts of the cerebral hemisphere that evolved along with the olfactory system. Sometimes the term rhinencephalon is used as a synonym. In the strict olfactory sense, the paleoencephalon would include the olfactory bulb, anterior olfactory nucleus, olfactory tubercle, and portions of the amygdala and nearby piriform cortex.

## Paleoneurology

### Definition
The study of the endocasts of fossil animals.

►Evolution of the Brain in Humans – Paleoneurology

## Paleopallium

### Definition
The palopallium refers to the cortex of the paleoencephalon, i.e., paleocortex (see above).

## Paleopallium and Archipallium

►Evolution of the Pallium: in Amphibians

## Pallia Dorsale and Piriforme

►Evolution of the Pallium: in Amphibians

## Pallial Amygdala

### Definition
Portion of the amygdaloid complex derived from pallial regions. It posses layered cortical and nuclear components in amniotes, whereas only a nuclear portion is present in anamniotes (anurans amphibians).

►Evolution of the Amygdala: Tetrapods

## Pallial Primordia

►Evolution of the Pallium: in Amphibians

## Palliative

►Placebo Analgesic Response

## Pallidum

►Globus pallidus
►Diencephalon

## Pallidum, Ventral

### Definition
A rostroventral extension of the globus pallidus that protrudes into the basal forebrain and olfactory tubercle beneath the anterior commissure. The ventral pallidum receives projections from the accumbens and medium cell (striatal) districts of the olfactory tubercle and projects to the lateral hypothalamus, medial extremity of the subthalamic nucleus, ventral tegmental area and adjacent medial part of the substantia nigra and ventrolateral part of the periaqueductal gray.

►Hypothalamus
►Hypothalamus, Lateral
►Striatopallidum

## Pallium

### Definition
The roof of the forebrain (telencephalon) which includes the cerebral cortex, hippocampus, olfactory cortex, claustrum, and some amygdalar groups – pallial is the adjective.

►Evolution of the Brain in Reptiles
►Evolution of the Wulst

## Pallium (Medial, Dorsal)

### Definition

The dorsal portion of the telencephalon with a cytoarchitectural organization that is primarily cortical (suggestively layered).

►Evolution of Hippocampal Formation

## Palmitoylation

### Definition

Addition of palmitic acid, a saturated fatty acid containing 16 carbon molecules via an enzymatic reaction involving a Palmitoyl-acyl transferase enzyme.

Palmitic acid is covalently attached to proteins via thioester bonds at cytosolic cysteine residues and it is reversible reaction.

►Receptor Trafficking

## PAN/PVC Tube

### Definition

Semipermeable polyacrylonitrile/polyvinylcholoride polymer guidance tube for placing cells within and transplantation to the spinal cord.

►Transplantation of Olfactory Ensheathing Cells

## Papez Neuronal Circuit

### Definition

The mammillothalamic fasciculus, Vicq d'Azyr bundle conducts efferents of the mammillary body to the thalamus (anterior thalamic nucleus). This in turn projects via the cingulum to the hipppocampus, while the latter projects back via the fornix to the mammillary body and anterior thalamic nucleus.

This creates a neuronal feedback circuit, which is called the Papez neuronal circuit and plays a role in memory formation. Being a vital component of the Papez neuronal circuit, the hippocampus is involved in memory formation. Lesions result in loss of the ability transfer the contents from short-term memory to long-term memory (anterograde amnesia).

►General CNS

## Par Protein

### Definition

Partitioning defective (Par) proteins include par-3, par-6, cdc42, and atypical protein kinase-C (aPKC). These proteins form a complex that exhibits a polarized distribution in the cell and is involved in establishing cellular polarity.

## Parabolic Flight

### Definition

A flight trajectory of parabolic climbs and dives in which the aircraft and its contents are in free fall during the pushover periods, simulating a 0 g environment in the sense that objects in the aircraft are weightless. The length of the weightless phases depends on the air speed of the aircraft.

►Autonomic Function in Space
►Proprioception Effect of Gravity

## Parabrachial Area

### Synonyms

►Nuclei parabrachiales; ►Parabrachial nuclei

### Definition

The parabrachial area comprises three nuclear areas:

- Lateral parabrachial nucleus
- Medial parabrachial nucleus
- Kolliker-Fuse nucleus

Brainstem second relay station both for taste and visceral sensory pathways located in the pons. It is formed by several nuclei. The medial parabrachial area receives gustatory afferents from the nucleus of the tractus solitarius while the lateral parabrachial receives visceral afferents both vagal and from the area postrema. It is considered a primary site for taste– visceral integration relevant for conditioned taste aversion acquisition in rodents.

►Conditioned Taste Aversion
►Diencephalon
►Parabrachial Nuclei

## Parabrachial Complex

### Definition

A compact cluster of relay nuclei located rostrally in the dorsolateral pons, surrounding the middle cerebral peduncle (brachium conjunctivum). Individual nuclei within the parabrachial complex receive various ascending axonal inputs that provide information about viscerosensory function, metabolic status, and pain (arriving from nuclei in the spinal cord, nucleus of the solitary tract, and other brainstem sites). This ascending information is integrated with substantial descending inputs from the hypothalamus, amygdala, bed nucleus of the stria terminalis, and other brain sites. Different nuclei within the parabrachial complex deliver this integrated information to subcortical regions of the forebrain (primarily to subnuclei within the amygdala, hypothalamus, thalamus, and basal forebrain), and to nuclei in the midbrain and brainstem, thus influencing processes that include ingestive behavior, arousal, emotion, and autonomic function.

## Parabrachial Nuclei

### Definition

Latin: Nuclei Parabrachiales; Nuclear complex that is located in the dorsolateral tegmentum of the pons and serves as a major relay center for converging visceral, nociceptive, and thermoreceptive information to the forebrain. The parabrachial complex includes several subnuclei involved in taste sensation and control of gastrointestinal, cardiovascular activity, and respiratory functions.

## Paradoxical Embolism

### Definition

Cardiac embolism that contains material from the venous system and reached the arterial system through a cardiac shunt.

►Ischemic Stroke
►Stroke

## Parahippocampal Gyrus

### Synonyms

►Gyrus parahippocampalis

### Definition

The gyrus marks the transition from hippocampus with its allocortex to the isocortical structure of the temporal lobe. A cross-section shows four discrete cortical regions: presubiculum and parasubiculum on the hippocampal sulcus, entorhinal area and the perirhinal cortex deep in the calcarine sulcus.

►Telencephalon

## Parallel Arrangement

### Definition

A combination of two rheological elements, such that the elongation is common to both and the forces are to be added to obtain the force of the combined element.

►Mechanics

## Parallel Processing

### Definition

In the brain information is processed not only in one stream as in a typical computer but in many parallel and independent streams. Good examples are the different sensory pathways.

## Parallel Visual Processing Streams

►Visual Processing Streams in Primates

## Parallelism

### Definition

Mental and physical events run parallel to each other without any causal relations obtaining between mental and physical events.

►Causality

## Paralysis

### Definition

Severe loss of motor strength resulting from damage to ►motor units or to descending tracts impinging on them. Lower motoneuron paralysis presents with possible involvement of individual muscles, severe atrophy, flaccidity and ►hypotonia with absent ►tendon reflexes, possible ►fasciculations and ►fibrillations. Upper motoneuron paralysis usually presents with diffuse distribution of affected muscles, little atrophy, ►spasticity, ►Babinski sign, ►fasciculations.

## Paramedian Pontine Reticular Formation (PPRF)

### Definition

Anatomically, the PPRF is just the medial portion of the pontine reticular formation (<2 mm from the midline in macaques), but in the oculomotor literature, the PPRF is a functional unit that contains many of the neuronal populations and much of the neuronal circuitry involved in the generation of (mainly horizontal) eye movements. It first came to prominence when it was shown that lesions of the PPRF eliminated or drastically impaired most horizontal eye movements. The PPRF includes most elements of the brainstem burst generator involved in the generation of horizontal saccades, namely excitatory burst neurons, long-lead burst neurons, omnipause neurons, and arguably, inhibitory burst neurons which are on the ponto-medullary border.

Intermixed with these neurons are saccade-related neurons that project to the cerebellum, and reticulospinal neurons that mediate head movements and eye-head coordination. Embedded in the PPRF are other nuclei that are usually considered to be distinct from the reticular formation. The most important is the abducens nucleus, which contains lateral rectus motoneurons and internuclear neurons that project to

medial rectus motoneurons. There are also circumscribed precerebellar relay nuclei that convey oculomotor signals to the oculomotor vermis, fastigial nucleus, and the floccular lobe, namely raphe pontis, the intrafascicular nucleus, the rostral pole of the abducens nucleus, and medial nucleus reticularis tegmenti pontis. Finally, the PPRF contains the fibers connecting these and other oculomotor structures (e.g., the superior colliculus and the vestibular nuclei), so the drastic effects of lesions are a product of destroying both the neuronal populations and the inputs to these populations.

## Parameters

### Definition

Constants or variables that are not conditioned by natural laws but define essential characteristics of the system's behavior under the action of the laws.

►Equilibrium Point Control

## Parametric Control

### Definition

►Equilibrium Point Control

## Paramyotonia Congenita

### Definition

►Non-dystrophic myotonias

## Paraphasia

### Definition

Incorrect use of words occurring in conduction aphasia.

►Aphasias

## Paraplegia

### Definition

Bilateral paralysis of the lower body including the two legs, most commonly resulting from damage to the spinal cord (complete transection), spinal nerve roots or peripheral nerves.

## Parasomnias

### Definition

Undesired physical events that occur during the entry into sleep, within sleep or during arousals from sleep. They include sleep walking and sleep terrors.

►Sleep-Wake Cycle

## Parasthesia

### Definition

Altered sensation, usually ascribed to pins and needles or tingling but which can also be ascribed to burning or pricking.

►Proprioception: Effect of Neurological Disease

## Parasympathetic

►Central Integration of Cardiovascular and Respiratory Activity Studied In Situ

## Parasympathetic Ganglia

►Autonomic Ganglia

## Parasympathetic Nervous System

### Definition

Parasympathetic refers to the branch of the autonomic nervous system that arises from specific cranial nerve nuclei and from the sacral spinal segments. This system supplies visceral organs with specific functions, such as the sphincter pupillae and the ciliary body in the eye, secretory glands producing fluid including acid in the stomach, enhancing motility of stomach and distal colon, bladder, etc.

►Ageing of Autonomic/Enteric Function
►Autonomic Ganglia
►Autonomic Reflexes
►Parasympathetic Pathways

## Parasympathetic Pathways

### Definition

Beside the sympathetic pathways, the parasympathetic pathways are the second major component of the autonomic nervous system (there are also enteric pathways and an afferent or sensory component). Some parasympathetic pathways involve brain stem and cranial ganglia, and some are centered on the sacral region of the spinal cord and the pelvic ganglia.

In the brain stem the main nuclei of the parasympathetic pathways (the cranial parasympathetic outflow) are the Edinger-Westphal nucleus, the superior and inferior salivatory nuclei, dorsal vagal nucleus and nucleus ambiguus. The neurons of these nuclei issue axons then enter the oculomotor nerve, the facial, the glosso-pharyngeal nerve and vagus nerve, respectively.

The oculomotor branch projects to the ciliary ganglion (its neurons innervate the iris and the ciliary muscle, hence providing accommodation and pupil constriction).

The facial nerve branch project to the pterygopalatine and the submandibular ganglia (their neurons innervate the lachrymal, the submandibular and the sublingual glands), and the glosso-pharyngeal branch project to the otic ganglion (its neurons innervate the parotid gland). The fibers from the nucleus ambiguus and dorsal vagal nucleus enter the vagus nerve, of which they represent the motor component, and extend a long distance in the neck, thorax and upper part of the abdomen. The fibers terminate synapsing on neurons in small ganglia close to the tracheal and bronchial muscles and the esophagus and in some enteric ganglia of stomach and intestine. From these minute intramural ganglia, post-ganglionic fibers emerge that innervate glands and smooth musculature of airways, esophagus and gastro-intestinal tract. In the spinal cord, preganglionic parasympathetic neurons are assembled into columns in the second, third and fourth sacral segments. Their preganglionic fibers, predominantly cholinergic, project onto pelvic ganglia, whose post-ganglionic fibers innervate mainly the urogenital organs. In some organs, typically the heart or the pupil, which receive both sympathetic and parasympathetic fibers, these exert antagonistic effect. Many organs, however, are controlled predominantly by one or the other of the two pathways.

►Sympathetic Pathways

## Paraventricular Nucleus (PVN)

### Definition

A subdivision of the hypothalamus located adjacent to the third ventricle. The PVN contains many distinct neurosecretory cells that regulate important physiological functions in the neuroendocrine system. These cells can be anatomically and functionally divided into a magnocellular division and a parvocellular division.

Magnocellular neurons produce the hormones oxytocin and vasopressin and project to the posterior pituitary gland. Parvocellular neurons that synthesize corticotrophin releasing hormone project to the median eminence at the ventral surface of the brain where they release peptides into the blood vessels of the hypothalamo- pituitary portal system, vasculature that carries peptides to the anterior pituitary gland. Some neurons, projecting to autonomic nuclei of the brainstem and spinal cord, are activated, in a stimulus-specific fashion, by hypoglycemia, hypovolemia, cytokines, pain, and environmental stressors. The PVN receives

afferent projections from multiple brain areas, such as the brainstem and other hypothalamic regions, that provide information about the homeostatic state of the organism.

## Paravertebral Ganglia

### Definition

The paravertebral ganglia are interconnected autonomic ganglia that lie close to the spinal nerves and the vertebrae, from the lower cervical/upper thoracic level to the sacral level of the spinal cord. The chains of paravertebral ganglia are paired, and lie just lateral to the bodies of the vertebrae.

►Autonomic Ganglia
►Sympathetic Nervous System
►Sympathetic Pathways

## Paresis

### Definition

A weakening of a muscle due to pathology of the muscle, the motoneurons that innervate it, or the efferent nerve that carries the latter's axons.

## Paresthesia

### Definition

Abnormal sensory experiences such as numbness, pins-and-needles sensations and tingling, occurring spontaneously without external sensory stimulation and with some sensory ►peripheral neuropathies.

►Peripheral Neuropathies

## Parietal Lobe

### Synonyms

►Lobus parietalis

### Definition

Extends from the central sulcus to the parietooccipital sulcus.

►Telencephalon

## Parietal Organ

### Definition

A heritage of ancient, sea bottom-dweller vertebrates, an "eye" on the top of the head, the pineal body evolved in correlation with it.

►Evolution of the Brain: At the Reptile-Bird Transition

## Parinaud Syndrome

### Definition

This syndrome results from dorsal midbrain lesions and is characterized by impaired vertical eye movements (especially upwards) and absence of the pupillary light reflex.

►Pupillary Light Reflexes

# Parkinson Disease

Ali Samii
Department of Neurology, University of Washington Medical Center, Seattle, WA, USA

## Synonyms

Idiopathic Parkinson's disease; Idiopathic Parkinsonism

## Definition

A progressive neurological disease named after James Parkinson.

## Characteristics

### Clinical Features, Epidemiology, and Etiology

The four cardinal features of Parkinson disease are tremor, bradykinesia, rigidity, and ►postural instability. ►Parkinsonism is a non-specific term used to describe a constellation of signs on physical examination similar to those seen in Parkinson disease. Parkinson disease is defined as asymmetric Parkinsonism with no known cause, characterized by most of the four cardinal features, and responsive to anti-Parkinson medications (usually ►dopaminergic drugs) [1]. The diagnostic criteria for Parkinson disease have become more rigorous with gradations of diagnostic certainty. Any one of resting tremor, rigidity, or bradykinesia would suggest clinically possible Parkinson disease. Any two of the four cardinal signs (especially if asymmetric) would suggest clinically probable Parkinson disease. Clinically probable Parkinson disease with significant improvement in motor signs with dopaminergic drugs would suggest clinically definite Parkinson disease. The non-motor features of Parkinson disease include loss of sense of smell, depression, anxiety, autonomic dysfunction (constipation, urinary urgency, sexual dysfunction, orthostatic hypotension), sleep disturbance, including ►rapid-eye-movement (REM) sleep behavior disorder, and cognitive impairment. The non-motor symptoms of Parkinson disease are gaining much more attention than before since they contribute greatly to disability as the disease progresses and they do not respond to dopaminergic drugs.

The prevalence of Parkinson disease in industrialized countries is estimated at 0.3% of the general population and approximately 1% of the population aged over 60 [2]. The prevalence is slightly higher in men than in women. The mean age of onset is about 60, but approximately 5% of patients have young onset Parkinson disease, with motor symptoms appearing before age 40. *The pathology underlying the motor symptoms of PD is injury to the dopaminergic projections from the substantia nigra pars compacta to the striatum. Lewy Bodies are the pathological hallmarks of PD, but they are not confined to the substantia nigra. Pathology is widespread in PD and involves the amygdala, the olfactory bulb, dorsal motor nucleus of the vagus nerve, locus ceruleus, pedunculopontine nucleus, raphe nuclei, the cortex, and the peripheral autonomic nervous system. This extensive pathology may account for the non motor symptoms of PD.* The etiology of PD is unknown, but aging, environmental factors, and genetic predisposition probably all play a role in causing Parkinson disease [3]. The recent discovery of several genetic loci related to familial Parkinson disease has led to the hypothesis that failure of the ►ubiquitin-proteasome system and protein misfolding are the final common pathways in the pathogenesis of Parkinson disease [4]. Mutations of the leucine-rich repeat kinase 2 (LRRK2) gene are the most common identifiable cause of Parkinson disease, in that 1% of patients without a family history and more than 5% of patients with a first degree relative with Parkinson disease have a LRRK2 mutation [5].

### Medical Treatment of Motor Symptoms

There is no definitive agent known to slow down disease progression at the cellular level in Parkinson disease [6]. Therefore, treatment remains symptomatic with mostly dopaminergic drugs. A pilot study suggested that high dose ►coenzyme Q10 may slow symptom progression in early Parkinson disease [7]. These results have yet to be confirmed in larger studies with longer follow-up periods. Treatment is typically initiated when motor symptoms cause disability. The treatment of early Parkinson disease is with either a monoamine oxidase-B (MAO-B) inhibitor (selegiline or rasagiline), a non-ergot-derived dopamine agonist (pramipexole, ropinirole, transdermally absorbed rotigotine) or levodopa [8]. MAO-B inhibitors are generally safe and well tolerated, although there are warnings about certain drug interactions and tyramine containing foods when using MAO-B inhibitors. Side effects of dopamine agonists include nausea, hypotension, leg edema, vivid dreams, hallucinations (especially in the older population with cognitive deficits), somnolence (even sleep attacks), and disinhibited behavior (such as gambling). Dopamine agonists have more antiparkinson efficacy than MAO-B inhibitors, but they are less effective than levodopa. Treatment with an MAO-B inhibitor combined with a dopamine agonist may control motor symptoms for the first 2–5 years, but the likelihood of requiring levodopa after that increases significantly.

Levodopa remains the most potent anti-parkinson drug and is the backbone of therapy throughout much of the course of the disease. It is the preferred initial drug

in the older population and those with cognitive deficits or serious co-morbid conditions. Levodopa is combined with carbidopa or benserazide to prevent peripheral conversion to dopamine by dopa-decarboxylase. Side effects of levodopa are similar to those of dopamine agonists, except that somnolence, hallucinations, and leg edema are less common. Complications of long-term levodopa therapy include ►motor fluctuations, including "►end-of-dose wearing off", and dyskinesia [9]. Dividing protein intake throughout the day may help reduce motor fluctuations. Controlled-release forms of levodopa may provide a longer duration of benefit, but their absorption is more unpredictable than immediate-release levodopa. ►Catechol-O-methyl transferase (COMT) inhibitors, entacapone or tolcapone, prolong the half-life of circulating levodopa and improve end-of dose wearing off. Dyskinesia can be reduced by decreasing levodopa dosage, but at the expense of worsening motor symptoms. In a patient with motor fluctuations and dyskinesia, adding a dopamine agonist to levodopa may help reduce motor fluctuations. It may also allow for levodopa reduction, which in turn alleviates dyskinesia. The subcutaneously injectable dopamine agonist, apomorphine, is useful for rapid treatment of "off" periods in Parkinson disease. However, given the severity of apomorphine-induced nausea, pre-medication with domperidone or trimethobenzamide is needed. Amantadine may help suppress dyskinesia. MAO-B inhibitors may also be added to levodopa to help alleviate motor fluctuations.

## Medical Treatment of Non-Motor Symptoms

Non-motor symptoms in Parkinson disease may occur as part of the disease or as complications of treatment [10]. These include depression, cognitive impairment, psychosis, constipation, sleep disturbance, orthostatic hypotension, drooling, and urinary symptoms. Depression in Parkinson disease is usually treated with a selective serotonin reuptake inhibitor (SSRI). There are no controlled head-to-head studies to suggest one SSRI is superior to another in Parkinson disease. Constipation should be treated aggressively using multiple modalities such as stool softeners, increased fiber intake, and suppositories. Disorders of sleep in Parkinson disease include daytime somnolence, sleep attacks, night-time awakenings due to over night bradykinesia, rapid eye movement (REM) behavior disorder, and restless legs/periodic limb movements. Daytime somnolence and sleep attacks may be associated with dopamine agonists and the agonist may have to be stopped. Overnight bradykinesia and restless legs may be alleviated with a bedtime dose of long acting levodopa sometimes with entacapone, or a dopamine agonist. Clonazepam is effective in treating REM behavior disorder. Psychosis in Parkinson disease is thought to be mostly drug-induced, and it occurs more frequently in demented patients. Dopamine agonists are more likely to cause hallucinations than levodopa. First, the agonist and/or anticholinergic agent should be stopped, and the lowest dose of levodopa should be used. Adding an ►atypical neuroleptic may be necessary. Quetiapine is the more popular atypical neuroleptic in Parkinson disease. It has fewer extrapyramidal adverse effects than risperidone and olanzapine and there is no need for weekly or bi-weekly blood count measurements that would be required with clozapine. ►Centrally acting cholinesterase inhibitors (rivastigmine, donepezil, and galantamine) are somewhat effective in treating the dementia associated with Parkinson disease. Rivastigmine is more commonly used because the data to support its efficacy in Parkinson disease are more robust. Treatment options for hypotension include reducing the dosage of antiparkinson medications, increased salt and fluid intake, and adding fludrocortisone or midodrine. Drooling may be reduced by the peripheral anticholinergic agent, glycopyrrolate, but this drug may worsen constipation. Injection of botulinum toxin into salivary glands improves drooling. Urinary urgency may be treated with peripheral anticholinergic agents (oxybutynin and tolterodine) or alpha-adrenergic blocking agents (prazosin and terazosin). Unfortunately, the former worsen constipation and the latter exacerbate hypotension.

## Surgical Treatment of Motor Symptoms

Deep brain stimulation of "hyperactive" nuclei relieve motor symptoms in patients who have severe motor fluctuations and dyskinesia [9]. High frequency stimulation of deep brain targets presumably reduces neural activity in tissue surrounding the electrode contact. The "suppression" of the target induced by deep brain stimulation can be sculpted by adjustments of the electrode configuration, stimulation intensity, pulse width, and frequency. Bilateral stimulation of the globus pallidus internus (GPi) or the subthalamic nucleus (STN) is effective in relieving motor symptoms. Some claim that bilateral STN stimulation is superior to bilateral GPi stimulation because it allows a reduction in antiparkinson medications, but there is continued debate about the optimal stimulation target for Parkinson disease. A large randomized multi-center study comparing bilateral STN to bilateral GPi stimulation in 300 patients with Parkinson disease is currently under way in the United States, the results of which should be available by 2009. Adverse effects of deep brain stimulation surgery include brain hemorrhage, infarct, seizures, and death. Other complications include lead breakage, other hardware failure, pulse generator malfunction, and hardware infection. Side effects from the stimulation itself include worsening dyskinesia, paresthesias, and cognitive, mood, speech, and gait disturbances. The stimulation-related side effects may be reversible by adjusting stimulation

parameters. The key to successful outcome is appropriate patient selection. The surgical patient must have clinically definite Parkinson disease with documented motor improvement on levodopa. There should be no dementia, untreated psychiatric condition, or serious medical illness. ►Fetal mesencephalic tissue transplantation has been studied in Parkinson disease. Although there was marginal improvement in some patients, disabling dyskinesia occurred in many patients. Therefore, fetal mesencephalic tissue transplantation is not a treatment option for Parkinson disease at present.

# Parkinsonism

## Definition

Syndrome characterized by rigidity, tremor, and bradykinesia, of which Parkinson disease is the most common cause.

►Parkinson Disease

# Parosmia

## Definition

Distorted perception of smells in the presence of an odor source. Many patients not only suffer from quantitative olfactory dysfunction (anosmia, hyposmia), but also experience qualitative olfactory dysfunctions, classified under terms such as dysosmia or olfactory distortion.

These distortions can be roughly divided into parosmias (also called troposmia) and phantosmias with the major difference that distorted olfactory sensations are experienced in the presence (parosmia) or absence of an odor (phantosmia), respectively. Patients suffering from parosmia have distorted sensations of smell elicited by an odorant, therefore it is also called stimulated olfactory distiortion. Parosmia is described as a qualitatively "wrong" perception of odors. For example, a patient may perceive the smell of rotten eggs whenever he takes a smell at roses. In most cases, the "wrong" smell is considered unpleasant. Parosmia is typically, but not always associated with quantitative olfactory loss (hyposmia). Parosmia mainly occurs in combination with post-traumatic or post-infectious olfactory loss. Rare causes of parosmia such

as brain tumors, side-effects of drugs, paraneoplastic syndromes, endocrine disorders, neurologic disorders, psychiatric disorders or intracerebral haemorrhage have been reported. Although the exact site of the generation of parosmia remains unknown, most parosmias are likely to be generated at the level of the olfactory epithelium and/or the olfactory bulb. On the other hand, parosmia may also be a problem of the central nervous system. Important clinically is the observation that most parosmic impressions tend to diminish over months and finally disappear after years.

►Olfactory Pathways
►Smell Disorders

## Paroxysmal Extreme Pain Disorder (PEPD)

### Definition

Previously referred to as familial rectal pain. The severe pain in PEPD patients along with redness in the lower body can start in infancy (and possibly in utero), and is induced by defecation or probing of the perianal areas, and is accompanied sometimes by tonic non-epileptic seizures, syncopes, bradycardia and occasionally asystole.

Pain progresses with age to ocular and maxillary/mandibular areas and is triggered by cold, eating or emotional state. Pain episodes can last seconds to minutes (and hours in extreme cases), and gradually subside over minutes.

►Voltage-gated Sodium Channels: Multiple Roles in the Pathophysiology of Pain

## Paroxysmal Hemicrania (PH)

### Definition

Rare headache belonging to the group of ►trigeminal autonomic cephalalgias and is characterized by severe, unilateral pain attacks localized to orbital, supraorbital, and temporal areas, lasting 2 to 30 minutes, and accompanied by ipsilateral ►autonomic features.

►Headache

## Pars Tubualis

### Definition

An area of the pituitary stalk rich in melatonin receptors.

►Melatonin

## Partial Seizures (Focal Seizures)

### Definition

These seizures are characterized by focal motor or sensory symptoms indicating the location of brain lesions. For instance, aversive seizures characterized by deviation of eyes or head to one side indicate a focus in the opposite ►prefrontal cortex. Focal (Jacksonian) motor seizures may result from localized lesions (injury or tumor) to the contralateral ►primary motor cortex (M1) and may start as local rapid (clonic) contractions, often at a finger, great toe or mouth corner, and then spreading over the body with loss of consciousness (Jacksonian march).

►Jacksonian Motor Seizures
►Prefrontal cortex
►Primary Motor Cortex (M1)

## Parvocellular Cells

### Definition

Small cells located in two to four layers of the LGN of primates that have been proposed to be part of a pathway (the P pathway) from the retina to visual cortex concerned with detail and color vision.

►Evolution of the Visual System: Mammals – Color Vision and the Function of Parallel Visual Pathways in Primates

## Passband

### Definition

The frequency region is which the magnitudes of sound are not attenuated by a filter.

►Acoustics

## Passive Avoidance Learning

### Definition

Passive avoidance is a task in which animals avoid an aversive stimulus by inhibiting a previously punished response (compare with Active avoidance learning).

Behaviors that are more compatible with natural defensive responses to aversive stimuli (see SSDR in glossary) are more easily learned.

►Active Avoidance Learning
►Aversive Learning

## Patch Clamp

### Definition

Erwin Neher and Bert Sakmann developed the patch clamp in the late 1970s and early 1980s. They received the Nobel Prize in Physiology or Medicine in 1991 for this work. This electrophysiological method allows to record ion channels' activity in an individual cell using a glass electrode with an open tip diameter of about 1 μm. There are three major configurations of this method. The "cell attached" mode (the glass pipette is tightly sealed on the cell membrane), the "excised configuration" (the patch of membrane isolated by the pipette is removed from the cell) and the "whole cell" configuration (the membrane under the pipette is broken, providing an access to the intracellular space of the cell). The "cell attached" and the "excised" configurations allow recording the activity of individual ion channels embedded in the patch of membrane isolated by the glass pipette. The "whole cell" configuration allows to record global electrical activity passing through the entire cell membrane. This technique can be used in the "voltage clamp" mode, keeping the voltage constant in order to see changes in the current. Conversely, it can be used in the "current clamp" mode, in order to see changes in the voltage.

►Intracellular Recording

## Path Integration

### Definition

A process of estimating one's own position in space by integrating (vectorially summing) the distances and directions covered by previous self-movement (idiothetic inputs). This is also known as dead reckoning. The composite vector points from the start position to the current position. There are two forms of path integration: path integration with a map and path integration without a map. When path integration is used with a map it can be used to update the traveler's location on the map. Therefore, it is an important contributor to mapping. When path integration is used without a map it can only be used for returning to a start location, or "homing". This is done by the simple process computing the outbound vector from a start (home) location, inverting the composite vector and following the inverted vector. Homing by means of path integration has been shown in insects (ants) and rodents.

►Optic Flow
►Spatial Learning/Memory

## Pathology

### Definition

Pathology literally is the study of pathos (disease, suffering). Traditionally, pathology is a morphologic study of histological abnormalities detected by microscopic examination. More recently, pathology uses molecular, microbiological, and immunological techniques.

Pathology also means a condition produced by disease.

## Pause Neurons (pns)

►Omnipause Neurons

## Paw Preference

### Definition

Preference of paw in taking food.

# Pax Genes

Noriko Osumi
Division of Developmental Neuroscience, CTAAR, Tohoku University School of Medicine, Sendai, Japan

## Definition

*Pax* genes are originally identified as homologs structurally related to the *Drosophila* pair-rule gene, *paired*, which encodes a ►transcription factor [1]. There are nine members in the *Pax* gene family, which are categorized into four subclasses (Fig. 1) [2,3].

All members have a DNA-binding paired domain (PD) together with or without an octapeptide (OP), and the members except Pax1 and Pax9 have another DNA-binding homeodomain (HD). Group 1 (Pax1, Pax9) have only PD and OP, Group 2 (Pax2, Pax5, Pax8) have PD, OP, and incomplete HD, Group 3 (Pax3, Pax7) have PD, OP, and complete HD, and Group 4 (Pax4, Pax6) have PD and complete HD. PD consists of 6 alpha-helices, and is divided into two subdomains (N-terminal PAI domain and C-terminal RED domain), each recognizing distinct half-sites of the bipartite binding site in adjacent major grooves of the DNA helix [4].

## Characteristics

Expression patterns of each *Pax* gene are highly region-specific, and observed in ►CNS, ►PNS, and various ectodermal, mesodermal, and endodermal tissues. The importance of the Pax family in organogenesis can be assumed from various congenital diseases and cancers related to mutations of *Pax* genes and down- or up-regulation of *Pax* gene expressions [5]. Interestingly, there are spontaneous mouse mutants for *Pax1* (*undulated*), *Pax3* (*Splotch*), and *Pax6* (*Small eye*), which is quite in contrast with other transcriptional factors that are crucial in organogenesis. Since *Pax1* and *Pax9* are predominantly expressed in mesodermal tissues, and *Pax4* is more important in pancreatic development, the other members of the *Pax* family are taken into consideration here.

## Pax2/5/8

Pax2, Pax5, and Pax8 are structurally close and work similarly. Pax5 is originally identified as BSAP (B-cell specific activator protein) that is essential for development of B-lymphocytes. Pax2/5/8 expressed in the boundary region between the midbrain and hindbrain (midbrain/hindbrain boundary: MHB; (Fig. 2a), and important in establishment of MHB that works as an organizer for brain patterning [6].

*In ovo* mis-expression of Pax2 and Pax5 by electroporation in chick embryos can change the fate of presumptive diencephalons to the tectum. Expression of Pax2, Pax5, En, Wnt1, and Fgf8 consists of a feedback loop at the MHB in formation of the optic tectum in the midbrain and of the cerebellum in the hindbrain. Similar machineries are also work in the formation of MHB in mammalian embryos, which is shown by the phenotype

| Group | Pax genes | Basic structure PD | OP | HD | Localization Mouse | Human | Mouse mutant Natural | Targeted | Human syndrome |

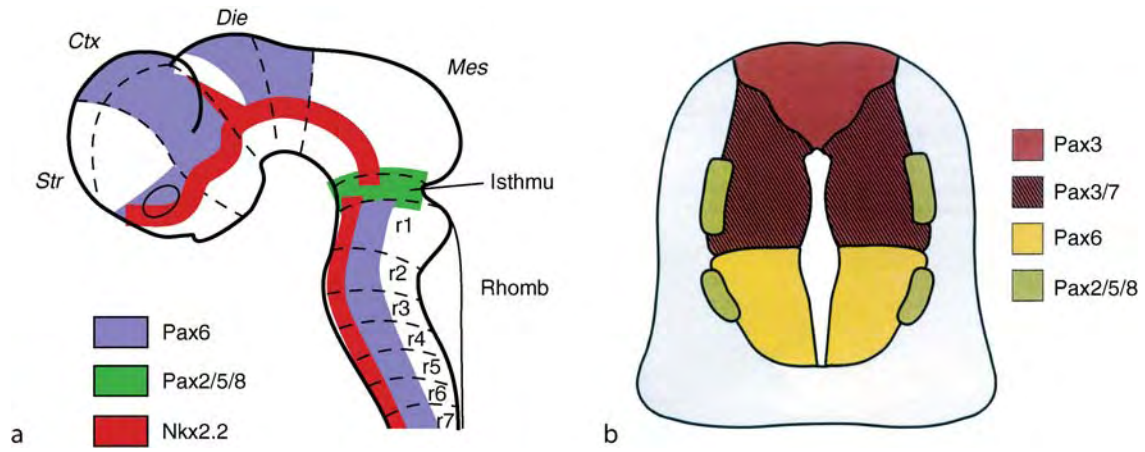
**Pax Genes. Figure 1** Structures and genomic positions of *Pax* genes. *Pax1-9* genes are categorized into four groups from their molecular structures. Natural mutations of *Pax* genes in the mouse and human diseases are also shown. PD paired domain; OP octapeptide; HD homeodomain.



**Pax Genes. Figure 2** Expression patterns of *Pax* genes in the early neural tube. Schematic illustration of the lateral (a) and transverse (b) views showing region specific expression of *Pax* genes. (b) is taken from ref. [1]. *Ctx* cerebral cortex; *Str* striatum; *Die* diencephalon; *Mes* mesencephalon; *r1-7* rhomobomere 1–7.

of knockout mice of the genes. Pax2 and Pax5 are also expressed in the specific dorsoventral region of the developing neural tube (Fig. 2b) [7], and may be involved in specification of inverneurons. Pax2 also works to establish the forebrain/midbrain boundary through interaction with Pax6 (see below). Mutation in *Pax2* is reported to be related to a kidney disease, renal coloboma.

## Pax3/7

Pax3 and Pax7 are structurally close and work similarly. Pax3/7 is expressed in the dorsal region of the developing neural tube (Fig. 2b) [1] and the dermomyotome, an embryonic primordium of the muscle and dermis. Electroporated Pax3/7 forces the midbrain to differentiate into the tectum in chick embryos. Spontaneous mutant *Splotch* (*Sp*) mice have mutations in *Pax3* and show abnormalities in development of tissues originated from the neural crest that is formed at the most dorsal part of the neural tube. Heterozygous *Sp/+* mice show white spots in the abdomen, legs, and tail, which is due to abnormal development of melanocytes derived from the neural crest. Homozygous *Sp/Sp* mice show spina bifida (separated spinal bones), exencephaly (open brain), reduced or loss of dorsal root ganglia, and hypoplastic leg muscles [1–3]. Pax7 is expressed in neuronal cells of the optic tectum/superior colliculus. Neurons expressing Pax7 migrate towards the pia and concentrate in the stratum griseum superficiale, the target site for retinal axons.

In humans, patients of Waardenburg syndrome type 1 show mutation at 2q37, and those of type 3 show deletion in 2q35-37 covering *PAX3* gene [5]; both sets of patients suffer from hearing loss and abnormal skin color. The hearing loss of Waardenburg patients is thought to be caused by abnormal migration of neural crest cells into the otic primordium from the similar phenotype seen in *Sp/+* mice. Involvement of *Pax3* and *Pax7* in cancer is also reported [5]. For example, alveolar rhabdomyosalcoma is caused by translocation of chromosomes including *PAX3* or *PAX7*.

## Pax6

*PAX6/Pax6* gene is first isolated as a responsible gene for human congenital aniridia (lack of the iris in the eye) and mouse *Small eye* mutant [8], and more intensively studied than any other *Pax* genes. *Pax6* gene is highly conserved throughout the phylogeny, and related to development of the sense organs, eyes, brain, pancreas, and pituitary gland [1–3]. In the early eye primordium, Pax6 is strongly expressed in the head ectoderm that will form the lens and cornea, and in the optic cup that will form the neural and pigment retina. Later in development, Pax6 is expressed in prospective ganglion-cells and amacrine-cells, but not in photoreceptors. Pax6 also influences eye development through a non-cell autonomous manner by regulating migration of neural crest cells.

In the vertebrate CNS, Pax6 is expressed in the forebrain, hindbrain, and spinal cord from the earliest stage of brain development. *Small eye* mice and rats are spontaneous *Pax6* mutant strains, homozygotes which lack the eyes and nasal structures. They also exhibit severe malformation in various brain regions where *Pax6* is expressed, showing the importance of the gene in brain patterning, neuronal migration, and axon extension [9,10]. For example, mutual repression of Pax6 and Pax2 defines the boundary between the forebrain and midbrain, and that of Pax6 and Gsh2 in the telencephalon establishes the boundary between the cerebral cortex and the striatum. In the dorsal telencephalon, Pax6 and Emx1 show gradient expression patterns in opposite directions, thereby patterning the

telencephalon along the anterior-posterior axis. In the hindbrain and spinal cord, Pax6 is essential in specification of the ventral neurons: *Pax6* homozygous mutant mouse and rat embryos lack the hypoglossal nerve (a somatic motor nerve of the XIIth cranial nerves) and En1-expressing interneurons. Pax6 is involved in navigation of certain neurons such as mitral cells in the olfactory bulb and olfactory cortex neurons, which is done by non-cell autonomous manners. *Pax6* homozygous mutant rats show defects in thalamocortical projection, which may include Neuregulin1 signaling pathways.

In the adult brain, Pax6 is expressed in neurons of the olfactory bulb, amygdala, thalamus, and cerebellum [7]. Since homozygous *Pax6* mutants die at birth and therefore cannot survive into the postnatal stage, the function of Pax6 in the adult brain remains largely unsolved. It has recently been shown that Pax6 is important in postnatal neurogenesis by maintaining neural stem/progenitor cells; Pax6 heterozygous rats show decreased cell proliferation in the hippocampus and subventricular zone of the lateral ventricle. Pax6 can also promote neuronal differentiation, so it is likely that Pax6 works multifunctionally in highly context-dependent manners.

Known target/downstream molecules for Pax6 transcription factor in CNS are a bHLH transcription factor Neurogenin2, cell adhesion molecules L1 and R-cadherin, a secreted factor Wnt7b, a fucosyltransferase FucT9, and a fatty acid binding protein Fabp7 (BLBP). It is of interest that FucT is involved in the synthesis of LewisX carbohydrate epitopes that are used as markers in blastcystes, hematopoietic stem cells, and neural stem cells, and that Fabp7/BLBP is a well-known marker of radial glia and works to maintain embryonic stem cells. For patterning the brain, mutual repression of Pax6 and other transcription factors such as Pax2 (forebrain/midbrain regionalization), Gsh2 (cortex/striatum regionalization), and Nkx2.2 (somatic motor precursor domain formation) delineates distinct brain regions.

Clinically, expression of *PAX6* is reported to be significantly reduced in glioblastoma, the most common primary malignant brain tumors, molecular mechanisms of which remain unsolved.

## Pedunculopontine Tegmental Nucleus

### Synonyms
►Nucl tegmentalis pedunculopontinus (Ch.5)

### Definition
An important nucleus from the cholinergic cell group of the lateral reticular formation. It has two parts:

- Pedunculopontine tegmental nucleus, compact part
- Pedunculopontine tegmental nucleus, diffus part

## Pedunculopontine Tegmental Nucleus, Compact Part

### Synonyms
►Nucl tegmentalis pedunculopontinus; Pars compacta

### Definition
This densely packed part of the pedunculopontine tegmental nucleus lies in the caudo-lateral Mesencephalon and has reciprocal connections with the motor centers and the limbic system. Efferents go to the spinal cord. Electrical stimulation of this area causes coordinated locomotion ("mesencephalic locomotor region") in decerebrated animals.

►Mesencephalon

## Pedunculopontine Tegmental Nucleus, Diffuse Part

### Synonyms
►Nucl tegmentalis pedunculopontinus; Pars dissipata; ►Pedunculopontine tegmental nucleus; Dissipated part

### Definition
In addition to the pedunculopontine tegmental nucleus, compact part, the pedunculopontine tegmental nucleus also contains a cholinergic region with loosely arranged cell bodies. But their function is not clear unlike that of the locomotor tasks of the compact part.

►Mesencephalon

## Pelvic Afferents

►Visceral Afferents

## Pelvic Floor

### Definition
The pelvic organs are supported by striated muscles (levator ani and coccygeus) and connective tissue that close the caudal end of the abdomen spanning the space between the pubic bones anteriorly, the ischial spines laterally and the sacrum posteriorly.

►Micturition

## Pelvic Nerve

### Definition

The pelvic nerve connects the pelvic viscera (urinary bladder, urethra, distal bowel, vagina, uterine cervix) with the sacral S2-S4 (and in some species the lower lumbar) segments of the spinal cord. The nerve contains efferent autonomic neurons (mainly parasympathetic, but not entirely so), and also afferent nerves that convey sensory information to the central nervous system. It is responsible for the neural control of the hindgut, bladder and reproductive organs.

## Percept

### Definition

The conscious experience of a sensory stimulus. The percept reflects stimulation of the sensory system (e.g. eye, ear, skin), but is also determined by higher-level cognitive processes (e.g. attention, memory).

►Perception

## Perception in Vision

Dirk Kerzel
Faculté de Psychologie et des Sciences de l'Éducation, Université de Genève, Genève, Switzerland

### Definition

Perception is the conscious experience of sensory stimulation. The perceptual process begins with the transformation of the external stimulus energy into the firing of neurons. The sensory signals originating in the sense organs are analyzed into different perceptual attributes such as pitch, color, form, or motion.

What is perceived depends not only on the raw sensory signal, but also on higher-level cognitive processes such as attention and memory. These processes are not always conscious, and they organize and interpret the information coming from the eyes (vision), ears (audition), nose (olfaction), tongue (taste), skin (tactile sense), and inner ears (vestibular senses). As a result, we perceive meaningful objects and events that are defined in both space and time. The perceptual process is very different from a mere image taken by a camera because objects and events are recognized and thereby linked to previously acquired knowledge stored in memory.

## Characteristics

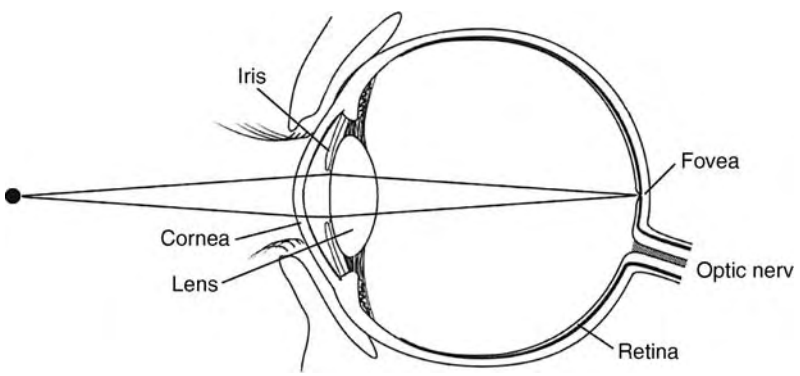
Perception is our mind's window on the world. It enables us to create mental representations of objects (flowers, cars, etc.) or events (walks in a park, accidents, etc.), and enables us to interact with objects in the world. Vision is by far the most important sensory modality and this contribution is restricted to this modality. Nonetheless, most of the concepts presented here can be applied to other sensory modalities (audition, olfaction, taste, tactile and vestibular senses). The importance of vision is evident in the space allotted to it in the human neocortex: the primary visual cortex occupies about 15% of the neocortex, and more than 30 visual areas have been identified. Altogether, 60% of the human neocortex is involved in the processing of visual stimuli.

Intuitively, visual perception is a passive process; as soon as we open our eyes, we see the world around us. Another intuition about visual perception is that the basic units of visual perception are objects because we typically talk about objects (cars, flowers, etc.) when we report what we see. Both intuitions are wrong. Research in psychology and neurophysiology has shown that perception is a highly active process and that the attributes of an object such as its color or its movement are processed independently. The characteristic division of labor starts in the retina, and continues as visual information is transmitted to the corpus geniculatum laterale (CGL) in the thalamus, and from there to the primary visual cortex. We will examine each of these stages in turn and show how complementary systems guarantee reliable perception under different conditions and for different purposes.

Light enters the eye through a small aperture, the pupil, and passes through the cornea and the lens before it reaches the retina (see Fig. 1).

Cornea and lens bring the image that is projected onto the retina into focus [1]. While the cornea has a larger focusing power (42 diopters), only the lens' focusing power (about 18 diopters) can be adjusted to bring objects into focus. To this end, the ciliar muscles contract and the curvature of the lens increases, a process that is called accommodation. A high curvature of the lens is associated with high focusing power that is necessary to project a clear image of nearby objects on the fovea. Across the lifetime, the lens loses elasticity and its maximal curvature decreases. As a consequence, a clear image would be projected on a plane behind the retina, but what is captured by the retina is blurred. This condition is known as presbyopia ("old eye"). Similar blurred retinal images result when the eye ball is too long or too short such that the focusing power of the lens is too weak or too strong, respectively. All these impairments may be corrected by glasses that either focus and thereby increase the focusing power of the optical system or disperse the light and thereby decrease its focusing power.

To be treated in the nervous system, the stimulus energy has to be transformed into electrical signals of neurons. In the visual modality, the process of transduction is achieved by two types of receptors: rods and cones. They are hidden behind a transparent layer containing amacrine, horizontal, bipolar and ganglion cells. The ganglion cells transmit the neuronal signals originating in the receptors to subcortical centers. Their axons leave the eye through an aperture in the retina



**Perception in Vision. Figure 1** A cross section of the human eye. The light passes through a small aperture (pupil) and is focused by the cornea and lens. The rays of light reach receptors in the retina that are hidden behind a translucent layer of cells (not shown).

devoid of receptors, the blind spot. Although no visual information is received in this region, we do not perceive a "hole" in our visual field when we close one eye. The visual system fills the void rather actively by extrapolating visual information from the neighboring retina.

Light entering the receptor engenders a biochemical cascade when hitting a photopigment contained in the receptor. The electrical potential of the receptor changes as a result of the cascade. This process is extremely sensitive: A single photon may change the potential of the receptor and light is perceived when only seven receptors are stimulated simultaneously. However, receptors respond only to electromagnetic energy at wavelengths between 400 and 700 nm. Small wavelengths evoke the color blue, medium wavelengths the colors green and yellow, and long wavelengths the color red. Wavelengths shorter (e.g. X-rays) than 400 or longer than 700 nm (e.g. radio waves) are not absorbed by the receptors.

The two receptor classes, rods and cones, have very different characteristics and involve different neural circuits. Rods are larger than cones and contain a photopigment that responds best to light at a wavelength of 500 nm. That is, light of this wavelength evokes a response more easily than light with higher or lower wavelengths. In contrast, cones may contain one of three different photopigments that differ in their preferred frequency: the short wave pigment (419 nm), the medium-wavelength pigment (531 nm) and the long wavelength pigment (558 nm). Taken together, the three cone types respond best to a wavelength of 560 nm. The difference in the preferred wavelength of rods and cones is evident in the Purkinje phenomenon: The colors in the lower part of the spectrum seem brighter (e.g. green objects appear more salient) when seen under conditions where rods are active compared to conditions where cones are active.

Rods enable us to see at low light intensities, but do not contribute to our visual experience in the daylight. The rod's high sensibility is achieved by summing up signals across a large number of neighboring rods. While this strategy makes the system more sensitive, it produces a loss in spatial resolution. The activity of neighboring receptors cannot be discriminated and we only see blurred outlines in the dark. Also, the rod system cannot discriminate between different wavelengths and is therefore color-blind.

Cones are active during the daylight and do not contribute to nocturnal vision. They show far less summation across space than rods and thereby allow for the discrimination of spatial detail. Because the three types of cone receptors have different spectral sensitivities, they are differently activated by the incoming light. For instance, a monochrome yellow light of 575 nm will activate the long wavelength cone more than the medium and short-wavelength cones. The pattern of activation of the three receptors is the basis for color vision and any physical stimulus that produces the same pattern of activity in the receptors will be perceived as equal (a so-called metamer color). For instance, a blend of medium and long wavelength is also perceived as yellow. If one of the cone types is missing due to a genetic deficiency, color vision is abnormal. Dichromats are predominantly male because the deficient gene is on the X-chromosome. They cannot discriminate between red and green and their color perception is limited to a continuum from blue to yellow or from blue to red, depending on the missing cone type.

The distribution of rods and cones across the retina is not uniform. While most of the retina contains both rods and cones, there is a small area located on the line of sight, referred to as fovea, which contains only cones. Few of the foveal cones (as few as one) converge on one ganglion cell and the density of cones and ganglion cells is higher than in the periphery. Therefore, the fovea is the retinal area with the highest spatial resolution (acuity). Most of what we consciously perceive is being projected on the fovea, in part because of the disproportionately large cortical representation of the fovea with respect to the rest of the retina. The cortical magnification of the fovea is due to the high density of ganglion cells in the fovea and to a larger cortical representation of ganglion cells projecting from the fovea.

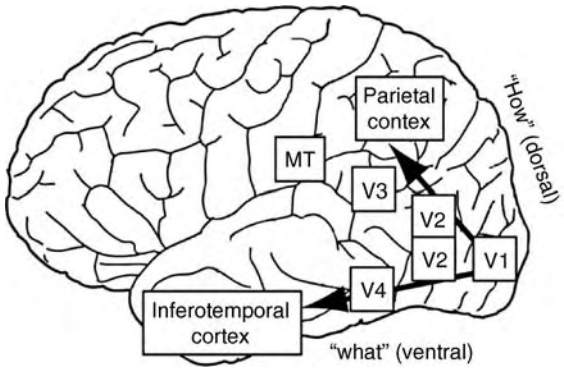
The projections from the fovea to the cortex are highly ordered [2]. Adjacent locations on the retina will also be represented in adjacent locations in V1, a principle that is referred to as retinotopy. Cells in V1 combine the circular receptive fields of ganglion cells to form elongated receptive fields. The receptive field of a neuron refers to the area on the receptor surface from where the neuron receives information. While ganglion cells are maximally stimulated by small points of light, cells in V1 respond best to lines or bars. Cells in V1 have been classified according to their preferred stimulus. Simple cells in V1 respond best to bars of a certain orientation. Complex cells respond to oriented bars moving in a certain direction. End-stopped cells are selective to oriented bars of a certain length moving in a certain direction. Another characteristic of V1 is its organization into columns that share common processing characteristics. Location columns comprise neurons that respond to one particular location of the retina. Within such a location column, each eye is represented by two ocular dominance columns with neurons responding preferably to stimulation of the left or right eye. Finally, each ocular dominance column is composed of a complete set of orientation columns covering vertical to horizontal orientations. Neurons in an orientation column respond best to lines at a certain orientation.

While we do not directly perceive the representation of the stimulus in V1, V1 is necessary for conscious perception. Lesions of V1 lead to blindness in the

affected region. While this deficit, referred to as scotoma, eliminates conscious perception of stimuli presented in the respective visual area, it may not completely eliminate perceptual processing of those stimuli [3]. If patients who deny conscious perception of stimuli presented in the scotoma are forced to respond to these stimuli, their responses may show some residual sensitivity. For instance, they may be able to point to a stimulus presented in the scotoma with above chance (but far from perfect) performance. Even if cortical stimulus processing is precluded in this condition, retinal projections to a subcortical center in the midbrain are still intact. About 10% of the projections from the retina go to the superior colliculus, a structure that is also implied in the control of eye movements. Subcortical processing via this route may enable us to localize an object while circumventing consciousness.

From V1, visual processing in the cortex continues along two major pathways: A ventral pathway from V1 to the inferotemporal cortex and a dorsal pathway from V1 to the posterior parietal cortex (see Fig. 2).

Even if there is considerable crosstalk between the two pathways, they show important functional specialization. The dorsal pathway is responsible for determining an object's location ("where" pathway), while the ventral pathway is responsible for determining an object's identity ("what" pathway). More recently, the dorsal pathway has been characterized as action pathway ("how" pathway) because it determines how a motor action is being carried out [4]. Obviously, information about where an object is located in space is crucial for successful motor interaction with it. A case study provided neuropsychological evidence for the distinction of "what" and "how." Patient DF suffered from damage to her ventral pathway after carbon monoxide poisoning. She was unable to identify simple geometrical forms or to name objects, a condition known as visual form agnosia. For instance, she could not identify a screwdriver or describe the orientation of a slot. However, her actions toward these objects were unimpaired and she could place a card in the slot which cannot be done without information about its orientation. Presumably, information about the slot's orientation was available in the dorsal pathway that guided her actions, but not in the ventral pathway where conscious recognition of the object would usually take place. Conversely, patients with lesions in the posterior parietal area often show impairments in the visual guidance of actions, while object recognition is unimpaired.



**Perception in Vision. Figure 2** Pathways from V1, in the occipital lobes, to the temporal and parietal cortices. The dorsal pathway from V1 to the posterior parietal cortex is important for object localization and action control. The ventral pathway from V1 to the inferotemporal cortex is important for object recognition.

The broad distinction between two visual pathways was further refined by the identification of cortical modules. Modules are cortical areas specialized in the processing of a particular perceptual dimension, such as form (see above), color, or motion in the visual modality. Damage to such a module results in an inability to perceive the respective dimension appropriately; a condition referred to as agnosia [5]. For instance, lesions of V4 make the perception of color difficult and patients perceive the world in shades of gray even if their cone system (see above) is intact. Lesions of V5 make the perception of motion impossible. In one such patient, moving objects appeared as static images in separate positions with no transitions between these positions. Thus, the patient was unable to pour a liquid into a glass because the liquid seemed to be frozen. Also, her interaction with other people was disturbed because she could not follow the movements of her interlocutor's mouth.

After demonstrating the modular, analytic processing of visual information, the intuitive unity of objects mentioned at the beginning requires further explanation. How can we perceive objects as basic units given that the brain analyzes objects into their component attributes? According to feature integration theory, the binding of attributes belonging to one and the same object requires attention [6]. That is, visual focal attention "glues" together the various properties of an object that are processed in a distributed manner in various modules. The role of attention has been studied using a paradigm referred to as visual search. In a typical trial, the observer is asked to look for a target, for instance a blue circle (features "blue" and "round"), and to indicate its absence or presence by a key press. The target is accompanied by a number of distractors. If the target can be discriminated from the distractors on the basis of a single attribute, the search is effortless and the target is readily detected even in a large set of distractors. For instance, the blue circle is easily seen among red circles. In this case, attention is not necessary to tie together the form and shape of the objects because the work of the color module is sufficient to signal the presence of the target. In this condition, the blue target is "salient" and will "pop out"

from the red distractors. If, however, a conjunction of attributes has to be detected, the search is more effortful. For example, it is more difficult to detect a blue circle among blue squares and red circles. According to the feature integration theory, the observer has to scan one object after another and focus attention on each individual object to determine whether the required conjunction is present. The work of a single module is not sufficient (color and form is important), such that serial, attention-demanding integration of attributes is necessary. Consequently, reaction times in a conjunction search increase with the number of distractors.

There is general consensus that attention is necessary for conscious perception to occur. In a phenomenon called "inattentional blindness," observers fail to detect large changes in a picture if their attention is diverted by a secondary task [7]. For instance, observers may fail to notice a black gorilla walking through a scene if they are asked to count the passes of a team dressed in white playing against a team dressed in black. Even if the gorilla was clearly processed at the sensory level, it failed to be consciously perceived because the observer was focusing on white elements in the scene. Thus, both high-level cognitive and low-level sensory processes determine our visual world.

# Perception, Philosophy

Alexander Staudacher
Otto-von-Guericke-Universitaet Magdeburg, Institut für Philosophie, Magdeburg, Germany

## Definition

In current philosophical debates on perception the term "perception" refers almost exclusively to sense perception, although it can be used (like the French "perception" or the German "Wahrnehmung" as well) for the acquisition of knowledge in general. Commonly there are taken to be five senses: sight, hearing, smell, touch and taste. Discussions concentrate for the most part on the sense of sight, however. Although it was at one time argued that perceptual verbs like "to see," "to hear" etc. don't refer to a kind of mental state, episode or event, because they qualify certain observations as successful in the same vein as "to win" does not describe an event or episode but reports an achievement, it is common now to acknowledge the existence of perceptual states and to take perceptual verbs as referring to those states.

## Description of the Theory

One may distinguish in the philosophy of perception basically two kinds of different issues: the first issue concerns the question of how perception as a particular mental phenomenon is to be construed. The second issue concerns epistemological questions, that is, questions dealing with the role of perception in the acquisition of factual knowledge. Making such a distinction is not to deny that both issues are connected in many ways. Indeed, it seems obvious that satisfying answers to the epistemological questions presuppose that at least some questions concerning the first issue have been settled. The main focus of this article will lie, however, on the first issue. The following questions are of particular importance: How is the representational content (henceforth simply: content) of perceptual states to be understood? Mental states in general represent the world to be a certain way; they tell us how the world is in certain respects. In this sense my perception of the tree outside the window represents the world to be a certain way. Correspondingly, there can arise two cases of misrepresentation here, illusion and hallucination. Illusions are cases where something in perception appears to be different from the way it actually is (e.g. a dummy of a tree appearing as a tree). In hallucinations objects appear to be there where no such object is present at all (e.g. the rats hallucinated by a delirious alcoholic). Accordingly, the philosophy of perception not only has to specify the nature of perceptual content (including the question as to whether or not it is similar to the content of other mental states like belief or thought) but has to give also an adequate account of illusion and hallucination. Mental states and their contents are related in various ways to one another and to our actions: we entertain beliefs with certain contents (e.g. that it will rain soon) because we have other contentful mental states (e.g. we perceive a sky full of grey and heavy clouds, we believe this to be a reliable sign of coming rain etc.) and we will therefore act in a certain way (we take our umbrella with us) and so on. This leads to the question of how perceptual content is related to other mental content and to the further question of what

kind of structure it has to possess in order to be able to stand in these relations.

A further question concerning the nature of perceptual states is whether they can be exhaustingly characterized by reference to their content. Perceptual states are often taken to be phenomenally conscious, that is, it is somehow for the perceiving subject to have them. They have a certain distinctive "feel" to them which distinguishes them from mere beliefs and thoughts. While seeing a tree I experience the colors of its leaves in a vividly conscious way which is lacking when I am merely thinking of these colors.

At a most general level one can divide theories of perception into two different classes which give different answers to the question what we have to take as the immediate objects of perceptual awareness. According to the one class we are immediately aware of the physical objects of perception, such as tables, trees, clouds and people etc. These objects are public in the sense that they can be perceived by more than one subject and they exist independently of whether someone preceives them. Furthermore, they change their properties neither when perceived under different perceptual conditions (e.g. varying perspectives or lighting-conditions) nor in the light of varying mental conditions of the perceiver which can influence her perceptions (e.g. expectations, drugs etc.). Theories belonging to the first class are generally called ►direct realism.

According to the other class we are immediately aware of "►sense data." An example of a sense datum is the more or less round, red, bulgy expanse you are immediately aware of when you are seeing a ripe tomato in normal daylight. A sense datum isn't public in the sense that two subjects can be aware of it. Furthermore, it has been assumed that sense data cannot exist independently of our awareness of them and that they regularly change when the perceptual conditions or our mental preconditions change. If we look, for example, at the tomato under different lighting-conditions what we will be immediately aware of will be a sense datum of a different color than before. Furthermore, you will also be directly aware of sense data in cases where no physical object is present at all (hallucination) or where this object is different from the way it appears to you in perception (illusion) (see sense data).

Sense data theories have claimed that an adequate picture of our perceptual awareness in cases of hallucinations and illusions requires the assumption that we are in these cases immediately aware of sense data which instantiate the properties no physical object actually present has. Furthermore, they have tried to show that the immediate objects of our perceptual awareness in cases of veridical perception have to be sense data as well. The vividly experienced colors (felt temperatures etc.) making up the phenomenal aspect of conscious perception can be seen according to these theories as properties of the sense data we are aware of. Concerning the question of how perceptions are related to other mental states sense data theories have traditionally assumed that perceptual states can be a secure fundament for all our empirical knowledge because we are immune against error as far as our sense data are concerned. These data will be as they appear to us. More recent defenses of sense data have put more emphasis on the role of these data in an adequate account of perceptual awareness; the epistemological presuppositions which gave rise to the search for a secure fundament of empirical knowledge have come into discredit in the last decades. There are basically two rival theories within this class, ►indirect or representative realism and a certain version of ►phenomenalism. According to ►indirect realism we have to distinguish between sense data and the mind-independent physical objects of the world surrounding us. Whereas we are in perception directly or immediately aware of sense data, our perceptual awareness of physical objects is only indirect in the following way: in the case of veridical perception the physical object is the cause of the sense datum; it is the first member of the causal chain that leads via the stimulation of our senses and the ensuing processes in the brain to the occurrence of the latter. Sometimes this causal account is supplemented with the claim that sense data function as natural signs for the physical objects they are caused by. In the case of hallucinations the causal chain won't start with the physical object; in the case of illusions the physical object will play a causal role but the chain will be influenced by further factors. Historically, this account has also been strongly motivated by the claim that physical objects don't possess the kind of properties they seem to possess according to our perceptions of them; meaning they are, e.g. neither colored in the way they appear to our eyes nor warm or cold in the way they feel to our hands, but possess only those properties physics must postulate in order to explain their causal interaction (including the interaction with our bodies). A theory of this kind can be traced back to the writings of René Descartes (1596–1650) and John Locke (1623–1704); for more recent defenses see [2].

Given that our perception of physical objects is indirect in that indicated way it seems that our knowledge of them is also indirect. We may either conclude that physical objects are the causes of our sense data or we just believe it to be that way, but are such beliefs or conclusions justified at all? According to one of the major objections to indirect realism the answer has to be negative and consequently indirect realism can't be justified either because one of its central claims is that physical objects are often among the causes of our sense

data. According to this objection indirect realism cannot justify this claim because information about causal relationships has to be established empirically by the observation of cause and effect. But if indirect realism is right, the only available empirical information is our immediate perceptual awareness of our sense data. Therefore, the only information we can get will be about the effect but not about the cause. Consequently, indirect realism seems to undermine itself and to lead to skepticism concerning the existence of the physical world.

A typical indirect realist answer to this challenge is to use a strategy which is familiar in the philosophy of science when it comes to justifying the existence of unobservable scientific theoretical entities like molecules, atoms and so on. It is admitted that we have no empirical access to physical objects in the strict sense but it is held that we are nevertheless justified in claiming their existence, because this claim gives us the best explanation for the fact that the sequence of our sense data possesses the order and structure it actually does [2].

Phenomenalism can be traced back to central claims of the philosophy of George Berkeley (1685–1753); for a classical defense in the twentieth century see [1]. Roughly put, phenomenalism holds that physical objects can be identified with complex sequences of actual and possible sense data, and concludes that direct awareness of these comes down to direct awareness of physical objects. A tomato is then nothing but the complex sequence of sense data I have when I am actually looking at it or I would have if I took a different perspective of it or touched it and so on. If physical objects are nothing but sequences of actual or possible sense data a claim like "There exists a rock in the desert nobody has seen so far" has to be interpreted as the claim "If you go to a certain place in the desert you will enjoy sense data of a rock."

It has been objected to phenomenalism that our talk about existing physical objects can't be replaced in that way by talk about actual and possible sense data. To be complete, the required interpretations would not only have to be of a kind of complexity no one has been able to arrive at so far (note, that these analyses would also have to comprise phrases like "you go to a certain place in the desert"), they seem to be at odds with the causal roles we ascribe to physical objects that no one perceives (think of the roots supporting the trunk of a tree); to be the cause of something requires that it actually exists. However, unperceived objects are according to phenomenalism only sequences of possible sense data a perceiver would have if he were in the right situation. More recent statements of phenomenalism have therefore tried to defend versions which don't require such interpretations [4].

Direct realism has been traced back to Aristotle (384–322 B.C.), Thomas Aquinas (c. 1224–1274), and the Scottish common sense philosopher Thomas Reid (1710–1796), although these historical ascriptions are a matter of controversy. Direct realism comes in a variety of different forms, differing are mainly as to how the content of perceptual states is best to be construed.

According to the ▶belief-theory of perception, perceptions are a certain kinds of beliefs we acquire with the help of our sense organs (for more qualifications as to what special kind of beliefs perceptions are see [9]). Beliefs have propositional content, that is, content which can be specified with the help of a that-clause in which something is classified in a certain respect with the help of a concept (e.g. "Peter believes that grass is green"). The possession of concepts ("grass," "green") implies among other things at least the ability of the believer to recognize things as being able to under that concept. This proposal accords well with the fact that we often express the content of perceptions with the help of that-clauses and imply the possession of the relevant concepts by the perceiver when we say things like "Sarah sees that there is milk left in the fridge." It can also explain how perceptions serve to justify other beliefs (Sarah's belief that she doesn't have to go the super-market now), because justification proceeds by inferences and inferential relations can be explained best by reference to a content with propositional structure.

Nevertheless, this account faces serious difficulties: Sometimes the content of our perceptions can't be equated with the contents of our beliefs: we may perceive the arrows of the well known Müller-Lyer figure to be of a different length, although we know quite well that they are in fact of the same length. Although we modify our beliefs in the light of new beliefs, our perceptions often aren't accessible to this kind of revision. Perception in contrast to beliefs seems to be, as it is called, "modular" (for more on modularity see [6]). With their equation of perception to belief and thought belief-theories have notorious difficulties in doing justice to the fact that perceptions are phenomenally conscious. In order to avoid the introduction of sense data at this point the so-called ▶adverbial theory of experience has held that the phenomenal aspect of our sense experiences can be analyzed in the following way: a vivid conscious experience of something red (be it veridical or not) can be understood as a certain way of perceiving; that is, we are not conscious of something instantiating the property which is responsible for the character of our conscious experience (a sense datum), but our perceptual state itself is characterized by that property, in the case of an experience as of something red we "sense in a redly manner", as it has been put [7]. It has been claimed, however, that this account cannot deal adequately with situations where we have an awareness of a manifold of different items with different colors and forms because this requires

being aware of different items instantiating these properties [2]. An alternative account that may be able to deal with the problems of the belief-theory is ►representationalism (not to be confounded with representative or indirect realism) [8]. Representationalism seems especially apt to avoid a third problem of the belief-theory, the fact that we can also perceive things without disposing of the relevant concepts; or, as it is often put, that perception can have nonconceptual content. We not only render the content of perceptions with the help of that-clauses, but by saying also things like "He sees the computer" or "He heard the Tristan-accord." With statements like these we often don't imply that the perceiving subject has to have the concept of a computer or of the Tristan-accord in order to see or hear these things (think of a baby or a dog as the perceiving subjects). According to representationalism we have non-conceptual perceptual representations of the items in question. The admission of the existence nonconceptual content leads to the question of how this kind of content is related to conceptual content and how it can play a role in the justification of our empirical beliefs. Here it has been argued that perceptual content can fulfill its role in the justification of empirical beliefs only if it is taken to be conceptual, which means that the representationalist claim concerning the nonconceptual character of our perceptual experience finally can't be right [9]. Whether this objection is sound is a matter of ongoing discussions.

Representationalism also uses the idea that perceptions have nonconceptual content in order to explain the fact that perceptions are phenomenally conscious. To put it very roughly, phenomenally conscious states are conceived as nonconceptual representations which deliver information to the perceiver he which can use to form his beliefs and desires. These states acquire their nonconceptual content by being dependent in the right way on the features they represent (e.g. they are caused by them under optimal conditions; therefore the presence of red objects leads in general to perceptions of red). Because the typical phenomenal aspects of our sense experiences are experienced by the perceiver as features of the represented surroundings (e.g. in a conscious perception of the blue sky the blue is experienced as a feature of the sky), representationalism claims that perceptual states acquire their phenomenal character by being related in the right way to certain features of our surroundings: we represent the blue of the sky in a nonconceptual way. Whether such a conception of the nonconceptual content of perception can be used to explain the phenomenally conscious aspect of perception is, however, also a matter of controversy [1].

All positions considered so far share the presupposition that veridical perceptions and hallucinations have something in common. In both cases the perceiver will either have sense data, or perceptual beliefs, or nonconceptual representations or states that can be characterized by an adverbial modification. There is, however with the so-called "►disjunctive account" of sense experience [10] a further variety of direct realism which puts this presupposition in question: according to this position a perceptual experience is either a perception or a hallucination (a disjunction of these two types of states), but these two types of states need not share a common element: perception implies that we are aware of physical objects and the content is just constituted by the perceived aspect of the physical object itself, hallucinations however don't imply this because there is no such object present. In the case of hallucinations we simply take ourselves to perceive something although it isn't the case.

One consequence of this position which might be hard to swallow is that it demands that we are in the case of hallucinations not only in error about the physical world but also about the conscious mental states we are in; we assume that we are perceiving while we aren't. A second problem is that the disjunctive account has difficulties with the fact that hallucinations and veridical perceptions are the causal consequences of the same type of brain states; one may evoke a hallucination by a stimulation of those parts of the brain which are also activated in the case of veridical perception. However according to a widely held principle on causation the same kinds of causes lead to the same kind of effects. It seems, therefore, that the adherent of the disjunctive account has to give up this principle, because according to his account there is nothing in common between hallucinations and veridical perceptions eventhough they result from the same kind of brain stimulation (for further discussion see [4]).

## Perceptive Field

### Definition

Psychophysical counterpart of receptive field organization.

Term first introduced by Jung and Spillmann (1970) to link perceptual properties to neuronal function. Although psychophysical data represent the final stage of integration of the activity of numerous neurons, they typically resemble those obtained with single cell recordings (single neuron doctrine by Barlow 1972). Perceptive fields may thus be regarded as psychophysical equivalents of receptive fields with their various forms of center-surround antagonism and selective spatio-temporal sampling characteristics that allows for non-additive, Gestalt-like integration of the stimulus input.

►Psychophysics

## Perceptron

### Definition

The Perceptron was the first neurocomputer (artificial neural network) to be developed. The original Perceptron consisted of two layers of units (input and output layer) and used a simple learning rule for weight adjustment according to the difference of the network output and the target vector. It is capable of solving linearly separable problems. It can be proven that the network converges to a solution (i.e., reaches its error minimum) within a finite number of steps for any linearly separable problem. Multilayer Perceptrons with hidden (intermediate) layers of units are more powerful and can learn complex non-linearly separable problems.

►Connectionism
►Neural Networks

## Perceptual Completion

►Perceptual Filling-In

## Perceptual Constancy (in Vision)

### Definition

The tendency of perceiving objects and scenes as being invariant in size, shape, lightness, color, etc., despite variation of sensory inputs originating in the same objects and scenes observed from varying viewing distance, at varying viewing angle, in varying illumination, etc.

►Color Constancy

## Perceptual Correlates

►Visual Neuropsychology

## Perceptual Discrimination

### Definition

Ability to distinguish between different levels of a perceptual dimension such as color, pitch, or pressure.

The perceptual dimension may map directly onto a physical dimension (e.g. the perceived length of a bar may also be measured) or may be created by the perceptual system (e.g. we perceive colors but the rays of light are not colored).

►Perceptual Impairment
►Perception

## Perceptual Filling-In

Ikuya Murakami
Department of Life Sciences, University of Tokyo, Tokyo, Japan

### Synonyms

Perceptual completion

### Definition

Perceptual filling-in refers to the visual phenomenon in which a certain part of the ►visual field appears to be

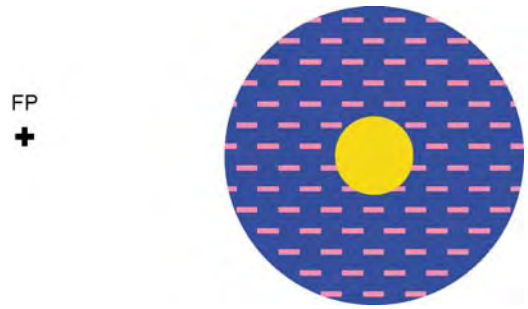
overwhelmed or filled with the visual attributes, such as brightness, color, and texture, of the surrounding area. Filling-in connotes planar interpolation of surface properties; linear interpolation of contour and bar is often referred to as perceptual completion. Though filling-in at the ►blind spot has been studied most extensively, mechanisms of perceptual filling-in are considered to be rather ubiquitous in the normal visual field as well.

## Characteristics

### Phenomenal Variations

Since vision is a process of ecologically valid estimation of our outer world, our visual system has evolved so as to infer object properties from impoverished visual inputs on the ►retina. As a result, in a great variety of situations the brain assumes a surface to be filled with color and texture from outside, especially when retinal inputs to that surface part are unavailable or poor.

One of the most striking examples is filling-in at the blind spot, an oval-shaped area (approximately 5 degrees in diameter) defined for each eye, located at approximately 15 degrees horizontally from the center of the visual field. This area is insensitive to light stimulation because ►photoreceptors are totally absent at the corresponding retinal region (optic disc). Why does this visual deficit go unnoticed? As the blind spot of one eye is a normal field of view for the fellow eye, a complete visual scene is of course available with both eyes open. However, the visual world also seems as complete with only one eye open. Clearly, perceptual filling-in is constantly at work there. One can easily convince oneself of this phenomenon by looking at an annular shape fully covering the border of the blind spot (Fig. 1): the annulus appears to be a large solid disk uniformly filled with the color and texture of the figure.



**Perceptual Filling-In. Figure 1** Perceptual filling-in at the blind spot. As the annulus covers the border of the blind spot of the right eye, the yellow inner disk perceptually disappears; the inside appears to be filled with the same color and texture as in the annulus. The reader can experience filling-in by looking straight at the fixation point labeled "FP" with only the right eye open, from an appropriate viewing distance.

Perceptual filling-in can also occur at a small deficit (►scotoma) of the visual field that arises for a few people from an acquired local damage to the retina (or other visual pathways). This might explain why patients with local ►retinal degenerations are sometimes unaware of their scotoma before they take ophthalmologic testing across the visual field. The monkey has also been shown to see perceptual filling-in both at the natural blind spot and at a scotoma caused by retinal damage [1].

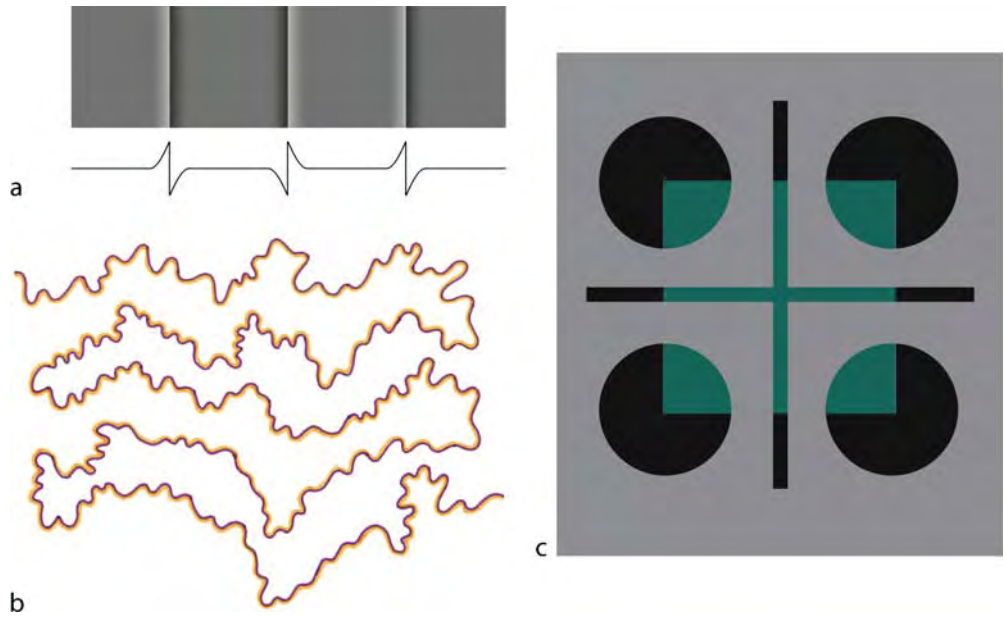
Whereas perceptual filling-in at the blind spot and scotoma occurs in the region without visual inputs, filling-in also occurs in the region without visual-input *changes*. When an image is artificially stabilized on just the same part of the retina by using a special experimental device, this image is initially visible but soon fades away from one's ►perception, filled-in with its background color. Normally, incessant ►fixational eye movements produce tiny wobbling of retinal images, preventing such perceptual fading of stationary things in everyday life. Nevertheless, by looking sideways at a faint or blurry stationary figure on a uniform background for a long time, one may experience similar image fading and filling-in with background color (►Troxler effect). Likewise, when one looks sideways at a stationary surface stimulus on a background of randomly twinkling texture, this surface gradually disappears from perception, filled-in with similar random twinkles of texture (►artificial scotoma) [2].

Other phenomena of perceptual filling-in in normal observations include the ►Craik-O'Brien-Cornsweet effect (Fig. 2a) and the ►watercolor illusion (Fig. 2b).

In these illusions, different surface parts physically share identical luminance and chromaticity, but they are perceived to have different colors when there are sharp ►contrasts of luminance and chromaticity at the very boundary [3]. In these cases, clear physical edges delineate one area to fill-in with one color and another area with another color. Interestingly, however, perceptual filling-in of surface can also be bounded by contours that are perceptually completed themselves (Fig. 2c). In a figure designed to induce an ►illusory contour, the color of certain parts of the figure perceptually fills-in the inside of the subjective square of the illusory contour but not beyond (►neon-color spreading effect). Altogether, these phenomena may be viewed as examples demonstrating that the visual system infers surface properties of featureless areas by using conspicuous cues nearby.

## Models

How are such ►percepts of filling-in accomplished? To the extent that the phenomenal variety is diverse, there may exist as many theories for the mechanisms underlying them. Of these, three influential ideas have been proposed for perceptual filling-in at the blind spot and other poor regions [4].



**Perceptual Filling-In. Figure 2** Various filling-in phenomena. (a) The Craik-O'Brien-Cornsweet effect. The inset indicates luminance as a function of horizontal position. The area just to the left of the central edge appears uniformly darker than adjacent areas, although the luminance changes are confined within the borders between areas. (b) Watercolor illusion. The two areas delineated by the wiggly borders appear to be filled uniformly with faint yellowish and bluish colors, although the color changes are confined within the borders, with the remaining areas left achromatic, in reality, Adapted from [3], with kind permission from the author. (c), Neon-color spreading effect. A square-shaped illusory contour is formed by the black inducers, and a bluish translucent color appears to be spreading inside the subjective square seen in front.

1. *Isomorphism.* When perceptual filling-in occurs, a two-dimensional neural map (or ►visual topography) representing that location of the visual field is actually activated as such, so that individual neurons within that map are actually excited in some fashion parallel with perceived surface properties.
2. *Symbolic Labeling.* Attributes inside a poor region can be cognitively designated by symbolic or logical operations using reliable information nearby, without invoking isomorphic activation – the brain is not "filling in but finding out" the missing surface properties.
3. *Ignorance.* One does not see a black hole of the blind spot simply because one is only aware of visual events that are abundant in the surround and "ignores the absence."

Some recent findings have been more or less in favor of isomorphism, as we will see below, although labeling and ignorance may operate at crucial processing stages for one's ►conscious perception and ►awareness.

## Neurophysiological Studies

In the brain, visual signals from the retina are registered in visual topography, or a two-dimensional map of neurons topographically representing the visual field. Are the neural representations of the blind spot and scotoma on this topography really activated when perceptual filling-in occurs? Physiologists are still on their way to solving this important question.

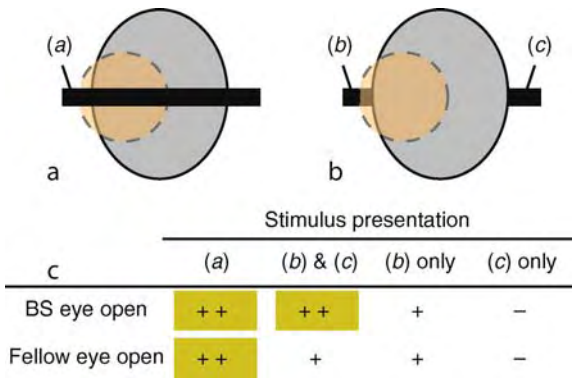
Perhaps the simplest way of neural activation would be to distort the map itself (often called the "►sewn-up" model). The representation of the blind spot could "see" its surroundings if it received direct innervations from retinal portions surrounding the blind spot. However, current studies of functional anatomy have indicated quite orderly mapping from retina to ►striate cortex without distortion at the blind spot, and at the scotoma as well [5]. Nonetheless, some ►single-unit recording studies have suggested re-mapping of visual topography of a scotoma [6]. This scotoma was induced in an animal by producing small local lesions in the retinae. After the damage, cortical neurons that had originally coded positions inside the scotoma expanded and shifted their ►receptive fields towards the outside – as if they abandoned the damaged part and started to look out. Thus, some ►cortical plasticity might be initiated in certain conditions for adaptive compensation for retinal damage.

Besides the feedforward mapping, there are at least a couple of hypothetical schemes to make neural filling-in possible in early visual cortex. The first is lateral

propagation of visual signals into the cortical representation of the blind-spot region via horizontal connections. The second is feedback from ►extrastriate visual cortex back to early visual cortex. Yet another scenario would be that the neural correlate of filling-in resides not in early visual cortex containing neurons with tiny receptive fields, but in higher cortical areas where neurons have larger receptive fields covering the blind spot and beyond. More research is needed to determine which is the case.

A few attempts have been made to seek activities of individual neurons that parallel the filling-in phenomenon. One of the most recent findings is about the neuronal activity in striate cortex (►primary visual cortex, ►V1) of a behaving monkey (Fig. 3) [7].

These neurons had receptive fields largely overlapping the blind spot of one eye, i.e., with the other eye open, the neurons were excited by visual stimuli presented in these fields. The blind-spot eye only was open. A small bar stimulus (labeled *b*) on one side of the blind spot fell onto the tip of the receptive field, and thus caused mild firing responses as expected. Interestingly, responses increased when another bar stimulus (labeled *c*) was added on the other side, so as to induce perceptual completion of a single bar across. The second bar stimulus per se did not cover the receptive field, but the perceptually completed bar did. In contrast, such a response increase was not observed with the fellow eye only open. Therefore, these neurons fired vigorously when the filled-in bar coincided with their receptive fields inside the blind spot.



**Perceptual Filling-In. Figure 3** Perceptual completion at the blind spot and neuronal responses [7]. (a) Schematic illustration of the stimulus. The receptive field (*broken circle*) of the recorded neuron partially overlapped the blind spot (*solid oval*). A horizontal bar (*a*) was presented such that it should penetrate both the receptive field and the blind spot. (b) In other cases, the retinal input was confined within a small sub-region (*b* and/or *c*). (c) Schematic diagram illustrating responses of a few V1 neurons exhibiting increased activities during perceptual filling-in. The neuronal responses were recorded during four types of stimulus presentations while either the blind-spot eye (BS eye) only or the fellow eye only was opened. The symbols "++," "+," and "–" indicate strong, weak, and no responses, respectively. The *yellow boxes* indicate the viewing conditions in which the monkey would perceive a long bar across the blind spot.

The neural correlate of the "artificial scotoma" (see above) has also been investigated in the awake monkey [8]. A static, gray square was located to cover the receptive field of the recorded neuron, and the background was filled with twinkling random noise (Fig. 4a). Over prolonged observation, the static square was perceptually replaced with twinkling noise at some time. The firing activities of neurons in a higher visual area, ►V3, were initially weak but became stronger just at the time this "artificial scotoma" would be perceptually filled-in with noise (Fig. 4b).

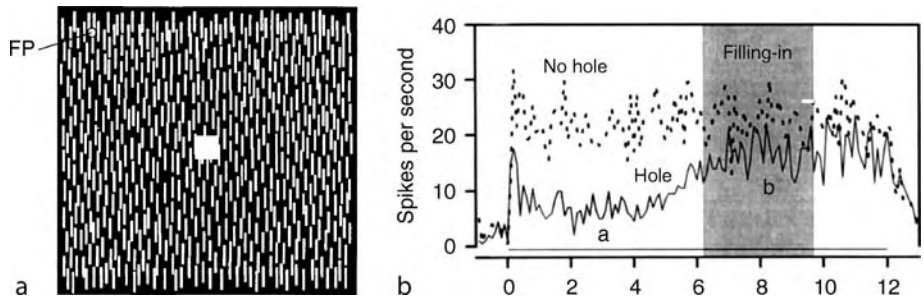
These findings seem consistent with isomorphic activations in the two-dimensional cortical map of the visual field during perceptual filling-in. Meanwhile, other studies indicate mixed results among different types of neurons, cortical areas, methodologies, and types of filling-in phenomena. At present, many important questions yet remain to be answered: what kinds of isomorphic activations of visual neurons are necessary and sufficient, how these could be implemented in a biologically feasible manner, and whether only one kind of architecture is enough for all kinds of filling-in to occur.

## Perceptual Studies

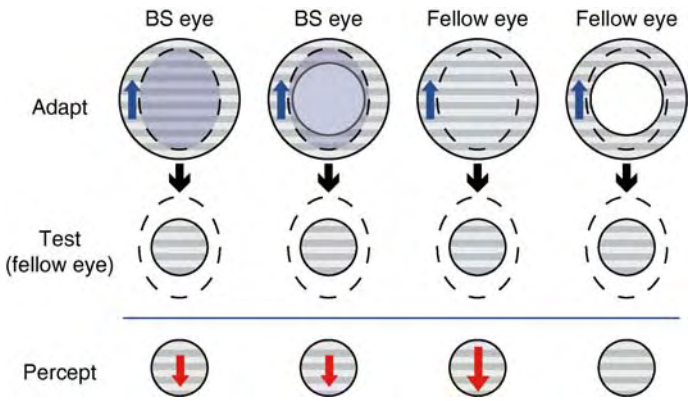
Other lines of evidence for explicit representations corresponding to perceptual filling-in come from ►psychophysics of ►visual illusions. In one such study, a phenomenon of ►motion aftereffect was used (Fig. 5) [9].

After prolonged viewing of a moving stimulus, a static stimulus presented at the adapted location appears to move in the opposite direction, and this effect is known to transfer between eyes if different eyes are used in adaptation and subsequent test. The observer was adapted to a moving stimulus covering the blind spot of one eye and thus perceptually filling-in the inside of it. Later, the stimulus was abruptly switched to a smaller static stimulus well inside the blind spot of the adapted eye, but as it was now given to the fellow eye, the observer could see it. It was perceived to move in the opposite direction to the adapting stimulus, thus the motion aftereffect was elicited after adaptation to motion filling-in inside the blind spot without direct stimulation. This finding suggests that filled-in motion and actual motion share a common pathway.

Another observation of brightness filling-in suggests topographic representation (Fig. 6) [10]. Presented on a white background was a uniformly lit disk-shaped figure, whose luminance decreased continuously from white



**Perceptual Filling-In. Figure 4** "Artificial scotoma" and neuronal responses [8]. (a) Schematic illustration of the stimulus, which consisted of randomly positioned bars and a gray square covering the receptive field of the recorded neuron. Three such random-bar patterns alternated at 20 Hz. The monkey was rewarded for maintaining fixation at the fixation point (FP). (b) Typical responses from a single neuron in area V3. The firing rate is plotted against time after stimulus onset. The neuron initially exhibited a transient response to the stimulus onset followed by a low firing rate (labeled "Hole"). With prolonged observation, however, the neuron's responses gradually increased, reaching a plateau (labeled "Filling-in") at the time observers would experience perceptual filling-in of the square with random bars. The plateau was comparable to the firing rate of the same neuron to the same stimulus without the gray square (labeled "No-hole"). Adapted from [8], with kind permission from Nature Publishing Group.

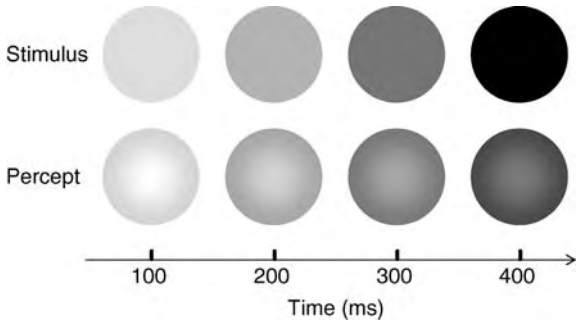


**Perceptual Filling-In. Figure 5** Perceptual filling-in of motion and a subsequent motion aftereffect inside the blind spot [9]. The adapting stimulus was a horizontal grating drifting vertically (its direction is indicated by the *blue arrows*). The stimulus region was either a disk covering the entire blind spot (*broken oval*) or an annulus covering the border of the blind spot. The observer was adapted with only the blind-spot eye (BS eye) or only the fellow eye open. Note that the disk and annulus were equivalent for the BS eye. The test stimulus was a stationary horizontal grating well inside the blind spot, delivered to the fellow eye. A motion aftereffect occurred (its direction indicated by the *red arrows*) where motion had been perceptually filled-in during adaptation.

to black in half a second. The observer saw it darkening continuously, but its brightness was perceived as inhomogeneous: the brightness change towards the center of the disk appeared to lag behind the change at its edge. In other words, the center appeared brighter than the edge at each time slice, and darkness "swept" inward. This phenomenon could be seen in a disk placed in a normal visual field and in the same disk covering the blind spot just as well, either with the blind-spot eye or the fellow eye open. This effect appears to corroborate the propagation of brightness signals from edge to interior on the cortical map, suggesting that neural filling-in operations obey the same principle all around the visual field.

## Functional Significance

The retinal image is a two-dimensional array of "raw" light intensity. From this image, the visual system has to estimate lots of things, such as object contours, surface assignment to objects, their volumetric structures, and their material properties, just to list a few. On the other hand, retinal inputs never provide the brain with sufficient information for solving these problems. For example, the brain has to determine what surface is lit by what light source, but the retinal image is only a result of their interactions. Thus, the same surface can project very different images onto the retina depending on viewing conditions. Also, the image of the same surface under the same illumination may be registered



**Perceptual Filling-In. Figure 6** Brightness filling-in in a normal visual field [10]. On a computer monitor, a small spot of light (1 degree in diameter) gradually changed its luminance from white to black over time. Its perceived brightness was different between the edge and inside: the brightness at the edge appears to fill inward. The same phenomenon occurs at the blind spot as well, with a larger spot of light (8–10 degrees in diameter).

as having different values of chromaticity, because of differences in our spectral sensitivity across space and time. Furthermore, the same surface may even be partially unregistered (blind spot and scotoma). Therefore, filling-in has a clear functional significance of maintaining our ►perceptual constancy in spite of imperfection of visual information from the eye. As perceptual filling-in is viewed this generic way, a great number of puzzles remain to be solved in future research.

# Perceptual Grouping

## Definition

►Form Perception

# Perceptual Impairment

## Definition

Inability to distinguish between different levels of a perceptual dimension such as color, pitch, or pressure.

The impairment may originate at a peripheral level (e.g. absence of a particular cone type in the retina leads to color blindness) or at a central level (e.g. lesions of a cortical region). The impairment may regard particular regions of space, particular perceptual dimensions (e.g. color, movement, etc.) or the recognition of what is perceived (e.g. inability to recognize familiar faces).

►Perceptual Discrimination
►Perception

# Perceptual Processing

►Visual Neuropsychology

# Perceptual Saliency (in Vision)

## Definition

Degree to which a target stimulus "pops out" in a set of stimuli. If the target stimulus differs by a single attribute (e.g. its color) from the other objects, it is highly salient.

If the target stimulus differs by a combination of attributes (e.g. a combination of color and form) from the others, it is less salient.

►Perception

# Perceptual Task

## Definition

Detection or classification of a stimulus or discrimination between different stimuli.

►Sensory Plasticity and Perceptual Learning

# Perforated Patch

## Definition

A form of patch-clamp recording in which an antibiotic such as nystatin, amphotericin, or gramicidin are included in the patch solution to create ionophores in the plasma membrane that permit intracellular recording without modifying the cytosolic contents of the neuron.

►Patch Clamp

# Perforated Synapse

Daniel A. Nicholson, Yuri Geinisman
Department of Cell and Molecular Biology, Northwestern University's Feinberg School of Medicine and Institute of Neuroscience, East Chicago Avenue, Chicago, IL, USA

## Synonyms

Synapse with a perforated or discontinuous postsynaptic density (PSD); Synapse with subsynaptic plate perforations; Synapse with a fenestrated, Horseshoe-shaped or segmented PSD; Synapse with an annulate, Horseshoe-shaped or multifocal presynaptic vesicular grid

## Definition

►Perforated synapses belong to a special morphological variety of synaptic junctions, characterized by the presence of aligned discontinuities (gaps) in their postsynaptic and presynaptic densities.

## Characteristics

### Quantitative Description

Ultrastructural features of perforated synapses, their quantitative characteristics and changes under various experimental conditions were the subject of numerous investigations. The results of these studies, which were previously reviewed in detail [1–5], are summarized below.

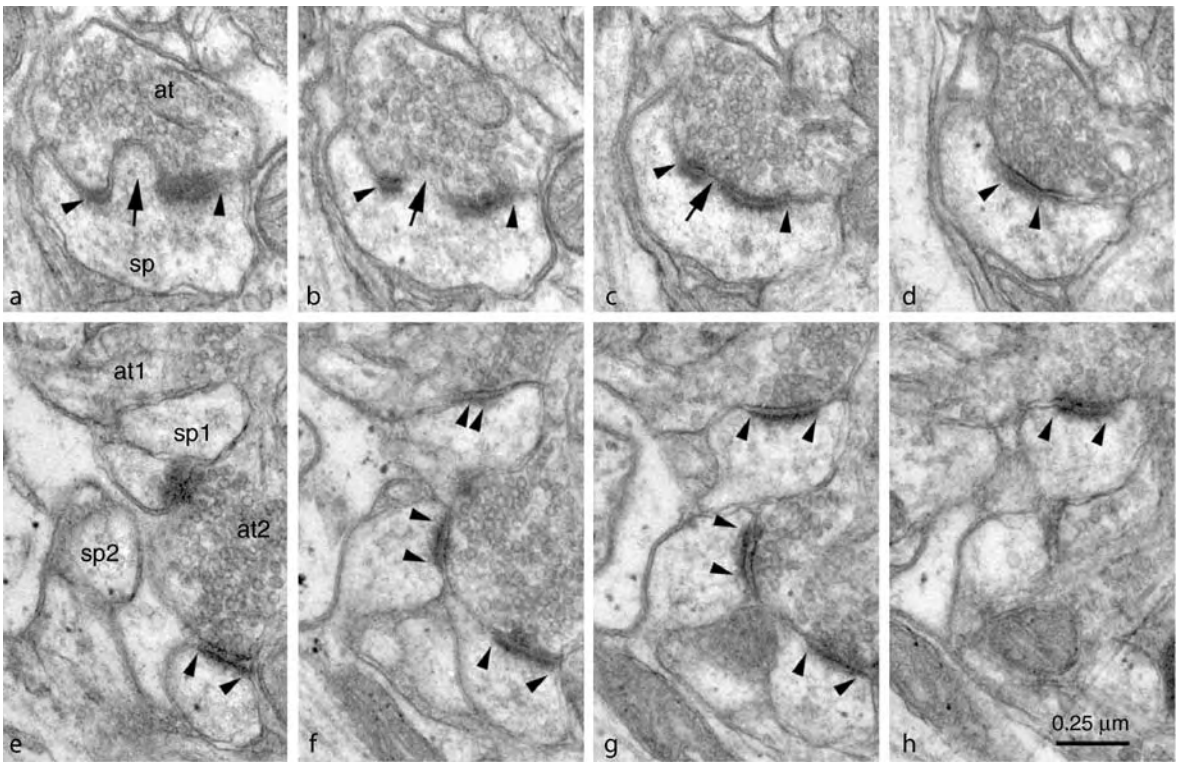
#### *Ultrastructure*

The hallmark of a synapse at the electron microscopic level is the ►postsynaptic density (PSD). The PSD is a plate(s) of electron-dense material on the cytoplasmic face of the postsynaptic membrane. PSDs are most noticeable in ultra thin sections of tissue conventionally prepared (i.e., osmicated) for electron microscopy (Fig. 1).

Synapses can be subdivided based on the thickness of their PSD, relative to that of the ►presynaptic density, into two main types: asymmetric synaptic junctions with a thicker PSD are considered to be excitatory; and symmetric ones with a PSD nearly as thin as the presynaptic density are considered to be inhibitory. Electron microscopic analyses of asymmetric synapses have demonstrated that they can be further subdivided, based on the configuration of their PSDs into either perforated or nonperforated (or macular) ones. When sections are made perpendicular or at an angle to a perforated PSD, a discontinuity or perforation is usually observed in a subset of its sectional profiles (Fig. 1a–c). Perforated PSD shapes can also be visualized in sections passing parallel to PSDs. Planar reconstructions of perforated PSDs from consecutive serial sections show that they assume three basic shapes: a fenestrated PSD exhibiting a hole(s) in its single plate; a horseshoe-shaped PSD having a single plate; and a segmented PSD consisting of several (2–4) separate plates. ►Nonperforated synapses, on the contrary, are characterized by a continuous PSD plate of a relatively simple shape, which may be approximated by that of a circular or elliptical disk. Sectioning of such a plate at different angles produces PSD profiles that lack perforations (Fig. 1e–h). Although dimensions of nonperforated PSDs are generally smaller than those of perforated ones, this is not an invariant feature of nonperforated PSDs because some of them overlap in size with perforated PSDs.

#### *Distribution*

Perforated synapses are widely distributed throughout the mammalian brain, including various neocortical areas, the hippocampal formation, striatum, putamen,



**Perforated Synapse. Figure 1** Perforated (a–d) and nonperforated (e–h) axospinous synapses, seen in electron micrographs of consecutive serial sections through the middle molecular layer of rat dentate gyrus. (a–d) The perforated synapse (its presynaptic axon terminal and postsynaptic spine head are labeled in (a) by "at" and "sp," respectively) exhibits PSD profiles (*arrowheads*) that have a discontinuity (arrowheads) in some sections (a–c). A synaptic spinule (a, b) is a finger-like protrusion of the spine head, which invaginates through a discontinuity in the PSD (*arrows* in a and b) into the axon terminal. (e–h), The nonperforated synapses formed between axon terminals (labeled in (e) by "at1" and "at2") and spine heads (labeled in e by "sp1," "sp2" and "sp3") display continuous PSD profiles (*arrowheads*) in all sections.

deep cerebellar nuclei, and hypothalamus. Both perforated and nonperforated ►asymmetrical synapses are found mainly on dendritic spines and occasionally on dendrites. Axospinous perforated synapses have been extensively studied, and the present essay is focused on these synaptic junctions, which will be referred to as perforated synapses.

### *Frequency*

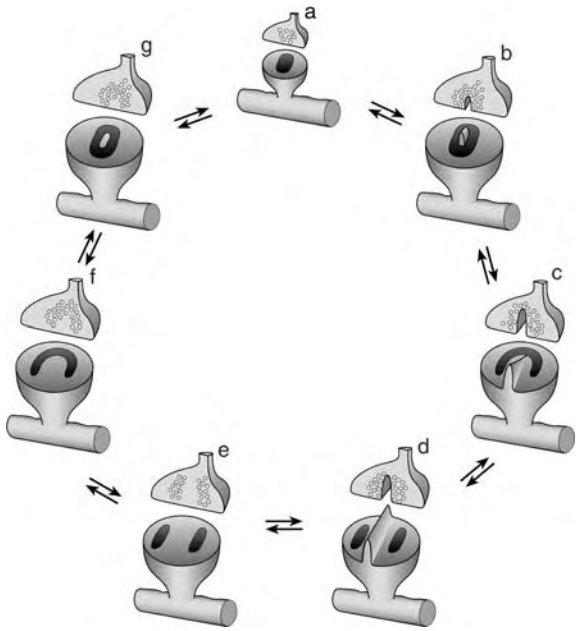
Perforated synapses constitute 10–25% of the entire axospinous synaptic population. Nevertheless, the number of perforated synapses per neuron is substantial. For example, the total number of pyramidal neurons in rat CA1 hippocampal region is ~400,000, whereas the total number of perforated synapses in one of its layers (stratum radiatum) reaches ~800,000,000. Therefore, each CA1 pyramidal neuron receives ~2,000 perforated synapses in the stratum radiatum alone.

## Lower Level Components

A ►synaptic spinule or spine partition is a postsynaptic component of some perforated synapses. In single sections, it is seen as a small outgrowth that arises from the spine head at a PSD discontinuity and protrudes into the presynaptic axon terminal (Fig. 1a, b). Three-dimensional reconstructions of perforated synapses demonstrate that the extent of spinules differs depending on the shape of perforated PSDs [2]. In fenestrated synapses, they assume the form of a focal partition, the base of which is limited to a hole in the PSD plate (Fig. 2b).

Horseshoe-shaped synapses exhibit a spinule whose base is restricted to the interval between the two arms of the PSD horseshoe (Fig. 2c). In segmented synapses, however, a complete spine partition divides the spine head cavity into separate compartments, each one containing a discrete transmission zone between the axon terminal and a PSD segment (Fig. 2d). Each perforated synaptic subtype can have or lack spine partitions (Fig. 2e–g). In the molecular layer of rat dentate gyrus, the proportion of synaptic junctions with partitions in total samples of fenestrated, horseshoe-shaped and segmented synapses amounts to 38, 60 and 92%, respectively.

P



**Perforated Synapse. Figure 2** Diagram illustrating a hypothetical synapse restructuring that may underlie activity-dependent alterations in synaptic strength. The schematic shows the following axospinous synaptic subtypes: nonperforated synapse (a) perforated synapses that have a fenestrated PSD and focal spine partition (b) a horseshoe-shaped PSD and sectional partition (c) a segmented PSD and complete partition (d) or that lack spine partitions but exhibit a segmented (e) horseshoe-shaped (f) and fenestrated (g) PSD. The sequence of synapse remodeling from a through to b, and c to d is postulated to be a rapid process that supports an initial maximal synaptic enhancement. The sequence from d through to e, f and g to a may lead to the return of elevated synaptic responses to the control level.

►AMPA receptors and NMDA receptors (AMPARs and NMDARs, respectively) are types of ionotropic glutamate receptors associated with the PSD of excitatory synapses. These PSDs also contain cytoskeletal scaffolding and adaptor proteins as well as signaling molecules, which together form a cluster of synaptic signal transduction machinery located at or near the site of synaptic transmission. Compelling electrophysiological evidence indicates that the number of postsynaptic AMPARs and NMDARs is the major determinant of synaptic strength. ►Postembedding immunogold electron microscopy reveals striking differences in the expression of AMPARs and NMDARs between perforated and nonperforated axospinous synapses, which may indicate corresponding differences in the strength of synaptic transmission at these synaptic subtypes [6,7]. Interestingly, some nonperforated synapses exhibit NMDAR but not AMPAR immunoreactivity, whereas perforated synapses are invariably immunostained for both receptor types. This finding may mean that perforated synapses are never postsynaptically "silent" at resting membrane potentials. Moreover, perforated synapses from rat CA1 stratum radiatum express significantly more AMPARs (by 660%) and NMDARs (by 80%) than their immunopositive nonperforated counterparts. The total area of the PSD plate(s) is generally larger in perforated synapses as compared to nonperforated ones, and postsynaptic AMPAR content positively correlates with PSD size. The difference in the expression of glutamate receptors between the two synaptic subtypes remains significant, however, when their PSD areas are equalized, indicating that this difference is related to both PSD configuration and PSD size.

## Function

Numerous studies report activity-dependent increases in the number or proportion of perforated synapses. Such changes occur in cortical regions of the rodent brain during postnatal development and under various experimental conditions including housing of animals in complex environments, hippocampal kindling, NMDA-dependent hippocampal LTP and behavioral learning. Based on these observations, perforated synapses have been widely implicated in synaptic plasticity. It is necessary, however, to note here that many of the reported results should be considered with caution. The majority of studies published so far employed inappropriate procedures for quantification of perforated synapses. For example, in studies that analyzed synapses on single (rather than consecutive serial) sections, perforated synapses might not have been reliably recognized and quantified because they frequently exhibit nonperforated PSD profiles (Fig. 1b).

Such methodological drawbacks notwithstanding, there is a growing body of evidence in favor of the long-standing notion that an addition of perforated synapses is required to support an enhancement of synaptic strength. Especially demonstrative in this respect are the findings of LTP experiments [8,9], showing that perforated synapse number is markedly increased early (15–60 min) after LTP induction, when synaptic responses are maximally enhanced, and returns to control levels afterwards. The observed increase in the proportion of perforated synapses reflects a selective change in the number of segmented, completely partitioned synaptic junctions [8,9].

The existence of distinct morphological subtypes of axospinous synapses suggests a hypothetical model [2,4] of structural synaptic modifications associated with activity-induced alterations of synaptic strength (Fig. 2). According to this model, LTP induction triggers an enlargement of nonperforated PSDs, which is followed by the consecutive formation of perforated

synapses having initially a focal spine partition with a fenestrated PSD (Fig. 2b), then a sectional partition with a horseshoe-shaped PSD (Fig. 2c), and finally a complete partition with a segmented PSD (Fig. 2d). The latter perforated subtype has an exceptionally high level of AMPAR immunoreactivity [7], which likely translates into an unusually strong synaptic conductance relative to that at other axospinous synapses. A high number of AMPARs at segmented synapses may be necessary for mediating the maximal level of synaptic responses characteristic of certain forms of synaptic plasticity, such as the early LTP phase. The subsequent enduring retention of a relatively lower level of synaptic enhancement during the late LTP phase, and its return to control levels over time, may involve the conversion of segmented, completely partitioned synapses into nonpartitioned perforated subtypes (Fig. 2e–g) and eventually back into nonperforated synaptic junctions (Fig. 2a). The proposed model helps to explain the large degree of morphological heterogeneity among perforated synapses, and indicates a likely association between activity-dependent synaptic restructuring and enhancements in synaptic strength. It has also been postulated that the perforated synaptic subtypes may be intermediates in the process of synapse splitting and division, but there are no data demonstrating the existence of this process.

### Pathology

Recent observations indicate that learning and memory disturbances during aging are associated with structural changes in perforated synapses that are likely to have a deleterious effect on their function. It has long been known that aging-related impairments of cognitive functions do not affect all aged individuals: some of them have preserved learning and memory capacities even at advanced chronological age. The reason for such pronounced individual differences in mnemonic functions remains unknown. In a study exploring this problem [10], aged rats were behaviorally tested on a hippocampus-dependent water maze task and separated into groups with impaired or unimpaired spatial learning as compared with young adults. PSD area was estimated in perforated and nonperforated synapses from the stratum radiatum of hippocampal field CA1. The results show that aged learning-impaired rats exhibit a marked (~30%) reduction in perforated PSD area, whereas learning-unimpaired rats do not. This change is highly selective because it does not involve nonperforated PSDs. Given the strong positive correlation between PSD size and AMPAR content among perforated synapses [7], the removal of postsynaptic AMPARs from the PSD may underlie the reduction in PSD area and weaken the efficacy of synaptic transmission. Such a mechanism is also a prime candidate for contributing to the cognitive decline in the subset of aged learning-impaired animals.

## Periamygdaloid Cortex

### Definition

The periamygdaloid cortex is a paleocortical brain region on the medial surface of the amygdala. It belongs to the uncus of the temporal lobe, and has been described as anatomically heterogeneous.

►Olfactory Pathways

## Periaqueductal Gray Matter (PAG)

### Definition

The periaqueductal gray matter is the midbrain area surrounding the cerebral aqueduct (of Sylvius) and consisting of different longitudinal columns that initiate stimulus-specific autonomic and antinociceptive responses to external stressors. The lateral column of the periaqueductal gray initiates flight-or-flight sympathoexcitatory responses associated with opioid-indendependent analgesia. The ventrolateral column elicits hypotension, bradycardia, immobility, and hyporeactivity to the environment, associated with opioid-dependent analgesia.

►Central Regulation of Autonomic Function

## Periaxin

### Definition

Periaxin is a Schwann cell-specific protein of 147 kDa. It is expressed exclusively by myelinating Schwann cells and is predominately localized to their abaxonal surface. Periaxin is a myelin-related protein that undergoes dynamic changes in its localization during ensheathment and myelination.

## Periglomerular Cell in Olfactory Bulb

### Definition

Periglomerular cells constitute one type of intrinsic neurons of the olfactory bulb. Their cell bodies are among the smallest in the brain and surround olfactory glomeruli. They usually give rise to a single dendrite that arborizes within a glomerule, and an axon, that extends laterally in the periglomerular region, as far as five glomeruli. Therefore, periglomerular cells participate in both intraglomerular and interglomerular circuits.

Periglomerular cells are not homogeneous, but occur in several distinct subtypes that differ in connectivity, neurochemical content (expressing GABA, dopamine, calbindin, or calretinin, or combinations of these) and electrophysiological properties. Based on connectivity, they are currently classified as type 1 cells, which receive excitatory input from the olfactory nerve, and type 2 cells, which establish few or no synapses with olfactory nerve axons.

Periglomerular cells are one of the few types of neurons that undergo continuous neurogenesis throughout life.

## Period (Tau, $\tau$) of Circadian Rhythm

### Definition

The time that it takes for the biological oscillator to complete one cycle, to go from start to finish. In the case of circadian oscillators, the period is close to, but not equal to, 24 h. The measurement of period should be made over the course of a number of cycles when the organism is held under conditions of constant dark and fixed temperature. The periods of circadian oscillators are also temperature compensated; that is, the period length does not change in response to alterations in the external temperature. For diurnal organisms, the period is typically longer than 24 h; for nocturnal organisms, however, the period is typically less than 24 h (a finding referred to as Aschoff's rule). The molecular genetic factors responsible for the generation of the circadian period have been the subject of much research.

Although the period length of circadian oscillations is largely determined by these genetic factors, there is also evidence for modest history-dependent regulation of period. The persistence of circadian oscillations under constant conditions and the maintenance of period in the face of temperature changes are fundamental features of circadian oscillators.

►Circadian Rhythm
►Phase Response Curve (PRC)

## Periodic Behavior

### Definition

A rhythmic behavior which can be observed to repeat, and is separated by a regular interval of time between adjacent events.

►Peripheral Feedback and Rhythm Generation

## Periodic Brain Activation

### Definition

Periodic brain activation is associated with the REM state and plays a role in localized recuperative processes and in emotional regulation during sleep.

►Memory and Sleep

## Periodic Limb Movements of Sleep

### Definition

A sleep related movement disorder consisting of repetitive, involuntary limb movements during sleep.

Electromyographic sensors on the limbs reveal trains of muscle contractions with characteristic shape, amplitude, frequency, and distribution. The limb movements may be temporally associated with arousals from sleep.

The high association with restless leg syndrome and the same targets of therapy suggest that the two disorders share common mechanisms.

## Peripheral Autonomic (Parasympathetic, Sympathetic) Pathway

### Definition

Pathway consisting of a population of preganglionic neurons and a population of postganglionic neurons transmitting impulses in the autonomic ganglia and to the effector cells. Each pathway is specified by the target cells it innervates, i.e. as muscle vasoconstrictor, cutaneous vasoconstrictor, sudomotor, cardiomotor etc pathway.

►Autonomic Reflexes

## Peripheral Chemoreception in Respiration

### Definition

The major peripheral chemoreceptors are the carotid bodies and the aortic bodies, which convert the hypoxic signals into an increased neural activity to produce reflex responses in the respiratory system. Hypoxic signals from the arterial chemoreceptors are conveyed through the carotid sinus and vagal afferents, which terminate almost exclusively in the nucleus tractus solitarii (NTS) area.The neurons in the NTS project excitatory inputs to the ventral respiratory group (VRG) neurons. Hypoxia initially increases and then slowly decreases ventilation. The initial increase is attributed to stimulation of arterial chemoreceptors and the ensuing slow decline of ventilation is due to the resulting hypocapnia and the central effects of hypoxia.

## Peripheral Feedback and Rhythm Generation

Harold J. Bell
Department of Cell Biology and Anatomy, University of Calgary, Calgary, AB, Canada

### Synonyms

Sensory modulation of central pattern generators; CPGs; Afferent input to rhythm generating networks

### Definition

Rhythmic motor behaviors such as walking, wing beating, chewing and breathing are all governed by networks of one or more neurons, named central pattern generators (CPGs). By definition, the CPG is able to generate and maintain a basic patterned neuronal activity that is absolutely fundamental to producing the behavior which it governs. However, an animal's behavior must take into account conditions or changes in the environment such that the behavior remains relevant and appropriate. Behavior is kept relevant and appropriate by integrating sensory feedback into the rhythm generation process. Sensory feedback is a general term which refers to neural signals transduced through a wide variety of sensory modalities (chemoreception, mechanoreception (►Mechanoreceptor), etc.). Peripheral feedback specifically refers to sensory feedback that is transduced outside of the central nervous system, and provides the CPG network with neural signals encoding information relevant to behavior. Thus, peripheral feedback is intimately related to and is an important component of the process of rhythm generation.

### Characteristics

#### Rhythm Generation and Behavior

Repetitive motor acts are involved in a seemingly endless number of behaviors across animal species: walking, crawling, flying, swimming, feeding and breathing are all excellent examples. Because of the complex and repetitive nature of the motor acts involved in coordinating these behaviors, networks of neurons have evolved that are extremely efficient at generating the basic timing and pattern of motor neuron discharge that underlie them, in a highly reproducible fashion. These networks of neurons are almost exclusively located in ganglia or the nuclei of brains within intricate central nervous systems, and therefore are commonly called central pattern generators (CPGs).

By definition, a CPG network is capable of spontaneously generating a rhythmic activity that is sufficient for eliciting the motor behavior that it governs, even in the absence of other synaptic inputs.

CPGs have been studied in considerable depth for a number of behaviors observed across numerous species [1]. Given the diversity of behaviors and therefore the CPGs that govern them, it is difficult to suggest that any one specific behavior or CPG is typical of all others. Nevertheless, this diversity also means it is advantageous to focus upon a specific behavior in order to discuss how CPGs can be modulated by peripheral feedback. For this reason we shall focus our discussion upon breathing behavior, and the respiratory rhythm generator that drives this behavior.

#### Respiratory Rhythm

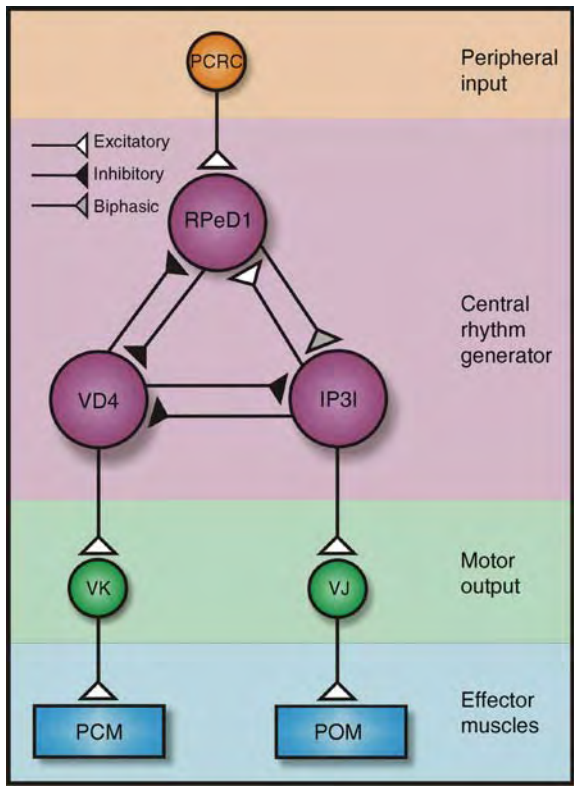
Breathing is perhaps the quintessential example of a rhythmic behavior, as it is essential to the survival of countless animal species from insects, to fish, to mammals. Breathing is a homeostatic motor behavior, which allows the animal to obtain oxygen from, and eliminate carbon dioxide into the external environment. Across *Animalia* many breathing patterns, from regular periodic rhythms (►Periodic behavior), to episodic patterns (►Episodic behavior) can be found, and even within some species these patterns are labile. As a motor behavior, breathing requires the coordinated activation of respiratory pump muscles. The CPGs controlling breathing in most animals are very complicated, and so in most cases very little is known about the detailed synaptic connectivity and neurons involved in respiratory rhythm generation. Indeed, if one considers the extent of behaviors and therefore related CPGs present in the animal kingdom, relatively few examples are available of fully described networks.

Invertebrate model systems have been fundamental in advancing our understanding of nearly every aspect of modern neuroscience, and in no field has this been more so than in the study of central rhythm generation.

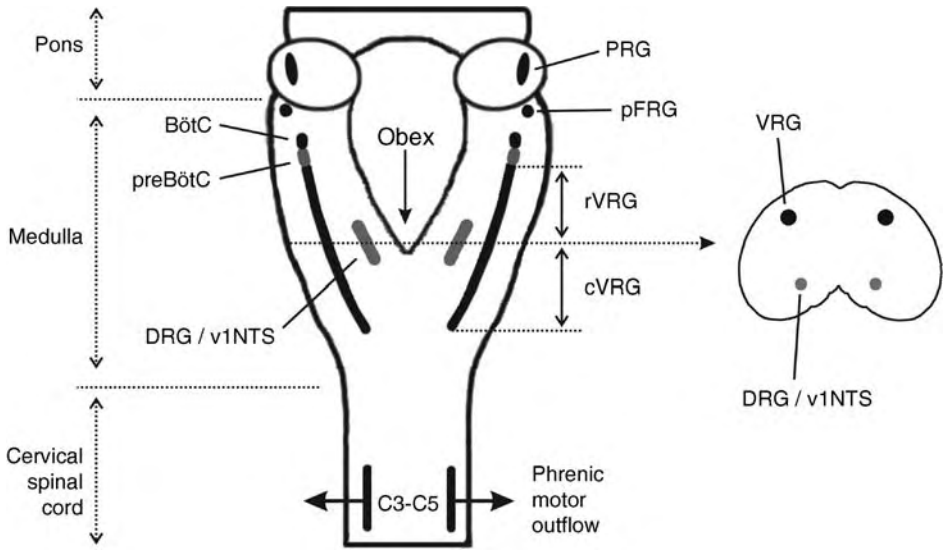
Presently, fully described CPG networks are limited to those identified in invertebrate species. This is because the central neurons of invertebrates exist within ganglia, and many are readily identifiable based upon location and morphology, making it possible to study an individual cell involved in a particular behavior across multiple animals of the same species. Therefore invertebrates are especially amenable to the study of rhythm generation since networks can be mapped from identified cells. One model system wherein the essential central neuronal components of the respiratory CPG have been identified is the pulmonate freshwater mollusk *Lymnaea stagnalis* [2]. *Lymnaea* are aquatic air breathers, and their breathing is a hypoxia-dependent behavior. *Lymnaea* breathe through coordinated motor output to the muscles of the mantle cavity and pneumostome. Contraction of muscles in the mantle cavity and pneumostome opening muscles allow stale air to be expelled from and fresh air to subsequently be drawn into the animal's rudimentary lung. The core of the CPG controlling this behavior consists of three identified cells which have been studied both *in vivo* and *in vitro* (see Fig. 1).

By contrast, in mammals the respiratory central pattern generator is comparatively complex, and for good reason; respiratory control also needs to accommodate other related behaviors aside from breathing such as feeding, sniffing, licking, and vocalization. Not surprisingly, the intricacy of the mammalian central nervous system has made it rather difficult to characterize the respiratory CPG. Impressive progress has been made however, and central respiratory-related neuronal populations are known to be distributed bilaterally throughout a number of nuclei in the medulla and pons (see Fig. 2). Species differences aside, the mammalian CPG controlling breathing behavior is the topic of great controversy and active research [3]. Regardless of this complexity, breathing remains a motor behavior involving the rhythmic activation of respiratory pump muscles enabling lung ventilation.

Inspiratory muscles, mainly the diaphragm and external intercostal muscles, act to increase thoracic volume and draw atmospheric air into the lungs. Expiration is normally a passive process of elastic recoil during resting breathing, however expiratory muscles are required for forceful expiration at higher levels of ventilation, and these muscles are mainly the abdominal muscles and the internal intercostal muscles. During resting breathing, the most important respiratory muscle by far is the diaphragm, which contracts during inspiration and is controlled by motor innervation via the phrenic nerve. Characterization of respiratory neurons in the medulla has therefore been accomplished by describing their activity in relation to phrenic nerve activity. If the rhythmic activity of a central neuron has the same period as phrenic activity, then the cell can be designated a respiratory neuron. Further characterization takes into account the phase relationship between the cell and phrenic activity (see Fig. 3). For example a respiratory neuron that fires bursts of action potentials in sync with phrenic activity is called an inspiratory neuron. Conversely, a cell that fires during phrenic quiescence, it is called an expiratory neuron. More specific classification takes into account more specific phases of the respiratory cycle (e.g. pre-inspiratory, late expiratory), and the pattern of discharge of the neuron during its period of activity (e.g. augmenting, decrementing, or constant), and



**Peripheral Feedback and Rhythm Generation.**
**Figure 1** A schematic representation of the only fully described respiratory CPG; that identified in the pulmonate freshwater snail, *Lymnaea stagnalis*. This respiratory CPG is composed of three interneurons, which have been identified and named as follows: right pedal dorsal 1 (RPeD1), visceral dorsal 4 (VD4), and the "input 3" interneuron IP3I. The opening and closing of the respiratory orifice, the pneumostome, is accomplished through patterned activity of motor neurons controlling pneumostome opening muscles (POM) and pneumostome closing muscles (PCM). Note that the central rhythm generating neuron RPeD1 receives an excitatory chemical synaptic input from oxygen-sensitive peripheral ▶chemoreceptor cells (PCRCs) located in the periphery, which act to initiate and subsequently regulate the activity of this rhythm generator network. As such, peripheral inputs to the CPG are an important component of the rhythm generation process.



**Peripheral Feedback and Rhythm Generation. Figure 2** A schematic representation of those brainstem regions known to contain respiratory neurons in mammals, along with their approximate anatomical locations. Shown, is a schematic view of the brainstem from the dorsal coronal perspective, with a transverse section at the level of the obex. In contrast to the respiratory CPG of *Lymnaea* (shown in Fig. 1), the rhythmic motor output to respiratory muscles in mammals is generated by a complex network of many neurons bi-laterally distributed throughout several regions of the pons and medulla. Relevant neuronal populations are represented as follows: *PRG*, pontine respiratory group; *pFRG*, parafacial respiratory group; *BötC*, Bötzinger complex; *preBötC*, pre Bötzinger complex; *DRG*, dorsal respiratory group; *cVRG*, caudal ventral respiratory group; *rVRG*, rostral ventral respiratory group; *vlNTS*, ventrolateral nucleus tractus solitarii.

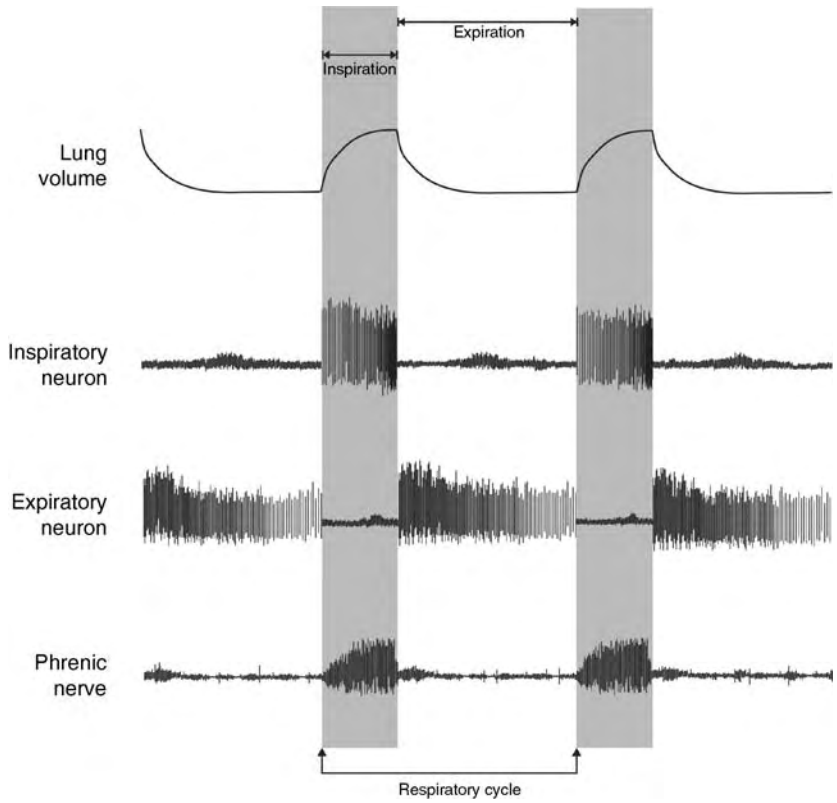
these characteristics are used to functionally differentiate respiratory neurons from one another [4].

Of the populations of neurons in the medulla that have been classified as respiratory neurons, it has long been debated as to which of these were actually involved in generating the base rhythm, and could therefore be designated, "the CPG." Two groups of neurons in the brainstem have been identified that are presently believed to be essential to the generation of a basic respiratory rhythm: (i) A region of the ventrolateral medulla named the preBötzinger complex (PreBÖT), and (ii) a region of the medulla ventrolateral to the facial nucleus near the ventral surface, named the parafacial respiratory group (pFRG). While the precise role of these two neuronal populations in respiratory rhythm generation remains the focus of much ongoing research, it has recently been proposed they may form a coupled network oscillator, with the former responsible for generating inspiration, and the latter generating active expiration phases of the respiratory cycle.

## The Role of Peripheral Feedback in Respiratory Rhythm

It has been widely accepted since the early 1960s that while a CPG can independently function to generate a basic rhythmic motor behavior, sensory feedback from the periphery is necessary for modulating the timing and amplitude of events so that this behavior remains relevant to the environmental demands on the animal [5]. In this regard, the respiratory CPG is certainly no different, and several forms of afferent information provide a potent modulating influence over rhythmic output. Input from airway receptors can elicit cough or sneeze airway defense mechanisms. Inputs from ►carotid body chemoreceptors provide a potent drive to ventilation when arterial blood becomes hypoxic, hypercapnic, or acidic. Group III and IV afferents in the skeletal muscle are able to stimulate breathing, and are believed to be important in coupling the cardiovascular and respiratory systems to regulate gas exchange. Stretch receptors in the lungs are important in shaping the respiratory cycle and timing the inspiratory and expiratory phases of the breathing cycle. Cutaneous thermoreceptors can elicit a powerful gasp reflex which has been documented during sudden cold water immersion. In aquatic air breathing mollusk *Lymnaea stagnalis*, mechanosensory input to the respiratory CPG is required to gate the episodic breathing rhythm so that the respiratory orifice only opens at the water surface, and a similar mechanism is likely to exist in other aquatic air breathers.

Clearly there are many different modalities of peripheral ►sensory input which modulate the respiratory CPG, but there are also a range of influences that sensory input can have on the characteristics of the respiratory rhythm. Some inputs typically affect rhythm only very briefly over one respiratory cycle (i.e. cough or sneeze reflexes), while some involve



**Peripheral Feedback and Rhythm Generation. Figure 3** Phase relationships between rhythmic breathing behavior, phrenic nerve activity, and inspiratory and expiratory respiratory neurons in the mammalian brainstem. A neuron which fires during the interval of phrenic activity can be described as an inspiratory neuron, since this neuron is active during the inspiratory phase of rhythmic breathing behavior (i.e. when lung volume is increasing). Conversely, a neuron which selectively fires during phrenic quiescence can be designated a expiratory neuron since it is active during the expiratory phase of rhythmic breathing behavior (i.e. when lung volume decreases). Further characterization takes into account the firing pattern of the respiratory neuron during its period of activity (e.g. augmenting, decrementing or constant firing frequency), and the specific phase of the inspiratory or expiratory cycle in which it is active (e.g. early or late).

shaping the rhythm during each breath cycle (i.e. lung stretch receptors) and others affect the entire respiratory cycle over the course of many breaths (carotid body chemoreceptors).

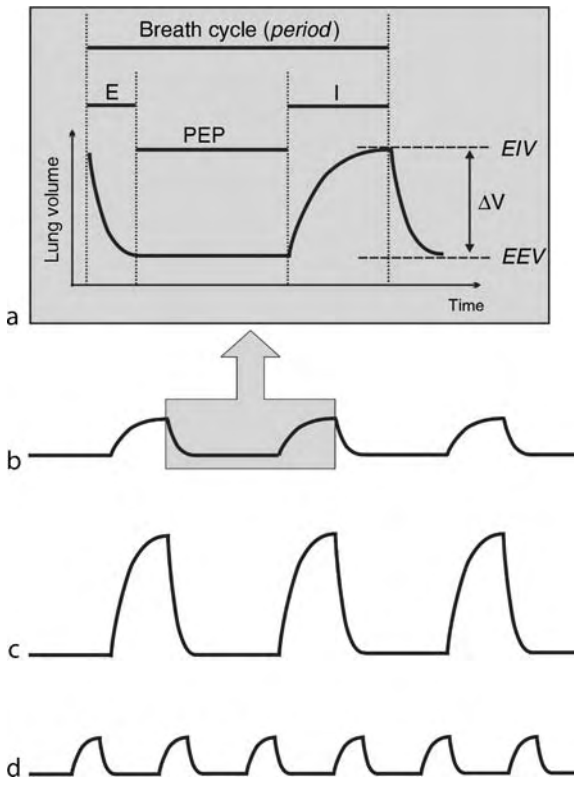
## Mechanisms of Peripheral Modulation of Respiratory Rhythm

As we have seen, peripheral feedback is involved in modulating respiratory rhythm such that breathing can be matched to the needs of the organism. Whether this is a sustained respiratory drive as occurs during exercise, or a transient effect as occurs during protective airway reflexes, the respiratory rhythm is open to modulation from afferent input.

The main characteristics of respiratory rhythm that can be modulated are breathing frequency, or the number or breathing cycles per unit time, and the amplitude of the motor act, or breath size. These features of the breath cycle are shown in more detail in Fig. 4. Since the pathways and putative mechanisms of modulation of breathing rhythm depend greatly upon the input signal, we will examine one select example at greater depth.

## Carotid Body Chemoreceptor Inputs

The mammalian carotid body chemoreceptors are arterial chemosensory organs that increase breathing in conditions of ►hypoxia, hypercapnia, or acidosis. Increased chemoreceptor stimulation causes an increase in afferent output that can be measured in the carotid sinus nerve which innervates the organ. Carotid body afferent inputs to the brainstem are first conducted via neurons located mainly within the petrosal ganglion, subsequently via afferent fibers in the glossopharyngeal ($IX^{th}$ cranial) nerve. The ►carotid body chemoreceptor inputs (►Chemosensory input) affect respiratory rhythm as follows: Afferent input resulting from either carotid body stimulation or direct stimulation of the carotid sinus nerve elicits a decrease in inspiratory duration leading to an increase in breathing frequency, and an increase in the amplitude of integrated phrenic



**Peripheral Feedback and Rhythm Generation.**
**Figure 4** A diagrammatic representation of those aspects of the breathing cycle which are dictated by final output of the respiratory rhythm generator. (a) an expanded view of one cycle of rhythmic breathing behavior, as shown in (b). The change in lung volume during the breath cycle (ΔV) can be altered by changing the end-inspiratory volume (EIV) or the end-expiratory volume (EEV). In addition, the durations of inspiration (I), expiration (E), and the post-expiratory pause (PEP) can be altered so as to change the period of the breath cycle. Lung ventilation can be increased by augmenting ΔV (as shown in (c) or by decreasing the period of the breath cycle (as shown in (d), or any combination of the two. Peripheral inputs modulate respiratory rhythm and therefore aspects of the breath cycle, as shown in (a), such that rhythmic breathing behavior remains relevant to the needs of the animal.

whole nerve activity. Simply stated, carotid input to the respiratory CPG leads to an increase in ventilation through increasing breathing rate and breath size.

The central respiratory pathways involved in this response have been studied in some further detail. Within the brainstem, most of the sensory afferents from the carotid sinus nerve show arborizations within the nucleus of the solitary tract, or nucleus tractus solitarii (NTS), specifically an area of the commissural subnucleus of the NTS including what has been named the dorsal respiratory group (DRG) [6]. The synaptic connectivity and therefore the mechanisms of influence of carotid sensory afferents are not well described beyond this level of the medullary respiratory network. However, carotid sensory afferents are known to release glutamate in the NTS which is believed to be primarily responsible for the increase in breathing via its action on NMDA receptors at this site. The involvement of multiple neurotransmitters and neuromodulators is likely, though specific details remain a topic of ongoing study.

The overt effects of activation of carotid afferents terminating in the NTS upon rhythm generation have been further documented at the level of respiratory neuronal populations in the medulla including those neurons of the Pre-BÖT complex believed to be an important component of the respiratory CPG. Unilateral activation of carotid afferents terminating in the NTS elicits bi-lateral changes in the rhythmic activity of inspiratory driver neurons in the rostroventrolateral medulla; these inspiratory neurons are inhibited and therefore their firing duration is decreased. Afferent stimulation also has the effect of concurrently exciting pre-motor inspiratory neurons in the caudal ventral respiratory group and in the DRG, increasing the drive to phrenic motoneurons [7].

### *Kinetics of Neuromodulation of Respiratory Rhythm*

The activation of carotid afferents is able to elicit changes in respiratory rhythm, which take only a couple of respiratory cycles to achieve their maximal effect ($\tau \sim 10$ s in cats). The removal of carotid input results in a return to baseline rhythmic activity that has a slightly longer time course ($\tau \sim 45$ s, again in cats). This apparent "inertia" in the respiratory rhythm generator, which has been called "short term potentiation" (STP) [8] has been well documented, yet the mechanisms involved are not well understood. Slower onset, longer-lasting alterations in respiratory rhythm have also been documented, that can persist long after the input stimulus has returned to baseline levels. This phenomenon, called long term facilitation (LTF), results in augmented respiratory rhythm lasting for more than one hour after removal of peripheral input to the CPG. One particular stimulus that is capable of eliciting LTF is ►intermittent hypoxia, as sensed by the carotid body chemoreceptors. After repeated hypoxic episodes (for example 3 × 5 min episodes, separated by 5 min of normoxia), both the frequency and amplitude of phrenic nerve discharge has been documented to remain augmented for hours post-stimulus [9]. This phenomenon has now been documented to various extents in multiple animals in different degrees of reduction, including rats, cats and rabbits. While the phenomenon has proven less robust in some cases than others, LTF in respiratory rhythm is nevertheless a fascinating example of how afferent input can modulate rhythm generation via a CPG, even long after the afferent signal has been removed.

**Summary**

As we have seen, breathing is an excellent example of a rhythmic behavior that is governed by a central network of neurons. This network in mammals resides in the ponto-medullary brainstem, and receives peripheral inputs from many modalities that are capable of modulating the depth and rate of breathing. While the pathways and mechanisms by which the respiratory CPG is influenced by sensory afferents are specific to this system, it nevertheless illustrates the importance of peripheral feedback in the process of rhythm generation. This is a general neurophysiological principle that applies equally to most rhythmic behaviors across *Animalia*: afferent feedback is essential for ensuring that rhythm generation via CPG networks remains appropriate to the environmental demands on the organism.

# Peripheral Nerve Regeneration and Nerve Repair

Rajiv Midha
Division of Neurosurgery, Department of Clinical Neurosciences, University of Calgary, AB, Canada

## Synonyms

Axonal regeneration

## Definition

►Nerve regeneration is the process of axonal regrowth within peripheral nerve following injury. Basic science and clinical studies underscore both the possibilities and failure of spontaneous axonal regeneration after peripheral nerve injuries. Historical and current methods of nerve repair at the tissue level take advantage of the natural tendency of peripheral axons to grow when provided with a suitable (micro)environment. New and emerging nerve repair strategies, building on key discoveries at the cellular and molecular, have the potential to further significantly improve the outcome from the repair of nerve injuries.

## Characteristics

### Nerve Regeneration Outcomes and Challenges

Peripheral nerves have the potential to regenerate axons and reinnervate end-organs, with resulting good functional recovery. Indeed, this is the case with all minor nerve injuries, such as neuropraxia, where the axon remains intact, and most purely axontemetic injuries, where axons are interrupted but the degree of internal damage is minimal. In the latter circumstance, regenerating axons use their existing ►endoneurial pathways to specifically reinnervate their own precise target end-organs, as confirmed in recent experiments using bioengineered fluorescent mice [1].

Outcome following more severe peripheral nerve injury (PNI) however remains variable and often very poor. At least three important factors contribute to the relatively poor outcome. The first challenge is the pathology at the tissue level. The majority of clinical PNI exhibit both a loss of axon continuity and a significant disruption in the internal connective tissue structures. The resulting scarring within the nerve or a frank gap (with lacerating injuries) presents a formidable barrier to regenerating axons, preventing them from effectively innervating the distal nerve stump. These are currently managed with a repair of the divided nerve or, for the usual scenario of longer gaps or scar segments that need to be resected, placement of interposed nerve grafts. Direct nerve or nerve graft repair unfortunately do not obviate the misdirection of axons. This

introduces the second biological challenge, which is at the cellular level. Even with the most meticulous repair, the endoneurial tubes can never be reapproximated exactly and this results in mismatching of regenerating axons at the site of suture, or within the graft, leading to inappropriate (non-specific) reinnervation and subsequent poor recovery in function. The third challenge may be considered as a quantitative one, which is associated with chronic denervation (►Chronic nerve denervation) of the distal nerve. Chronic denervation is common because of the often extensive injury zone that prevents any axonal outgrowth or (even if outgrowth occurs) the relatively slow rate of regeneration. As a consequence, the distal nerve segment remains chronically devoid of regrowing axons. The resulting prolonged denervation of Schwann cells (SCs) appears to a critical factor which makes them unreceptive for axonal regeneration, and is the single most important quantitative contributor to poor end-organ reinnervation [2].

## Spontaneous Axonal Regeneration After Nerve Injuries

The details of the basic processes involved in nerve degeneration and early regeneration are outlined in detail elsewhere in this Encyclopedic Series (see the contribution by Doug Zochodne). Herein, I will summarize some key concepts, with a more detailed focus on the critical role played by the denervated nerve, distal to the nerve injury.

The injury to an axon is associated with a plethora of changes in the neuronal cell body that shift its phenotype from a neuron involved in maintenance/neurotransmission, to a regenerating one, with a corresponding up-regulation of ►regeneration associated genes (RAGs). Regeneration from neurons requires severed axons to redeem their original axoplasmic volume by extending their processes distally. New axons sprout from one or two internodes proximal to an injury zone. These spontaneously sprouting daughter axons, supported by SCs, and surrounded by a common basal lamina tube are termed a "regenerating unit." Therefore in regeneration, the number of neurons does not increase, but rather surviving neurons regenerate their cellular processes in concert with their surrounding microenvironment. Key components of the microenvironment involve a very close and intimate relationship between regrowing axons, and the supporting glial SCs, which must both proliferate and migrate [3]. Indeed, the initial stages of axonal regeneration are highly dependent on SCs which lead the regrowing axons across the nerve injury site.

Severance of a peripheral nerve results in ►Wallerian degeneration in all axons distal to the injury site, evidenced by the disintegration of axoplasmic microtubules and neurofilaments. The majority of axons along the distal stumps of transected nerves are reduced to granular and amorphous debris within 24 h; by 48 h, the myelin sheath has begun to transform into short segments that then form into ovoids. Activated macrophages invade the degenerating distal nerve stump and phagocytose the disintegrating nerve fibers and myelin. There is an accompanying proliferation of the acutely denervated SCs, which now alter their gene expression, and change phenotypically from myelinating to growth supportive [4].

As axons from the proximal nerve stump arrive in the nerve distal to original injury, SCs and basal lamina tubes are reinnervated and thereby supported, which in turn, provides an excellent trophic and cell-adhesive environment for further axonal regeneration [5]. Regenerating axons, when contacting SCs, release neuregulins from their growth cones which bind to erbB receptors on the SCs to mediate a second phase of SC proliferation. SCs secrete chemoattractive factors, including cytokines such as interleukin-1β, leukemia inhibitory factor and monocyte chemoattractant protein-1, that recruit macrophages into the denervated nerve stumps [5]. Cytokines, derived from both the SCs as well as the macrophages that enter the nerve, drive the expression of the non-myelinating, dedifferentiated "denervated" phenotype of the SCs which proliferate, form the ►bands of Bungner (SC lined basal lamina tubes) and guide regenerating axons within the distal nerve stump [4]. The switch in SC phenotype is associated with up-regulation of several growth associated genes including several neurotrophic factors, p75 NTR, glial fibrillary acidic protein, GAP-43, netrin-1 and the transcription factor, Krox-24, which all support axonal regeneration [5]. In summary, the capacity of the denervated distal nerve to support axonal regeneration depends on proliferating acutely denervated SCs within the basal lamina tube which are essential for guiding regenerating axons to the end-organs.

## Repairing Nerve Injury Gaps: Nerve Grafts, Electrical Stimulation and Nerve Conduits

The majority of clinical PNI leave the nerve grossly intact, but nevertheless exhibit loss of axon continuity and a severe disruption in the internal connective tissue structures. Scarring within the nerve presents a barrier to regenerating axons. Nerve repair requires resection of the scarred segment and repair of the resulting lengthy nerve gap, usually with a nerve graft, typically procured from another area of the patient's own body (nerve autograft). The nerve graft contains surviving SCs and basal lamina endoneurial tubes, which provide neurotrophic support, as well as favorable cell and endoneurial tube surface adhesion molecules to regenerating axons [5]. Nerve grafts therefore provide a seemingly optimal tissue bridge that regenerating axons from the proximal nerve stump exploit to innervate the distal stump. With the advent of the operating microscope and microsurgical techniques, Millesi improved clinical results and

popularized the use of nerve autografts. The outcomes, associated with using nerve grafts, are best for nerves which are primarily innervating one or a few discrete motor or sensory targets, and especially where the repair is close to the target end-organ. For the more proximal injuries, ones requiring lengthy grafts and ones involving nerve elements which innervate a variety of motor and sensory targets, the outcomes remain poor. Moreover, results of microsurgical repair, which is essentially at the tissue level, have reached a plateau over the last few decades.

A major shortcoming with the nerve graft technique is the biological constraint, which cannot be overcome by further progress in microsurgical techniques. Even with the most meticulous repair, regenerating axons at the site of suture, or within the graft, get misdirected or lost, leading to inappropriate (non-specific) and incomplete reinnervation, respectively. Innovative recent investigations with nanoscale engineered devices suggest that some day surgery at the cellular level to splice and repair individual axons may be feasible. Recent insights into the nuances of axonal regeneration however provide potential for some new therapies that are even readily accessible soon. We now understand that axonal outgrowth is not synchronous, but rather staggered, so that some pioneering axons grow out early, while others lag far behind. In fact, many of the lagging axons get delayed at suture repair sites, which in the case of a nerve graft are compounded, involving two separate repair locations. Emerging evidence also suggests that pioneering motor axons, for example, may prefer to associate with corresponding "motor" SCs, based on their surface-specific basement membrane molecules. These pioneering axons may start the process, and they together with their migrating SCs facilitate similar axons to follow by offering these cues as required. Studies by Brushart and colleagues show that motor axons particularly may be biased in their selection of distal targets, preferring phenotypically appropriate rather than inappropriate endoneurial pathways in the distal nerve, so that ultimately some ►preferential motor reinnervation (PMR) is exhibited [6]. Exciting recent work by Gordon and Brushart suggests that epochs of electrical stimulation as short as one hour have a significant influence not only on synchronizing the initial re-growth of motor axons, but also on possibly enhancing PMR. Clinical trials to assess the utility of short duration electrical stimulation on improving the outcome of nerve repair are therefore warranted.

In an attempt to provide a more suitable environment for regenerating axons to sample and respond to appropriate *endogenous* directional cues, many investigators have proposed using an artificial (non-nerve) conduit interposed between the proximal and distal nerve stumps. Moreover, a bioengineered graft may allow the introduction of *exogenous* therapies that build on our rapidly expanding knowledge of axonal guidance. Axons are guided to their targets by growth cones, specialized structures at the tip of axons, that respond to the coordinated action of many contact-mediated cues provided directly or indirectly by SCs and diffusible cues, which are either attractive or repulsive. A short list of candidate molecules to consider include the classical neurotrophins, neuropoietic cytokines (including CNTF, IL-6, oncostatin, and LIF), other neurotrophic factors (including insulin, IGF-1 and GDNF), cell adhesion molecules (including NCAM, L1 and N-cadherin), and extracellular matrix proteins (including laminin, tenascin C, fibronectin and heparan sulfate proteoglycan) [5]. By exogenously providing the most appropriate or suitable cues, we may be able to profoundly influence axonal regeneration within the nerve conduit. The clinical utility of such a strategy is apparent when considering the example of repair of nerves to the hand, where the median nerve is paramount for sensation whereas the ulnar nerve is critical for discrete motor function of the digits. In these instances, the conduit repair can be endowed with specific growth factors or other molecules that will bias the regeneration towards a population of axons (motor vs. sensory) to achieve improved specificity of reinnervation. Artificial nerve conduits or tubes are already proven and in clinical use for short injury gaps of 3 cm or less in humans. Advances in bioengineering, coupled with our understanding of how to effectively deliver growth factors, cell adhesion molecules and other therapies within the artificial nerve graft, should lead to major advances in improving both the quantity and specificity of axonal regeneration through the nerve conduit [7].

## Deleterious Changes Associated with Chronic Nerve Denervation

So far, the therapies considered in this essay have focused on the repair of the nerve injury site or nerve injury gap. We now turn our attention to the critical distal nerve environment. Denervated SCs initially up-regulate neural cell adhesion molecule and basement membrane components (including laminin), which are used for attachment and growth of the regenerating axons. A growth supportive environment of the distal nerve is unfortunately not maintained unless axonal contact is re-established. Progressive regression of the capacity of the denervated SCs to sustain their growth permissive phenotype [8] and the progressive decline in numbers of SCs in the chronically denervated distal nerve stumps underlie the loss of capacity to support axonal regeneration [9]. Deleterious changes that affect axonal growth become increasingly pronounced over time, and are coupled with a progressive decline in the number of reinnervated motor units after chronic denervation [2]. In recent experiments, we have demonstrated that immediate innervation of the distal nerve, as

compared to chronic denervation, greatly improves subsequent re-innervation, confirming that the failure in regeneration is related to the profound changes in the distal stump from chronic denervation. A critical component of this unreceptive environment in the distal nerve is the chronically denervated SC whose growth support properties appears to be "turned off" [5].

The above biological issue is very clinically relevant as delayed nerve repairs occur frequently in clinical practice. The reason this occurs is because the majority of nerve injuries leave the nerve in physical continuity with an often unknown propensity to spontaneously recover, a process which unfolds over several weeks to months. Hence, most patients undergo appropriate surgical exploration several months after injury and receive a delayed nerve repair. Even patients who have immediate nerve repair are subject to distal nerve denervation for considerable periods as the rate of regeneration is relatively slow (~1 mm/day in humans), and, given that nerve injuries are far from their end-organs, the distances that regenerating nerve fiber need to grow very long. Hence, almost all severe human nerve injuries creates a situation in which the SCs of the distal nerve are chronically denervated [5].

## Therapies to Counteract Chronic Distal Nerve Denervation

Fortunately, the clinical paradigm of ►nerve transfers has emerged a powerful means of bypassing the long zone of chronically denervated nerve. Nerve transfers essentially involve the repair of a distal denervated nerve element using a proximal foreign nerve as the donor of neurons and their axons which will reinnervate the distal targets. The concept initially arose to sacrifice the function of a donor (lesser valued) nerve/muscle to revive function in the recipient nerve and muscle that will undergo reinnervation. Nerve transfers have become increasingly utilized for the repair of brachial plexus injuries, especially where the proximal motor source of the denervated element is absent because of avulsion from the spinal cord. Increasingly advocated are the use of transfers in situations where the proximal motor source is available, but the regeneration distance is so long that the outcome would be poor. A nerve transfer into the denervated distal nerve stump, but deliberately chosen so as to be very close to the motor end-organ, would then restore greater function as compared to a very proximal nerve graft repair.

Biological means of protecting the distal denervated nerve are emerging. One strategy is the exogenous use of cytokines (such as TGF-β), normally produced during Wallerian degeneration, to counteract the deleterious effects of chronic denervation and to maintain the growth-promoting denervated SC. In a recent experiment, chronically denervated SCs, exposed to TGF-β and forskolin, when infused into a nerve regeneration chamber, dramatically increased the number, size and myelination of regenerating axons, as compared to SCs without pre-treatment. Other research laboratories are exploring gene therapy approaches, using lentiviruses or other vectors to augment or resurrect the repertoire of regeneration associated molecules expressed by the denervated SC.

Since chronically denervated SCs appear to become effete, another logical approach is to support the distal denervated nerve environment by replacing lost cells with those derived exogenously. SC infusion has been successful in promoting regeneration and remyelination of the injured peripheral nerve. However, human SCs must be derived from invasive nerve biopsies and have a limited, lengthy expansion *in vitro*. It is thus desirable to identify a more accessible source of SCs for transplant therapies. Bone marrow stromal cells, adipose tissue derived stem cells and skin derived precursor stem cells have all been shown to generate functional SCs that can be used for transplantation in nerves [10]. When stem cells derived from skin were transplanted into artificial nerve guidance tubes bridging a 16-mm gap in rodent sciatic nerve, there was promising improvement in behavioral, electrophysiological, and morphometric parameters measured over vehicle control. It is therefore conceivable that skin derived SCs may be very useful in models of chronic nerve injury, either by infusing them into a chronically denervated distal nerve or perhaps immediately after injury as a protective treatment in an attempt to avoid distal changes associated with chronic injury. If experimental studies prove benefit, we anticipate that nerve repair in the future in patients will be augmented by the use of their own (autologous and cultured) skin-derived SCs, easily procured, via relatively non-invasive skin graft harvesting.

## Conclusion

Our basic understanding of nerve and axonal regeneration has increased tremendously over the last century, with corresponding gains in our ability to repair clinical nerve injuries. We can already overcome the challenge associated with lacerating nerve injuries and severe nerve injuries in continuity with precise repairs at a tissue level using microsurgical techniques, nerve grafts and short length artificial nerve conduits. We are on the verge of the next (cellular) generation of nerve repair using modalities such as specific molecular therapy, electrical stimulation, and bioengineered and micro fabricated devices. These approaches promise to allow improved synchronization of axonal regeneration and more exact specificity of reinnervation, While distal targeted nerve transfers have already had a clinical impact, in the near future gene and (stem) cell therapy approaches to augment and resurrect the distal denervated nerve environment are anticipated.

# Peripheral Nervous System (PNS)

## Definition

Peripheral Nervous System (PNS) is part of the vertebrate nervous system comprised of the nerves outside of the central nervous system and including cranial, spinal nerves and sympathetic and parasympathetic systems.

# Peripheral Neurons

## Definition

Motor, sensory and autonomic neurons with axons that connect the body to the central nervous system (brain, spinal cord).

►Peripheral Nervous System

# Peripheral Neuropathies

## Definition

Peripheral neuropathies are diseases of peripheral nerves and can occur in acute and chronic forms. Often motor and sensory fibers are afflicted together. Motor symptoms include muscle weakness and depression or loss of tendon reflexes. Sensory symptoms vary and may include ►paresthesias such as numbness, pins-and-needles sensations, tingling, impaired cutaneous pain and temperature sensations (with risk of injuries), varied impairment of cutaneous mechanical sensation and ►proprioception. Often, peripheral body parts are involved most strongly, leading to the so-called glove-and-stocking pattern. There is a specific form of ►large-fiber sensory neuropathy.

►Tendon reflex

# Peripheral Oscillator

Achim Kramer
Laboratory of Chronobiology, Charité Universitätsmediain Berlin, Berlin, Germany

## Synonyms

Peripheral clock

## Definition

The term "peripheral oscillator" refers to a circadian oscillator, which is located in cells, tissues or organs outside of the suprachiasmatic nucleus (the site of the master oscillator in mammals).

## Characteristics

### Properties

In mammals, the circadian system is organized in a hierarchical manner. In addition to the ►master clock in the ►suprachiasmatic nucleus (►SCN), peripheral tissues (such as liver, kidney, heart, skeletal muscle etc.), some extra-SCN neuronal tissues (such as the olfactory bulb) as well as even some immortalized cell lines (e.g. rat-1 and NIH3T3 fibroblasts [1]) exhibit circadian gene expression. The molecular mechanism of these ►oscillations is similar to that in the SCN [2].

Peripheral oscillators are cell-autonomous and ►self-sustained, but – in contrast to ►cellular clocks in SCN neurons – probably not synchronized within a tissue. Therefore, explants of peripheral tissues display

damped oscillations on the tissue-level *ex vivo* with self-sustained, but gradually desynchronizing individual ►cellular oscillators [3].

*In vivo*, peripheral oscillations ►phase-lag the rhythms in the SCN by several hours and are dominated by the circadian ►pacemaker in the SCN (master-slave oscillators). For example, embryonic fibroblasts from ►*Period1*-deficient mice (which have an ►endogenous period of 20 h) exhibit wild-type period oscillations when implanted in wild-type mice [4].

## Function

Peripheral oscillators are thought to regulate ►circadian rhythms in local physiology. Genome-wide transcriptional profiling of various peripheral tissues revealed that about 5–10% of all mRNAs show a circadian expression pattern. Interestingly, while rhythmic transcripts expressed in many or all peripheral tissues are rare (they include components of the core oscillator machinery), the majority of oscillating transcripts are either only expressed or only rhythmic in one particular tissue. In the liver, for example, some of these rhythmic genes code for enzymes involved in rate-limiting steps of rhythmic hepatocytic processes suggesting that these rhythms are generated by a local liver oscillator.

Formally, however, it is difficult to decide whether a tissue-specific rhythm is regulated by a peripheral oscillator or driven by rhythmic systemic factors or by a combination thereof. To investigate these possibilities, tissue-specific clock knockout mice have been investigated. In the liver, for example, the majority of rhythmic transcripts are only rhythmic when the liver clock is functioning. A small fraction of transcripts (including *Period2*), however, continue to oscillate without a functional liver clock suggesting that these rhythms are driven by systemic circadian cues [5]. In the ►retina, the local clock seems to be required for a normal physiology of vision. It regulates both the rhythmic expression of genes in a ►light-dark cycle that are not rhythmic in ►constant conditions as well as inner retinal electrical responses to light [6]. In the heart, disruption of the local clock leads to a severely attenuated induction of myocardial fatty acid-responsive genes during fasting [7]. Together, these results indicate that peripheral clocks significantly contribute to important physiological functions *in vivo*.

The circadian expression of genes within a given tissue is often widely distributed among circadian phases. This ensures that within a single cell biochemically incompatible processes are separated in time. Molecularly, different phases of expression can be regulated in various ways: the expression of so-called first-order ►clock-controlled genes is directly regulated by components of the core oscillator. These rhythmic gene products themselves can regulate rhythmic processes further downstream, which may even be tissue-specific. Thereby, a complex hierarchy of rhythmic expression patterns with varying phases may emerge regulating the rhythmic physiology specific for a given tissue.

## Entrainment

While the SCN clock is synchronized to the geophysical time (►entrainment) by light-dark cycles, peripheral cells of mammals are not light-sensitive. Hence, daily ►non-photic resetting cues are required for a correct phase relation among SCN and peripheral tissues. Up to now, the identity of these cues is unknown, although it is likely that many factors contribute to the entrainment of peripheral oscillators. Humoral as well as neuronal signals emanating from the SCN have been suggested to entrain peripheral oscillators. There are neural outputs from the SCN to peripheral organs via the autonomic nervous system, indicating direct (multisynaptic) neural control. Glucocorticoid hormones are prominent candidate factors, since (i) they are able to strongly phase-shift peripheral oscillators both *in vitro* and *in vivo* and (ii) the SCN regulates the rhythmic expression of glucocorticoid hormones *via* the hypothalamic-pituitary-adrenal axis. In addition, several more indirect routes are discussed to be involved in the daily resetting of peripheral oscillators. (i) The SCN directly regulates daily activity-rest cycles and thus also rhythmic food consumption. While feeding time has almost no effect on the SCN clock, peripheral oscillators are strongly influenced by restricted feeding schedules [8]. If food is available only in the inactive phase, the molecular circadian clock in the periphery is completely uncoupled from the SCN and synchronizes to the restricted feeding rhythm (see also: ►food entrainable oscillator). It has therefore been speculated that peripheral clocks sense the metabolic state, which would impinge on the molecular properties of the cellular oscillator and thereby phase-reset the molecular clock [9]. (ii) The circadian clock in the SCN regulates rhythmic fluctuations in core body temperature. These temperature rhythms are sufficient to entrain cultured fibroblasts [10]. Thus, it is conceivable that body temperature rhythms contribute to the entrainment of peripheral oscillators. Together, it seems likely that a variety of pathways are involved in the daily entrainment of peripheral oscillators, and different tissues may require different resetting cues.

## Peripheral Proteins

### Definition

Protein molecules that are anchored to either the cytoplasmic or extracellular side, such as intracellular signaling components, immunoglobulins and structural proteins.

►Membrane Components

## Peripheral Receptor

### Definition

The peripheral receptor is the junction site of peripheral autonomic nerve terminals on target organs. Receptors of sympathetic nerves contain noradrenaline (norepinephrine), except sweat glands, as neurotransmitter. These include adrenergic α and β receptors. Receptors of sweat glands contain acetylcholine as a neurotransmitter. Parasympathetic nerve receptors contain acetylcholine as a transmitter.

►Acetylcholine
►Noradrenaline
►Parasympathetic Pathways
►Sympathetic Pathways

## Peripheral Rhythms

### Definition

Circadian rhythms of molecular, physiological or behavioural parameters, which are generated in cells, tissues or organs outside of the suprachiasmatic nucleus (the site of the master oscillator in mammals).

►Circadian Rhythm
►Clock Coupling Factors
►Suprachiasmatic Nucleus

## Peripheral Sensitization

### Definition

Sensitization of nociceptors for mechanical, thermal and chemical stimuli.

►Hyperalgesia and Allodynia
►Joint Pain

## Peripheral Synapse

### Definition

A synapse that is located outside of the central nervous system. An example of a peripheral synapse is the neuromuscular junction where axons of motoneurons synapse with muscle fibers. Another example is the myenteric plexus of the enteric nervous system.

►Neuromuscular Junction (NMJ)

# Peripheral Vestibular Apparatus

J. David Dickman
Department of Anatomy and Neurobiology,
Washington University, St. Louis, MO, USA

## Definition

The *peripheral vestibular apparatus* detects head motion and position of the head in space relative to gravity. Motion detection and our sense of position in space are determined by receptors of the vestibular system that lie in the inner ear. Although not considered to be a cognitive sense, the vestibular system nonetheless contributes to the fine control of visual gaze, posture, spatial orientation and navigation. Here the peripheral receptor apparatus and its role in motion detection and spatial orientation is discussed.

## Characteristics

### Structure of the Peripheral Vestibular Sensors

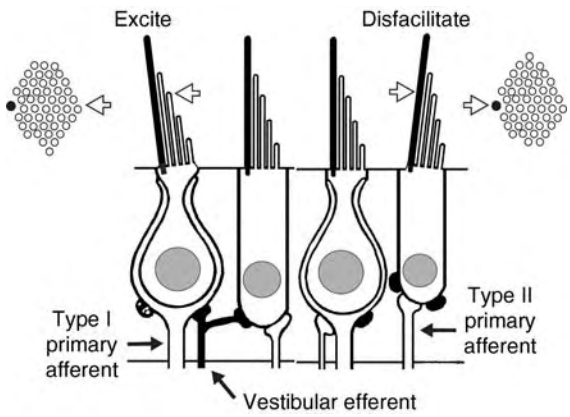
In every day life, two types of motion, rotational and linear are experienced. Orientation relative to gravity is constantly updated. Rotational motion *(angular acceleration)* is experienced during head turns, while *linear acceleration* occurs during walking, falling, leaning and during vehicular travel. *Linear accelerations* are also are experienced during head tilts relative to gravity. Detection of motion and spatial position begins with the vestibular receptors lying in the inner ear. These receptors then send this information to the brain, where it is integrated into a uniform signal regarding direction and speed of motion, as well as the position of the head in space. In the brain, signals from vestibular receptors combine with information from other systems detecting motion such as the muscle proprioceptors and visual receptors. Central processing of these multimodal signals occurs very rapidly to ensure adequate coordination of visual gaze and postural responses (balance), autonomic responses and awareness of spatial orientation.

### Vestibular Labyrinth

The vestibular labyrinth of the inner ear is located in the temporal bone, lateral and posterior to the cochlea. It consists of two parts. The *bony labyrinth* houses and protects the more fragile sensory structures contained inside the *membranous labyrinth*. Five separate receptor structures are represented in the vestibular portion of the membranous labyrinth. These include *three* ►semicircular canals and *two* ►otolith organs. The five vestibular receptor organs on each side of the head complement each other in function. The three semicircular canals, including the horizontal, anterior and posterior canals, lie in three different head planes and respond to rotational head movements [1]. The two otolith organs, including the ►utricle and ►saccule, perceive linear motions of the head (*linear accelerations*) and the orientation of the head relative to gravity [2]. Each of the semicircular canals and otolith organs are spatially aligned so as to be maximally sensitive to movements in specific directions. For example, the horizontal semicircular canal and the utricle both lie in a plane roughly equivalent to that of the head held during normal walking posture. In humans, that plane lies about 30° elevated from the naso-occipital axis. In contrast, the vertical canals and the saccule lie in vertical head planes, nearly orthogonal to the horizontal semicircular canal. Each of the canals on one side of the head works in opposite fashion to their counterparts in the contralateral ear. Together, receptors inside the semicircular canals and otolith organs can respond to head motion in any spatial direction. The membranous labyrinth consists of a series of fluid-filled tubes and sacs where the mechanics of motion detection and transduction occur. Surrounding the membranous labyrinth is a fluid called ►perilymph. It is similar to cerebral spinal fluid and has a high concentration of sodium. Inside the membranous labyrinth, where the vestibular receptors lie is a very different fluid called ►endolymph, which is similar to intracellular fluid, with a high concentration of potassium. Endolymph is important, because it is the high potassium concentration that drives transduction of the motion detection mechanoreceptors. The receptor cells of the vestibular organs are innervated by primary afferent neurons that make up part of the *vestibulocochlear* or *VIIIth cranial nerve*. The somas of these bipolar afferents lie in the vestibular ganglion (Scarpa's ganglion) nestled in the internal *acoustic meatus*, a small shelf-like opening through which axons from the ganglion pass into the ipsilateral brainstem, cerebellum and reticular formation.

### Hair Cells

Motion detection begins with mechanoreceptor cells in the vestibular system called ►hair cells due to the many ►stereocilia that project from the apical portion of the receptor cell. Each hair cell contains 50–100 stereocilia and a single longer ►kinocilium. The stereocilia are oriented in a number of rows of ascending height, where the tallest stereocilia lie next to the kinocilium. There are two types of hair cells that differ in their morphology, afferent terminations and channel currents. Type I hair cells look like chalices (Fig. 1). They are completely surrounded by a unique calyx-shaped afferent terminal [3]. These type I hair cells are characterized by an inward-rectifying potassium current. Type II hair cells are cylindrically shaped and are innervated by simple synaptic boutons from the vestibular afferent fibers. Both types of hair cells exhibit excitatory synapses upon VIIIth nerve afferents, with glutamate or aspartate as the neurotransmitter. Both types of hair



**Peripheral Vestibular Apparatus. Figure 1** Schematic of hair cells. Type I hair cells have a calyx-like form that is encapsulated by a primary afferent. Type II hair cells have a cylindrical form. The hair cell bundles contain a single kinocilium (*black*) and multiple stereocilia (*clear*). The *open arrows* indicate a deflecting force applied to hair cell bundles. To the *left*, the Type I hair cell bundle is deflected in towards the kinocilium, exciting the hair cell, increasing release of transmitter (aspartate or glutamate) and increasing the discharge of the vestibular primary afferent. To the *right*, the Type II hair cell bundle is deflected away from the kinocilium, disfacilitating the hair cell, decreasing release of transmitter and decreasing the discharge of the vestibular primary afferent. Vestibular efferents (*illustrated in black*) synapse on the primary vestibular afferents of Type I hair cells and directly on Type II hair cells.

cells also receive vestibular efferent input (acetylcholine, calcitonin gene-related peptide) from the brainstem, which is believed to be involved in controlling receptor sensitivity.

For each of the semicircular canals, the receptor hair cells lie in a specialized patch of neuroepithelium termed the *crista*. The crista is contained in an enlarged region of the membranous duct termed the ▶ampulla, in the approximate center of the canal. A gelatinous structure, termed the ▶cupula, completely covers the crista and forms a fluid-tight partition across the ampulla. The stereocilia of the hair cells are embedded in the gelatinous cupula. During rotational head movements, endolymph is displaced (lags behind) inside the membranous ducts due to inertia and pushes the cupular partition in a direction opposite to the head turn. In each of the three semicircular canals, the hair cells have a uniform anatomical orientation. In each hair cell the kinocilium and stereocilia have the same spatial polarization. Cupular movement causes the stereocilia and kinocilium to flex towards or away from each other. When the stereocilia bend towards the kinocilium, an excitatory generator potential is produced (see below). When they bend away from the kinocilium, hair cells become less polarized. The anatomical polarization of hair cells within a particular semicircular canal gives rise to the directional selectivity of each vestibular organ.

Linear accelerations are detected by receptor hair cells in the otolith organs, which lie in a specialized neuroepithelium termed the *macula*. The stereocilia of the otolith hair cells extend into a gelatinous coating above the macula that is covered by thousands of calcium carbonate crystals, termed ▶otoconia (Greek for ear stones). The otoconia, being much more dense than the surrounding endolymph are not displaced by normal endolymph movements, but instead are only moved during linear motion or changes in head position relative to gravity (linear accelerations) due to their inertia. These otoconia displacements produce bending of the underlying hair cell stereocilia.

## Mechanoelectric Transduction

Motion detection begins with the receptor hair cells, which are directionally selective to stereocilia displacement. With movements of the stereocilia towards the kinocilium, hair cell membranes are depolarized and the innervating vestibular afferent fibers increase their firing rate. However, if the stereocilia are deflected away from the kinocilium, the hair cell is hyperpolarized and the afferent fibers decrease their firing rate. This works through *mechanoelectric transduction* of specific potassium ($K^+$) channels in the apical portion of the kinocilium [4]. When the stereocilia are deflected toward the kinocilium, small actin filaments open the potassium channels, allowing $K^+$ to enter the hair cell (due to concentration gradients from the endolymph) and depolarize the cell membrane. Through a cascade of events, depolarization leads to synaptic vesicle and neurotransmitter (aspartate or glutamate) release. The transmitter binds with excitatory receptors in the post-synaptic terminal of the vestibular afferent, depolarizing the afferent and increasing its action potential firing rate. When the kinocilium and stereocilia are returned to their normal positions, voltage sensitive potassium channels at the base of the hair cell are allowed to open and release $K^+$, thereby repolarizing the membrane to its resting potential. When the stereocilia are deflected away from the kinocilium, more potassium channels close and further release of $K^+$ through the basolateral potassium channels occurs, resulting in cell hyperpolarization. When the head is stationary, vestibular primary afferent fibers have a high spontaneous firing rate (approximately 90 impulses/s). The high rate allows for bidirectional response of the afferents so that silencing (rectification) of the neural response to most natural head motions does not occur.

## Morphological Polarization of Hair Cells

Since the hair cells are directionally selective, their orientation on the cristae and maculae are important for signaling direction of movement. For example, all

hair cells in the horizontal semicircular canal cristae are arranged similarly, with their kinocilium lying closest to (i.e. pointing toward) the utricle. Horizontal head rotations that produce endolymph movement toward the utricle causes deflections of the stereocilia towards the kinocilium and all of the hair cells in the horizontal semicircular canal are depolarized. Since all hair cells in each of the semicircular canals have the same anatomical orientation, the geometry of the canals determines directional selectivity (Fig. 2a).

The kinocilia of utricular hair cells are oriented towards an imaginary line that runs through the center of the utricular macula. This imaginary line corresponds to a physical structure termed the ►striola, a dense pile of small otoconia on the surface membrane of the macula. (Fig. 2c). On either side of the striola the kinocilium-stereocilia axes are oppositely polarized. The hair cells in the saccular macula have a similar polarization on opposite sides of the striola (Fig. 2b).

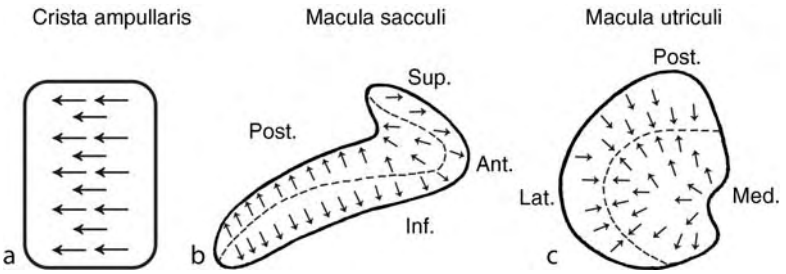
Hair cells in the utricular macula encode linear acceleration in the horizontal plane. Hair cells in the saccular macula encode linear acceleration in the vertical plane. However, since both the saccular and utricular maculae have curved surfaces and since the striola is also curved, linear motions along any direction in three-dimensional space will excite a subpopulation of hair cells.

## Semicircular Canal Function

The membranous semicircular duct consists of a fluid-filled tube with a partition (the cupula) in the middle. When the head is stationary, no rotational acceleration is imparted to the semicircular canals and no endolymph flow occurs. The afferents from the complementary canals on both sides of the head have nearly equivalent firing rates. When the head turns, say about the vertical axis, as in shaking the head to indicate "no," the horizontal semicircular canals turn with it, leaving the endolymph fluid behind (lagging the duct) due to inertial forces and viscous drag between the fluid and the walls of the canals. The relative endolymph movement on one side of the head pushes the cupula partition and produces stereocilia deflection towards the kinocilium, while the endolymph movement on the opposite side causes stereocilia deflection away from the kinocilium. Depending upon the direction (toward/away from the kinocilium) stereocilial deflection elicits either depolarization or hyperpolarization of the hair cell membrane. With a leftward head turn, the stereocilia in the left horizontal semicircular canal will be deflected toward the kinocilium resulting in increased discharge of the left VIIIth nerve afferents. Conversely, the right horizontal canal hair cells will be hyperpolarized, since the stereocilia are deflected away from the kinocilium, producing decreased firing rates in right VIIIth nerve fibers. With a rightward head turn, the opposite activation pattern in the hair cells and afferents will be produced.

This functional coupling of the two horizontal semicircular canals also applies to pairs of vertical semicircular canals. For example, the left posterior semicircular canal lies in roughly the same plane as the right anterior semicircular canal. When the head is moved in an angle of about 45° off an imaginary sagittal plane through the head, the discharge from afferents of one of these vertical canals increases and the discharge from the other decreases.

Neural information carried on vestibular afferent fibers from both the left and right semicircular canals is transmitted into the vestibular nuclei. Many neurons in the vestibular nuclei receive information from receptors on both sides of the head, so that coding of rotation direction can be very precise. Due to the mechanics of the semicircular canal system, as well as the transduction properties of pre- and post-synaptic processing, semicircular canal afferents encode head velocity and



**Peripheral Vestibular Apparatus. Figure 2** Hair cell polarization a semicircular canal crista and in saccular and utricular maculae. Hair cell polarization is indicated by the orientation of the multiple stereocilia with respect to the single kinocilium. (a) In a semicircular canal crista ampullaris the polarization of hair cells is uniform as indicated by the alignment of the *arrows*. (b) The polarization of hair cells in the saccular macula is opposite on either side of the dividing line that corresponds to the striola, indicated by the *dashed line*. Note that the saccular macula is aligned with the sagittal plane. (c) The polarization of hair cells in the utricular macula is also opposite on either side of the striola. The predominant polarization of hair cells in the utricular macula is mediolateral.

are band limited in their response to motion. Very slow head rotations (e.g. less than 3–4°/s) produce little response. Instead, afferents are most responsive to rotation speeds between 10 and 150°/s [5], which is in the most often produced range of human head movements.

## Otolith Function

Linear motion or changes of head position with respect to gravity (rolled or pitched) causes otoconial displacement due to inertia and consequent deflection of stereocilia in otolithic hair cells. Similar to semicircular canal receptors, otolith hair cells are either depolarized or hyperpolarized by stereocilial deflection toward or away from the kinocilium. Thus, a topographic coding of directional space or movement is represented by the activation of hair cells in particular regions of the maculae. The innervating VIIIth nerve fibers maintain the directional signal, since each afferent only innervates hair cells from a small region on the macular neuroepithelium. Unlike semicircular canal afferents, otolith afferents respond to static head positions, slow head movements, fast head movements and even very fast vibrations with high fidelity.

## Vestibular Efferent System

Hair cells and vestibular primary afferents receive information from the brain conveyed by vestibular efferents. The vestibular efferent system (VES) consists of a group of 100–500 cells bordering the genu of the facial nerve in the dorsal brainstem whose axons terminate on vestibular primary afferents and hair cells in the labyrinth [6,7]. Neurons of the VES are cholinergic, identified by acetylcholinesterase histochemistry [7] and choline acetyltransferase immunohistochemistry [8] as well as by the retrograde transport of [$^3$H]-choline.

The functional importance of the VES has remained an enigma because of the technical difficulty of physiologically identifying putative neurons of the VES and analyzing the response characteristics of these neurons *in vivo*. In fish, vestibular efferents can be identified physiologically and intracellularly labeled [9]. In the chinchilla, indirect evidence suggests that vestibular efferents receive vestibular inputs from both the ipsilateral and contralateral labyrinths.

In the cat and the monkey, it is possible to study the action of the VES indirectly by electrically stimulating the region of the brain stem where the cell bodies of vestibular efferents are located and simultaneously recording the effect on the activity of single primary afferents [6]. Primary vestibular afferents in both the fish and the monkey are excited by electrical stimulation of vestibular efferents [6,9].

Two similar ideas have been proposed to explain the function of the VES. (i) Vestibular efferents are used to establish an operating point on the sensitivity curve for primary vestibular afferents so that in different vestibular environments these afferents can be modulated within a linear range [6] and (ii) vestibular efferents detect behavioral arousal and thereby lower the threshold of vestibular primary afferents, thereby facilitating guidance of escape behaviors [9]. Implicit in these two ideas is the necessity of a central correlative efferent signal, so that changes in primary afferent activity induced by vestibular efferent signals can be distinguished from changes in primary afferent activity caused by peripheral vestibular stimulation. Such modifications could take tens of millisecsonds or tens of minutes.

## Regeneration of Hair Cells

Remarkably, in many vertebrates including amphibians, reptiles and birds, hair cells and their innervating afferents spontaneously regenerate [10]. Spontaneous *regeneration* of mammalian hair cells does not occur. However, recent developments in promoting mammalian regeneration provide renewed hope for restoring hearing and balance following hair cell loss.

## Peripheral Vision

### Definition

Vision excluding the 5°–10° most central area of the visual field (foveal and peri-foveal vision). Peripheral vision is specialized for low spatial frequency and high temporal frequency stimuli, is not sensitive to wavelength (achromatic) and has a low sensitivity/rapid adaptation to light intensity (scotopic).

►Visual Field

## Peristalsis

### Definition

Peristalsis is the propagating contraction of the circular muscle layer of the bowel. The contractions develop into peristaltic waves moving along the gut and provide the forces for propelling bowel contents usually in an aboral direction. The peristaltic waves occur intrinsically at a frequency of 3 per/min, but they usually travel only a short distance.

## Peristalsis in the Small Bowel

### Definition

Peristalsis is the propagating contraction of the circular muscle layer. The contractions develop into peristaltic waves moving along the gut and provide the forces for propelling bowel contents usually in an aboral direction.

The peristaltic waves occur intrinsically at the frequency of 3/min, but they usually travel only a short distance.

►Bowel Disorders

## Peristimulus Time Histogram (PSTH)

### Definition

Cumulative histogram of the number of spikes occurring within discrete time bins in and around the time of a repeated presentation of an auditory stimulus.

## Perisynaptic Schwann Cells

### Definition

Schwann cells normally encase axons in peripheral nerves to form the insulating myelin sheath. At the neuromuscular junction between the motor nerve and the endplate region of each skeletal muscle cell, there are Schwann cells that do not form myelin but normally respond to the chemical neurotransmitter substance, acetylcholine, that s released from active nerve terminals to excite the skeletal muscle fibers and in turn, lead to muscle contraction. These Schwann cells are termed perisynaptic Schwann cells because they are at the synaptic region of each muscle fiber.

►Acetylcholine

►Myelin
►Schwann Cell

## Periventricular Zone

### Definition

The periventricular region of the thalamus has poorly-defined cell groups that are sometimes homologized with the midline thalamic groups seen in non-primates such as nucleus reunions, rhomboid nucleus, and median central nucleus. It is likely that the region is involved in visceral activities in that it has connections to the hypothalamus, amygdala, and cingulate cortex.

## Permeabilized Skeletal Muscle Fibers

### Definition

Experimental model using single muscle fibers after membrane destruction via detergents or other means. Membrane destruction renders the contractile proteins actin and myosin directly accessible to the external media.

►Force Potentiation in Skeletal Muscle

## Per-Rotatory Vestibular Nystagmus

### Definition

Nystagmus produced during prolonged rotation of the head in space. For rapid initiation of rotation, the slow phase velocity rises sharply at the start of rotation and declines to zero as the rotation continues at a constant velocity.

►Nystagmus

## Persephin

### Definition

A member of the glial cell line-derived neurotrophic factor (GDNF) family of neurotrophic factors that also includes artemin and neuroturin. GDNF family members use a receptor complex that consist of the common receptor tyrosine kinase signaling component Ret and one of the GPI-linked receptors (GFRα1 to 4) that regulate ligand binding specificity. GFRα4 is the preferred receptor for persephin.

►Neurotrophic Factors in Nerve Regeneration

## Persistent $Na^+$ Currents

### Definition

Persistent $Na^+$ currents are TTX-sensitive, voltage-dependent $Na^+$ currents flowing at voltages between −65 and −40 mV, and thus significantly influencing sub-threshold membrane potential changes and the firing rate and pattern of discharge.

►Action Potential
►Sodium Channels
►Tetrodotoxin

## Persistent Vegetative State

### Definition

This state results from damage of cortical neurons (particularly ►pyramidal cells) in ►hippocampus and ►cerebral cortex after prolonged hypoxia or ischemia. One to two weeks of coma may be followed by a state similar to that of ►hydrencephalic children, in which patients appear awake, may smile, cry, fixate objects, or eat food put in their mouth, but have no cognitive relation to their environment.

## Personal Knowledge

### Definition

Personal knowledge is knowledge possessed by a person (not for example by a scientific community or culture etc.).

►Knowledge

## Personality Disorder

Annette Bölter, Jörg Frommer
Universitätsklinikum Magdeburg, Abteilung für Psychosomatische Medizin und Psychotherapie, Magdeburg, Germany

### Synonyms

Character neurosis; Characterogenic neurosis; Autopsychic neurosis; Psychopathic personality

### Definition

A heterogeneous group of disorders, regarded as long-standing, pervasive, inflexible and maladaptive personality traits, patterns of behavior and thinking that impair social and occupational functioning.

### Characteristics

Personality disorders are coded on Axis II of DSM. They are often comorbid with an Axis I disorder and can serve as a context for Axis I problems, for example depression or anxiety disorder, shaping them in different ways. The symptoms come close to describing characteristics that all people possess from time to time and in varying degrees, however the diagnoses of a personality disorder is defined by the extremes of several traits and is not used unless the patterns of behavior are enduring, pervasive and dysfunctional.

Beside personality disorders DSM-IV distinguishes personality change, for example after a major medical condition. Five subtypes of personality change are listed: labile, disinhibited, aggressive, apathetic and paranoid.

### Catergories and Clusters of Personality Disorders

DSM-IV distinguishes ten subgroups: (i) Paranoid, (ii) Schizoid, (iii) Schizotypal, (iv) Borderline, (v) Histrionic, (iv) Narcissistic, (vii) Antisocial, (viii) Dependent, (ix) Avoidant, (x) Obsessive-compulsive (►Obsessive-Compulsive Disorder [OCD]). In DSM-IV these subtypes are also grouped into three clusters: Cluster A (paranoid, schizoid, schizotypal) is defined by characteristics of being odd or eccentric. Because the symtpoms of these disorders are similar to those of the prodromal or residual phases of schizophrenia, they are considered by some researchers to be less severe variants of schizophrenia. Individuals in cluster B (antisocial, borderline, histrionic and narcissistic) appear dramatic, emotional or erratic. Those in cluster C (avoidant, dependent and obsessive-compulsive) seem anxious or fearful.

## Diagnosis

Although there do exist some diagnostic questionnaires, personality disorders are preferably assessed by structured interviews. In recent years these diagnoses have become reliable in some degree. But it is still usual for a disordered person to meet diagnostic criteria for more than one personality disorder. The categorical diagnostic system of DSM-IV therefore may not be ideal for classifying personality disorders. A dimensional approach may be more appropriate. During recent years different contributions on personality disorders emerged from several psychological paradigms: understanding on the basis of modern psychoanalysis and attachment theory, approaches based upon the five-factor model of personality, cognitive theories and Linehan`s behavioristic approach, interpersonal concepts as shown by Benjamin, neurobiological models, and a self-developed approach focusing on private theories of the patients themselves.

## Therapy

A therapist who is working with patients that have a personality disorder is typically also concerned with Axis I problems because most patients even enter treatment because of Axis I disorder. For example, a person with avoidant personality disorder may be seen for social phobia. Psychodynamic therapy of personality disorders has a long tradition. It aims to remove repressions and to correct the problems underlying the personality disorder. Transference-Focuses Psychotherapy as developed by Kernberg is a psychodynamic treatment designed especially for patients with severe personality disorders, e.g. ►borderline personality disorders. The focus of treatment is on a deep psychological make up – a mind structured around a fundamental split that determines the patient's way of experiencing self and others and the environment. Since this internal split determines the nature of the patient's perceptions, it leads to the chaotic interpersonal relations, impulsive self-destructive behaviors, and other symptoms. The core task in Transference-Focused Psychotherapy is to identify the patient's moment-to-moment experience of the therapist because it is believed that the patient lives out his/her predominant object relation patterns in the patient-therapist-relationship. Another successful approach is Dialectical Behavior Therapy as developed by Linehan. During individual and group therapy, therapist and client work towards improving skill use. These skills are broken down into four modules: mindfulness (derived from Zen tradition), interpersonal effectiveness, distress tolerance, and emotion regulation. In addition common treatments of personality disorder are psychopharmacological drugs. The choice is determined by the associated Axis I disorder.

## PGO Spikes

### Definition
Ponto-geniculo-occipital; high amplitude sharp waves, which originate in the pons, are transmitted to the lateral geniculate and from there up to the occipital cortex, where they are recorded in cats during rapid eye movement (REM) sleep. PGO spikes reflect bursts of discharge by neurons in the pontine reticular formation which are transmitted rostrally into the visual and also other relay nuclei of the thalamus by which they are transmitted to cortical areas. This phasic activity is also transmitted to brainstem motor nuclei, as reflected in rapid eye movements, and spinal motor nuclei, as reflected in twitches of the distal extremities. Such twitches can be observed as manifestation of the phasic excitation through the brain during REM sleep which occurs in all mammals. As proposed by some, PGO spiking might signify a programming of the brain and organism during development in species-specific motor activities and behaviors. It might also entail enhancement of learning new information and behaviors in the adult during REM sleep.

Activity of cells called phagocytes which engulfs and absorbs waste material, harmful microorganisms, or other foreign bodies in the bloodstream and tissues.

## Phantom Limb Sensation and Pain

Mike B. Calford
School of Biomedical Sciences and Hunter Medical Research Institute, The University of Newcastle, Newcastle, NSW, Australia

### Definition
When appropriately studied, it is usually reported that all adults who have had a limb amputated either by trauma or surgery have at some stage experienced the continued presence of the missing limb within their perceptual body image. The full range of somatosensory percepts (cutaneous touch, deep touch, vibration, itch, tickle, joint movement etc) are variously ascribed to the phantom. Attribution of pain to a phantom limb is a distinct phenomenon with widely varying reports of prevalence. Recent studies have reported higher proportions of cases with phantom limb

pain (60–80%) and there is a possibility that earlier reports were affected by patient reluctance to describe their experience.

Those with spinal cord injury (paraplegia, quadriplegia) rarely localize non-painful somatosensory percepts to their affected limbs. However they usually retain these limbs within their body image and sometimes attribute full function to them – a form of *anosognosia* also found in some cases of stroke-induced hemiplegia. There is no consensus view of the prevalence of phantom pain after spinal cord injury. This may be attributable to varying pathology and to the extent of the lesion. Irrespective of this, there are many well-described cases of phantom limb pain after complete spinal transection.

*Supernumerary limb* is a term that encompasses various presentations of the appearance of a third (or more) arm or leg in the perceptual body image. A similar misperception can occur temporarily with brachial plexus nerve block, but it is a rare chronic condition usually following transient middle cerebral artery ischemia or mild neurotrauma. *Alien hand* syndrome describes the converse condition in which, after mild neurotrauma, an intact limb is lost to the perceptual body image and its presence denied or disowned.

## Characteristics

Phantom limb experiences manifest immediately or within a few days of an amputation. In a minority of cases, phantom sensations persist relatively unchanged. In other cases, the phantom sensations and the perceptual body image alters. With upper limb amputation, a loss of the image of the arm but retention of the phantom hand is classically described – but there are many variations. The phantom sensations disappear after a few months to years in around 50% of cases. However, in laboratory conditions with stimulation of the amputation stump (or other body parts) or with imagery, elements of a phantom limb experience can be elicited in most amputees even years after they have reported loss of the phantom sensations. Cortical activation achieved through caloric ear stimulation is reported to recall lost phantom sensations and also to alleviate temporarily painful phantom sensation by replacement with a nonpainful phantom [1].

Phantom limb pain shares many characteristics with neuropathic pain and is equally difficult to account for. Pain sensations are rarely continuous but chronic presentation of repetitive bouts is common. Phantom pain can mimic the presentation of a pre-amputation chronic pain. It is becoming widespread practice to provide limb analgesia prior to a surgical amputation. This practice has followed a number of case reports indicating that such post-amputation mimicry is thereby avoided. Nevertheless, clear evidence of efficacy for pre-surgery limb analgesia is not apparent [2].

The highly plastic nature of the somatosensory perception of the limbs can be easily demonstrated. When operating a hammer, pointer, golf club, stilts or sword, we readily telescope our body image to include the extension. In such an operation, sensory inputs from receptors in the hand or arm are combined and interpreted to provide a "percept" from the tip of the extension. While training improves performance, the extension of percept to encompass tool use by either upper or lower limb is largely automatic. In complex multisensorimotor tasks with machines (such as driving a car), we are capable of integrating a variety of somatosensory, visual and auditory cues to expand our body image to the limits of the machine or task. Within this context, it is then somewhat surprising that essentially 100% of limb amputees experience a phantom experience of their missing part, rather than adapt their body image to encompass the amputation. Nevertheless, after amputation the plastic nature of the body image is not lost, for in most cases the phantom image locks onto a prosthetic and adapts to tool use.

Melzack [3] reasoned that the perceptual experience of a limb does not derive from activation of a single brain area but from the combined output of a distributed network, termed the neuromatrix. To account for the persistent nature of phantom limb perception, in the light of considerable physiological and psychophysical evidence of plasticity, it was concluded that, when activated, elements of the overall network retain the identity of the former limb. On the basis of reports of phantom limb experiences in some cases of congenitally missing limbs, it was further suggested that the identity of a given neuromatrix is genetically predetermined. This latter suggestion remains contentious, but the broader neuromatrix concept is well accepted and is consistent with recent work.

Ramachandran and others [4,5] have described many cases in which passive cutaneous stimulation of either the amputation stump or a distant body area (e.g. face for upper limb amputation) produces a dual sensation with one being localized to the phantom. In some cases, a clear topographic map of the phantom can be plotted. These demonstrations reveal both plasticity and rigidity in the somatosensory representation of the limb consistent with the concept that some elements of the neuromatrix retain their original perceptual attribution.

Extensive plasticity of the primary somatosensory representation has been demonstrated in monkeys and other mammals. With upper limb amputation or deafferentation the former arm and hand representation is taken over by a responsiveness to adjacent body areas, the back of the head and the face [6]. There is a considerable immediate unmasking effect [7] such that some areas immediately switch to show new responsiveness, but the total filling-in of the former representation develops over a longer period. The

somatosensory representation in the cortex is distributed across at least seven fields in central and parietal regions. Each is organized as a topographic map of the contralateral body and there is a partial specialization of function. Thus, for example, muscle spindles are the predominant input to one field (area 3a) while cutaneous receptors dominate others. There is, however, no cortical field devoted to or dominated by pain perception. Rather the nociceptive pathway, although separate in the spinal cord and brainstem, feeds into the major (lemniscal) somatosensory thalamocortical pathway. This may be an important aspect in any explanation of phantom limb pain, as those with persistent phantom pain could be shown with neuroimaging to have a reorganization within the primary somatosensory cortex, whereas those with an innocuous phantom did not [8]. Consistent with the reorganization reported in the monkey studies, this reorganization involved expansion of the cutaneous representation of the chin and lips into the former arm and hand area. The extent of the reorganization was highly correlated with the degree of phantom pain suggesting that activation of the cutaneous receptors of other body areas provides inappropriate stimulation to the cortical representation of the former pain signaling neurons of the missing limb. It needs to be noted that such reasoning is over simplistic if applied to any single representation since pain perception is likely to involve activation of multiple fields.

A consistent approach to managing or treating phantom pain has not developed to date. The linking of phantom pain to cortical reorganization phenomena and the knowledge that cortical representations are inherently plastic has led to investigations of potential therapies based around manipulating the reorganization, using pharmacological or physical therapy approaches [2]. Use of mirrors to aid in mental imagery to "move" the phantom limb has been reported to be successful in some cases [9]. Whereas treatments (e.g. stump analgesia) aimed at silencing a supposed overly active peripheral nerve are not generally useful, there were persistent early reports that a subgroup are helped by reducing sympathetic activity and sympathetic disturbance is often found. A plausible explanation for sympathetic activity directly affecting sensory nerves has come from animal work showing sprouting of noradrenergic sympathetic axons into the dorsal root ganglion following a peripheral nerve injury. Nevertheless, overall there is no supporting evidence for using sympathectomy as a treatment for neuropathic pain and hence for phantom pain [10].

# Phantosmia

## Definition

Describes the distorted perception of smells in the absence of an odor source. Most often, phantosmias occur after trauma or URTI and consist of unpleasant odors occurring without being elicited through environmental odor sources. Phantosmias also have a tendency to disappear over the course of years.

►Smell Disorders
►Olfactory Hallucinations

# Pharmacodynamics

## Definition

Pharmacodynamics refers to the biochemical and physiological effects of drugs on the body.

## Pharmacogenomics

### Definition

The science of understanding how an organism's genetic inheritance (i.e. genotype) affects the body's response to drugs.

## Pharmacokinetics

### Definition

A branch of pharmacology that concerns itself with the process in which drug is absorbed, distributed, metabolized and eliminated by the body.

## Pharmacophore

### Definition

Pharmacore is defined as a set of structural features in a molecule that is recognized at a receptor site and is responsible for that molecule's biological activity.

## Phase

### Definition

Any point on a cycle; the instantaneous state of a periodic process.

## Phase Advance

### Definition

A shift that accelerates (advances) the arrival of an oscillator at a particular event marker (phase). For example, flying from New York to Paris results in a 6 h phase advance of the light-dark cycle, since dawn in Paris is 6 h ahead of dawn in New York. When people are getting up in New York, people in Paris are eating lunch – they are already at a later phase of their daily routine. (Lunch typically tastes better in Paris.) In order for an oscillator to entrain to signals from a pacemaker that has a shorter period, it must execute phase advances.

►Phase Advance Curve
►Oscillator
►Pacemaker

## Phase Angle

### Definition

The displacement, in units of time or angular degrees, between phases of two coupled oscillators, e.g., a circadian oscillator and a light-dark cycle.

►Circadian Rhythm
►Phase Advance Curve

## Phase Delay

### Definition

A shift that sets back the time of arrival of an oscillator at a particular event marker phase. For example, flying from Paris to New York results in a 6 h phase delay of the light-dark cycle, since dusk arrives 6 h later in New York than in Paris. When people are eating supper in Paris, people in New York are eating lunch – they are at an earlier phase of their daily routine. In order for an oscillator to entrain to signals from a pacemaker that has a longer period, it must execute phase delays.

►Oscillator
►Pacemaker
►Phase Advance Curve

## Phase Locking

### Definition

Phase locking is a term that describes the auditory nerve's ability to discharge in synchrony with the acoustic stimulus. Auditory neurons no not fire on

every cycle of a sinusoidal acoustic sound, but rather fire stochastically on a specific phase of the stimulus.

►Cochlear Implants

## Phase Locking in Auditory System

### Definition

Phase locking describes the ability of a neuron to fire action potentials that are time locked to a stimulus event. In auditory neurons, phase locking is used in the context of pure tones, consisting of a single sine wave. Auditory neurons in barn owls phase lock to as high as 10 kHz, in mammals phase locking does not occur above, roughly, 4 kHz.

Phase locking requires temporal precision in action potential timing, with standard deviations of fewer than 100 μs at some frequencies.

►Intrinsic Properties of Auditory Neurons
►Neuroethology of Sound Localization in Barn Owls

## Phase Relations

### Definition

Phase relations refer to the temporal relationship between coupled elements expressed as a fraction (degrees or radians) of the cycle time.

## Phase Response Curve

Christopher S. Colwell
Department of Psychiatry, University of California, Los Angeles, USA

### Synonyms

PRC

### Definition

Phase response curve (PRC) in a graph that plots the magnitude of phase shifts resulting from perturbations from discrete stimuli.

### Characteristics

The discrete stimuli often come in the form of light pulses, which induce ►phase delays and ►phase advances during early and late ►subjective night, respectively, but produce negligible phase shifts during subjective day. The phases in which light does not produce a ►phase shift (ΔΦ) is referred to as the "dead zone" of the PRC. A variety of non-photic stimuli can also generate phase-dependent phase shifts and could potentially be used to entrain the circadian system [1]. In general, these non-photic PRCs are characterized by phase shifts during the subjective day and a dead zone during the subjective night. With both photic and non-photic stimuli, the amplitude of the PRC can vary with the strength of the stimulus.

The most straightforward way to generate a PRC is to have a population of animals in constant conditions and to measure their ►free-running rhythms. Based on these rhythms, individual organisms can then be exposed to stimuli at discrete phases of the daily cycle and the resulting phase shifts (see definition) measured by the next cycle. By convention, phase advances are plotted as positive values while phase delays are plotted as negative values. After some perturbations (especially those that cause phase advances), there can be a few days of transients before the full magnitude of the phase shift can be determined. Under the constant conditions required for these measurements, the ►period (Tau, τ) of the rhythm will not be equal to 24-h and the phase will need to be normalized by the endogenous period. Typically, the phases of the endogenous cycle are designated as circadian time (CT) 0–24 with the number of minutes in each hour of CT being equal to Tau/24 multiplied by 60. By definition, CT 0 is the time of activity onset for a diurnal organism while CT 12 is the time of activity onset for a nocturnal one. The phases of the endogenous cycle that coincide with the prior daytime are called "subjective day" while the phases that coincide with the prior nighttime are called "subjective night".

PRCs have been used to explain how 24-h ►entrainment is maintained between an endogenous circadian oscillator (which has a period that is not equal to 24-h) and environmental cues. While a description of this model is well beyond the scope of this article, a simple example may be useful. If the PRC is known, then the phase relationship between environment and the endogenous ►oscillator can be predicted based on the periods of the biological oscillation (Tau) and the ►zeitgeber cycle (T) [2]. For example, if the circadian oscillator has a period of 25 h and is entrained to a light pulse every 24 h. Stable entrainment can only be reached when the light causes a phase shift that corrects the difference between Tau and T which in this case would be a phase delay of 1-h per cycle (Tau – T = ΔΦ). Only when the light falls on the portion of the PRC

in the early night causing the 1-h phase delay will the biological oscillator be entrained to the physical cycle.

## Phase Shift ($\Delta\Phi$)

### Definition

A shift in the phase of the biological oscillation. Phase ($\Phi$) is one of the most important parameters describing any oscillation as it refers to the time points within the cycle. To measure the phase of the rhythm, a reliable reference point must be chosen. In the case of circadian oscillations, the onset of activity or the peak expression of a biochemical parameter are commonly used. These biological markers are typically expressed relative to the time of lights-on or lights-off when the organism is in a light cycle. For circadian oscillators, exposure to light is the most physiologically relevant and widely studied perturbation that results in phase shifts. Many treatments that cause phase shifts of the circadian system produce different effects depending on the time of day during which the treatment was applied.

►Circadian Rhythm
►Phase Response Curve

## Phase Spectrum

### Definition

A description of the relationship between starting phase and frequency of the sinusoidal components of a complex sound wave.

►Acoustics

## Phasic

### Definition

Transiently occurring at the onset or offset of an event.

Phasic responses indicate that the adaptation of the nervous system under consideration is rapid. Opposite term is tonic.

## Phenethylamine

### Definition

A simple molecule that serves as the framework for many biologically-active molecules, including dopamine, noradrenaline (norepinephrine), and certain hallucinogens. It is essentially a phenyl ring separated by a two carbon chain from an amino group.

►Dopamine
►Noradrenaline
►Hallucinogens

## Phenomenal Character

### Definition

The basic feature of many mental states to feel a certain way. It is somehow for an organism to be in pain, and it is also somehow for an organism to have a sensation of warmth. But these two mental states differ in phenomenal character in that it feels different for an organism to be in pain and to have a sensation of warmth.

►Behaviorism
►Logical

## Phenomenal Concepts

### Definition

Phenomenal concepts are those concepts that are immediately related to perceptions and sensations, in

such a way that one is immediately inclined to apply these concepts whenever one undergoes the appropriate experience and introspects on one's experience. Having a red experience, for example, makes one inclined to apply the phenomenal concept of a red experience.

►The Knowledge Argument

## Phenomenology

### Definition

"Phenomenology" means doctrine of appearances. In general it means the reflective inquiry into one's own [→] consciousness. It also names Edmund Husserl's philosophical project of studying how the world appears to us in [→] intentional consciousness. He held that intentional consciousness is intrinsically "directed" to objects. In some intentional episodes objects are merely "meant," while in others (intuitions) objects are (partially) "given." The "fulfillment" of the former episodes by intuitions is the basis of knowledge.

►Argument
►Logic

## Phenophysics

►Psychophysics

## Phenotype

### Definition

Two specimens of a diploid organism, such as a flowering plant, may look alike (same phenotype), even though one is homozygous for, say, red petal color (identical alleles for the gene concerned on the two homologous chromosomes) and one is heterozygous (one allele coding for white, the other one for red which is dominant in certain plants; different genotypes).

►Electric Fish

## Pheomelanin

### Definition

A polymeric pigment varying in color from yellow to red and produced from 1,4-benzothiazinylalanine derived from L-tyrosine and L-cysteine by melanocytic cells.

►Melanin and Neuromelanin in the Nervous System

## Pheomelanosomes

### Definition

Spherical organelles 0.7 μm diameter found within melanocytes that compartmentalize pheomelanin synthesis and storage.

## Pheromone

### Definition

Pheromones were originally defined in relation to insects as "substances secreted to the outside of an individual and received by a second individual of the same species in which they release a specific reaction, for example, a definite behavior or developmental process." This led to the distinction between two categories of pheromonal effect: releaser pheromones that elicit immediate and relatively stereotyped behavioral responses, such as sexual attraction; and primer pheromones that elicit a longer-term change in hormonal or developmental state, such as acceleration of puberty. Many in the field now regard the original definition as over-restrictive and would expand the term to include signaler pheromones that convey information such as individual identity, and modulator pheromones that have an effect on mood or emotion.

## Philosophy of Action

►Action, Action-Theory

## Phobic Neurosis

### Definition

An anxiety disorder in which there is intense fear and avoidance of specific objects or situations, most frequently fear of wide places (agoraphobia), closed spaces (claustrophobia) or animals. The fear is recognized as irrational by the individual.

►Personality Disorder

## Phoneme

### Definition

The minimal contrastive unit in the sound system of a language; substituting one phoneme for another changes the meaning of a word (e.g., /t/ vs. /n/ because/bat/ differs in meaning to /ban/).

## Phonotaxis

### Definition

Sound-induced, directional movement of an organism relative to the sound source. It is usually either directed towards the source (positive phonotaxis) or away from it (negative phonotaxis). It is most commonly found in acoustic communication behaviors in insects.

►Auditory-Motor Interactions

## Phosphacan

### Definition

One kind of axon growth inhibitors. It is expressed in the CNS as a secreted splice variant of the gene encoding the extracellular domain.

►Regeneration of Optic Nerve

## Phosphagen

### Definition

The term given to both high-energy phosphate compounds, 5'-adenosine triphosphate and phosphocreatine.

►Energy Sensing and Signal Transduction in Skeletal Muscle

## Phosphatidyl Inositol-3-kinase (PI 3-kinase or PI3K)

### Definition

Part of a family of related enzymes that phosphorylate the 3 position hydroxyl group of the inositol ring of phosphatidylinositol. The phosphorylated phosphoinositides produced by PI 3-kinases function via the phosphoinositide-binding domains, which are recruited to cellular membranes for various signaling funtions.

PI3K and its downstream effector the actin-associating Protein kinase (Akt) pathway are involved in the regulation of neuronal soma size and axon caliber.

►Neurotrophic Factors in Nerve Regeneration

## Phosphene

### Definition

A phosphene is a consciously perceived visual experience, typically a localized flash of light, which, rather

than being elicited by a visual stimulus, is induced by non-visual stimulation of nerves within the visual system. Phosphenes may, for example, be produced by pressure in the eyeball inducing neural activity in the retina or by magnetic or electrical stimulation of visual areas in the cerebral cortex.

►Blindsight

## Phosphodiesterase Inhibitors (PDEIs)

### Definition

Drugs that inhibit the function of phosphodiesterases (PDEs). These molecules elevate cAMP, resulting in upregulation of PKA and CREB signaling and down-regulation of NF-κB. Consequently, they are neuroprotective and anti-inflammatory agents.

►CREB
►Cyclic AMP
►Neuroinflammation – PDE Family Inhibitors in the Regulation of Neuroinflammation
►NF-κB

## Phosphodiesterase (PDE)

### Definition

Denotes a class of enzymes that hydrolyze the cyclic nucleotides cAMP and cGMP (second messengers).

PDEs have an important role as regulators of signal transduction mediated by these second messengers.

There are 11 families of proteins with this enzymatic activity (PDE1-PDE11) and more than 50 isoforms in total.

## Phospholipids

### Definition

The major lipid molecule of the cell membrane, composed of two fatty acids linked through glycerol phosphate to a polar group.

►Membrane Components
►Plasma Membrane - Structure and Functions

## Phosphorylation

### Definition

A reaction involving the addition of a phosphate group to a molecule. Many enzymes are activated by the covalent bonding of a phosphate group. The oxidative phosphorylation of ADP forms ATP.

►Energy Sensing and Signal Transduction in Skeletal Muscle

## Photocycles

### Definition

Cycles, or rhythms, in environmental lighting condition.

As with any rhythm, these can vary with respect to several parameters such as their period, phase and amplitude. Photocycles also vary with respect to the relative duration of their different phases and their waveforms. Some, for example, are sinusoidal and others have abrupt transitions between their light and dark phases. Animals use changing photocycles to anticipate and prepare for daily and seasonal changes in the environment, and their responses to these changes can be influenced by all of the parameters noted above.

## Photo-Inactivation Technique

### Definition

A technique to selectively lesion individual neurons within the nervous system. Fluorescent dyes are intracellularly injected into cells that die upon illumination by a laser beam or ultraviolet light source. Other nearby neurons are not affected. This technique has been successfully used to isolate putative pacemaker neurons in functional neuronal networks.

►Bursting Pacemakers
►Stomatogastric Ganglion

## Photon Catch

### Definition

The number of photons absorbed over a given duration by an individual photoreceptor, or class of photoreceptors. The probability of photon absorption depends on photon wavelength, but all subsequent steps of phototransduction are wavelength-independent.

►Photoreceptors
►Phototransduction
►Retinal Color Vision in Primates

## Photoperiod

### Definition

The term "photoperiod" refers to the duration of the light phase of a light-dark cycle. In biology, the term is most commonly used in the context of changes in daylength that many temperate zone organisms use to anticipate and prepare for seasonal changes in their environments.

►Photocycle

## Photoperiodic Time Measurement

### Definition

The measurement by organisms of the duration of the light relative to the dark phase of a light-dark cycle, often abbreviated as PTM. Photoperiodic time measurement enables temperate zone organisms to anticipate and prepare for seasonal changes in their environments.

In vertebrates, the pineal gland plays an important role in the system via its seasonally changing patterns of secretion of the hormone melatonin.

►Photocycle
►Pineal Gland

## Photoperiodism

### Definition

The use of daylength by organisms to prepare for seasonal changes in their environments. Animals may use either the rising or the falling phase of the annual rhythm in photoperiod as a signal to anticipate the arrival of spring or the coming of winter conditions, respectively. In mammals, photoperiodism can promote changes in a variety of parameters including, for example, pelage, body weight, reproductive function, activity levels, and aggressive behavior. Some animals use declining photoperiods to prepare for winter conditions and others use the rising phase to prepare for the arrival of spring. In mammals, photoperiodism involves the pineal gland, which signals the changing seasons via its changing pattern of secretion of the hormone melatonin.

►Hibernation
►Seasonality

## Photopic

### Definition

Daylight conditions or vision.

# Photopigments

Nathan S. Hart
School of Biomedical Sciences, University of Queensland, St. Lucia, Brisbane, QLD, Australia

## Synonyms

Visual pigments; Rhodopsins; Porphyropsins; Visual purple

## Definition

Photopigments are ►G-protein-coupled transmembrane proteins contained within the ►photoreceptors. Their function is to absorb the incident light and trigger a biochemical cascade that alters the electrical properties of the photoreceptors and, ultimately, modulates the rate of ►glutamate release (see ►Phototransduction).

## Characteristics

### Description of the Structure

Photopigments are light-sensitive single-chain polypeptides, belonging to the family of ►G-protein-coupled receptors (GPCRs), capable of activating heterotrimeric G-proteins such as *transducin* (see ►Phototransduction). The photopigments of all animals, and even some archaebacteria, share a common structural conformation that consists of seven α-helical transmembrane segments and an extracellular (or, in the case of vertebrate rod photoreceptors (►Photoreceptors), intradiscal) amino (N) terminus [1]. These similarities reflect the ancient evolutionary origin of photopigment molecules. Photopigments differ from other GPCRs in that light, rather than another molecule, is the ►ligand that stimulates the receptor. This photosensitivity arises from the physical behavior of a ►chromophore molecule embedded in a pocket formed by the protein's transmembrane domain [2].

#### *Opsins*

The proteinaceous component of the photopigment is called an ►opsin, and the amino acid sequence of its polypeptide chain determines both its receptor properties and, in combination with the chromophore, its spectral absorbance. Opsins contain 350–500 amino acids, and comparisons of sequence homology reveal that all vertebrate ►visual pigments belong to one of five distinct classes: SWS1, SWS2, RH1, RH2 and M/LWS [3]. Moreover, the gene duplication events that led to the separation of these different opsin classes predate the divergence of the jawed and jawless vertebrate lineages [4].

In functional terms, photopigments are classified by their wavelength of maximum absorbance ($\lambda_{max}$). In most instances, photopigments belonging to the same opsin gene class have a $\lambda_{max}$ value in a similar region of the visible spectrum, although there is considerable overlap between classes. SWS1 opsin genes code for ultraviolet- or violet-sensitive cone photopigments with $\lambda_{max}$ values between 355–440 nm. SWS2 opsin genes produce short-wavelength-sensitive ("blue") photopigments with $\lambda_{max}$ values between 410 and 475 nm. RH1 and RH2 opsin genes generate medium-wavelength-sensitive ("green") photopigments with $\lambda_{max}$ values between 460–540 nm in rod and cone photoreceptors, respectively. M/LWS opsin genes code for long-wavelength-sensitive ("red") cone photopigments with $\lambda_{max}$ values between 505–630 nm.

Birds, turtles and some fish have retained and express all five opsin genes. These species usually possess at least four spectrally distinct cone types and have tetrachromatic color vision (►Color processing). However, throughout vertebrate evolution there has been a tendency for certain taxa to lose opsin classes that were present in their ancestors. For example, some reptiles (e.g. lizards) have lost the RH1 rod opsin as a consequence of the loss of rod photoreceptors from their ►retina. Most placental mammals lack both the SWS2 and RH2 cone opsin genes and are dichromats. Many marine mammals have even lost the SWS1 gene and with it any chance of color vision. However, some primates (including humans) have re-evolved a third cone opsin via a duplication of their M/LWS opsin gene and have trichromatic color vision.

In most species, only one type of opsin is expressed in a given photoreceptor type. However, there are instances where two or more opsins are co-expressed, giving rise to a mixture of photopigments with different $\lambda_{max}$ values in a single *outer segment* (►Photoreceptors). In mice and rabbits, SWS1 and M/LWS opsins are co-expressed within the same cone photoreceptor and the relative proportion of the two photopigments varies with retinal location. Co-expression of two or more opsins may also occur in some fish while they undergo an ontogenetic shift in habitat light environment.

#### *Chromophores*

Vertebrate photopigments employ two different chromophores, 11-*cis* retinal and 11-*cis*-3,4-didehydroretinal, which are the aldehydes of vitamin $A_1$ and $A_2$, respectively. Photopigments based on 11-*cis* retinal (►rhodopsins), are generally found in mammals, birds and marine fish. Photopigments based on 11-*cis*-3,4-didehydroretinal (►porphyropsins) are characteristic of freshwater fish and turtles. Different chromophores can

be used interchangeably with the same opsin. However, a porphyropsin photopigment will have a $\lambda_{max}$ value shifted towards longer wavelengths compared to a rhodopsin photopigment utilizing the same opsin, a phenomenon called the "chromophore shift".

Many aquatic species, including some lampreys, teleost fish, elasmobranchs and amphibians, are capable of producing both rhodopsin and porphyropsin photopigments. In most cases, the chromophore type changes from 11-*cis* retinal to 11-*cis*-3,4-didehydroretinal in response to an ontogenetic shift in habitat type from fresh to salt water (or vice versa). The long-wavelength spectral shift induced by porphyropsin use is considered to be an adaptation to the relatively red-shifted illumination in most freshwater or estuarine habitats compared to terrestrial or marine light environments. Intriguingly, some terrestrial reptiles, such as the true chameleons (Chamaeleondiae), maintain ►rhodopsin/►porphyropsin mixtures of the same opsin type within individual cone photoreceptors, although in the absence of ontogenetic shifts in habitat type the functional significance is unclear.

### *Spectral Absorbance*

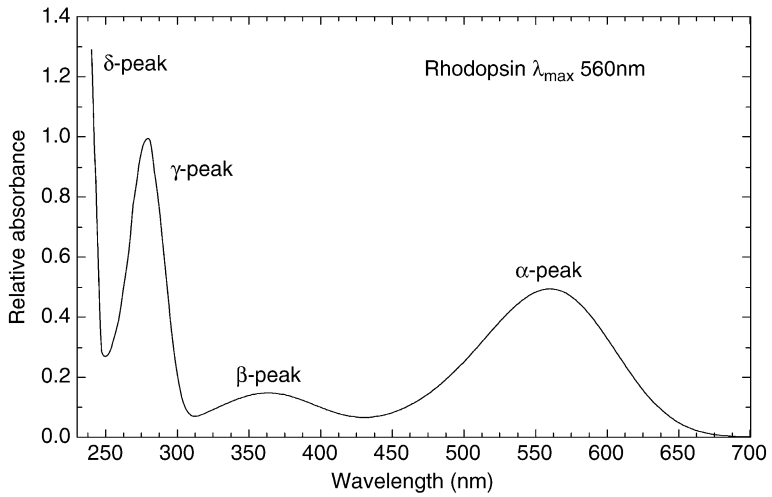
The absorbance spectrum of an unbleached photopigment is characterized by four distinct peaks (Fig. 1). The first and most visually relevant of these is the so called α-peak. When classifying the spectral absorbance of photopigments, the $\lambda_{max}$ value quoted usually refers to the wavelength position of the α-peak, which represents the main absorbance band of the bound chromophore. The α-peak varies in $\lambda_{max}$ from about 350 to 620 nm, depending on both chromophore type and its physicochemical interactions with the opsin apoprotein (see section entitled Spectral Tuning and the Opsin Shift). A second, smaller peak (β-peak) occurs at shorter wavelengths and is due to the *cis*-band of the chromophore. The wavelength position of the β-peak is positively correlated to that of the α-peak but varies over a much smaller wavelength range (310–390 nm). The third (γ-peak; 280 nm) and fourth (δ-peak; 231 nm) absorbance peaks are caused by tyrosine and tryptophan residues in the opsin and a variety of organic bonds in the photopigment, respectively [5].

Generally speaking, we are only concerned with the absorbance of the α-peak because wavelengths to which the other absorbance peaks are sensitive are prevented from reaching the photoreceptors by absorption of short wavelengths by the ►ocular media or other spectral filters in the retina. For example, the human lens and macula contain carotenoid pigments (lutein and zeaxanthin) that prevent light of wavelengths shorter than about 400 nm from reaching the photoreceptors. However, in several other vertebrate (and invertebrate) species, ultraviolet light (UV, 300–400 nm) is allowed to enter the eye to stimulate specialized UV-sensitive photopigments and the β-peak of photopigments with longer $\lambda_{max}$ values may absorb some of this light.

## Regulation of the Structure

### *Chromophore Photosensitivity and the Schiff's Base Linkage*

All opsins contain a lysine residue at a particular site on the interior surface of the chromophore-binding pocket that couples to the chromophore via a Schiff's base bond (aldimine linkage). In vertebrate photopigments, the Schiff's base is usually ►protonated, and its positive charge is balanced by a negatively charged residue



**Photopigments. Figure 1** Absorbance spectrum of a rhodopsin (11-*cis* retinal-based) photopigment. See text for details.

(almost invariably glutamate) that acts as a ►counterion to stabilize the linkage electrostatically. This charge distribution is fundamental to the photosensitivity and wavelength specificity of the photopigment. When the chromophore absorbs a photon of light, it undergoes a conformational change and flips from the less stable 11-*cis* configuration to the more stable all-*trans* ►isomer (see ►Phototransduction). This causes a major structural rearrangement that displaces the Schiff's base from its interaction with the glutamate counterion. The subsequent loss of electrostatic stability results in further structural rearrangement of the opsin, deprotonation of the Schiff's base and generation of the active form of the photopigment (metarhodopsin II) [6].

### Spectral Tuning and the Opsin Shift

Free chromophore (retinaldehyde) has a peak absorbance at 375 nm. When combined with a simple amino-group (-$NH_2$) containing-compound (n-butylamine), the protonated retinaldehyde-Schiff's base complex formed has a $\lambda_{max}$ at 440 nm [7]. The difference in $\lambda_{max}$ between the protonated retinaldehyde-Schiff's base complex and the α-peak of a given opsin-retinaldehyde photopigment is called the "opsin shift."

The magnitude and direction of the opsin shift depend on a variety of molecular interactions, all of which are directly attributable to the amino acid sequence of the opsin. In particular, the interactions of charged, polar or polarisable amino acid residues with the chromophore may affect the strength of the interaction between the protonated Schiff's base and the glutamate counterion, and/or alter the delocalization of charge along the length of the chromophore. A reduction in charge delocalisation along the chromophore, or a strengthening of the Schiff's base-counterion interaction (which helps to prevent charge delocalisation) increases the stability of the chromophore and short-wavelength-shifts the photopigment $\lambda_{max}$ as a result of the higher energy required for photoisomerization. In contrast, an increase in charge delocalisation, or a weakening of the Schiff's base-counterion interaction, decreases the energy required for photoisomerization and results in a long-wavelength-shifted photopigment [8].

Thus, by altering the types of amino acid present within the opsin polypeptide, at specific locations that are close enough to interact electrostatically with the chromophore, the $\lambda_{max}$ of a rhodopsin photopigment can be varied almost continuously from 350 to 575 nm (as far as 630 nm in the case of porphyropsin photopigments). In addition to a $\lambda_{max}$ 500nm RH1 rod photopigment, the human retina contains three cone photopigments with $\lambda_{max}$ values at 430 (SWS1), 530 and 560 nm (M/LWS). The mechanisms of spectral tuning of vertebrate (especially mammalian) M/LWS photopigments are probably the best understood of all opsin genes and, in most species, their $\lambda_{max}$ values are determined by various combinations of amino acid substitutions at just five locations in the opsin apoprotein, the so called "five sites rule" [3].

### Anion Sensitivity and Spectral Tuning

In addition, most vertebrate M/LWS photopigments are thought to be spectrally tuned in part by the binding of anions, more specifically chloride ions, at locations on the opsin close to the Schiff's base linkage. For example, chicken M/LWS photopigment has a native $\lambda_{max}$ value of 565 nm that can shift to 520 nm in the absence of chloride ions. It is thought that the Schiff's base counterion is complex, and the inclusion of an exchangeable chloride ion helps to maintain a relatively delocalized distribution of charge on the chromophore and, consequently, red shifts the $\lambda_{max}$ of the photopigment [9].

## Function

Photopigments absorb photons of light and trigger the enzymatic activity of the photoreceptor G-protein transducin. This leads to a biochemical cascade that ultimately results in a change in the rate of release of ►neurotransmitter by the photoreceptor and a detectable neural signal. Although the primary function of a photopigment is to detect light of any wavelength, the divergence of the ancestral photopigment gene into multiple spectral types very early in evolution suggests that there is considerable selection pressure on the spectral tuning of photopigments. Although generalisations are difficult to make, the number of different photopigment types and their $\lambda_{max}$ values are almost certainly determined by the spectral distribution of the available light, the need to find food and potential mates, and avoid predators.

## Pathology

►Retinitis pigmentosa (RP) (►Inherited retinal degenerations) is a collection of genetically inherited diseases that result in the degeneration of photoreceptors and the retinal pigment epithelium. Symptoms include night blindness and the loss of peripheral vision. Over 100 different point (single amino acid) mutations in the gene encoding rod opsin, located on autosomal chromosome 8, are known to cause RP, possibly as a result of the failure of the mutant opsin to fold correctly, bind retinal or activate transducin [6].

The genes coding for green- and red-sensitive cone pigments (M/LWS opsins) in humans are carried on the X chromosome. Mutations in these genes are responsible for the different forms of red-green ►color blindness and, because of their location on the X chromosome, are more apparent in males, which have only one copy of the gene.

These include amino acid substitutions that alter the $\lambda_{max}$ of the green- (deuteranomaly) or red-sensitive (protanomaly) photopigments and result in anomalous color vision, or cause the complete loss of green- (deuteranopia) or red-sensitive (protanopia) cones [10].

The SWS1 gene encoding the human blue-sensitive cone opsin is located on chromosome 7. Mutations in the SWS1 gene that cause a spectral shift in the expressed pigment (tritanomaly) or a loss of functional blue cones (tritanopia) result in blue-yellow color blindness. As the SWS1 gene is carried on a pair of autosomal chromosomes, mutations in both copies are required to produce tritanopia. Consequently, blue-yellow color blindness occurs less frequently than red-green color blindness.

## Definition

Photoreceptors regulate light-dependent physiologies; image formation and non-image forming adaptation such as regulation of circadian entrainment, seasonal reproduction and body color change. The vertebrate retina contains three types of photoreceptors: rods, cones and ipRGCs. In non-mammalian vertebrates, the pineal complex, deep brain, skin, parapineal and parietal eye are also known to contain photoreceptors. Each vertebrate photoreceptor contains a photopigment consisting of a protein called opsin and vitamin-A-based light-absorbing molecule (chromophore), 11-*cis* retinal.

## Characteristics

### Introduction

Dynamic adaptation to ambient light is central to survival of most animals. Light adaptation is achieved by two basic mechanisms: image formation for rapid adaptation to the physical environment and non-image forming adaptation of physiology and behavior to ambient light quality. The image-forming function is exclusively mediated by the eye – a specialized optical structure with a lens that projects an image to the ►retina. ►Cone and ►rod photoreceptors of the retina capture the image and send the information to the visual cortex for image reconstruction [1]. The non-image forming (NIF) photoresponses vary widely, from rapid adjustment of pupil diameter to progressively slow responses, such as skin color adaptation in amphibians, adaptation of the circadian clock to the daily day–night cycle, and seasonal reproductive behavior. Accordingly, the underlying ►photopigments vary widely in (i) the cell types of expression, (ii) anatomical location and (iii) target cells or effecter process.

The photopigment for most of the above responses comprises an opsin family of G-protein coupled receptor and a light-sensitive vitamin-A based chromophore. The amino acid sequence of the opsin scaffold determines (i) the spectral properties, (ii) specificity of the downstream signaling pathway and (iii) interaction with other regulatory molecules. Although flavin-based photopigments, such as ►cryptochromes, have been implicated in the circadian photoresponses of insects, no such light-dependent function of cryptochrome molecules in vertebrates has been conclusively established.

In mammalian vertebrates all of the photoresponses originate from photopigments of the retina. In non-mammalian vertebrates, however, additional anatomical

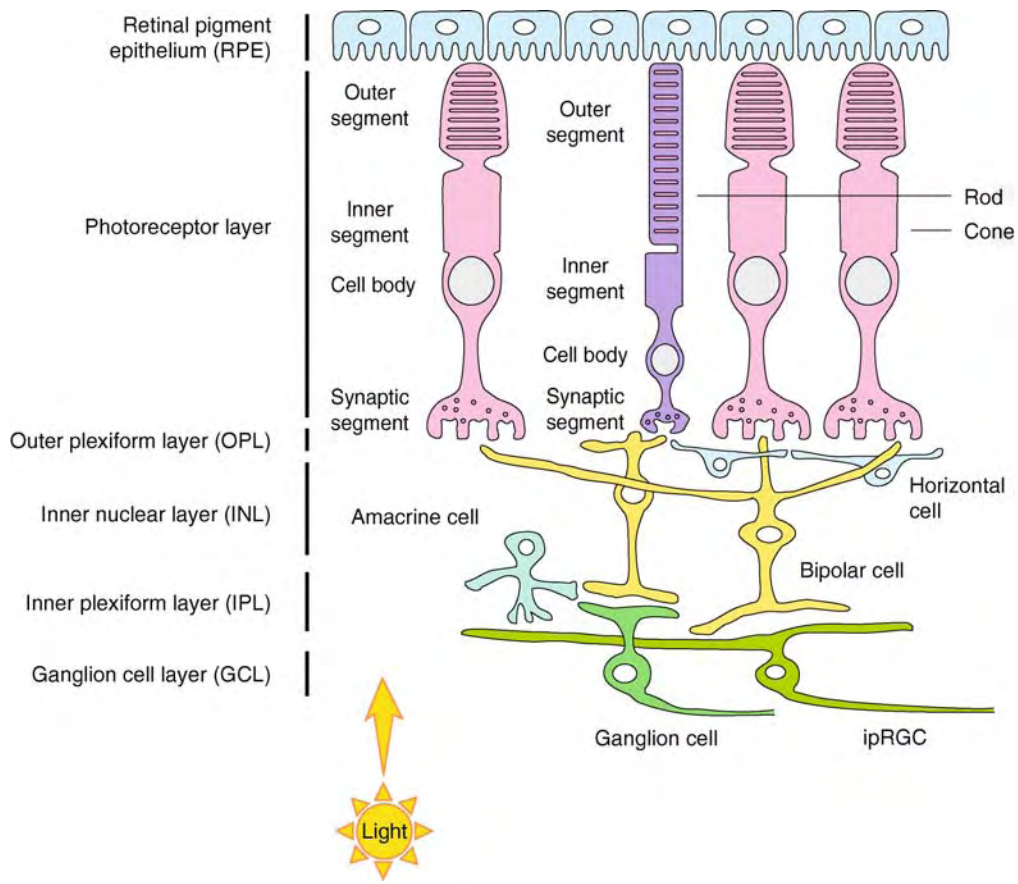
structures such as the parietal eye, ►pineal-, parapineal-complex, deep brain, and skin are also known to contain functional photoreceptors which primarily mediate NIF photoresponses.

### *Ocular Photoreceptors in the Vertebrates*

The rod and cone cells are the predominant photoreceptors of the retina. They exhibit exquisite subcellular specialization such that the different cellular functions are stratified along the length of the cells. The nuclei mark a virtual functional boundary, with the distal segment functioning in photoreception, while the segment proximal to the lens makes synaptic connections to other cell types of the retina. The photopigment in these cells is tightly packed into specialized membranes that are organized into rod or cone like structures in the outer segment of rod or cone cells, respectively (Fig. 1).

The outer segment is connected to the rest of the cells by a narrow structure, the ciliary stalk. Between the ciliary stalk and the nuclei, various organelles such as mitochondria, the Golgi apparatus and the endoplasmic reticulum are concentrated in stratified layers. The inner segment of the rod/cone cells contain the synaptic structures for signal transduction to other cell types of the retina, which ultimately connect to the ►retinal ganglion cells (RGCs) – the only retinal cell type that makes synaptic connections to the brain. No other cell types of the mammalian vertebrate retina were known to be directly light sensitive until the discovery of ►intrinsically photosensitive RGCs (see section ►*ipRGCs*).

In non-mammalian vertebrates, however, opsin photopigments are expressed in additional retina cell types. The horizontal and amacrine cells in the retina of teleost fish express vertebrate ancient (VA)-opsin. In birds and amphibians melanopsin mRNA is extensively expressed in both inner and outer nuclear layers of the retina. However, in all animals the rod and cone cells are the most characterized photoreceptors of the retina.



**Photoreceptor, Variety and Occurence. Figure 1** Schematic structure of the vertebrate retina. Vertebrate retina is composed of multiple cell layers with specialized functions. The rods and cones of the outer nuclear layer and a few RGCs of the ganglion cell layers are bona fide photoreceptors or intrinsically photosensitive. Other cell types such as horizontal, bipolar, amacrine and ganglion cells participate in light signal processing and signal transduction to the brain.

### *Rods*

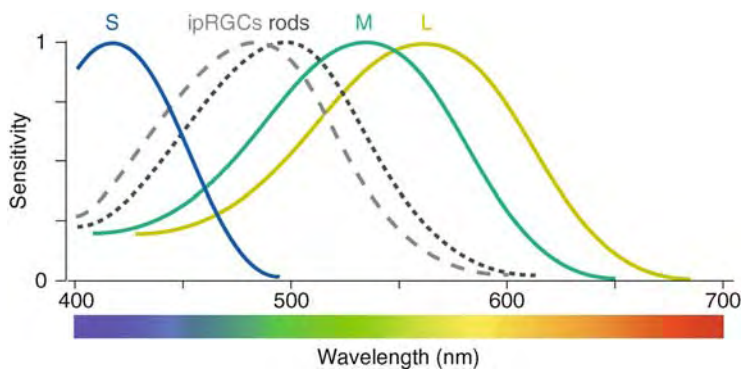
Typically, a rod cell is sensitive enough to respond to a single photon of light and therefore is responsible for scotopic or dim-light vision in night (Table 1) [1,2]. With increasing light intensity at dawn, the rods become saturated or "bleached", thus under daylight the less sensitive cones mediate visual function. Rods respond slowly to light and have longer integration time than cones do.

Generally, each rod or cone cell expresses only one type of opsin photopigment, thus the photoresponses of the cell reflect that of the photopigment. Most vertebrate retina contain a single type of rod expressing rhodopsin with peak sensitivity ~500 nm (Fig. 2), although several amphibians like toads and salamanders are known to have two types of rods, called the red-rods and the green-rods, which have distinct absorbance spectra.

The photopigment in rod cells is densely packed into specialized disc membranes that are stacked to form the rod outer segment. The outer segment of both rods and cones are continuously renewed. In rods, new rhodopsin molecules are synthesized just before dawn and the distal discs are shed and phagocytosed by the retinal pigment epithelium (RPE) cells in the morning.

**Photoreceptor, Variety and Occurence. Table 1** Comparison of rods, cones and ipRGCs. Modified from [3]

| | Rods | Cones | ipRGCs |
|---|---|---|---|
| Major function | Scotopic/night vision | Photopic/daytime vision | Non-image forming photoresponses |
| Location | Outer nuclear layer | Outer nuclear layer | Ganglion cell layer |
| Photopigment | Rod opsin (rhodopsin) | Cone opsins | Melanopsin |
| Localization of opsins | Outer segment | Outer segment | Soma, dendrites, and axon. |
| Sensitivity | High | Moderate (less sensitive than rods) | Low |
| Integration time | Longer integration time than cones (tens of milliseconds) | Respond faster than rods | Seconds |
| Light response of membrane potential | Fast hyperpolarizing | Fast hyperpolarizing | Slow depolarizing |
| Action potentials | No | No | Yes |
| Role of RPE for photopigment regeneration | Essential | Essential | Apparently unnecessary |
| Receptive field | Very small | Very small | Very large (tens of microns) |
| Number of cells in human eye | ~ 120 million | ~ 6 million | <5,000 |
| Spatial distribution in human eye | Peripheral | Fovea | Uniform |



**Photoreceptor, Variety and Occurence. Figure 2** Spectral sensitivity of mammalian ocular photoreceptors. Spectral sensitivities of cones (S-cones, M-cones and L-cones), rods and ipRGCs.

Such temporal regeneration of rods coincides with their primary role in scotopic vision.

### Cones

Cones are cone-shaped photoreceptors in the retina that can function under bright light and are responsible for photopic or bright-light vision (Table 1) [1,2]. Cones are less sensitive to light intensity than the rods. On the other hand, response times to stimuli are faster than those of rods, and they are also able to perceive color, finer detail and more rapid changes in images. Unlike the disc membranes of the rod, the outer segment of the cones is formed by invagination of the plasma membranes. The photopigments of the cones are primarily synthesized prior to dusk, and membranes from the tips of the cones are shed in the evening. Based on peak spectral sensitivity, most animals contain two types of cones, one at >500 nm (long wavelength cone or L-cone) and one at <500 nm (short wavelength cone or S-Cone). Some animals including teleost fish, Old World monkeys and humans have one additional cone-type absorbing in the medium wave (M-cone). There are several exceptions; for example, several nocturnal mammals like owl monkeys, a New World monkey, have only one type of cone. Sensitivities of human S-cones, M-cones and L-cones are to ~420 nm (blue), ~530 nm (green) and ~560 nm (yellowish–green) wavelengths, respectively (Fig. 2). S-cones are smaller in number than M- and L-cones and are sparse in the fovea region. The difference in the signals received from the three cone types allows the brain to distinguish millions of colors. As cones are functional under bright light, they require rapid regeneration of the *all-trans* retinal. There is some evidence that unlike the rods which depend on the RPE cells, the cones depend on a different type of retinal cycle involving cones and the Müller cells of the retina.

### ipRGCs (Intrinsically Photosensitive Retinal Ganglion Cells)

The ipRGCs are intrinsically photosensitive and constitute only 1–2% of the retinal ganglion cells of the adult mammalian retina. They do not play any major role in image-forming vision but are important photoreceptors for NIF photoresponses, which include light entrainment of the master circadian oscillator resident in the hypothalamic ►suprachiasmatic nucleus (SCN), light suppression of pineal melatonin synthesis and release, light modulation of activity and pupillary light reflex (Table 1) [3,4].

These adaptive photoresponses are almost intact in several animal models with complete rod/cone degeneration and exhibit an action spectrum characteristic of the absorption spectrum of the opsin class of photopigments with a peak around 480 nm. ►Melanopsin, a novel photopigment expressed in these cells, mediates photosensitivity (Fig. 2). Unlike the rod/cone photoreceptors, ipRGCs exhibit no polarized expression of the photopigment; melanopsin immunoreactivity is localized to membranes of the dendrites, somas and possibly axons of these cells. Cell bodies of the ipRGCs are mostly resident in the RGC sublayer, while the dendrites heavily arborize within the inner plexiform layer spreading to as many as tens-of-microns in diameter of receptive fields (Fig. 1). The dendrites make synaptic contacts with both rod and cone bipolar cells and receive rod/cone inputs, and hence are unique photoreceptor cells of the retina with two almost independent major functions: (i) to initiate photochemical reaction by melanopsin as well as (ii) to transmit rod/cone initiated photoresponse. Unlike other RGCs, axons of these ipRGCs primarily project to the SCN, where they are almost equally distributed between contra- and ipsi-lateral SCN. They also send additional projections to other brain regions implicated in NIF photoresponses.

Isolated ipRGCs depolarize in response to light and generate action potentials in a melanopsin-dependent manner. They exhibit long latency of light response and are depolarized as long as the lights are on and have long deactivation kinetics. The native molecules and channels underlying the photoresponses of the ipRGCs have not conclusively been established. However, the persistence of the non-image forming adaptive photoresponses in animal models deficient in several signaling components and channels mediating rod/cone photoresponses imply the ipRGCs recruit a distinct set of signaling molecules.

### Phototransduction Mechanism

In all opsin-based photopigments, the first step in photoresponse begins with the photoisomerization of a vitamin-A based *cis*-isomer of retinal to its *trans*-isomer. The resultant conformational change of the protein triggers activation and release of a Gαi/Gαo (most vertebrate opsins) or Gαq/Gα11 (melanopsin) class of G-protein. The Gαi/Gαo class of effector G-protein of rod/cones, also known as transducin (Gt), activates a phosphodiesterase, which in turn rapidly degrades cGMP and causes closing of the cyclic nucleotide gated channels. Hence, photoactivation of rod/cone photoreceptors leads to membrane hyperpolarization and a pause in neurotransmitter glutamate release. On the other hand, it is presumed that photoactivated melanopsin activates the Gαq/Gα11 class of G-proteins, which in turn activates phospholipase C (PLC). Activated PLC can signal through several mechanisms, including intracellular calcium release, increase in IP3 and DAG, and ultimately opening of a channel leading to membrane depolarization, and release of neurotransmitters, such as glutamate and adenylate cyclase- activating peptide 1. Signal

termination occurs at various steps including receptor, G-protein and downstream components. Finally, regeneration of active photopigment occurs, enabling another round of photoresponses to be initiated. The all-*trans* retinal from rod/cone cells is transported to the RPE cells where an elaborate multistep enzymatic process ensures sufficient retinal regeneration for use by the rod/cone photoreceptors. Melanopsin, on the other hand is presumed to isomerize the resultant all-*trans* retinal to the active 11-*cis* isomer by an intrinsic photoisomerase activity.

### Extraocular Photoreceptors in Nonmammalian Vertebrates

While mammals use ocular photopigments for all types of photoresponses, several non-mammalian vertebrates express functional photopigments outside their eyes, including the parietal eyes, pineal, parapineal glands, dermal cells, and in brain. Organisms use them primarily for physiological adaptation to the ambient light quality. Some of these tissues such as pineal and parietal eyes develop embryologically from the diencephalons, which also gives rise to the eye. Accordingly the photoreceptor cells of these organs show some morphological similarities with those of the retina, and they also express multiple photopigments in distinct or in the same cell types.

#### Pineal Photoreceptor

In lower vertebrates such as lampreys, fishes, amphibians, lizards and birds, the pinealocytes have both intrinsic photosensitivity as well as neuroendocrine function, such that under cultured conditions of isolated pineal gland, they are light-sensitive and have the ability to produce ►melatonin in a circadian and light-dependent manners.

The action spectrum of the photosensitivity of the isolated chicken pineal resembles the absorption spectrum of rhodopsin. Consistent with this prediction, an opsin-like protein was identified in the chicken pineal gland and named pinopsin (=pineal opsin), the first functional opsin to be discovered outside the retina [5]. Pinopsin upon reconstitution with 11-*cis* retinal forms a functional photopigment with peak sensitivity at 468 nm and can couple to Gt. Besides pinopsin, a chicken red-sensitive cone pigment, called iodopsin, and melanopsin are also expressed in the chicken pineal gland. Pinopsin is not detected in fish and mammals. Alternatively, the pineal gland of zebrafish expresses exo-rhodopsin (=extra-ocular ►rhodopsin). Exo-rhodopsin is expressed in the majority of pineal cells, but not in retinal cells. The pineal photopigments might function to modulate melatonin secretion in a cell autonomous manner. Additionally, they also make synaptic connections with neurons that project to various thalamic and hypothalamic regions. Mammals have lost the intrinsic photosensitivity of pinealocytes, but they still retain circadian regulation of melatonin secretion, which is also light regulated by ocular photopigments via a multisynaptic pathway.

#### Parietal Eye Photoreceptors

Several lizards harbor an extra eye-like structure called the parietal eye that does not appear to have any role in image-forming vision, but rather helps adapt to light quality. Like the eye, the parietal eyes also contain various cell types stratified into distinct layers. However, unlike the image-forming photoreceptors, which hyperpolarize in response to light, the parietal eye photoreceptors either depolarize or hyperpolarize in response to specific wavelengths of light. These photoreceptor cells express two different types of opsins – pinopsin and parietopsin in the same cell type [6]. Distinct absorption spectra of these two opsins and functional coupling to distinct signaling mechanisms may produce such unique membrane potential properties of the parietal eye photoreceptor cells.

#### Photoreceptors in the Deep Brain

Most photoreceptor cells described above are located outside or immediately beneath the skull. However, in some vertebrates there is evidence for photoreceptors in the deep brain which largely mediate long term seasonal photo-adaptations. The photoperiodic change in gonad function persists in pinealectomized and enucleated Japanese quails and exhibits peak sensitivity around 500 nm. Actually, ~500 nm wave-length light can transmit through the scalp and skull and reach to the deep brain.

Several opsins of the eye and pineal glands are shown to be expressed in deep brain, but their functions are still almost unknown. Rhodopsin was cloned from lateral septum of pigeons, pinopsin-expressing cells exist in the anterior preoptic nucleus of toads, VAL (vertebrate ancient-long) opsin is localized in a small portion of cells surrounding the diencephalic ventricle of central thalamus in zebrafish, and melanopsin is expressed in hypothalamic sites of *Xenopus laevis*.

## Synonyms

Visual transduction cascade

## Definition

Phototransduction is the process by which light energy that is absorbed by ►photopigments contained within ►retinal photoreceptors (►Photoreceptors) is converted into a biochemical signal that leads to a ►hyperpolarization of the photoreceptors.

## Characteristics

### Description of the Process

#### *Photoisomerization*

Phototransduction begins when a photon of light is absorbed by a photopigment molecule. The energy imparted by the photon induces a conformational change in the ►chromophore (see ►Photopigments), in the case of 11-*cis* retinal causing it to flip to the all-*trans* isomer. This transition is called ►photoisomerization, and is the only light-dependent step in the phototransduction process; it is also extremely rapid, taking less than 200 fs [1]. Photoreceptor ►outer segments are densely packed with photopigment molecules to capture as much of the incident light as possible. Nevertheless, only two out of every three photons absorbed by the photopigment succeed in isomerising the chromophore; photopigments have a ►quantum efficiency of about 0.67, regardless of photon wavelength [2]. Energy from photons that are absorbed but do not induce chromophore isomerization is dissipated as heat.

The probability that a photon of light will be absorbed by a photopigment of given spectral sensitivity is dependent on the photon's wavelength. However, an individual photoreceptor is incapable of discriminating between photoisomerization events caused by photons of different wavelength and can only signal the rate of photon capture, a concept known as the "principle of univariance." Wavelength discrimination requires photoreceptors with differing photopigment spectral sensitivities and the ancillary neural mechanisms to compare their output signals, i.e. color vision (►Color processing).

#### *Photopigment Activation*

The change in chromophore confirmation during photoisomerization alters the local structure of the chromophore-binding pocket of the photopigment apoprotein (►opsin). These structural rearrangements propagate throughout the tertiary structure of the photopigment, which progresses step-wise through a series of physically and spectroscopically distinct photobleaching intermediates until, through deprotonation of the Schiff's base linkage that binds the chromophore to the opsin, the biochemically active form of the photopigment (R*) is created [3]. In the case of ►rhodopsin (11-*cis* retinal based) photopigments, the activated form of the molecule is called metarhodopsin II and appears approximately 2 ms after photoisomerization [4].

#### *Transducin Activation*

The next stage in the phototransduction process occurs when R* triggers a biochemical cascade that amplifies the visual signal to a detectable threshold in a stereotyped fashion (Fig. 1). As each R* is free to diffuse rapidly within the plane of the outer segment disk membrane, and does so randomly as a result of ►Brownian motion, it encounters and activates several hundred ►transducin molecules within about 100 ms [5]. Transducin is a membrane-bound heterotrimeric G protein that consists of three subunits, $T_\alpha$, $T_\beta$ and $T_\gamma$. Rods and cones contain different isoforms of the three subunits, but the proteins perform the same function in the cascade [6].

Amino acids on the cytoplasmic loops of R* bind briefly (<0.1 ms) to ►epitopes on the transducin complex, and induce a conformational change in the structure of the $T_\alpha$ subunit that results in the release of a molecule of bound guanosine diphosphate (GDP). When the GDP released from the $T_\alpha$ nucleotide-binding pocket is subsequently replaced with a molecule of guanosine triphosphate (GTP), a further conformational change activates the transducin complex, causing both the detachment of R* and the dissociation of $T_\alpha$-GTP from the heterotrimer [1]. At this stage, R* is then free to move away and activate other transducin molecules before it is eventually deactivated through phosphorylation and binding to ►arrestin (see below).

#### *Phosphodiesterase Activation*

Activated GTP-bound transducin $T_\alpha$ subunits have a high affinity for guanosine 3′, 5′ cyclic monophosphate (cGMP)-specific phosphodiesterase (PDE). PDE is a membrane-bound protein consisting of two catalytic subunits ($PDE_\alpha$ and $PDE_\beta$) and two identical inhibitory subunits ($PDE_\gamma$). In the dark-adapted state, the catalytic activity of the $PDE_\alpha$ and $PDE_\beta$ subunits is blocked by their respective $PDE_\gamma$ subunits [7]. Following illumination and activation of transducin, $T_\alpha$-GTP binds to PDE and displaces either or both of the $PDE_\gamma$ subunits, thereby exposing its catalytic sites.

In this second stage of signal amplification, activated $PDE_\alpha$ and $PDE_\beta$ subunits catalyze the conversion of

Abbreviations: *R*, rhodopsin; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *T*, transducin; *PDE*, phosphodiesterase; *cGMP*, cyclic guanosine monophosphate; *GMP*, guanosine monophosphate; *GAP*, GTP-ase activating proteins; *GC*, guanylate cyclase, *GCAP*, guanylate cyclase activating proteins; *ATP*, adenosine triphosphate; *ADP*, adenosine diphosphate. An asterisk signifies the activated form of the enzyme. Subscripts indicate the enzymatic subunit(s) present. Dashed arrows represent regeneration steps.

P

many molecules of cytoplasmic cGMP to 5′ guanosine monophosphate (GMP) and rapidly reduce the concentration of cGMP molecules present in the outer segment. CGMP is a ►second messenger in the phototransduction process, and the fall in its concentration is detected by cGMP-gated cation channels in the outer segment plasma membrane, which close. The closure of ionic channels reduces the influx of $Na^+$ and $Ca^{2+}$ ions and, because $K^+$ ions continue to be removed from the cell via $K^+$-selective channels in the ►inner segment, causes a local hyperpolarization of the photoreceptor's transmembrane potential [4].

### Photoreceptor Dark Current, Photocurrents and Hyperpolarization

Phototransduction works by changing the electrical potential across the photoreceptor plasma membrane. Like all living cells, the interior of a photoreceptor is charged negatively with respect to the extracellular space (►Membrane potential – basics); the resting transmembrane potential of a rod is about −37 mV, whereas that of a cone is around −46 mV [8]. In the dark, this transmembrane potential is maintained by a balanced flow of cations (predominantly $Na^+$) into and out of the photoreceptor, known as the dark current (►Photoreceptor dark current), which has a magnitude of up to −34 pA in rods and −30 pA in cones. In the outer segment, voltage-insensitive cGMP-gated ionic channels allow the entry of ten $Na^+$ and one $Ca^{2+}$ for every $K^+$ they expel, and $Na^+/Ca^{2+}K^+$ exchangers (►Ion transporters) expel one $Ca^{2+}$ and one $K^+$ while allowing four $Na^+$ to enter. The influx of 14 $Na^+$ to the outer segment is balanced by the activity of ATP-driven $Na^+/K^+$ pumps (Ion transporters) in the inner segment, which admit 2 $K^+$ for every 3 $Na^+$ they expel. Several cycles of the $Na^+/K^+$ pump are required, and the additional $K^+$ that enter the cell reciprocally pass out of the cell down their concentration gradient via $K^+$-selective channels [1,4].

Each cGMP-gated cation channel consists of four subunits, and each subunit is capable of binding one molecule of cGMP at an intracellular domain close to

the C terminus of the polypeptide chain. The channel pore only allows the influx of cations when at least three molecules of cGMP are bound and, to a first approximation, the number of open channels varies as the cube of cytoplasmic cGMP concentration [4]. When the concentration of cGMP falls as a result of light-induced PDE catalytic activity, the number of open channels falls dramatically and the influx of cations to the outer segment is restricted. However, because $Na^+$ and $K^+$ ions are still pumped out of the inner segment there is a net loss of positive charge within the photoreceptor. The change in cation flow induced by the absorption of photons is called the ►photocurrent. In the case of rod photoreceptors, a single photoisomerization event can hyperpolarize the transmembrane potential with a photovoltage of 1.2 mV [8].

### Synaptic Deactivation

Initially, the transmembrane hyperpolarization induced by cGMP-gated cation channel closure is localized to the cytoplasm, near the activated segment of disk membrane (rods) or plasma membrane infolding (cones). However, this charge displacement is gradually redistributed along the entire surface area of the plasma membrane, and the hyperpolarization spreads electronically (►Electrotonic spread) to the inner segment and ►synaptic terminal.

The effect of hyperpolarization on the synaptic terminal is to close inward voltage-gated $Ca^{2+}$ channels (►Calcium channels – an overview) in the plasma membrane. However, free $Ca^{2+}$ ions continue to be extruded from the cell by $Na^+/Ca^{2+}K^+$ exchangers, and so the concentration of $Ca^{2+}$ in the synaptic terminal falls [1]. As the rate of ►synaptic vesicle fusion with the presynaptic membrane is proportional to the concentration of cytoplasmic $Ca^{2+}$, the hyperpolarization-induced closure of voltage-gated $Ca^{2+}$ channels results in a graded reduction in the rate of ►glutamate release into the synapse.

## Regulation of the Process

### Deactivation of R* and the Phototransduction Cascade

During its random diffusion across the membrane surface, R* inevitably encounters and binds to a molecule of ►rhodopsin kinase, which rapidly phosphorylates serine and threonine residues on the photopigment C-terminus [6]. Phosphorylation of R* dramatically increases its affinity for another cytoplasmic protein, arrestin, which replaces the kinase and deactivates R*. Arrestin remains bound to the deactivated photopigment until the chromophore is reduced to all-*trans* retinol by retinal dehydrogenase, and dissociates from the opsin protein, approximately 1 s after photoisomerization.

The other components of the biochemical cascade must also be deactivated to ensure a reliable stereotyped response to each photoisomerization event and allow recovery of the photoreceptor. Once $T_\alpha$-GTP has bound to and activated PDE, the complex is recognized by other membrane proteins, known as ►GTPase activating proteins (GAPs). Assisted by the inhibitory γ-subunit of PDE, GAP stimulates the intrinsic GTPase activity of $T_\alpha$, which hydrolyses the bound nucleotide to GDP [9]. Phosphorylated $T_\alpha$-GDP subsequently detaches from the $PDE_\gamma$ subunit, thereby inactivating the catalytic activity of PDE, and reassociates with the $T_{\beta,\gamma}$ dimer.

### Recovery and Light Adaptation

The fall in concentration of cytoplasmic $Ca^{2+}$ associated with cGMP-gated cation channel closure and transmembrane hyperpolarization provides a mechanism for negative feedback, which controls both the recovery of the photoreceptor and its response to increasing levels of illumination. Decreasing $Ca^{2+}$ levels stimulate, indirectly, the activity of a guanylate cyclase (GC) enzyme that synthesizes cGMP from GTP. GC is activated by guanylate cyclase activating proteins, or GCAPs, that are also $Ca^{2+}$-binding proteins [6]. The GCAPs in question are unable to activate GC when $Ca^{2+}$ ions occupy two of their specific $Ca^{2+}$-binding sites. However, when the $Ca^{2+}$ concentration drops, some of the GCAPs are disinhibited and stimulate GC to increase the rate of conversion of GTP to cGMP by a factor of 5–10 [4]. The subsequent increase in cGMP production counteracts the decrease caused by PDE activity and allows some of the cGMP-gated cation channels to reopen, thereby helping to restore the dark current.

Additionally, $Ca^{2+}$ levels modulate the behavior of the cGMP-gated cation channels through the actions of another $Ca^{2+}$-binding protein, ►calmodulin. Calmodulin is a small (17 kD) protein that becomes activated when at least three of its four $Ca^{2+}$-binding sites are occupied by $Ca^{2+}$ ions. The tetrameric cGMP-gated channel protein consists of two types of subunits, α and β. The β-subunit is larger (155 kD) than the α-subunit (80 kD), and has a calmodulin binding domain on an intracellular portion of the polypeptide chain near the N-terminus [4]. Activated calmodulin can bind to the β-subunit and reduce the affinity of the channel proteins for cGMP, leading to fewer open channels. However, when the cytoplasmic $Ca^{2+}$ concentration is reduced during phototransduction, the subsequent decrease in activated calmodulin levels results in an increased affinity of the channel proteins for cGMP [5]. This leads to a greater number of bound cGMP molecules and the opening of more cation channels.

Both of these $Ca^{2+}$-modulated negative feedback mechanisms subserve recovery, and potentially ►light adaptation, by preventing saturation of the light response, and allow the photoreceptors to respond to incremental changes in light intensity over a wide range of background illumination levels [10]. The importance of these feedback mechanisms is evident

if one considers the responses of photoreceptors to dim flashes of light. At very low light levels, the magnitude of the photocurrent scales linearly with light intensity. If the dark current of a rod is −34 pA and each photoisomerization event causes a photocurrent of 0.7 pA, the rod response would saturate with a flash intensity that caused less than 50 photoisomerizations. However, at higher flash intensities, typically those generating photocurrents of more than one third of the maximal dark current, the increase in photocurrent with increasing light intensity becomes increasingly smaller in an exponential fashion. In this way, rods are able to signal incremental changes in brightness, up to flash intensities that cause around 400–500 photoisomerizations before saturating [4].

### Function

Light is a visible form of electromagnetic radiation and, as such, exhibits both wave and particle properties. One property of the particle nature of light is that light energy travels in discrete packets (quanta) called photons. This has two important consequences for vision. Firstly, the visual system must detect quantal events that involve the transfer of miniscule amounts of energy. Secondly, the arrival of photons at the retina is a stochastic Poisson process. Photoreceptor neurons are exquisitely sensitive and can respond to the absorption of a single photon by a photopigment molecule. Phototransduction is the process by which this singular event is sufficiently amplified to create an electrical signal that can reliably be detected by the rest of the visual system.

### Pathology

A number of inherited diseases affecting the mammalian retina are caused by mutations in genes that encode components of the phototransduction cascade [1]. ►Retinitis pigmentosa (►Inherited retinal degenerations) – a general term for a number of inherited conditions that cause degeneration of the photoreceptors and retinal pigmented epithelium – can result from mutations in both guanylate cyclase and PDE. In addition, various forms of ►night blindness are caused by mutations in either the α-subunit of transducin, which reduce the endogenous GTPase activity that mediates PDE inactivation (autosomal dominant night blindness), or in arrestin or rhodopsin kinase (►Oguchi disease).

## Physicalism

Barbara Montero
Graduate Center, City University of New York, New York, NY, USA

### The Basic Formulation

The predominant philosophical theory about the world and our place in it is physicalism, the view, simply put, that everything is physical. In many circles, physicalism is not so much taken as the subject of debate but is rather assumed as the starting point around which other debates evolve. For example, a central problem in philosophy of mind is how to understand the mental given the truth of physicalism. But what, exactly, is the theory of physicalism? The simple formulation of physicalism as the view that everything is physical admits a number of interpretations, indeed, each term – "everything," "is," and "physical" – can be understood in different ways. To understand physicalism, then, let us look at these three aspects of the physicalist doctrine.

### Scope

For some, physicalism is a theory about everything whatsoever, where "everything" is interpreted in its broadest sense to include, for example, concrete objects such as rocks and trees, abstract objects such as numbers and sets, properties such as the property of being conscious, events such as the event of my thinking about philosophy, even God, if She exists.[1] Others, however, think that arguments for physicalism have to be restricted to a certain scope? go only so far and restrict its scope accordingly. For example, some take physicalism as a theory only about the concrete world, that is, roughly about phenomena[2] in space or time.[3] Others take it to be a theory about the empirical world, that is, about the phenomena that we come to know via our senses, or to put it more carefully, about the phenomena, the knowledge of which is justified via our sense experience. Still others take it to

[1] Or at least this is one way to state it. As a matter of terminology some physicalists reserve the term "physical" for the fundamental entities and properties of physics. Physicalism, on their view, can be true even if not everything is physical (in the narrow sense specified above), as long as everything nonundamental is related to the physical (again, in the narrow sense) in the right way.

[2] I use "phenomena" in the broadest sense to include whatever exists.

[3] The idea that the concrete also includes anything that is either spatial or temporal is important since if it were to include only the spatio-emporal than a disembodied nonspatial soul would not count as a counterexample to physicalism.

be a theory about or the contingent world, or the causal world, or the contingent and/or causal world.

How one restricts the scope of physicalism depends on one's purposes. And since the main physicalist target is typically the mental, it is not unusual to simply focus on the question of whether the mental is physical, or in other words, focus on physicalism with respect to the mental. Indeed, it is not unusual to see the theory that the mental is physical simply referred to as "physicalism." While "physicalism" in this sense refers just to the theory that the mental is physical, a more encompassing type of physicalism is sometimes evoked to justify physicalism with respect to the mental. One finds this when physicalists argue, that the mental is very likely to be physical because everything else is physical. Here, again, one wants to know, "just what is the scope of everything else?"

In considering physicalism about the mental, one sometimes finds another sort of restriction. While typically, philosophers speak of physicalism with respect to the mental as the view that all mental properties, such as the property of feeling pain, or seeing red, are physical properties, occasionally physicalism is taken to be a theory only about things and not about properties. For example, some will claim that the view that human beings are physical things with nonphysical properties is consistent with physicalism. Most, however, would take this to be an anti-physicalist view; if physicalism is true, all properties must be physical.

The view that all properties are physical is taken to imply the view that all entities are physical. The idea being that if all of your properties are physical, then you are physical.

Let us say, then, that physicalism in the broad sense is the view that everything, or some substantial subset of everything, is physical; in the narrow sense it is the view that all mental properties are physical.

## The Dependence Relation

When the physicalist claims everything is physical or that all mental properties are physical properties, what is being said of everything or of all mental properties? Typically something is taken to be physical if its existence depends in the right way on basic or fundamental physical properties, where the fundamental physical properties are taken to be the microphysical properties countenanced by physics, such as the property of having a charge, of being a quark, and so forth. But what exactly is the ►relation between the fundamental physical properties and the higher level properties, such as mental properties, that suffices to make the higher level properties count as physical. In other words, when we say that everything is physical, just what is meant by "is?"

Some hold that the relation between higher level properties and fundamental physical properties is that of explanation. On this view it is thought that physicalism is true only if everything is either a fundamental physical property or law, or it can be explained in terms of such properties and laws. As such, physicalism is an epistemic thesis that is, a thesis about what we know about the world rather than a thesis about what the world is really like. Still, it may have ontological implications since typically we think that a good indication of whether the fundamental nature of $r$ is $p$ is that we can explain $r$ in terms of $p$.

Most philosophers, however, see physicalism primarily as an ontological thesis, a thesis that tells us about what the world is like. For this reason dependence relations are typically not formulated in terms of explanation, but rather in terms of supervenience, determination, realization, or constitution. Let us look at these relations.

Supervenience-physicalists hold that physicalism is true if everything either is a fundamental physical phenomenon or supervenes on fundamental physical phenomena. In terms of physicalism with respect to the mental, the view is simply that the mental supervenes on the fundamentally physical.[4] What is the relation of supervenience? There are actually many supervenience relations and a large literature discussing them. The basic idea, however, is this: to say that $A$ properties supervene on $B$ properties, means that there cannot be a change in A properties without a change in B properties. So, for example, mental properties are said to supervene on fundamental physical properties if and only if there cannot be a change in mental properties without a change in fundamental physical properties. If your mood changes from being happy to being sad, for example, supervenience implies that there must be a change in your fundamental physical properties as well. Sometimes, the idea is explained in terms of mind and brain: when you change from feeling happy to sad, supervenience physicalism says there must be a change in your neural structure. But since a neural change, must ultimately involve a change the fundamental level, the idea amounts to the same thing.

Is supervenience physicalism really physicalism? Some think not since it seems that one kind of property could supervene, in this sense, on another kind of property yet be utterly different in kind from that property. For example, epiphenomenalism, a type of antiphysicalism, states that pain is a nonphysical property, which nonetheless supervenes on properties of the brain. Pain, on the epiphenomenalist view, is caused by the brain yet is utterly distinct from it and has no causal influence on it. Because of concerns such as these, supervenience is often thought of as merely a necessary condition for physicalism.

Philosophers who are looking for a sufficient condition for physicalism often turn to the relations of determination, constitution, and realization. While differing in details, these relations are all supposed to capture the idea that while the higher level properties,

[4] What if there is no fundamental level? Physicalism needs to be reformulated. I address this in the next section.

such as mental properties, are not identical to certain lower level properties, such as neural properties, they are still not entirely distinct from these properties. The determination relation between the mental and the physical is something like the relation between, say, Mt. Everest and the little pebbles that constitute it. Mt. Everest is arguably entirely determined by its parts (once you have all the little pebbles, you have the mountain) and in this sense it is not distinct from its parts. Yet nonetheless, it might be argued, it is not identical to its parts since you could easily substitute one pebble from another mountain for a pebble from Mt. Everest without turning Mt. Everest into a different mountain. As we say that Mt. Everest is constituted or determined by its parts, the physicalist says that the mind is entirely constituted or determined by its physical parts.

Often the physicalist's claim is spelled out in terms of a thought experiment about the creation of the world. Imagine that in the beginning God created all the fundamental particles of physics and set them in motion according to a plan. If after creating the quarks and leptons and so forth and making sure that their patterns of motion were in accord with certain laws, would God have more work to do? For example, would she also need to create human minds? Physicalists think not since they think that the world we are familiar with, which includes rocks and trees and people with thoughts, is entirely constituted by complex arrangements of microphysical particles. This is not to say that physicalists must hold that there is nothing but complex arrangements of microphysical particles. Rather, most physicalists hold that higher level features of the world, such as rocks and trees and minds, do exist. It is just that the higher level features of the world are created in creating all of the microphysical aspects of the world.[5]

## The Physical

Now we must address the question of what is the physical? When we say, for example, that everything is determined by fundamental physical phenomena what are these fundamental physical phenomena? As I said above, most define the fundamental physical in terms of the entities and properties and perhaps laws posited by microphysics: the fundamental physical phenomena are those entities and properties mentioned in the theories of microphysics. But what is meant by microphysics? Some take microphysics to refer to current microphysical theory. This gives us a relatively clear position: physicalism becomes the view that everything that exists either is or is determined by the entities, properties, and laws of current microphysics. Unfortunately, this is a theory that is rather difficult to accept since we know that current microphysics is most likely neither entirely true nor complete and thus we know now that it is not true that everything is determined by such phenomena.

Because formulating the microphysical in terms of current microphysics leads to a theory we currently know is false, most physicalists formulate physicalism in terms of a true and complete microphysics. As such, physicalism is the view that everything will be accounted for by the entities and properties of a true and complete microphysics. But what is a true and complete microphysics? It would seem to be a theory that tells us about the fundamental nature of everything. But if so, physicalism turns out to be true by definition since the fundamental nature of everything, of course, will be accounted for by a theory that accounts for the fundamental nature of everything. While there is nothing necessarily wrong with being true by definition, most philosophers working on the question of physicalism do not think that at this point in the debate the truth of physicalism simply follows from its definition. Rather, most think that physicalism requires argument and empirical support, support which they speculate is forthcoming.

If we can neither formulate physicalism in terms of current physics nor in terms of a true and complete physics, how are we to formulate physicalism? It is not clear that we can formulate physicalism so as to assign pride of place to physics, however, we can reformulate physicalism with respect to the mind so that it captures at least most of what physicalists and antiphysicalists think is at issue. This is done by turning physicalism into a thesis not about the fundamental physical aspects of the world, but rather about the fundamental non-mental aspects of the world. Physicalism with respect to the mind then amounts to the view that all mental properties are determined by nonmental properties. One way to think about this view is that the mind is physical if all mental properties are determined by neural properties (couldn't a physicalist concede that some mental properties may be determined by other physical properties, say those of silicon chips?) and neural properties are themselves ultimately determined by non-mental properties.[6]

[5] I have not discussed questions of the modality of the determination relation. Most physicalists think that physicalism could have been false, that God could have created nonphysical minds along with the creation of the fundamental physical particles, but some think of it as a necessary truth, that it is not possible that there could have been anything nonphysical. Moreover, while most think that physicalism could have been false, they also presumably think that it is not just by chance that it is true in our world; that is, they would deny that our world is such that if, say, two kinds of substances, which had never been brought together, were brought together, they would produce a nonphysical substance. In this sense, the creation thought experiment does not quite capture the content of physicalism.

[6] This formulation would not be acceptable to an externalist, that is to someone who thinks that some mental content depends on features of the world outside of the brain. Externalists, then must rely on the more general formulation of physicalism as the view that all mental properties are determined by nonmental properties.

This way of formulating physicalism captures a central point of contention between physicalists and antiphysicalist: whether mentality is a fundamental feature of the world. But what if there is no fundamental level of reality? For example, if mental properties are determined by non-mental properties, which are themselves determined by mental properties, which are determined by non-mental properties and so on *ad infinitum*, or if it is mental "all the way down," then, in either case, all fundamental properties are non-mental properties, vacuously, since there are no fundamental properties, yet physicalists would probably want to reject these world views. To address this issue, we can formulate physicalism with respect to the mental as the view that *all mental properties are eventually decomposable into non-mental properties such that all further decompositions of these properties are non-mental*.

As a general theory of physicalism, that is, as theory about the nature of everything, this formulation is inadequate. This is because there may be phenomena that for certain purposes would be unacceptable yet are nonmental. For example, a world with fundamental moral properties or abstract entities would seem to be inconsistent with physicalism, yet such things are not mental. That there is no general theory of physicalism, however, does not mean that much interesting work cannot proceed on specific topics, including questions about the ultimate nature of the mind.

## Physiological Cell Death

►Programmed Cell Death

## Physiological Pain Parameters

### Definition

Physiological pain measures include heart rate, respiration rate, blood pressure, palmar sweating, cortisol and cortisone levels, $O_2$ levels, vagal tone and endorphin concentrations. They are indirect pain measures and reflect a complex and generalized stress response, rather than correlate with a particular pain level.

►Pain in Children

## Physiology of Body Fluid Balance

►Blood Volume Regulation

## Pia Mater

### Synonyms

►Meninges; ►Cisterns

### Definition

Together with the arachnoid, the pia mater forms the leptomeninx.

Whereas the arachnoid follows the course of the dura mater and hence of the calvaria, the pia mater rests on the surface of the brain, pursuing a joint course along the sulci. Lying between the pia mater and arachnoid is the subarachnoid space that is filled with CSF.

## Pick's Disease

### Definition

Pick's disease is a severe neuro-degenerative disease in the neocortex of the ►frontal lobe and anterior ►temporal lobe, and at times of neurons in the ►striatum.

## Pickwickian Syndrome

### Definition

Named after a Charles Dickens tale involving a character with clinical signs of the syndrome of obstructive sleep apnea and obesity hypoventilation.

The combination of upper airway obstruction and reduced lung volumes from the restrictive ventilatory effect of obesity causes low blood oxygen and elevated carbon dioxide, with their associated physiological consequences.

►Sleep – Developmental Changes

## PID Control

### Definition

A popular closed-loop control method that uses a simple (Proportional-Integral-Derivative) linear controller with easily tunable parameters.

►Nonlinear Control Systems

## Piloerection or Pilomotor Reflex

### Definition

Piloerection or pilomotor reflex, also called horripilation, consists of involuntary hair erection induced by contraction of arrectores pilorum muscles, i.e., the tiny muscles located at the origin of each body hair. It is a reaction to cold temperature or strong emotions producing the so-called cutis anserina or goose bumps/pimples. Arrectores pilorum muscles receive the contractile command by the sympathetic nervous system.

►Sympathetic Nervous System

## Pineal Body

### Synonyms

►Glandula pinealis; ►Pineal gland

### Definition

This nuclear region, shaped like a pine cone, above the quadrigeminal lamina forms, together with the habenular nuclei, the so-called epithalamus. The function of the pineal body, also called epiphysis or pineal gland, is to produce the hormone melatonin, which plays a role in light-controlled circadian rhythms. Afferents come from the suprachiasmatic nucleus, pre-geniculate nucleus and posterior commissural nucleus.

►Diencephalon

## Pineal Gland

### Definition

The pineal gland (or the epiphysis cerebri, or epiphysis) is an endocrine gland located in the brain. The primary role of the pineal gland is the synthesis and release of the hormone melatonin. This hormone plays an important role in the regulation of many neurobiological aspects (e.g., circadian rhythms, sleep and reproduction).

The pineal gland receives a sympathetic innervation from the superior cervical ganglion. In nonmammalian vertebrates the pineal gland is directly photosensitive and usually contains circadian oscillators.

►Avian Pineal Gland as "Third Eye"
►Pineal Oscillators

## Pineal Hormone

►Melatonin

## Pineal Oscillators

### Definition

In many animals the pineal gland contains circadian pacemakers that directly control the synthesis of melatonin. A single pineal cell (pinealocyte) is capable of driving the circadian rhythms in melatonin release.

Therefore, it is composed of many "clocks" that are capable of producing a synchronized output (melatonin).

Indeed, in birds and in many non-mammalian vertebrates, the pineal gland acts as a circadian pacemaker that regulates the entire circadian system.

In mammals the pineal gland does not contain circadian oscillators. However, recent studies have reported that the mammalian pineal gland may also contain a circadian clock, although this circadian oscillator does not regulate melatonin synthesis and, therefore, its functional role is unclear.

►Circadian Rhythm

## Pinealectomy

### Definition

Surgical removal of the pineal gland.

►Seasonality

## Pioneer Axons

### Definition

Pioneer axons are the first axons to extend into novel regions of the developing embryo. Growth cones of pioneer axons generally have a broad hand-like appearance with filopodia, consistent with making guidance choices based on cues in the environment.

Later growing axons will often fasciculate with these pioneer axons and use them as tracks on which to grow to their target region. In most of the embryo, motor neurons of the CNS send out the pioneer axons traveling to peripheral structures and sensory axons later grow along these tracks. However, in the developing head, sensory ganglion neurons send out the pioneer axons and motor axons later travel along these tracks.

►Growth Cones

## Piriform Cortex

### Definition

The allocortical piriform cortex (also termed olfactory or pyriform or prepiriform cortex) is the largest primary area involved in the perception and learning of olfactory stimuli. It is located in the rostral part of the forebrain, ventrally to the rhinal sulcus, and it is reciprocally connected with other olfactory regions and with high order brain areas. It is commonly divided in two regions (an anterior and a posterior part) which are believed to have different functional roles.

►Olfactory Cortex

## Pit Organ

### Definition

Receptor of infrared radiation, pits near the nostrils, actually primitive "eyes," which register not only the heat, but also the direction of its source, e.g. a small rodent.

►Evolution of the Brain: At the Reptile-Bird Transition

## Pituitary Adenylate Cyclase-Activating Polypeptide1 (PACAP)

### Definition

Neuropeptide involved in the phase shift response of the circadian clock in response to nocturnal light and also stimulates the release of melatonin from the adult pineal gland.

►Clock-Controlled Genes

## Pituitary Gland

### Definition

Also called hypophysis. The pituitary gland is an appendix to the hypothalamus at the base of the forebrain. The pituitary consists of an anterior adenohypophysis and a posterior neurohypophysis.

The hypothalamus emits a number of releasing hormones and release-inhibiting hormones, which regulate the release of hormones from the adenohypophysis.

## Place Cells

### Definition

Neurons discharging selectively when the subject is in a delimited region of its environment referred to as a "firing field" or "place field." First discovered in the hippocampus by O'Keefe and Dostrovsky (1971).

Found in rats, mice, birds, bats, and primates including humans. Although most observers agree that the hippocampus has a critical role in learning and memory, there remains considerable debate about the precise functional contribution of the hippocampus to these processes.

Two of the most influential accounts hold that the primary function of the hippocampus is to generate cognitive maps and to mediate episodic memory processes. The well-documented spatial firing patterns (place fields) of hippocampal neurons in rodents, along with the spatial learning impairments observed with hippocampal damage support the cognitive mapping hypothesis. The amnesia for personally experienced events seen in humans with hippocampal damage and the data of animal models, which show severe memory deficits associated with hippocampal lesions, support the episodic memory account.

## Place-versus-Response Controversy

### Definition

This controversy was a well-known debate among groups of psychologists in the early twentieth century.

The response group (behaviorists) felt that all behavior, including navigation, must be described in simple stimulus-response terms. The place group (cognitivists) felt that complex behavior could only be explained by positing that the rat brain contained a central representation – a map of the places in the environment.

## Placebo Analgesic Response

Howard L. Fields
Ernest Gallo Clinic and Research Center, University of California, San Francisco, USA

### Synonyms

Expectancy effect; Palliative; Dummy treatment; Control treatment

### Definition

The ►placebo analgesic response is a reduction in ►pain resulting from the recipient's expectation that a treatment received has analgesic efficacy. The term placebo is usually used when the treatment is intentionally given deceptively and has no intrinsic analgesic efficacy.

### Characteristics

Some individuals experience a reduction of their pain when they are given a completely inert substance with the understanding that it is an effective treatment. If the person giving it knows that the treatment is inert (i.e., it is given with the intention to deceive the recipient), the treatment is a placebo. However, even if the individual receiving the placebo experiences a reduction in their pain following placebo administration, it is not necessarily the case that the placebo caused the reduction. The reason for the uncertainty is that in clinical syndromes it is common to observe frequent fluctuations in pain over time in the absence of any treatment. This fluctuation is called the ►natural history of the painful condition. Consequently, one cannot conclude that a given instance of a reduction in pain is due to the preceding treatment manipulation,

whether placebo or active medication. Because of this uncertainty, well designed clinical trials of analgesic medications generally require a comparison group receiving placebo treatment. The efficacy of an analgesic medication is established by showing that it produces a reduction in pain superior to placebo.

This uncertainty about the cause of a fluctuation in pain also presents challenges for research into the mechanisms underlying the placebo analgesic response [1]. One obvious difficulty is that if the individual improves, it is uncertain whether it is because of a placebo analgesic response or would have occurred in the absence of treatment. Thus, placebo analgesic responses in an individual are usually inferred, not observed. On the other hand, placebo analgesic effects are quite robust when studied comparing two *groups* of subjects, one of which receives a placebo and the other no treatment. The ►placebo effect in that situation is the difference between those two groups. The difficulty in identifying individual, as opposed to group placebo analgesic responses has made it very difficult to determine whether there are specific characteristics of individuals that make them more or less likely to respond to a placebo manipulation. On the other hand, comparing groups given placebo versus no-treatment has increased our understanding of the psychological and neural mechanisms of the placebo analgesic response.

In addition to its usefulness in controlled clinical trials, responses to placebo likely play a significant role in clinical practice. Placebo administration can provide effective relief for severe pain conditions, including those following major surgical procedures. It is also important to point out that even when effective analgesic agents are given to patients, part of the pain relief obtained may be due to a ►placebo response. For example, when a moderate dose of morphine is given to a pain patient by hidden infusion (i.e., from a preprogrammed remote pump at an unknown time), it is much less effective than when it is given openly. When patients with postoperative pain are told that they may receive morphine, but instead are given an open administration of saline through an intravenous catheter, they obtain pain relief equivalent to a moderate dose of morphine given by hidden infusion [2]. This suggests that in many cases the relief obtained when individuals take an analgesic agent is a sum of a placebo response plus the effect of the active agent.

Studies directed at the psychological determinants of the placebo response have identified ►expectancy as the most relevant psychological mediator. Expectancy can be manipulated verbally for example by simply informing the subject that the treatment they are about to receive is a powerful analgesic [3]. Expectancy can also be manipulated by explicit training, which leads to ►conditioned memory. One form of conditioning is to treat subjects in pain with a powerful analgesic agent and subsequently administering a similar appearing placebo treatment to them [4]. Another approach is through surreptitiously lowering the intensity of an experimental painful stimulus in the presence of a placebo treatment [5] and then re-administering the placebo treatment. For either approach, the conditioning markedly increases the analgesic effectiveness of a placebo treatment. Furthermore, there is a clear relationship between the subject's expectations and the degree of relief experienced [5].

Progress has also been made in understanding the neural mechanisms underlying the placebo analgesic effect. One of the first mechanistic proposals was that expectation of reward somehow led to the release of endogenous ►opioid peptides which acted at ►opioid receptors in the central nervous system to produce analgesia. This idea was supported by the finding that placebo relief of dental postoperative pain could be blocked by the opioid receptor antagonist ►naloxone [6]. Naloxone was later shown to block placebo analgesia in experimental pain models in normal volunteers [7]. Furthermore, there is a central nervous system pathway that modulates pain transmission (see ►Descending modulation of nociception). This pathway is organized in a top-down fashion. It includes the ►anterior cingulate cortex and other regions of the ►prefrontal cortex, the ►hypothalamus, ►amygdala and brainstem and it terminates in the ►spinal cord [8]. The anterior cingulate cortex and other prefrontal areas have been implicated in expectancy effects including placebo analgesia. Furthermore, endogenous opioid peptides are released throughout this pathway and contribute to its analgesic effects. Human ►functional imaging studies, including both ►positron emission tomography and ►functional magnetic resonance imaging, have provided evidence that supports a role for this ►pain modulating pathway in placebo analgesia. Placebo analgesic effects correlate with activation of prefrontal cortex and brainstem regions areas that overlap with the endogenous opioid mediated ►pain modulatory pathway [9,10].

In summary, the expectation of pain relief, whether induced by verbal instruction or conditioning, can bestow robust analgesic potency on a treatment that would otherwise be ineffective. The expectancy effect is mediated by a pain modulating pathway with endogenous opioid links. Placebo analgesic responses may also contribute to the efficacy of active analgesic agents through summation with direct drug effects.

## Planes of Section

### Definition

Planes of section are usually expressed in relation to the upright midline axis of the body (or spinal column). The plane of section that passes through or parallel to the midline and extends in the dorsal-ventral direction is the sagittal plane. Parasagittal planes pass to the left or to the right of the midline sagittal plane that is marked by the sagittal suture of the skull. The horizontal plane is at a right angle to the sagittal plane and parallel with the ground. Horizontal planes progress inferiorly or superiorly. The frontal (coronal) plane is orthogonal to the other two. It is in the plane of the coronal suture of the skull. Frontal planes progresses anteriorly and posteriorly.

►Somatosensory Cortex, Plasticity

# Plasticity in Central Auditory System

Dexter R. F. Irvine
Department of Psychology, Monash University, VIC, Australia

## Definition

Changes in the structural and functional characteristics of neurons in the central auditory system (CAS), which occur in response to altered patterns of input (i.e., not as a direct consequence of aging or of other changes in the organism's state), and are not explicable as passive consequences of the altered input, but involve some form of dynamic change in neural properties [1].

## Characteristics

### Higher Level Structures

The CAS comprises the various ►auditory subcortical nuclei and the multiple cortical fields that comprise the auditory cortex (►auditory cortical areas), together with the (ascending and descending) pathways that link these structures.

### Lower Level Components

The lower level components are the individual neurons and their processes that make up the various nuclei and fiber tracts comprising the CAS, the synaptic connections between these neurons, and the networks they comprise.

### Higher Level Processes

CAS plasticity has been demonstrated in a variety of experimental conditions, and is assumed to underlie a number of forms of auditory behavioral plasticity; however, it is by no means clear that the same mechanisms are involved in all cases. A broad distinction can be made between forms of plasticity that occur only during development (in many cases within restricted ►critical periods), and those that are observed in both young and adult animals. In the following sections, the major paradigms that have been used to study developmental and adult plasticity will be briefly reviewed.

### Developmental Plasticity: Neonatal Cochlear Ablation

Neonatal ablation of one ►cochlea in mammals, which eliminates afferent input from that ear to ►binaural neurons in the CAS, results in structural and functional changes in the input from the intact ear to these neurons. Axons from the ventral division of the ►cochlear nucleus (CN) on the side of the intact ear, which normally terminate in restricted regions of the major nuclei of the ►superior olivary complex, project to, and make synapses in, regions of these nuclei normally innervated by the CN on the side of the ablated cochlea. Similarly, the terminal fields in the central nucleus of the ipsilateral ►inferior colliculus (IC) of axons from the CN on the side of the intact ear are much larger than those in normal animals [2]. Both of these results indicate that, following unilateral cochlear ablation, axons from the CN on the intact side sprout to innervate additional territory. These structural changes are associated with increased excitatory responses to stimulation of the intact ear in the ipsilateral IC and ►primary auditory cortex (AI) [2].

### Developmental Plasticity: Space Map Plasticity

In barn owls, and in at least some mammals, the deep layers of the ►superior colliculus (SC) contain maps of auditory and visual space that are in register (i.e., bimodal neurons, or auditory and visual neurons at the same locus, have corresponding auditory and visual ►spatial receptive fields (RFs)). The auditory ►space map is derived via orderly projections from the ►external nucleus of the (ICX), and is based on neural sensitivity to ►interaural time and level differences (ITDs and ILDs, respectively) and, in mammals, on sensitivity to ►spectral cues produced by the effects of the head and ►pinnae on the sound field [2]. In both barn owls [3] and ferrets [2] reared from infancy with one ear plugged (thus altering the values of the interaural disparities associated with any given spatial location), the visual and auditory maps are in register. In the barn owl, this reflects the fact that the tuning to ITDs and ILDs of neurons in ICX and SC has changed to maintain alignment of the auditory and visual RFs. This change in neural tuning is associated with the appearance of novel projections from the central nucleus of IC (ICC) to ICX: axons sprout into, and form synapses in, regions outside their normal projection zone [3]. Immediately after ear plugging, young owls mislocalize sounds, but in parallel with the map changes, they recover accurate localization ability. Ear plugging in adult animals does not result in adaptive changes in interaural

disparity tuning, and the auditory and visual space maps therefore remain out of register while the plug is in position. Analogous developmental plasticity occurs when owls are raised wearing prismatic spectacles that displace the visual field in the horizontal plane: the tuning of SC neurons to ITDs (which serve as the cue for azimuthal location in barn owls) shifts to maintain the correspondence between auditory and visual RFs [3]. The plasticity demonstrated in these studies using experimental manipulations of sensory input occurs in all animals during development as the size of the head increases, and the values of ITDs and ILDs associated with particular spatial locations consequently change.

## Adult Plasticity: Injury-Induced

Lesions of a restricted region of the cochlea (which result in a partial hearing loss) result in a reorganization of the ►frequency map in AI. The nature of this reorganization is that the region deprived of its normal input by the cochlear lesion is occupied by an expanded representation of the frequencies represented at the edge(s) of the cochlear lesion. The thresholds, latencies, and sharpness of ►frequency tuning of neurons in this expanded representation at their new ►characteristic frequency (CF) indicate that the changed frequency organization is not a passive consequence of the peripheral lesion, but reflects a dynamic process of reorganization. Such reorganization is observed after mechanical cochlear lesions, and after lesions produced by ►ototoxic drugs or by ►noise trauma [1]. Analogous reorganization is seen in visual and somatosensory cortices after restricted retinal lesions and digit amputation, respectively [4]. After mechanical cochlear lesions, similar reorganization is seen in the major auditory thalamic nucleus (the ventral division of the ►medial geniculate nucleus), but reorganization is patchy in the ICC and is not observed in the dorsal nucleus of the CN, suggesting that this form of CAS plasticity is a characteristic of ►thalamo-cortical circuitry.

## Adult Plasticity: Learning-Induced

Changes in the stimulus selectivity of neurons in the higher levels of the auditory pathway, as a consequence of behavioral conditioning procedures in which an acoustic stimulus serves as the ►conditioned stimulus or discriminative (henceforth "training") stimulus, were the first demonstrations of CAS plasticity in adult animals, and this remains the most active area of research on this topic. The most common finding in these studies is that the response of cortical neurons at the training frequency increases, while the response at other frequencies decreases, such that the training frequency becomes the neurons' ►best frequency. Such effects have been described in AI and in secondary auditory cortical fields, and in the auditory thalamus [1,5,6]. These studies have commonly used ►fear conditioning procedures, but appropriate controls, and the specificity of the effects to the training frequency, establish that the observed effects are manifestations of plasticity rather than consequences of changes in state variables [6]. A substantial body of evidence indicates that the ►cholinergic basal forebrain plays an important modulatory role in this form of CAS plasticity [1].

Another form of auditory learning that might involve CAS plasticity is ►perceptual learning, the improvement in discriminative capacity with training that is a common observation in all sensory modalities both in psychophysical experiments and in everyday life [1,7,8]. The specificity of many forms of visual perceptual learning to particular features of the training stimuli, or to the region of the receptor to which the stimuli are presented, has led to the proposal that the learning might involve changes in neural tuning in primary sensory cortex [7,8]. In the auditory system, the evidence for changes in AI associated with perceptual learning is equivocal [7], and it is possible that the learning involves changes in higher-order decision making processes. Indirect evidence for auditory cortical changes is provided by ►functional imaging evidence of larger auditory cortical responses to musical tones in trained musicians, although in this case it is not clear whether the larger cortical responses are a consequence of training, or whether people with this innate characteristic are more likely to undertake such training [1].

Two forms of auditory perceptual learning that are of great practical significance relate to speech processing. The first is the effect of language experience on the perception of speech sounds, and thus on language acquisition, during a critical period of development [9]. The second is the improvement in speech discrimination shown by people with ►cochlear implants over the months and years following implantation. Whether these forms of learning reflect plasticity in the CAS itself or in regions involved in cognitive processes is not clear.

## Adult Plasticity: Microstimulation-Induced

A series of studies in adult bats and gerbils have indicated that focal electrical stimulation of a region of AI can change the frequency selectivity of neurons around the stimulation site in AI, and in the tonotopically corresponding area of the central nucleus of the IC [5]. ►Centrifugal fibers from AI to IC have been shown to play a role in this plasticity.

## Lower-Level Processes

The cellular mechanisms of CAS plasticity (and those of plasticity in other sensory systems) are incompletely understood. Different forms of plasticity have different time courses, as do different phases of particular forms of plasticity. The first stage of injury-induced plasticity

in sensory cortices appears to be an expansion of RFs, reflecting an unmasking of normally-inhibited excitatory inputs from outside the classically defined RF [10]. A similar unmasking is involved in space map plasticity in the barn owl [3]. The subsequent establishment of smaller RFs in injury-induced plasticity presumably involves changes in the efficacy of both excitatory and inhibitory synapses, and there is evidence for the strengthening of excitatory synapses via ►NMDA-receptor mediated ►long-term potentiation in developmental plasticity in the barn owl [3] and in adult plasticity in the visual and somatosensory systems [10]. Longer-term changes in the barn owl involve axonal sprouting and ►synaptogenesis [3]; axonal sprouting is also involved in the changes observed after unilateral cochlear ablation in neonatal animals [2]. Axonal sprouting of horizontal fibers in the superficial layers of the cortex has also been shown to be involved in visual cortical plasticity after retinal lesions in adults [8]. Structural changes of this sort have not yet been shown in injury-induced auditory plasticity in adults. Finally, as mentioned previously, corticofugal projections have been shown to be involved in some forms of plasticity [5,8].

### Function

Auditory developmental plasticity and learning-induced plasticity are undoubtedly adaptive, in that they enhance the organism's ability to adjust to altered patterns of input and, in the case of human language acquisition and adaptation to a cochlear implant, make important auditory discriminations. It is less-clear that adult injury-induced plasticity is adaptive, as the organism remains deaf in the frequency range affected by the cochlear lesion, and there is little evidence that the CAS reorganization consequent on the lesion in any way compensates for this deafness. It is likely that this form of plasticity is an extreme manifestation of the processes that underlie other forms of plasticity in response to altered input, but it is also possible that similar processes are involved in recovery of function after central damage such as that produced by stroke.

### Pathology

There is little evidence that these forms of plasticity have pathological consequences, although it has been suggested that tinnitus might be a consequence of cortical reorganization consequent on a peripheral lesion [1].

### Therapy

The possibility that some forms of learning impairment might involve deficiencies in aspects of auditory processing that exhibit plasticity, such that these deficiencies can be modified by training, has resulted in the recent development of a number of auditory training software packages. As discussed previously, the success of cochlear implants undoubtedly rests in part on the plasticity of CAS structures, and plasticity therefore contributes to the therapeutic effects of these devices.

## Plasticity in Nociception

### Definition

Plasticity with respect to nociception refers to modulation of nociceptive afferent signals. Plasticity with respect to pain refers to the modulation of pain perception. The biological response to tissue damage, and the subsequent perception of pain, can vary depending on activation of other ascending and descending sensory systems.

►Spinal Dorsal Horn Plasticity

## Plateau Potential

### Definition

A membrane potential depolarization that is sustained by intrinsic properties even after the stimulus that triggered it has been terminated. In contrast to a pacemaker potential, the plateau potential is not rhythmically activated and terminated by the neuron.

Instead, onset and termination of plateau potentials are typically triggered by excitatory and inhibitory synaptic inputs. Most commonly plateau potentials are caused by the action of persistent inward currents (e.g. persistent $Na^+$ current, low-voltage activated $Ca^{2+}$ currents, etc.). Once these currents have been activated by a synaptic input or brief depolarization, the resulting inward current is sufficient to sustain the depolarization and maintain their activation. The depolarization can be terminated by inhibitory synaptic inputs that hyperpolarize the membrane potential sufficiently to remove the activation of the persistent inward current. The plateau potential can also be terminated by intrinsic mechanisms, e.g. persistent $Ca^{2+}$ influx can activate $Ca^{2+}$-dependent $K^+$ channels that cause an outward current which will repolarize the membrane potential and terminate the plateau potential.

## p75NTR

### Definition

p75NTR (p75 neurotrophin receptor) is a 75 kDa member of the Tumour Necrosis Factor (TNF) receptor family whose members share a cysteine-rich common extracellular binding domain. It was originally identified as a low-affinity receptor for NGF (nerve growth factor). It has since been shown that p75NTR binds all known members of the neurotrophin family (NGF, BDNF, NT-3, NT-4/5), and subsequent intracellular activation is upstream of both the PKC and JNK pathways resulting either survival or death. Denervated Schwann cells express high levels of p75NTR as a consequence of the loss of axonal contact. The function of p75NTR in Schwann cells is currently not known.

# Pons (Varolius)

## Definition

The pons (Latin for bridge, describing the large fiber bundle running across the ventral surface of the brainstem, perpendicular to its long axis) is the portion of the brainstem between the medulla and midbrain. The cerebellum sits dorsal to the pons and is attached to it by the large fiber bundles of the middle cerebellar peduncle on each side. The pons consists of two parts: base of pons and tegmentum. The typical protruding base of pons accommodates the pyramidal tracts. Interspersed here are the pontine nuclei, where corticopontine fibers synapse. The tegmentum area contains cranial nerve nuclei (V,VI, VII, VIII), trapezoid body, medial lemniscus, parts of the reticular formation and the medial longitudinal fasciculus.

## Synonyms

Pontine respiratory group; Pneumotaxic center; Pontomedullary respiratory pattern generator

## Definition

Pontine control of respiration involves the modulation of the timing and amplitude of the muscle activities that execute breathing, and airflow in and out of the lungs. Breathing is a vital function. Together with the cardiovascular system, breathing supplies oxygen to maintain general metabolism and is thus essential for bodily function. Importantly, breathing is also integrated with other mammalian behaviors like vocalizing, swallowing, coughing, and sniffing. Thus, breathing interacts with the environment not only in terms of inhaling and exhaling gas but also in terms of communication, food consumption, airway protection, and odor detection. The pons modulates breathing not only for gas exchange but also in these different behaviors.

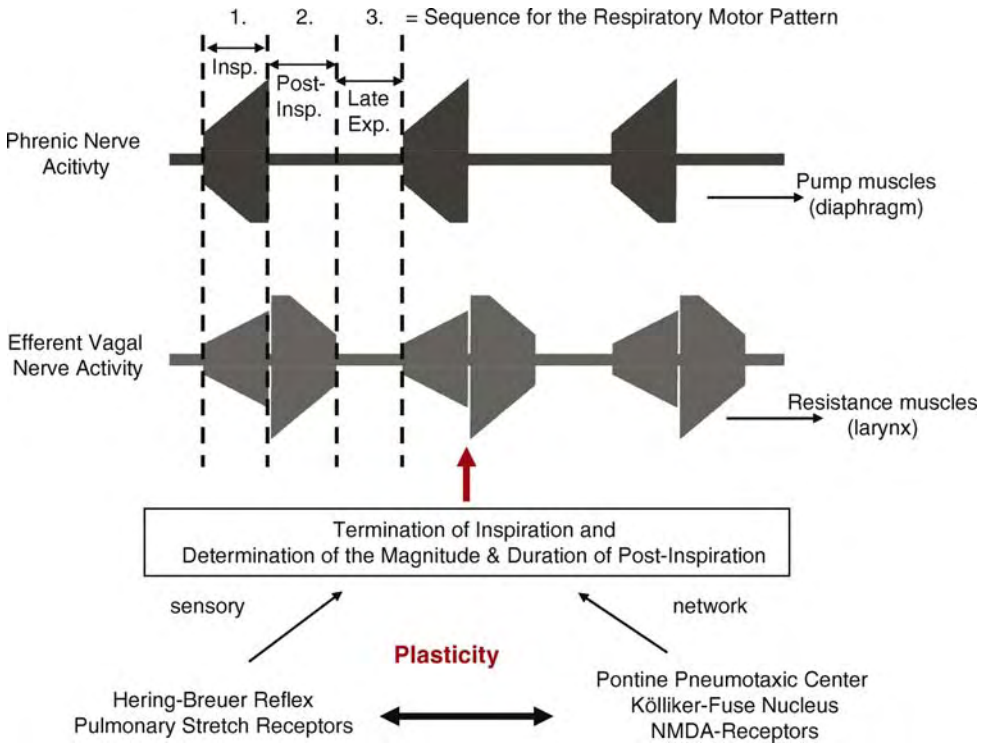
## Characteristics

### Pontine Influences on the Respiratory Motor Pattern

Breathing in mammals is controlled by a distributed network of neurons located bilaterally in columns of neurons that extend from the ventrolateral medulla to the parabrachial/Kölliker-Fuse complex in the rostral dorsolateral pons [1]. The medulla generates the primary respiratory rhythm and motor pattern, while the pontine nuclei exert strong modulatory influences on the respiratory frequency and shape of the respiratory motor pattern.

The respiratory motor pattern is defined by a sequence of bursts of different motor activities that are commonly divided into three major phases: (i) inspiration, (ii) postinspiration (early expiration or passive expiration), and (iii) late expiration (active expiration) (Fig. 1).

During the inspiratory and late expiratory phases, spinal motoneurons receive excitatory drive to contract thoracic and abdominal striated muscles including the diaphragm, to pump air in and out of the lungs (Fig. 1). Complementary motor activities transmitted in the cranial nerves (glossopharyngeal (IX), vagal (X), and hypoglossal (XII) nerves) target muscles that modulate airway resistance. During the inspiratory phase, posterior cricoarytenoid muscles and laryngeal abductors decrease upper airway resistance by pulling the vocal chords apart, whereas during the postinspiratory phase, the thyroarytenoid muscles that act as adductors increase resistance by drawing the vocal chords together. Laryngeal adductor activity depends on the pons (Fig. 2). Even in resting breathing, activity of laryngeal adductors (as well as inactivity of the airway dilators) limits or "brakes" expiratory airflow to prevent ►atelectasis especially in mammals with highly compliant chest walls. Thus, even though we separate pontine modulation of rhythm or timing from that of motor activity, these two variables are not independent. Pumping and resistance motor activities are associated with the phases of the respiratory cycle and



**Pontine Control of Respiration. Figure 1** Schematic drawing illustrating the coordinated pattern of two representative motor activities critical in defining the breathing pattern – phrenic nerve activity (top) and efferent vagal nerve activity (bottom). In these recordings, the sequential phases of the respiratory cycle ((i) inspiration, (ii) postinspiration, (iii) late expiration) can be identified. Two convergent pathways, an afferent pathway mediating the Hering-Breuer reflex and a central pathway that requires the dl pons, control the termination of inspiration and the duration of the postinspiratory phase of the breathing cycle. Plasticity in the expression of the breathing pattern depends on the pons and results from interaction between afferent and network pathways.

are coordinated by synaptic interactions within circuits of the pontomedullary respiratory network.

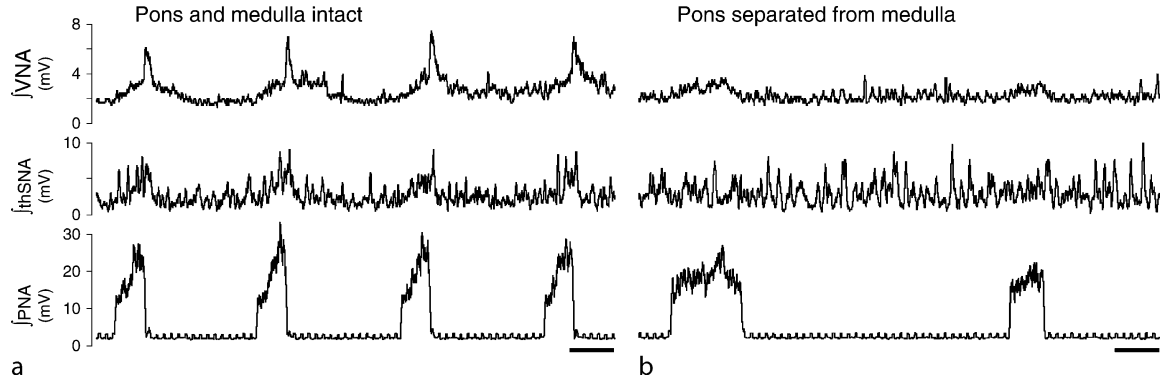
## Pontine and Vagal Afferent Interaction Influences Timing of the Pattern

The importance of the pons in the neuronal control of breathing was established by Marckwald in 1888 [1]. He investigated breathing in rabbits and noted that after transecting both vagal nerves, respiratory rhythm became apneustic (►apneusis) after mid-pontine transection (compare phrenic nerve activity pattern before and after pontomedullary transection in Fig. 2). These studies complement those of Breuer, conducted in Hering's laboratory in 1868 [2]. They showed that lung inflation evokes a reflex that shortens inspiration and lengthens expiration and that this reflex, namely, the "►Hering-Breuer Reflex" was vagally dependent and mediates the afferent input from pulmonary stretch receptors. An interpretation of Marckwald's work was that the pons acted like an "internal vagus" acting on the same medullary neurons that mediate the Hering Breuer reflex. Subsequent studies have supported this interpretation [3]. Stimulating the lateral pons evokes phase switching, and recording neuronal activity in the dl pons shows that the magnitude and strength of its respiratory modulation increases in the absence of vagal input [4,5].

Interestingly, the Hering-Breuer reflex is of minor importance in the regulation of breathing in humans. However, breathing is not simply a stereotyped rhythmic activity that is controlled reflexly from the pulmonary stretch receptors of the lungs and chemoreceptors of the vasculature but rather a behavior whose function and control is incorporated into the context of other behaviors like vocalizing. Thus, the importance of the pons in respiratory control may be in determining breathing pattern in the context of behavior.

## Expression of Plasticity in the Breathing Pattern Depends on the Pons

Activity-dependent plasticity (See Encyclopedia Article Respiratory Neuroplasticity by Morris and Bolser) of the breathing pattern is evident after brief (seconds to minutes) activation of afferent pathways whether they are mechanosensory (vagal afferent) [6] or chemosensory [7] pathways. Following stimulation, the breathing



**Pontine Control of Respiration. Figure 2** Recordings of respiratory-modulated motor activities recorded from a vagus nerve (VNA, upper trace), phrenic nerve (PNA, lower trace), and thoracic sympathetic chain (thSNA), before (left) and after (right) pontomedullary transection. (a) With the pons connected to the medulla (recording from working heart brainstem preparation, see Encyclopedia Article Central Integration of Cardiovascular and Respiratory Activity Studied *In Situ* by Paton), breathing is regular as depicted by uniform pattern of activity from cycle-to-cycle. Specifically, VNA, which has some inspiratory activity increases sharply in the postinspiratory phase immediately after inspiration ceases when PNA burst ends. Sympathorespiratory coupling is evident in the inspiratory modulation of thSNA. (b) After pontomedullary transection, the respiratory rhythm as well as motor activity is irregular and disrupted, in particular, nonuniform durations of respiratory phases and no postinspiratory activity in the vagal motor nerve (Bar 1s).

pattern does not return immediately to baseline even though the controlled physiological variables such as blood gases have returned to baseline. Instead, the pattern gradually returns to baseline and this depends on the lateral pons because if input from the lateral pons is blocked, then the breathing pattern returns to baseline immediately. The pons may be acting directly on the pattern generator, particularly postinspiratory medullary neurons and may be acting through its ability to gate or regulate the incorporation of afferent information by the medulla [6]. The regulation of sensory input is a common way that behaviors override reflex control.

Anatomical studies indicate that the lateral pons and nuclei of the solitary tract (nuclei of the medulla (NTS) that receive mechano- and chemo-sensory input) are connected reciprocally (Fig. 1 – horizontal two-headed arrow at the bottom). Sensory information is transmitted to the Kölliker-Fuse nucleus and, in turn, the Kölliker-Fuse nucleus "gates" or modulates the efficacy of afferent input in the NTS; in particular, activity of the Kölliker-Fuse nucleus can suppress sensory input in NTS [8]. However, the precise synaptic interactions between NTS and Kölliker-Fuse nucleus still need to be elucidated.

## The Role of the Pons in Respiratory Pattern Dysfunction

The respiratory pattern is highly variable in a mouse model for the Rett syndrome, which is a neurodevelopmental disease with severe respiratory disorders and lack of vocalization. This respiratory disturbance is associated with impairment of pontine and vagal modulation of postinspiratory activity [9]. These data suggest that disturbance of the postinspiratory gating mechanisms causes severe respiratory disorders and that the pons has influence over variability, especially for other behaviors like vocalization.

## Future Directions

Presently, while we know much about reflex control of the breathing and blood pressure both of which are controlled by pontomedullary networks, we know very little about the factors that integrate their control. This is especially true of those intrinsic to the brainstem. For instance, sympathorespiratory coupling is at least partially dependent on the pons (Fig. 2). Thus, the pons acts to coordinate the cardiorespiratory system to maintain homeostasis and oxygenation of vital organs including the CNS.

Oscillations (0.1 Hz) that are expressed in the blood pressure as ►Mayer Waves can influence the breathing pattern. Mayer Waves are thought to be related to baroreceptor reflex control of blood pressure. Preliminary analysis of pontine neuronal spike trains recorded continuously before and after vagal nerve transection suggests that in addition to the respiratory rhythm, a slow rhythm (~0.1 Hz) is also expressed by respiratory-modulated pontine activity. In some cases, this rhythm, which is normally masked, is strong enough that the respiratory rhythm itself becomes synchronized with it after vagotomy. The 0.1-Hz rhythm may be synchronized with Mayer Waves. In experiments in dogs, Mayer waves and the respiratory modulation of blood pressure, ►Traube-Hering waves,

were found to synchronize after vagotomy [10]. Additional preliminary analysis suggests that many pontine neurons that have respiratory modulation are also modulated with the blood pressure pulse of the cardiac cycle. These lines of evidence may indicate that individual pontine neurons are arranged in networks that help coordinate the intertwined control of breathing and perfusion. However, a great deal of work remains to elucidate the mechanisms of that coordination.

# Pontocerebellum

## Definition

The hemispheres belong to the phylogenetic young neocerebellum and receive their afferences via the moss fibers of the pontocerebellar tract from the pontine nuclei. Therefore, one also likes to summarize all hemispheric sections to the so-called pontocerebellum.

►Cerebellum

# Pontomedullary Respiratory Pattern Generator

►Pontine Control of Respiration

# Ponto-Pontine Long-Lead Burst Neurons

Charles Scudder
Portland, OR, USA

## Definition

Ponto-pontine neurons, in general, are neurons that have both their somata and terminal fields in the pontine reticular formation. Ponto-pontine ►long-lead burst neurons (►burst cells – long lead (LLBNs)) (PP-LLBNs) are ponto-pontine neurons that exhibit long-lead burst discharges during ►saccades. Although some PP-LLBNs have been experimentally identified, those having the well defined functions expected from theory remain hypothetical at this point.

## Characteristics

### Higher Order Processes

Based on experimental studies of the saccadic system and on models of the saccadic system that incorporate these experimental results, PP-LLBNs are needed to relay signals from higher saccadic command centers to the ►saccadic burst generator. These command centers consist of the deep and intermediate layers of the ►superior colliculus with weaker projections from ►frontal eye fields (FEF). The superior colliculus, in turn, coalesces saccade-related information from the frontal eye fields, the ►supplementary eye fields (SEF), the ►lateral intraparietal area (LIP), and the ►substantia nigra and issues the principal saccadic command. Neurons in the FEF and superior colliculus both have long-lead discharge patterns, and provide the long-lead signal to the PP-LLBNs.

### Lower Level Processes

PP-LLBNs are thought to convey the saccadic command to the ►excitatory burst neurons (EBNs), ►inhibitory burst neurons (IBNs), and ►omnipause neurons (OPNs) of the saccadic burst generator. There are at least two, and possibly three, populations of PP-LLBNs that project to these neurons.

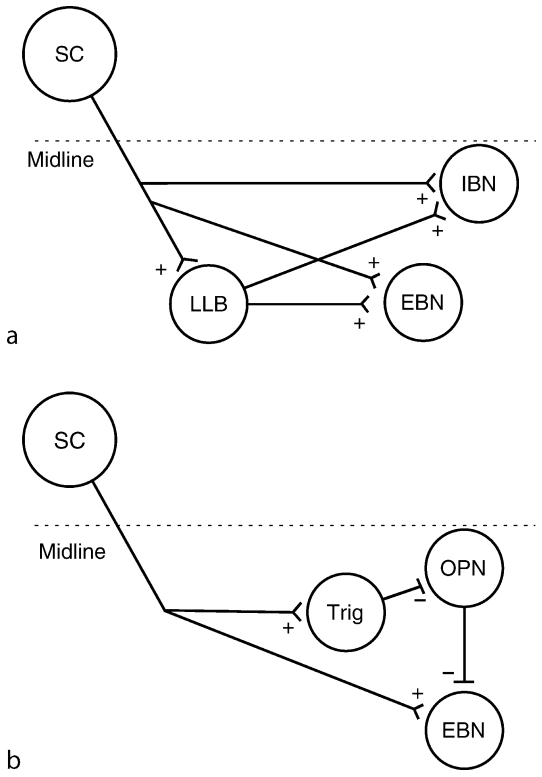
### Parts of the Ponto-Pontine LLBN System

#### *Excitatory Relay PP-LLBNs*

The generation of saccades requires a powerful excitatory input to the EBNs and IBNs. This excitation could be provided by a direct input from the superior colliculus, or by way of PP-LLBNs intercalated between the superior colliculus and the burst neurons [1]. Experimental data supports both possibilities. In the monkey, the superior colliculus does not project directly to EBNs, but does project to long-lead burst neurons (LLBNs) located in the pontine reticular formation [2]. PP-LLBNs do project to the region containing EBNs (see below), and must connect with EBNs, or else EBNs would have no suitable input. In the cat, a direct connection from the superior colliculus to EBNs has been demonstrated, but a parallel indirect pathway exists that most likely involves PP-LLBNs [3–5]. Similarly, cat IBNs receive direct and indirect input from the superior colliculus [3–6]. This set of connections is illustrated in Fig. 1a.

#### *Inhibitory Trigger Neurons*

Another population of PP-LLBNs, called ►trigger neurons, is needed to initiate the saccade. Activity in the superior colliculus activates the trigger neurons, which inhibit the tonically active OPNs. The pause



**Ponto-Pontine Long-Lead Burst Neurons.**
**Figure 1** A portion of the wiring of the saccadic burst generator showing the connections of two pools of PP-LLBNs. (A) Relay PP-LLBNs (LLB) convey the output of the superior colliculus (SC) to the premotor burst neurons; excitatory burst neurons (EBN) and inhibitory burst neurons (IBN). The connections are all excitatory (+). The SC also has direct connections to the EBNs and IBNs in the cat. (B) Inhibitory PP-LLBNs (Trig) convey the output of the SC to omnipause neurons (OPN) in order to silence them and trigger the start of the saccade. Inhibition is signified by the "–" sign. A more complete diagram showing the relation of these components to the whole burst generator is presented in the brainstem burst generator section.

in OPN activity disinhibits the burst neurons (see ►Brainstem burst generator) and allows them to discharge. The inhibitory trigger neurons intercalated between the superior colliculus and OPNs (Fig. 1b) are needed to accomplish the inhibition of the OPNs, because the efferents of the superior colliculus are excitatory. In agreement, microstimulation of the superior colliculus leads to inhibitory potentials in OPNs at disynaptic latencies, and intracellular recordings from OPNs in alert cats reveals a pre-saccadic phase of inhibition that is possibly mediated by trigger LLBNs [6–8]. Microstimulation in the ►paramedian pontine reticular formation (PPRF) where LLBN somata are prevalent produces inhibition in OPNs [6].

### *Identified PP-LLBNs*

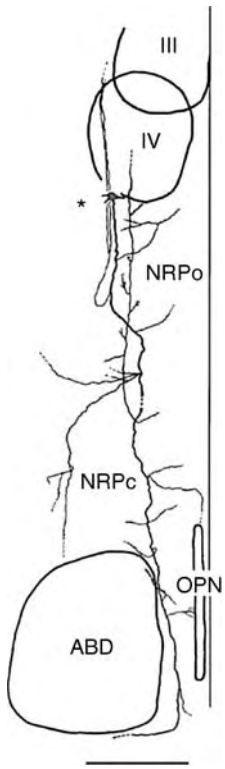
Definitive anatomical and physiological evidence for the existence of PP-LLBNs consists of four PP-LLBNs revealed using the intraaxonal labeling technique [9]. The small sample size probably does not reflect a paucity of PP-LLBNs, but rather the difficulty and biases of the intraaxonal technique. All four neurons are anatomically different, but nonetheless innervate many of the same parts of the reticular formation. The diversity of these neurons, together with various fragments of incompletely labeled neurons, shows that there may be a large variety of PP-LLBNs.

Somata of three neurons were located in the rostral PPRF (NRPo) caudal and ventral to the trochlear nucleus. The soma of the fourth was located at the mid PPRF just rostral to the EBN area. Axons of all four descended in the PPRF, and all four axons gave off one or two branches that ascended to, and sometimes terminated in, the ipsilateral mesencephalic reticular formation (cf. Fig. 2). Most (3/4) had branches that terminated in ipsilateral NRPo, and all had branches that terminated in the part of ipsilateral caudal PPRF (NRPc) where EBNs are located. They also all had branches that innervated ►raphe interpositus (the locus of OPNs) or the immediately adjacent region containing OPN dendrites. Less frequent targets included ►NRTP, raphe pontis, the contralateral PPRF, the IBN area, and ►nucleus reticularis gigantocellularis (one origin of reticulospinal pathways). One axon could be followed well into the medulla and may have been headed for the spinal cord.

As with other LLBNs, PP-LLBNs were mostly silent during fixation, and gradually began firing on average 44–107 ms preceding the start of ►ipsiversive saccades. Firing rate peaked just before the saccade start, and ended just before saccade end. The spatial properties of their discharges were as varied as their anatomy. Two were ordinary ►vectorial burst neurons (discharging only for saccades to a small circumscribed region of visual space – the ►movement field), one was a vectorial burst neuron with an unusually wide movement field, and the fourth was a ►directional burst neuron that discharged for all saccades into the ipsiversive visual space.

## Pathology

PP-LLBNs and their axonal and terminal processes are intermixed in the PPRF with a multitude of eye-movement related and other neurons. Experimental and natural lesions of the region that contains PP-LLBNs necessarily destroy these other neurons as well, so deficits cannot be attributed to one population alone. Lesions of the PPRF can impair most types of horizontal eye movements; ►VOR, ►smooth pursuit, ►optokinetic nystagmus, and saccades [10]. Many of these deficits can be traced to damage of fibers that traverse the PPRF, but



**Ponto-Pontine Long-Lead Burst Neurons.**
**Figure 2** Camera lucida drawing of a PP-LLBN in the left side of the pontine reticular formation reconstructed in a horizontal plane. The soma (*) is ventral and immediately caudal to the trochlear nucleus (IV), and the axon descends through the nucleus reticularis pontis oralis (NRPo) and ►nucleus reticularis pontis caudalis (NRPc). Terminal arborizations innervate these structures, including the part of NRPc containing excitatory burst neurons. Other branches terminate just lateral to the omnipause neurons (OPN). ABD = abducens nucleus, III = oculomotor nucleus. Dashed lines indicate fading of the label. Calibration bar is 1 mm.

deficits in saccades are surely the result of destruction of the saccade-related neurons in the PPRF. Small unilateral lesions cause a slowing and shortening of ipsiversive saccades. Larger unilateral lesions eliminate all ipsiversive saccades, and large bilateral lesions eliminate all horizontal saccades. Large caudal lesions that involve the OPNs also affect vertical saccades.

# Population Code

## Synonyms

Also Ensemble Code

## Definition

Population code (also ensemble code) denotes a code by which neural information is encoded in the spatiotemporal activity patterns of many neurons.

►Sensory Systems

# Population Vector

## Definition

An algorithm for estimating a vectorial quantity encoded by the spiking activity of a neuronal population given the response characteristics of each individual neuron to different values of that vectorial quantity (tuning curve). Originally proposed for decoding the

hand movement direction from the firing rate of a population of directionally tuned neurons in the motor cortex of macaque monkeys. To compute the population vector in a specific condition (e.g. a specific movement direction), given the tuning curve of each cell (determined from the cell's response in several conditions) and the response vector associated to its maximum (e.g. the cell's preferred direction), all the response vectors, weighted by the cell firing rates in that specific condition, are summed together.

►Reaching Movements

## Pore Loop

### Definition

The pore loop represents a short amino acid sequence that forms the ion permeation pathway of tetrameric cation channels. In voltage-gated cation channels this domain is localized between the S5 and S6 segment.

The X-ray structure of the pore loop has been resolved in the bacterial KcsA channel. The domain consists of an α helical portion (the pore helix) and an uncoiled strand of 4–5 amino acid residues (the selectivity filter) forming the narrowest part of the pore.

►Cyclic Nucleotide-Regulated Cation Channels

## Pore-loop Channels

### Definition

Pore-loop channels all bear an extracellular, re-entrant loop, which provides a highly selective aqueous pore for particular ions. All pore-loop channels are structural derivatives of inward rectifying potassium ($K^+$) channels, and are the largest class of channels within the ion channel family. Pore loop channels include the voltage-gated channels, including the potassium, calcium ($Ca^{2+}$) and sodium ($Na^+$)-selective channels, the inward rectifying and two pore potassium channels and the glutamate receptors.

## Position Sense

### Definition

The ability to detect the position of joints of the body. It is tested clinically as part of assessments of proprioception.

►Joint position sense
►Proprioception and Orthopedics
►Proprioception Role of Joint Receptors

## Positional Alcohol Nystagmus

### Definition

Nystagmus resulting from alcohol intoxication. The nystagmus is due to the passage of alcohol into the cupula of each of the semicircular canals, which renders them lighter than the surrounding endolymph. The semicircular canals then respond to changes in head position resulting in positional nystagmus. A second phase is noted when alcohol diffuses from the cupula and into the endolymph. An oppositely directed positional nystagmus is then noted.

►Disorders of the Vestibular Periphery
►Semicircular Canals

## Positional Cloning

### Definition

Positional cloning is a technique used to identify genes, either associated with disease or with a mutant in an animal model, based on their location on a chromosome.

# Position-Vestibular-Pause Neurons

Kathleen E. Cullen
Department of Physiology, Aerospace Medical Research Unit, McGill University, Montreal, QC, Canada

## Definition

Traditionally, the vestibulo-ocular reflex (VOR) is considered to be a stereotyped reflex that effectively stabilizes gaze by moving the eye in the opposite direction to concurrent head motion. The three neuron arc responsible for mediating the VOR was first described by Lorente de No' in 1933. This pathway consists of projections from vestibular afferents to interneurons in the vestibular nuclei, which in turn project to extraocular motoneurons. The simplicity of this three neuron arc is reflected in the fast response time of the VOR; compensatory eye movements lag head movements by only 5–6 ms in the primate [1]. Horizontal and vertical position-vestibular-pause (PVP) neurons are thought to constitute most of the intermediate leg of the direct pathway that mediate the VORs, which are evoked by yaw and pitch rotations, respectively. As the response of horizontal PVP neurons have been more extensively investigated in alert animals, they are the focus of this essay.

The results of recent investigations have changed our view of the VOR. In particular, neurophysiological recordings from PVP neurons provide firm evidence that the VOR is not a hard wired reflex, as had been commonly assumed. This essay first describes the responses of PVP neurons during field standard tests including passive whole body rotations and eye-movements in head-restrained monkeys. Next, the results of studies that have characterized PVP neurons during (i) redirections of gaze that are produced by coordinated eye-head movements, and (ii) gaze stabilization while viewing near versus far targets during head movements, are summarized. These findings are considered in relation to the sensory-motor transformations needed to guide behavior in a manner consistent with current gaze strategies.

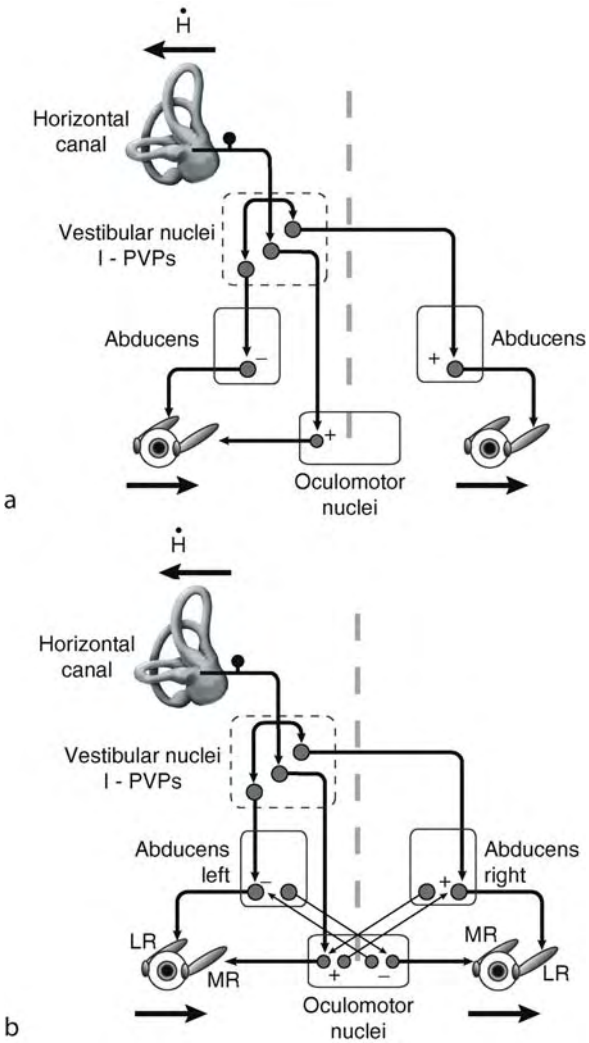
## Characteristics

### Response During Standard Head-Restrained Rotations and Eye Movements

#### *Type I Neurons*

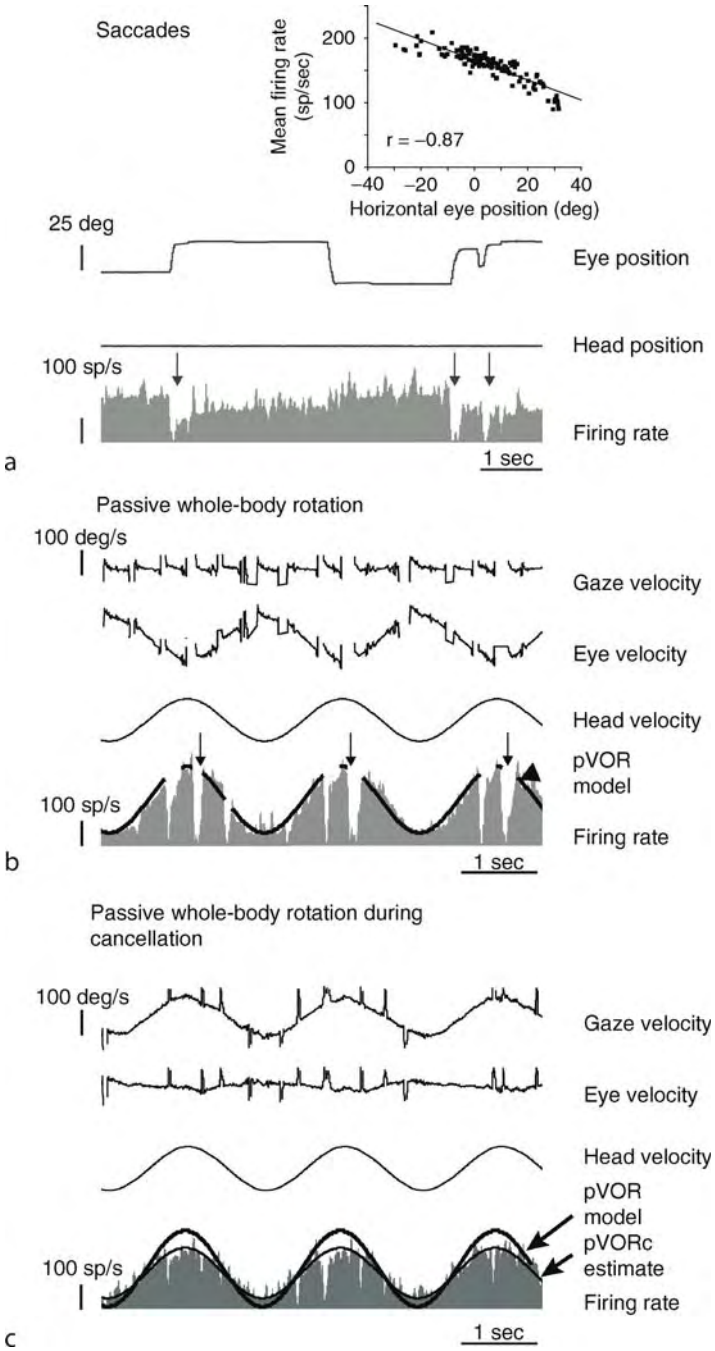
►Type I position-vestibular-pause (PVP) neuron constitute most of the intermediate leg of the direct pathway that produces the horizontal VOR (reviewed in [2]). The majority of type I PVP neurons are located in the rostral medial vestibular nucleus, and send an excitatory projection to the motoneurons of the (i) contralateral ►abducens nucleus, or (ii) ipsilateral medial rectus subdivision of the ►oculomotor nucleus (Fig. 1a). A minority send inhibitory projections to the motoneurons of the ipsilateral abducens nucleus. Within the abducens nucleus, motoneurons project directly to the ipsilateral lateral rectus muscle (LR), while a separate class of neurons (internuclear neurons) project to the contralateral oculomotor nucleus, which projects to the medial rectus muscle (MR; Fig. 1b). During horizontal eye movements, the effective force moving the eye is generated by the sum of the forces of the LR and MR.

Type I PVP neurons derive their name from the signals they carry during head-restrained rotation and eye movement paradigms. Their firing rates increase with contralaterally directed eye position; they are sensitive to



**Position-Vestibular-Pause Neurons.**
**Figure 1** (a) Direct VOR pathway; rotation of the head to the left generates right eye movements. (b) Connections between the abducens and oculomotor nuclei.

ipsilaterally directed head velocity during vestibular stimulation (i.e. a type I response); and their discharges cease (pause) for ipsilaterally directed saccades and vestibular quick phases. In addition, these neurons show modulation for contralaterally directed eye movements during ▶smooth pursuit tracking. The activity of a typical PVP neuron is illustrated in Figs. 2a–c. The neuron's mean firing rate is linearly related to eye position during periods of steady ocular fixation (Fig. 2a). During sinusoidal passive whole-body rotation in the dark at 0.5 Hz, neuronal modulation leads ipsilateral head rotation by about 10–20° (Fig. 2b), and the neuron pauses or stops



**Position-Vestibular-Pause Neurons. Figure 2** Activity of an example type I PVP neuron in the head-restrained condition. (a) Responses are correlated with horizontal eye position during periods of steady fixation. (b, c) Responses to passive whole-body rotation during (b) the VOR in the dark (pVOR), and (c) cancellation of the VOR by fixation of a target that moves with head (pVORC).

P

firing during ipsilaterally directed vestibular quick phases (Fig. 2b, downward arrows). The behavior of PVP neurons during the compensatory slow phase VOR evoked by passive rotation can be well described by the equation:

$$fr = a + kE + gH' + cH''$$

where fr = neuronal firing rate, a is the resting discharge, E is eye position, k is the eye position sensitivity of the neuron during ocular fixation, H′ and H″ are head velocity and acceleration, respectively, and g and c are neuronal sensitivities to head velocity and acceleration, respectively.

In order to dissociate the vestibular-related modulation of PVP neurons from their eye-movement related responses, vestibular physiologists have traditionally utilized a paradigm in which the monkey "cancels" its VOR by tracking a target that moves with the head. The resulting vestibular stimulation does not lead to eye motion in the opposite direction to the head motion, since trained subjects can accurately follow the target at frequencies <1.5 Hz. Type I PVP neurons respond robustly to ipsilaterally directed head velocity in this condition, but show a 30% decrease in modulation as compared to VOR in the dark (Fig. 2c [3,4]). This reduction in head-velocity sensitivity occurs at latencies that are too short to be mediated by smooth pursuit pathways (see Fig. [3]), and supports the idea that there is a parametric adjustment of the gain of the direct VOR pathway while the VOR is voluntarily suppressed. Signals carried to the extraocular motorneurons by other premotor inputs help offset the residual modulation of PVP neurons, so that the eye remains immobile (see essay on VOR suppression).

### *Type II Neurons*

During head-restrained rotations and eye movements, the head and eye movement sensitivities of type II PVP neurons are opposite to those of type I PVP neurons; firing rates increase in response to contralaterally-directed head rotation and ipsilaterally directed eye position and velocity. Otherwise, the firing pattern of these two types of neurons is very similar. The projections of type II PVP neurons are not known, however it is thought that they support inhibitory commissural pathways between vestibular nuclei [2] and that they contribute to the weak three neuron arc that, in part, mediates the translational VOR (see section on "Translational VOR" below). In addition, it is likely that the inhibitory inputs from type II PVP neurons contribute to the pause-behavior of type I PVP neurons during ipsilaterally directed saccades, vestibular quick phases, and ►gaze shifts. This proposal is consistent with known interconnections between the brainstem saccade generator and the vestibular nuclei [5].

## PVP Neuron Modulation: Voluntary Head Movements

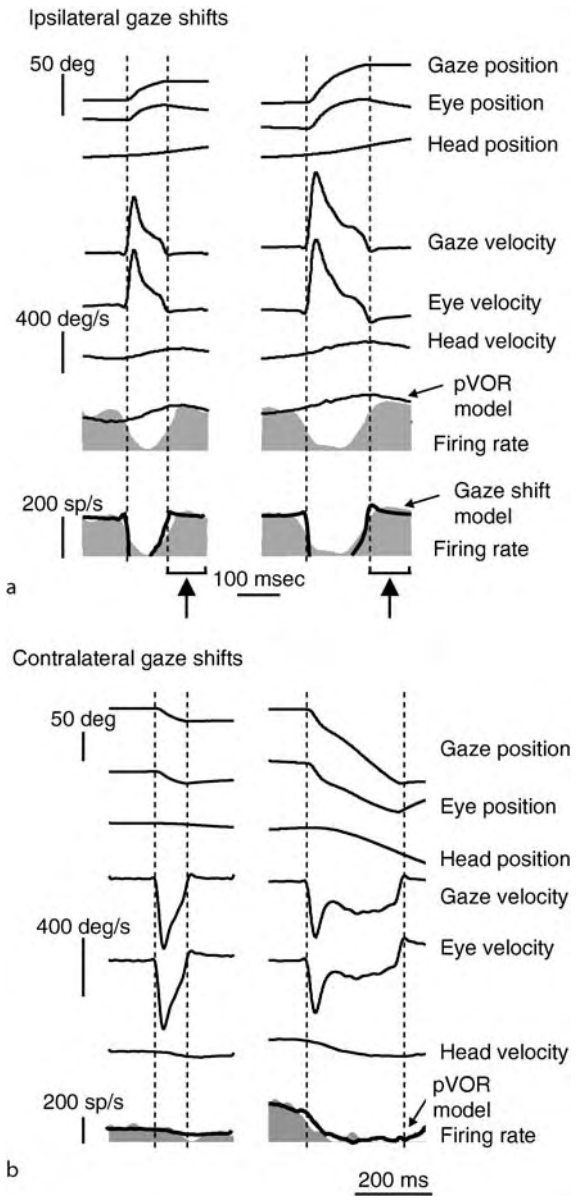
Recent work has shown that PVP neurons process vestibular information in a manner that depends principally on the subject's current gaze strategy, rather than whether the head movement was actively generated or passively applied. As described below, the head velocity signal carried by the direct VOR pathway is reduced when the behavioral goal is to redirect the visual axis of gaze. In contrast, PVP neurons robustly encode head velocity signals when the behavioral goal is to stabilize the visual axis of gaze relative to space, regardless of whether head movement is actively or passively generated.

### *Gaze Redirection*

There is much accumulated evidence from studies in head-restrained monkeys to indicate that both type I and II PVP neurons differentially encode head-velocity during gaze redirection versus gaze stabilization. First, as described above, while PVP neurons encode head velocity during the compensatory slow phase component of the VOR evoked by passive whole-body rotation, they pause or significantly decrease their firing during vestibular quick phases where gaze is redirected. In addition, PVP neuron responses are significantly attenuated, as compared to passive rotation in the dark, when the VOR is suppressed during passive whole-body rotation by tracking a target that moves with the head. In this latter condition, the goal is to redirect the axis of gaze relative to space rather than stabile gaze [3,4].

It is useful to suppress PVP transmission in each of the above circumstances, since eye movement commands generated by the direct VOR pathways would function to drive the eye in the opposite direction to the intended change in gaze. An analogous argument can be made for situations in which the axis of gaze is voluntarily redirected, a combination of eye and head movements. In order to rapidly redirect the visual axis towards a target of interest, primates commonly generate coordinated eye-head movements, termed gaze shifts. Similarly, coordinated smooth head and eye movements (i.e. ►gaze pursuit) are frequently generated in order to track moving targets. Attenuating the modulation of the direct VOR pathways (i.e. type I PVP neurons) during either gaze shifts or gaze pursuit would also be behaviorally advantageous.

Indeed, during rapid orienting gaze shifts, the head-velocity related signals carried by type I PVP neurons are dramatically reduced [2,5,6]. As shown in Fig. 3a, neuronal responses to head velocity during ipsilateral gaze shifts are consistently attenuated relative to passive whole-body rotation in the dark (i.e. during the VOR, Fig. 2c). As a result, a model based on a neuron's response during passive rotation (Fig. 3a; heavy line: pVOR model) will systematically over-predict



**Position-Vestibular-Pause Neurons. Figure 3** The activity of a type I PVP neuron during and following ipsilaterally (a) and contralaterally (b) directed gaze shifts. Arrows indicate the post gaze shift intervals in (a).

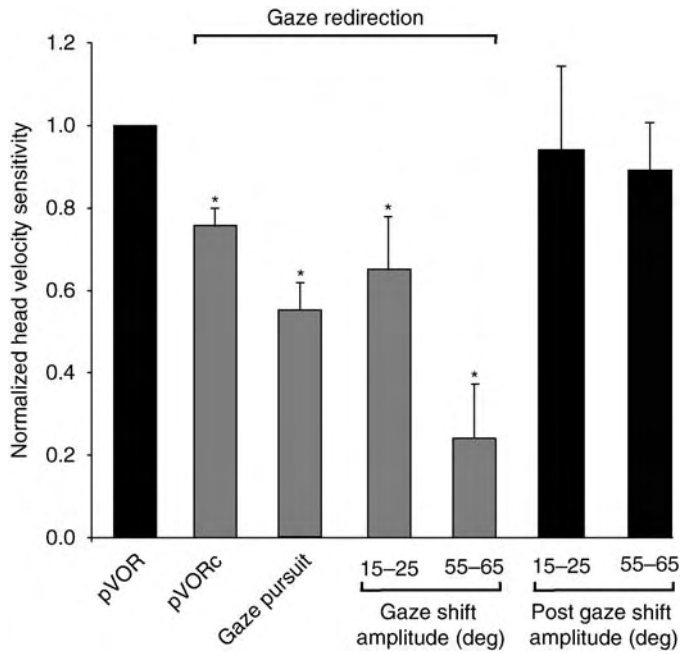
its discharge during gaze shifts. Moreover, neuronal modulation is increasingly attenuated for larger amplitude gaze shifts reaching 70% attenuation for gaze shifts >60°, [2,5]. Type I PVP neurons also contribute little to the generation of the VOR during large contralaterally directed gaze shifts, since they are typically driven into inhibitory cut-off (Fig. 3b). Overall, the amplitude-dependent attenuation of the discharge of these neurons is consistent with the results of behavioral studies demonstrating that the VOR is more strongly suppressed during large than during small gaze shifts (see essay on "VOR suppression"). Similar results have been obtained from characterizations of type II PVP neurons [2].

The head-velocity related modulation of PVP neurons is also reduced when gaze is redirected to follow a moving target by means of coordinated eye-head pursuit. Responses to the voluntary head movements that are generated during eye-head pursuit are attenuated by approximately 30% compared to responses to passive whole-body rotation. Thus, the attenuation observed during eye-head pursuit is comparable to that observed when the VOR is suppressed by fixating a target that moves with the head (Fig. 2c), as well as that observed during small rapid gaze shifts (<25°). The histogram in Fig. 4 summarizes the head velocity-related signals that are carried by PVP neurons across different voluntary behaviors, and emphasizes the fact that transmission through the VOR pathways is attenuated during all behaviors that involve gaze redirections.

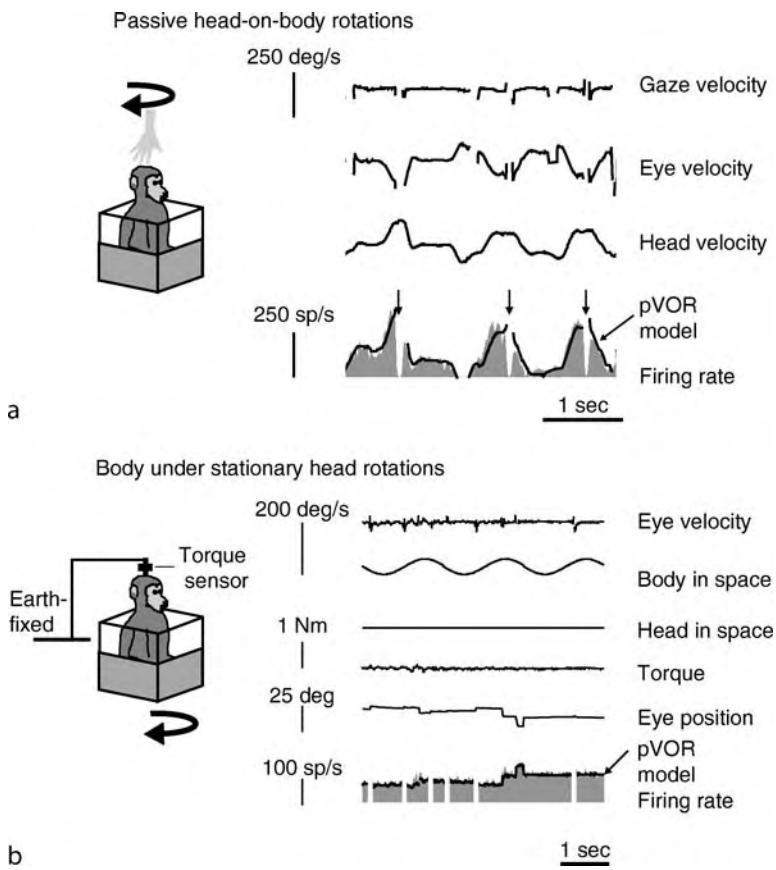
### Gaze Stabilization

As described above, an intact VOR is not beneficial when the behavioral goal is to redirect gaze to a new target. In contrast, a fully functional VOR is clearly critical when the behavioral goal is to maintain stable gaze. Moreover, there have been reports that VOR performance is enhanced in response to active head rotations compared to passive whole-body rotations [1]. These findings have led to the suggestion that neck proprioceptive signals and/or a copy of the command to the neck motoneurons might function to augment transmission in the VOR pathways (i.e. PVP neurons) during active head movements.

Single unit recording experiments, however, indicate that neither neck proprioceptive nor neck motor efference copy signals augment the modulation of PVP neurons during active head-on-body movements. First, in rhesus monkeys, PVP neurons encode head movement in the same manner during passive head-on-body rotations and passive whole-body rotations (Fig. 5a; [1,2]). In addition, PVP neurons are not modulated in response to passive rotation of the body under a stationary head (Fig. 5b [2]). Thus, the passive activation of neck proprioceptors does not significantly alter the sensorimotor transformations carried out at the level of the direct VOR pathways. Second, neuronal responses are comparable during passive whole-body rotations and active head movements that are produced during periods of stable gaze [2,5,6]. For example, as shown in Fig. 3a, immediately following a rapid orienting gaze shift, the head continues to move even after gaze has stabilized relative to space (intervals denoted by the arrows). During this interval, a neuron's activity can be predicted based on its response to



**Position-Vestibular-Pause Neurons. Figure 4** Summary of type I PVP neuron discharge activity during passive and voluntary head motion. The (*) symbol denotes significant attenuation as compared to pVOR.



**Position-Vestibular-Pause Neurons. Figure 5** (a) The head was passively rotated on a stationary body. (b) Neuronal responses are not modulated by passive stretching of neck proprioceptors produced by passively rotating the body under a stationary head.

passive whole body rotation (heavy line). Taken together, these results are consistent with accumulating evidence from behavioral studies showing that VOR performance is generally comparable during passive and active rotations of the head-on-body in primates [1].

### Summary

Recent single unit experiments show that the head velocity signals carried by the direct VOR pathways are modulated in a manner that is consistent with the current behavioral goal. PVP neurons demonstrate robust head-velocity related modulation in response to self-generated and passively applied head rotations when gaze is stable. In contrast, when the behavioral goal is to redirect gaze relative to space, the head-velocity signals carried by PVP neurons are significantly reduced.

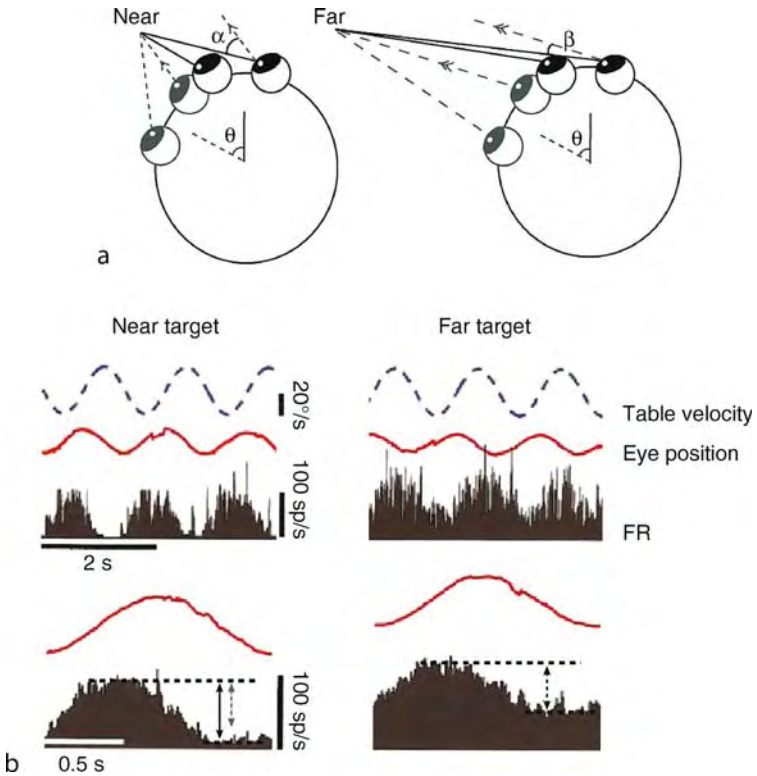
## PVP Neuron Modulation: Near Versus Far Viewing During Rotations and Translations

### Angular VOR

A second situation where the VOR shows behaviorally-dependent modulation is during the fixation of near versus far earth-fixed targets. During head rotations, the eyes translate as well as rotate relative to space, since they cannot both be perfectly aligned with the axis of rotation. Consequently, for the same amplitude of head rotation, a larger VOR gain is necessary to stabilize a near than a far earth-fixed target due to the differences in the translation of the target relative to the eyes (Fig. 6a). Differences in the responses of the type I PVP neurons that mediate the direct VOR pathways are consistent with these distance-related changes in VOR gain (Fig. 6b [7]).

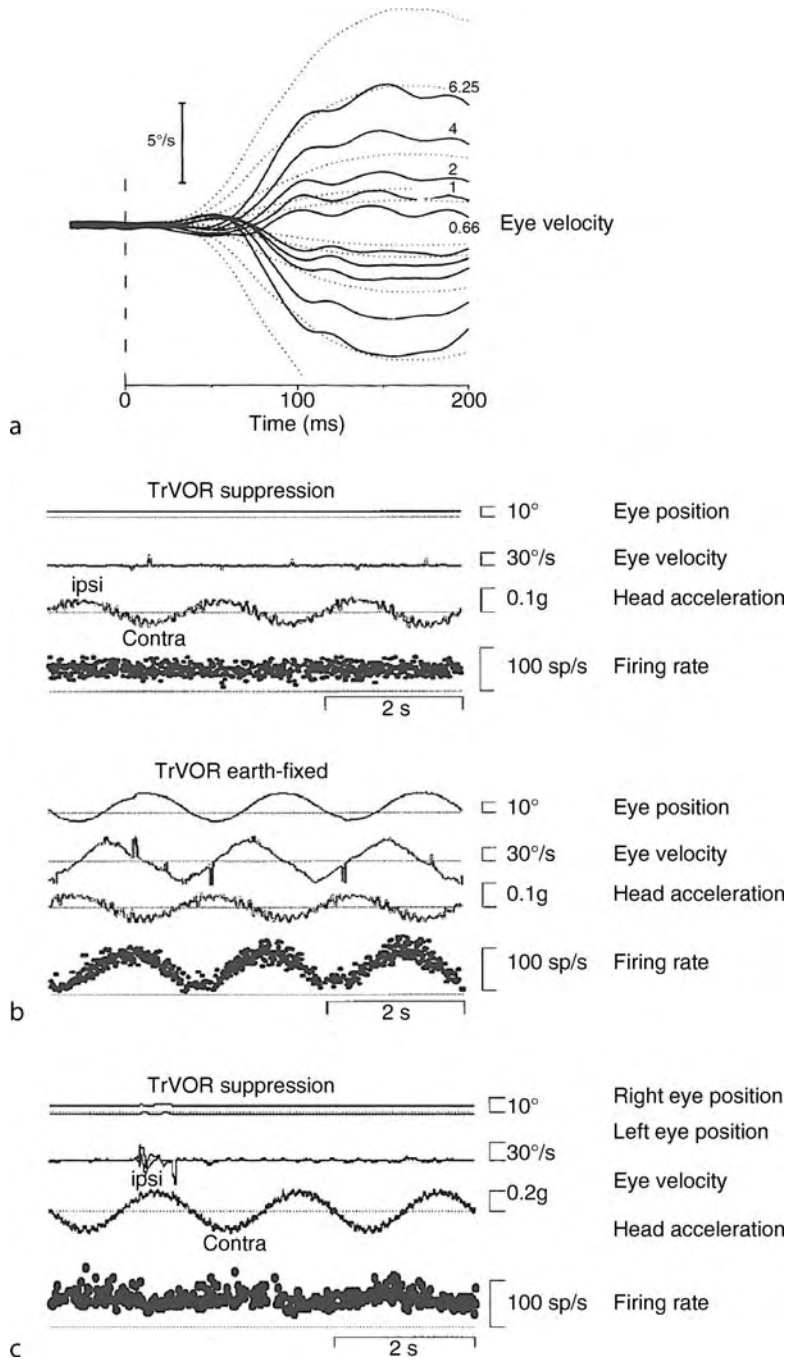
### Translational VOR

Recently, several investigations have specifically focused on the premotor pathways that generate the VOR in response to stimulation of the otoliths during translations (i.e. the translational VOR (TVOR); [8]). The latency of the TVOR is somewhat longer than that of the angular VOR; compensatory eye movements generally lag head movements by >10 ms in the primate. Although a direct disynaptic pathway has been shown to exist between the otoliths and the abducens nucleus, the longer latency of the TVOR suggests that it is primarily mediated by more complex polysynaptic pathways. During translation along the interaural axis, the gain of the horizontal TVOR response depends on



**Position-Vestibular-Pause Neurons. Figure 6** (a) Effect of varying fixation target distance (D) on VOR gain for a fixed axis of rotation. (b) Responses of a type I PVP neuron when passive whole body rotation was applied while viewing a near (*left panel*) versus far (*right panel*) target.

the distance of the target being viewed (Fig. 7a). Moreover for translations along the nasal-occipital axis, the amplitude and sign of the eye movements evoked by the TVOR depend on gaze angle as well as viewing distance. The latter finding is of particular interest, since it demonstrates that direction as well as the amplitude of the TVOR response is modified in a behaviorally-dependent manner.



**Position-Vestibular-Pause Neurons. Figure 7** (a) Effect of varying fixation target distance on VOR gain during translation along the interaural axis. Continuous lines represent average eye velocity, while dotted lines indicate the ideal response that would be required for perfect gaze stability. (b, c) Responses of an example type I (b) and type II (c) PVP neuron during lateral translation.

Type I PVP neurons, which constitute the main interneuron in the direct angular VOR pathway, do not receive direct otolith inputs and thus do not contribute to the three neuron pathway that mediates the direct TVOR pathway. This is shown in Fig. 7b, where a typical neuron shows negligible response modulation during translation when the subject fixates a head-fixed target (TrVOR suppression; [8,9]). Comparison with Fig. 2c highlights the striking difference in response to type I PVP neurons during suppression of the TVOR and suppression of the angular VOR. However, when a subject fixates an earth-fixed target during translation (Fig. 7b, TrVOR earth fixed), neurons modulate in a manner that is consistent with their oculomotor-related response during smooth pursuit [9]. These results are in general agreement with previous studies that have compared responses during on and off-centered rotations [7,10]. Given that the type I PVP neurons show robust modulation during the TVOR, and that they project directly to the extraocular motoneurons (Fig. 1), it can be concluded that they contribute to the generation of the reflex via inputs from polysynaptic (but not direct) pathways.

In contrast, type II PVP neurons show slight response modulation during suppression of the VOR during translation (Fig. 7c), suggesting that these neurons contribute to the relatively weak ipsilaterally projecting three neuron arc that mediates the direct TVOR pathway. However, these neurons do not change their response amplitude for near versus far viewing during TVOR suppression [9]. Additional inputs, most likely transmitted via cerebellar/floccular pathways, appear to be necessary to modulate the TVOR as a function of gaze angle and viewing distance [7,8,9].

# Positive Feedback Control

## Definition

A mechanism used to regulate the value or time course of an output variable or signal when the output variable is determined by the value of an input signal or the time course of an input signal. The control mechanism is said to be closed loop when the value of the output variable is sensed or measured, is fed back and compared to some desired reference value and is then used to determine the value of the input signal. The closed loop control mechanism is referred to as positive feedback control when a given change in the output variable produces a change in the input signal that causes a further change in the output in the same direction.

Positive feedback control is often unstable, but when appropriately configured systems can remain stable while using positive feedback control.

►Posture – Sensory Integration

# Positive Schizophrenic Symptoms

## Definition

Symptoms associated with reality distortion; most frequently auditory hallucinations (hearing voices), feeling of being observed or persecuted.

## Definition

Positron emission tomography (PET) is a nuclear imaging technique that allows quantitative evaluation of biochemical and physiological processes in vivo, by using ►radiopharmaceuticals (RPs) labeled with short-lived positron-emitting radionuclides, which are detected by their annihilation radiation with electronic coincidence detector systems.

## Purpose

PET can be used in both research and clinical purposes for quantitative mapping of various physiological and biochemical processes. A number of these processes depend on the ►radiotracers available.

## Clinical Purpose

Oncology: The most common application of PET is to determine the presence, severity and staging of cancer, its recurrences and responses to treatment. In neuro-oncology, PET has been found useful for the differentiation between radiation necrosis and ►glioma recurrence with 2–$^{18}$F-2-deoxy-D-glucose (►FDG) (less with labeled amino acids), glioma grade determination (FDG), and guidance for biopsy [1].

Whole-body FDG-PET enables the identification of primary lesions as well as local recurrence, lymph node involvement and distant metastases; so far, it has been quite a useful technique for tumor staging. PET provides more benefits for patients with non-small cell lung cancer (NSCLC), malignant melanoma, breast cancer, lymphoma, and colorectal cancer. PET also proved to be useful in radiation-treatment planning as well as in monitoring treatment responses (radio- or chemotherapy) [2,3].

Neurology: PET has significant implications in making a precise diagnosis of various ►neuropsychiatry and ►movement disorders. Clinical application includes lateralization of epileptic foci in ►temporal lobe epilepsy prior to surgery (FDG or rarely ►FMZ – flumazenil); differentiation between various types of ►dementia (FDG); assessment of dopaminergic neuron degeneration in ►Parkinsonism (6-FDOPA); and recognition of ►depression syndrome (WAY100635) [4].

Cardiology: PET is a modern tool for quantitative measurements of myocardial blood flow ($^{13}$N-ammonia; $^{82}$Rb) and assessment of myocardial viability (FDG), and provides important criteria for a patient's selection for a revascularization. Imaging of the ►sympathetic nervous system with PET is possible but not very common in clinical cardiology [5].

## Research

The most common research [4,6] application of PET involves ►activation studies using high-sensitivity imaging of regional cerebral blood flow (rCBF) from multiple [$^{15}$O]water injections. The alteration in neuronal activity in particular brain regions correlates with rCBF changes and the under performance of particular activities. Thus, PET is used to examine the spatial brain organization of the maintenance of cognitive, sensory, motor, emotional and other processes and responses to drug application.

Due to its high sensitivity and high specific activity (SA, the amount of radioactivity per mole) of the radiotracers, PET allows one to obtain quantitative information about the distribution of the target receptors throughout the brain, their affinity and density. The results are employed in fundamental studies of the pathogenesis of various neuropsychiatric disorders.

PET is a modern tool for the quantitative evaluation of drug-binding sites in living humans. By conducting PET studies with a suitable ►radioligand before and after treatment by a drug, the fraction of the total number of binding sites that are occupied by the drug can be quantified ("drug occupancy study)." Thus, the mechanism of drug action and optimal dosage can be evaluated in a very safe manner using the so-called "PET micro-dosing concept." With this approach, the number of patients to be studied in phase II clinical trials can be minimized from thousands to tens, resulting in a reduction in the time and costs of the studies.

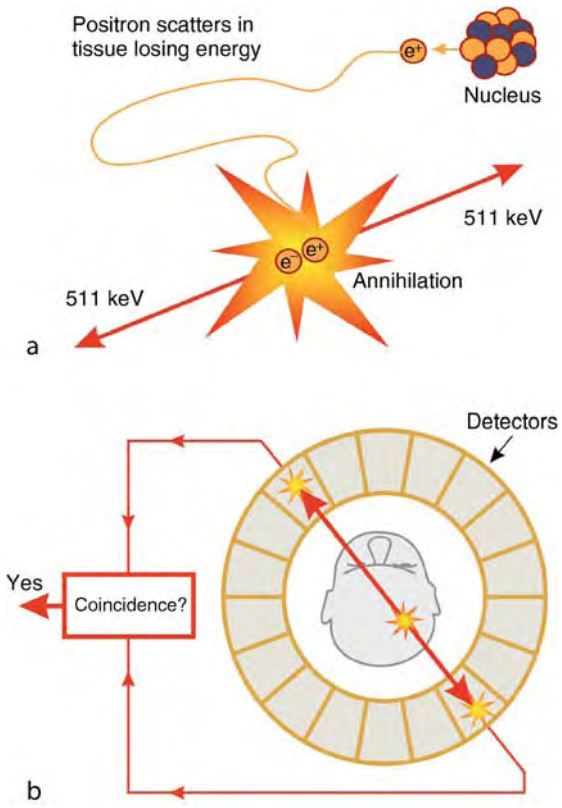
## Principles

### Basic Principles in PET Imaging

When a PET [4,7] ►radionuclide is introduced into the human body, at any given time, part of the nucleus will decay emitting a positron (positively charged electron) and a neutrino. The neutrino leaves the body without interaction. The positron, after a series of scatterings, annihilates with an electron. As a result, two photons (gamma quantum) of equal energy, i.e., 511 keV, are emitted in opposite directions at almost 180° (Fig. 1a) and can be detected by an external detector system.

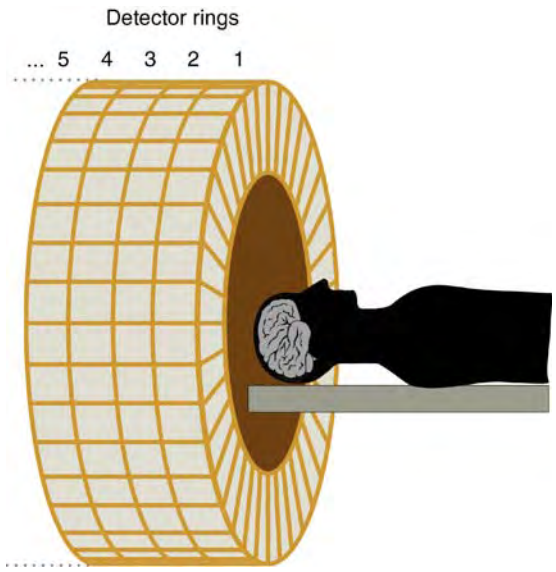
If arrays of gamma detectors are gathered around the body, a coincident event – simultaneous signal from a pair of detectors - means that annihilation took place somewhere on the straight line (line of response) connecting this pair (Fig. 1b).

The next annihilation induces coincident events, usually in another pair of detectors, and gives another line of response. The density of all intersections of such lines yields a spatial distribution corresponding to the



**Positron Emission Tomography. Figure 1** (a) When a PET radionuclide is introduced into the human body, at any given time part of the nucleus will decay emitting a positron. After a series of scattering, the positron annihilates with an electron. As a result, two photons (gamma quantum) of equal energy, i.e., 511 keV are emitted in opposite directions very close to 180° apart. (b). If arrays of gamma detectors are gathered around the body, a coincidence event – simultaneous signal from a pair of detectors – means that annihilation took place somewhere on the straight line (line of response) connecting this pair.

isotope concentration map. This method of coincidence registrations is the essence of PET and provides for its high efficiency. Information is contained in the direction of the photon movements. In other systems such as gamma cameras, this information is provided by using special metal tubes – collimators, which allow only the minority of all photons to enter the collimator and thus reach the detectors, while the majority is absorbed in the metal. Thus, in this system, each detector detects only photons coming from one given direction. The coincidence mode of registration and the use of short-lived radionuclides (2–110 min half-life) mostly contribute to the high sensitivity of PET, which allows the detection of pikomole amounts of substances. As a result, studies of drug abuse (cocaine, amphetamine) and toxic compounds become possible



**Positron Emission Tomography. Figure 2** A PET scanner consists of up to 30,000 detectors (scintillation crystals with photomultipliers), arranged in rings, formed in a cylinder around the body.

at concentration levels that do not cause any pharmacological effect [8].

A PET scanner consists of up to approximately 30,000 detectors (scintillation crystals with photomultipliers) arranged in rings formed in a cylinder around the body (Fig. 2).

These detectors involve a coincidence registration circuit, which collects information about coincidence events – counts. Using conventional algorithms for image reconstruction including different types of corrections, a volume isotope concentration map can be obtained. The unique feature of the PET coincidence technique is that corrections for radiation losses can be performed within the body (attenuation correction). This procedure is called "transmission scan."

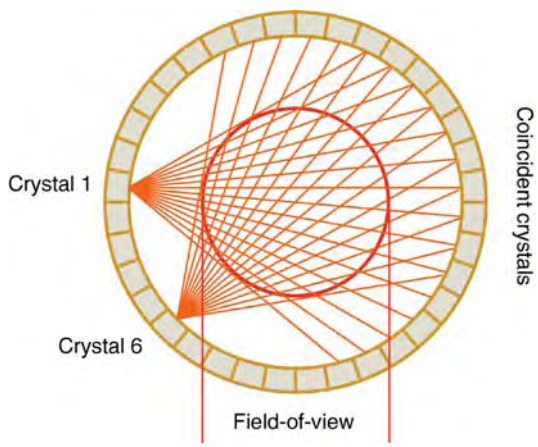
Theoretically, the spatial resolution of PET scanners is limited by physical characteristics of positron flight within the tissues. When a positron is emitted, it travels a short distance from the nucleus, typically about 2–8 mm maximum range. It loses its kinetic energy during this flight and then annihilates with an electron. It is the distance between the decaying nucleus and the point of annihilation, and the fact that the annihilation photons are not emitted at exactly 180° apart (deviation from 180° is up to 0.25°), which ultimately limit the spatial resolution of PET brain scanners to 4–5 mm (on average). However, in general, PET offers higher resolution than compared with 7–15 mm for single-photon emission computer tomography (SPECT).

PET allows registration of the counts per pixel, which are later transformed to counts per minute per ml of

tissue. However, in the counts acquisition process, the allowable radiation dose (regulated by the authorities) and limited acquisition time (depends on the instrumentation and study protocol) have to be considered. The result may be a poor ►signal-to-noise ratio, which can be overcome by the use of spatial filtration. The latter is an additional source for degradation in resolution.

In general, the collection time varies from tens of seconds to tens of minutes. It is like an exposition time in photography and creates a strong limitation to the study protocol. Only steady states or at least quasi-steady or periodic processes should be investigated during one scan.

In modern PET scanners for data acquisition, so-called 2D and 3D modes are widely accepted. In the 2D mode, special septa between rings are installed to reduce the effect of scattering and random coincidence.

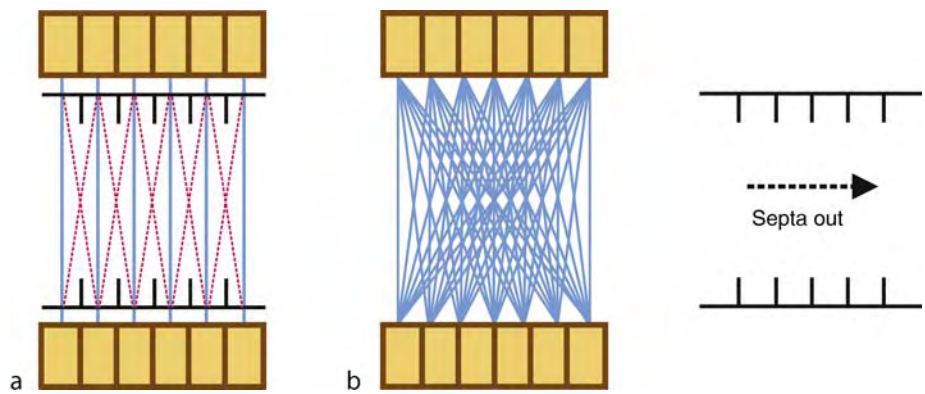


**Positron Emission Tomography. Figure 3** Each detector of the ring forms a fan with a number of opposite detectors. Overlapping of all fans forms the field of view.

As a result, each detector forms three fans between itself and an array of other detectors of the ring (Fig. 3) as well as the two nearest rings.

As a result, there is a reconstruction of three slices: one in the ring and two so-called cross slices. It means that 15 rings give 29 slices. This procedure gives better resolution and accuracy, but is rather wasteful because many lines of response between other rings are not collected. If the septa are retracted, coincidences are admitted from large axial acceptance angles. The 3D mode allows increasing the number of counts by five times. This results in increases of necessary computing resources and, what is more important, in increases of mis-positioned events caused by scattered photons and in the registration of accidental coincidences, including some caused by photons outside the field of view. This, however, reduces resolution and quantitative accuracy. On the other hand, the 3D mode allows the reduction of the injected dose, and/or the duration of study, and/or improving the signal-to-noise ratio. The 3D mode is mainly used in neurophysiology, where the duration of scan is important. The 2D mode is more often applied in oncology (Fig. 4).

Finally, PET provides a map of spatial distribution of a positron-emitting isotope density in the field of view of the rings. When a compound labeled by this isotope is introduced into humans (usually by intravenous injection), it distributes within the body via the blood circulation in accordance with the delivery, uptake, metabolism and excretion of the particular tracer. To translate the measured radioactivity distribution into functional or physiological parameters, compartment models are used for the radiotracers with known metabolism. One of the most important characteristics of cell functioning is energy consumption. It can be compared to "gasoline consumption" in an engine, so for the living cells, the gasoline is glucose. However, it is like a gas that an engine absorbs and excretes.



**Positron Emission Tomography. Figure 4** *Left*: 2D mode. Septa allow each detector to form lines of responses between itself and an array of other detectors of the same ring and the two nearest rings only. *Right*: 3D mode. Lines of responses between all rings are allowed.

2–$^{18}$F-2-deoxy-D-glucose (FDG), a glucose analog, has a similar rate of consumption as normal glucose, but a different way for excretion. It is accumulated in a cell at a rate proportional to the energy consumption (metabolism) of this cell. Therefore, PET with FDG allows direct assessment of the level of glucose consumption, which is one of the most important processes responsible for vital functions [6]. As glucose metabolism is greatly enhanced in malignancies, FDG is the most important and popular radiotracer for PET oncology. In fact, this tracer has many other applications in neurology and cardiology and is considered the "working horse" of PET (like $^{99}$mTc in conventional nuclear medicine).

In addition to the high sensitivity (see above), the use of short-lived radioisotopes allows injection of a relatively high activity of the tracer (185 MBq for FDG brain scan), leaving the total radiation dose within acceptable limit. As PET radionuclides belong to the major elements of life, unlimited numbers of radiotracers can be prepared to track various physiological processes. In practice, although more than 2000 RPs have been evaluated in PET, no more than 10–15 specimens have been introduced into clinical routines. The reasons are the difficult synthesis and the necessity for automation in operating high levels of radioactivity, high running costs, and very strict regulations.

The logic of a PET study is as follows. First, a field of interest has to be specified (i.e., neurophysiology, oncology, and cardiology). Within this field (let's say oncology), the process of interest has to be identified (glycolysis or amino acid transport) and an appropriate tracer considered (FDG or $^{11}$C-metionine). The next steps are radiotracer synthesis and PET study design using an appropriate pharmacokinetic model, after this the PET study itself. The final stage is data processing and assignment of the image to the pathology under study.

It should be emphasized that PET is a functional imaging technique, giving an isotope distribution map, which reflects a particular biochemical process, not the anatomy. The introduction of a hybrid system (PET-CT: PET-computer tomography) has greatly enhanced the performance and accuracy of PET imaging. The CT component is used to relate the signal of radiotracer to anatomical landmarks and to correct for non-uniform attenuation (instead of traditional transmission scans) [3].

## PET Radionuclides

PET employs radiotracers (radiopharmaceuticals, RPs) labeled with short-lived positron-emitting radionuclides [9]. The four conventional radionuclides are: $^{15}$O (half-life $T_{1/2}$ = 2 min); $^{13}$N ($T_{1/2}$ = 10 min); $^{11}$C ($T_{1/2}$ = 20.4 min) and $^{18}$F ($T_{1/2}$ = 110 min). Carbon, oxygen, and nitrogen are elements of life and the building blocks of nearly every molecule of biological importance. A fluorine-18 is often used to replace a hydrogen atom or hydroxyl group in a molecule.

Due to this short half-life, the PET radionuclides have to be produced in the vicinity, normally with a small dedicated cyclotron. PET cyclotrons accelerate charged particles (protons, deuterons) at a fixed energy (10–18 MeV for protons). Modern PET cyclotrons are negative-ions machines, which are characterized by an easy extraction process and dual beam option. PET radionuclides are produced in cyclotron targets via various nuclear reactions and delivered into a shielded hot cell by either gas flow (15O, 11C) or extra-pressure of helium ($^{13}$N, $^{18}$F).

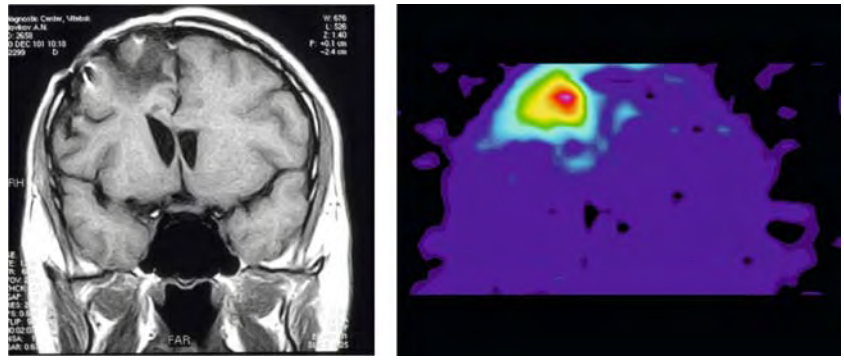
## PET Radiopharmaceuticals

For PET applications, the radionuclides have to be tagged to specific pharmaceuticals, referred to as "radiopharmaceuticals" [10]. PET radionuclides are produced in a simple chemical form. They have to be transferred into tracers of interest via a complex synthesis using special automated modules.

The 2-min half-life of $^{15}$O is very short; therefore, only very simple radiotracers like water-$^{15}$O and $^{15}$O-butanol are produced as rCBF agents. Quite rarely, $^{15}$O-labelled gases are used in inhalation studies. $^{13}$N-ammonia ($T_{1/2}$ = 10 min) is available from a cyclotron target to fulfill the needs of heart-perfusion tracers.

The chemistry of carbon-11 ($T_{1/2}$ = 20 min) is extensively developed. Depending on the target gas, $^{11}$C is taken from the target in the form of $^{11}CH_4$ or $^{11}CO_2$. The latter is a versatile agent for labeling of carboxylic acids, such as 1–$^{11}$C-acetate, a tracer for oxidative myocardial metabolism. Most of the $^{11}$C-preparations are based on $^{11}$C-methylations, including L-$^{11}$C-methyl-methionine, a second important tumor-seeking agent after FDG. Receptor radioligands such as $^{11}$C-SCH23390 ($D_1$), $^{11}$C-raclopride ($D_2$), $^{11}$C-PE2I (dopamine transporter), $^{11}$C-MADAM (serotonin transporter), $^{11}$C-flumazenil (central BZ), $^{11}$C-PK1195 (peripheral BZ), and $^{11}$C-OH-BTA1 (β-amyloids) are obtained by this method.

The longest-living $^{18}$F (110 min), allows several doses of the RPs to be obtained in one batch and to be delivered to other hospitals without access to a cyclotron. Irradiation of $^{18}$O-enriched water by protons is most commonly used for generating high amounts of $^{18}$F (35–70 GBq). Radionuclide is used in nucleophilic fluorination reactions to produce FDG. Although FDG is used in more than 80% of the routine PET studies, it is not a specific tracer for tumors as it enters other glucose-utilizing cells. New radiotracers for accurate characterization of tumors include *O*-(2′-$^{18}$F-fluoroethyl)-L-tyrosine (FET) or 2-[$^{18}$F]fluoro-L-tyrosine (2-FTYR). Due to the low accumulation in gray matter, these amino acids provide higher contrast



**Positron Emission Tomography. Figure 5** Patient after tumor removal and radiotherapy. *Left*: MRI diagnosis splits between radiation necrosis and recurrence of tumor. *Right*: PET with 11C-metionine proved recurrence.

images of brain tumors. FLT, a labeled thymidine analog, was introduced for prognostic assessment and evaluation of responses to anti-proliferative therapy in colorectal, lung and other cancers. Assessment of tumor hypoxia using hypoxia markers ($^{18}$F-FMISO, $^{18}$F-FAZA) allows one to select patients for treatments specifically designed to attack poorly oxygenated (hypoxic) tumor cells.

## Data Processing and Analysis

Modern software for PET data processing and analysis usually includes means for: (i) preliminary data processing (smoothing, filtering, co-registration of images from different modalities, spatial normalization, i.e., image deformation to match the standard one); (ii) data 2D and 3D visualization; and (iii) statistical analysis. The most widely used software for research environment is the Statistical Parametric Mapping (SPM) software package (http://www.fil.ion.ucl.ac.uk/spm/).

For some study purposes (activation study, some studies in oncology), it is often enough just to compare the numbers of counts from different body areas without calculating the real concentration of the radiotracer.

## Advantages and Disadvantages

At present, single-photon emission computer tomography (SPECT) makes up the majority of nuclear medicine procedures, mostly due to lower costs and availability of radiotracers from commercial sources ($^{123}$I, $^{111}$In) or isotopic generators ($^{99m}$Tc). Due to the higher sensitivity of PET, the detectable amounts of molecules are lower than with SPECT. This is extremely important for receptor and drug development studies with very low amounts (pikomoles) of the substances involved. Unlike SPECT, PET allows a quantitative evaluation of the results using tracer kinetic modeling. In clinical studies, PET is usually used after ►magnetic resonance imaging (MRI) studies, and sometimes PET results can radically change a diagnosis (Fig. 5). In whole-body PET studies, PET highlights peculiarities, which exist but are unrecognizable on MRI images. Due to the unlimited number of natural substrates, substrate analogs and drugs that can be labeled, PET allows the study of practically all varieties of physiological processes.

The major limitations of PET are the complexity of PET studies, high capital investments and running costs for the production of RPs requiring an on-site cyclotron. Recently, FDG has been delivered over distances corresponding to 2 h flight. Many stand-alone PET scanners are installed and served from one central "cyclotron/radiochemistry factory." PET has proved to be cost-effective in staging and managing of certain malignancies such as NSCLC, by reducing the overall health care reimbursement. Due to the higher diagnostic accuracies of PET procedures, patients always benefit, even though the costs may be higher than with CT or MRI, which basically rely on morphological changes for tumor detection.

With respect to activation studies, functional MRI (fMRI), using the ►blood oxygenation level-dependent (BOLD) contrast method with echo-planar imaging, competes with PET. However, high levels of noise and ►claustrophobia effects result in several limitations in cognitive function assessments using this technique.

## Posner Paradigm

### Definition

►Visual Attention

## Possibilism

### Definition

The view that possible worlds exist in addition to the actual world and have the same ontological status.

►Possible World

## Possible World

Volker Gadenne
Department of Philosophy and Theory of Science, Johannes-Kepler-University Linz, Linz, Germany

### Definition

A possible world is a complete way things might be. Possible worlds are alternative worlds one of which is the actual world. Philosophers use the notion of a possible world to define and discuss ideas such as possibility or necessity.

### Description of the Theory

#### *Leibniz's Idea of a Possible World*

Consider the actual world, that is, the whole of what is the case, not only here and now but also in the past and in the future throughout all time. Thinking how things are in the actual world, lots of other worlds can easily be imagined, simply by changing one or more features. In one possible world Schubert composed one more symphony. In another world, the dinosaurs did not die out, with all consequences and so on. Even the slightest difference, say one more atom in this table, makes a world different from the actual one.

Note that changes of states of affairs may have consequences. Some things that are possible in separate worlds are not possible in combination. There is a possible world in which George visits a conference in 2004 and there is another possible world in which George dies in a car accident in 2003. But there is (probably) no possible world that contains both these states of affairs.

Leibniz used the idea of possible worlds in his philosophy of creation. God had in his mind infinitely many worlds he could have created. He chose the best of these possible worlds and made it actual. On the basis of this theory, Leibniz attempted to provide a ►theodicy, a "justification of God" in the face of all the evils in the actual world. God had perfect reason to bring into existence the actual world despite all pain and suffering it contains, since it is the best of all possible worlds. Leibniz was convinced that even god could not create anything. He could have made other laws of nature, but not worlds that are logically impossible. [*Vielleicht genauer: Leibniz' Gott kann logisch Unmögliches nicht schaffen, wohl aber nomologisch unmögliches].

#### *Modal Logic and Possible World Semantics*

The concept of possible worlds plays a central role in ►modal logic. Kripke [1,2] was most influential on the development of ►possible world semantics and its application to metaphysical problems (for an introduction, see [3]). Modal claims are fundamental to the ways the world is talked about. Consider, for example, the sentence: "There might be ten planets." This is a sentence in the mode of *possibility*. Another modal notion is *necessity*, as in the sentence: "Bachelors are unmarried." [*Sollte man hier den modalen Charakter nicht explizit machen so wie in dem vorangegangenen Beispiel?] What makes such statements true or false? According to the traditional view, modal statements are made true or false by relations of ideas or by linguistic conventions. In this example, the meaning of "unmarried" is part of the meaning of "bachelor." However, some philosophers find it hard to see how all ►propositions thought to be necessarily true should be true by convention. How could the way that a thing is talked about make it true, e.g. that John is a human being or that infinitely many primes exist? Here the idea of possible worlds has its part. With its help the proposition may be expressed as follows. "There is at least one possible world in which the sun has exactly ten planets." Necessity can be defined as truth in all

possible worlds. "In all possible worlds bachelors are unmarried." "In all possible worlds there are infinitely many primes."

Generally speaking, to say that a proposition is true is just to say that it is true in the actual world. But to say that a proposition is necessary or necessarily true is to say that it is true in every possible world. And to say that a proposition is possible or possibly true is to say that it is true in some possible world. According to this theory, the modal notions of necessity and possibility are explained in terms of quantification over worlds. In order to speak of a proposition p as necessarily true, a *universal quantifier* over worlds is needed. "For all possible worlds W, p is true in W." To speak of a proposition p as possibly true, an *existential quantifier* over worlds has to be used. "There is at least one possible world W, such that p is true in W."

Logicians found that on this neo-Leibnizian account they could give clear sense to the modal notions as they function in the various modal logics. Further concepts such as "validity," "soundness" and "completeness" can be defined in terms of models constructed from sets of alternative worlds. Important results have been obtained by these methods (which can however not be presented here since they require a lot of technical details).

Modal notions are central to many of the traditional areas of philosophy, e.g. the nature of causation or free will. These notions have traditionally been challenged by empiricists. The most prominent critic was Quine [4]. In the 1950s, many philosophers became convinced that the ideas of necessity and possibility could have no place in philosophy. The development of possible world semantics gave many of them new reason to believe that the empiricist challenge can be met.

### The Existence of Possible Worlds: Possibilism and Actualism

One of the most difficult problems of possible world theories concerns the ontological status of such worlds. The quantification over worlds seems to require that all these worlds exist. There are two main views dealing with this question, ►possibilism and ►actualism. For *possibilism*, as held by Lewis [5], there really is a plurality of possible universes of the same kind as this one. Each of them is conceived as a very comprehensive *concrete object*, having as its parts less comprehensive concrete objects such as stones, trees and persons. All the concrete objects that inhabit the various possible worlds are fully real. They are supposed to be really out there. Lewis denies that this world, which is called the "actual" one, has a special ontological status. The actual world is just a part of total reality, it is the part spatially and temporally related to this world. There is however no causal interaction between different possible worlds, because each of them is spatiotemporally closed.

Can the same individuals exist in different worlds? Lewis denies this. There are no "transworld individuals." Each object exists in just one possible world. But how can he then account for the idea that there are different ways the same things could have gone? Instead of relating different possible worlds by strict numerical identity of some objects he ties them by what he calls the "counterpart relation." For example, a particular person is in the actual world and no other, but has "counterparts" in several other worlds. The counterpart is not really the person, but it resembles the person closely in important respects.

Lewis argues for his theory by emphasizing its fruitfulness. Starting with the concept of a possible world as a primitive and with the means of set theory, he could not only define necessity and possibility, but also concepts such as "property" or "proposition." His theory is committed to the program of an austere ►nominalism. Properties and propositions are reduced to sets of concrete objects. However, many philosophers find it hard to accept that all those possible objects should be regarded as fully real. The strict nominalistic account of modal notions was also criticized. It leads to some unsatisfactory consequences.

Another view about the existence of possible worlds is ►actualism. Actualists too, start with the assumption that the actual world is not the only possible world. But unlike possibilism, actualism gives the actual world a special ontological status. Only what actually exists, exists at all. This seems to imply that possible worlds do not exist. However, not all actualists draw this consequence. The leading advocates of actualism, like Plantinga [6] and Stalnaker [7], rather think that possible worlds can be identified with something that belongs to the actual world. To express this idea, they do not restrict themselves to the resources of nominalism, but refer to abstract entities (►abstract entity), especially, states of affairs. Every possible ►state of affairs is supposed to *exist in the actual world*. However, not all states of affairs *obtain*. Not everything that might be the case (and therefore exists as a state of affairs) is really the case (obtains). For example, the state of affairs that Aristotle became Plato's successor at the academy exists, but failed to obtain.

Possible worlds are regarded by Plantinga as "maximally comprehensive possible states of affairs." This is a possible state of affairs, W, so comprehensive that, for any state of affairs S, W either includes S or precludes S (and thus encompasses a whole world). As a consequence, all the possible worlds *exist*. But only one of them *obtains* – the *actual* world. Possible worlds are *abstract entities*, not concrete objects (►concrete entity). The same individuals can exist in different possible worlds. Actualism therefore needs no counterpart relation. Possible world theories raise a lot of problems, technical ones as well as metaphysical

difficulties, which are still unsolved. Nevertheless many philosophers are convinced of the fruitfulness of this program.

### Applications to Other Fields

The notion of a possible world has been applied to several areas of philosophy to formulate and discuss special problems, e.g. in the philosophy of mind. Kripke [2] himself used it to analyze *mind-brain identity* and he argued against identity theory. Roughly, the structure of his argument is identity theory implies that pain is identical with a certain type of brain state. Such an identity statement would have to be necessarily true, i.e. true in all possible worlds, if it was true at all. But the tie between pain and a certain type of brain state is plainly contingent. Therefore, they cannot be identical.

A central idea of contemporary philosophy of mind is *supervenience*. Kim [8] analyses mind-brain supervenience in terms of possible worlds. The assumption that two persons with the same brain states must necessarily have the same mental states can be formulated as follows. "Mental properties supervene on physical properties in that if any x (in any possible world) and y (in any possible world) have the same physical properties (in their respective worlds), then x and y have the same mental properties (in those worlds)."

## Possible World Semantics

### Definition

A type of formal semantics that uses the notion of a possible world as a central concept; formal semantics is the study of the interpretations of formal languages.

►Possible World
►Property

## Postactivation Potentiation (PAP)

►Force Potentiation in Skeletal Muscle

## Postcentral Gyrus

### Synonyms

►Gyrus postcentralis

### Definition

= primary somatosensory cortex = SI
= area 3 + 1 + 2

The postcentral gyrus lies in the parietal lobe directly behind the central sulcus. Observing strict somatotopic arrangement, the somatosensory tracts of the contralateral body half terminate here.

Conscious localization and differentiation of quality and intensity of a tactile stimulus are effected in cooperation with the postcentral gyrus. Lesions of the postcentral gyrus reduces the response to tactile, thermal and noci stimuli from the contralateral body half.

►Telencephalon

## Posterior Cerebellar Lobe

### Synonyms

►Lobus cerebelli post.; ►Posterior lobe of cerebellum

### Definition

The posterior lobe is the part of the cerebellum caudal to the primary fissure, and is composed of vermis portions (declive, folium, tuber, pyramid and uvula) as well as hemisphere portions (simple lobule, semilunar, gracile and biventer lobules as well as tonsil). Functionally this subdivision has practically no significance, since the cerebellum evidences a functional arrangement in a vertical direction (vermis, intermediate part, lateral part).

►Cerebellum

## Posterior Colliculus

►Inferior Colliculus

## Posterior Column

### Synonyms

►Funiculus post; ►Posterior funiculus

### Definition

The cuneate fasciculus and gracile fasciculus together form the posterior column and are the main axes of epicritic sensibility: – gracile fasciculus: it collects the epicritic fibers from the sacral, lumbar as well as lower thoracic cord and terminates in the gracile nucleus. – cuneate fasciculus: contains the fibers from the upper thoracic cord as well as from the cervical cord and terminates in the cuneate nucleus.

►Pathways

## Posterior Commissure

### Synonyms

►Commissura post

### Definition

Here cross the fibers that are vital for controlling vertical eye movement and consensual light reaction of the pupils, including fibers from the superior colliculus, pretectal region as well as tegmentum of Mesencephalon.

►Telencephalon

## Posterior Cortical Atrophy

### Definition

Degenerative disorder of the posterior part of the brain beginning with visual symptoms and then proceeding into more general ►dementia. Initially, elementary visual functions are lost, but then more complex syndromes show up, including visual agnosia, topographical problems, ►optic ataxia, simultanagnosia, ocular apraxia (►Balint's syndrome), right-left confusion, ►alexia, ►acalculia, ►agraphia (►Gerstmann's syndrome).

►Balint's Syndrome
►Gerstmann's Syndrome
►Optic Ataxia

## Posterior Horn

### Synonyms

►Cornu post

### Definition

He majority of primary afferents entering through the posterior horn terminate in the posterior horn of the spinal cord. Three zones can be distinguished:

- Marginal cells
- Substantia gelatinosa
- Nucleus proprius

►Medulla spinalis

## Posterior Lobe of the Hypophysis

### Synonyms

►Neurohypophysis

### Definition

The posterior lobe of the hypophysis is also called the neurohypophysis since it is composed of hypothalamic nervous tissue. Its proximal segment is formed by the tuber cinerum and infundibulum, and its distal segment is the posterior lobe of the hypophysis. Via the infundibular nucleus, axons of the paraventricular nucleus and of the supraoptic nucleus pass to the blood vessels in the posterior lobe, where they release the hormones ADH and oxytocin.

►Diencephalon

## Posterior Nuclei

### Definition
The thalamic nuclei that project to the parietal somatosensory cortex, relaying nociceptive inputs from the periphery.

►Somatosensory Cortex I

## Posterior Parietal Cortex (PPC)

### Definition
Cerebral cortex posterior to the postcentral gyrus.

►Visual Space Representation for Reaching

## Posterior Spinocerebellar Tract

### Synonyms
►Tractus spinocerebellars post

### Definition
The posterior spinocerebellar tract carries primary afferents from the spinal cord to the cerebellum.

It has its origin in Clarke's column in the thoracic cord and conducts proprio- and exteroceptive impulses (skin receptors, muscle spindles, tendon spindles) from the posterior limbs to the cerebellum.

►Cerebellum

## Posterior Tuberculum

### Definition
A caudal part of the diencephalon present in cartilaginous and bony fishes that contains some dopaminergic neurons as well as several laterally migrated nuclei of the preglomerular nuclear complex that are involved in the relay of ascending sensory pathways, particularly for the gustatory and lateral line systems.

►Evolution of the Somatosensory System: In Non-mammalian Vertebrates

## Posterolateral Column

### Synonyms
►Tractus postervlat. (Lissauer); ►Posterolateral tract (Lissauer)

### Definition
The white matter between the ventral root and dorsal root gives rise to the lateral column, containing:

1. anterolateral column with
   - anterolateral fasciculus
   - parts of the anterior spinocerebellar tract.
2. posterolateral column with
   - posterior spinocerebellar tract
   - parts of the anterior spinocerebellar tract
   - lateral pyramidal tract.

►Medulla Spinalis

## Posteromedial Barrel Subfield

►Barrel Cortex

## Postganglionic Fiber (Neuron)

### Definition
Ganglion neurons of autonomic ganglia all issue an axon (which turns into a nerve fiber), and virtually all these fibers exit the ganglion directed toward a peripheral target organ, along different paths depending on the ganglion of origin. Some form discrete nerves (splanchnic, pelvic, urinary), others reach somatic nerves and the mixed nerves of autonomic and somatic fibers thus formed reach the periphery (the limbs in particular and all the skin). The post-ganglionic fibers

can be very long and are usually unmyelinated, hence of slow conduction velocity. Upon reaching the target organ they branch extensively and make contact with muscle elements (mainly smooth muscle cells) and with secretory elements (glands). Post-ganglionic fibers exert their effect on muscle and glands by releasing neurotransmitters that stimulate (and sometimes inhibit) contraction and secretion. The neurotransmitters are released from "terminals" that are not only the expansions at the anatomical end of each nerve branch but also at bulbous expansion (varicosities) scattered along a substantial part of the terminal portion of the axons. Each ganglion neuron issues one fiber traveling to the periphery, which has many branches within the terminal organ, which have many thousands of varicosities along their terminal branches.

In the bladder muscle, for example, a few thousand ganglion neurons directly innervate millions of muscle cells.The exact relationship between varicosities (nerve endings) and muscle cells (or gland cells) varies from a close contact (a neuro-muscular junction) in some tissues (the bladder, for example) to a loose relationship with a wide gap (some blood vessels, for example).

►Autonomic Ganglia
►Parasympathetic Pathways
►Sympathetic Pathways

# Postganglionic Nerves

## Definition

Autonomic nerves going to the end organ, e.g., cavernous nerve and the dorsal nerve of the penis and clitoris.

►Sexual reflexes

# Postganglionic Neurotransmitter

Judy L. Morris, Ian L. Gibbins
Department of Anatomy & Histology, and Centre for Neuroscience, Flinders University, Adelaide, SA, Australia

## Synonyms

Autonomic neurotransmitter

## Definition

Postganglionic autonomic neurons have their cell body in an ►autonomic ganglion and an axon that extends out to a target organ. These neurons regulate activity of most organs of the body by releasing combinations of neurotransmitters. Postganglionic neurotransmitters are released from multiple swellings along the axons, or ►varicosities, separated from the target cell membrane by gaps of 20–100 nm to form ►neuroeffector junctions (Fig. 1).

Each axon has thousands of varicosities that can release neurotransmitter from the postganglionic neuron. It is now clear that the earliest identified neurotransmitters, acetylcholine and noradrenaline (adrenaline in some non-mammalian vertebrates), do not mediate all actions of postganglionic autonomic neurons. Nearly all neurons releasing acetylcholine or noradrenaline also synthesize and release various combinations of other neurotransmitter molecules including adenosine triphosphate (ATP), nitric oxide (NO) and one or more neuropeptides such as vasoactive intestinal peptide (VIP), neuropeptide Y (NPY) or opioid peptides [1,2,3,4,5]. Furthermore, many neurons intrinsic to the gastrointestinal tract or airways use nitric oxide, ATP and one or more neuropeptides but do not synthesize acetylcholine or noradrenaline (Table 1).

The release of more than one transmitter from the same postganglionic neuron, termed ►co-transmission, is now accepted as the rule rather than the exception. As well as regulating activity of the target organs (►postjunctional actions), transmitters released from postganglionic neurons can act back on terminals of the same or other nearby nerve terminals to alter further transmitter release (►prejunctional actions). Some transmitters have both pre-junctional and postjunctional actions, while others act at only one site (Fig. 1).

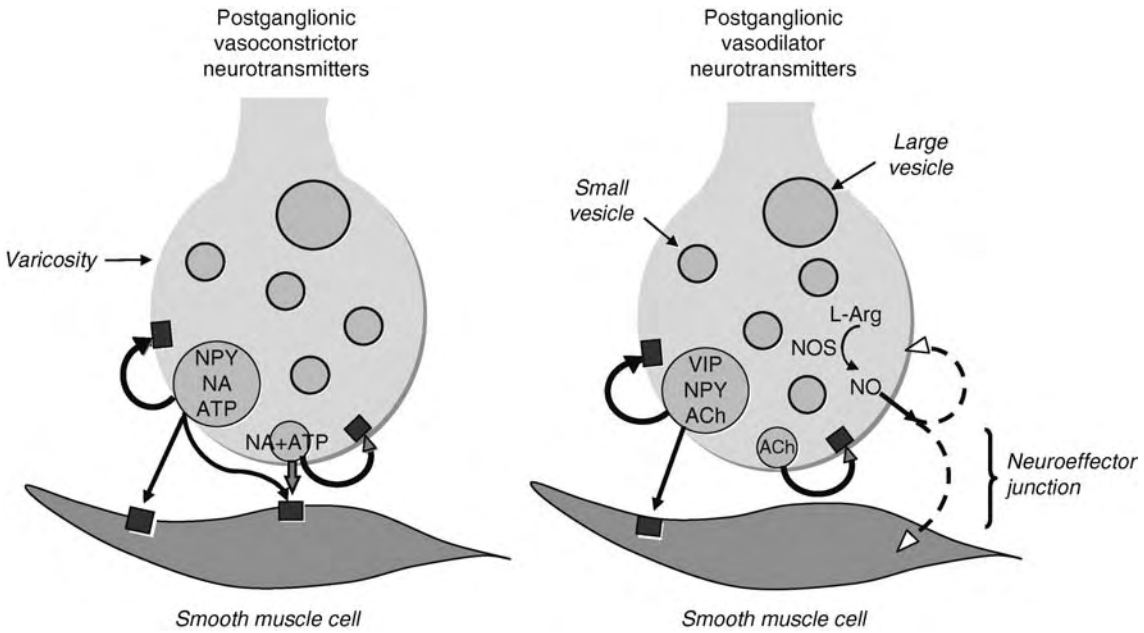
## Characteristics

### Quantitative Description

Twenty or more different molecules have been identified as neurotransmitters in postganglionic autonomic neurons including enteric neurons (Table 1). Some individual neurons contain five or more co-transmitters [1].

### Higher Level Structures

Neurotransmitters are stored in membrane-bound vesicles within axon terminals. Synaptic vesicles can vary in size from small (40–60 nm diameter) to large (80–120 nm diameter). Nerve terminals contain both small and large vesicles in varying ratios. In varicose terminals of most postganglionic autonomic neurons, small vesicles are more abundant than large vesicles. Sometimes small vesicles tend to be clustered towards the cell membrane adjacent to the neuroeffector junction, but this is not always apparent. In contrast, large vesicles are not concentrated near the neuroeffector junction. Small vesicles



**Postganglionic Neurotransmitter. Figure 1** Example of two types of postganglionic neurons releasing multiple neurotransmitters in a single blood vessel. Co-transmitters stored in and released from varicosities of postganglionic vasoconstrictor neurons and postganglionic vasodilator neurons into neuroeffector junctions with smooth muscle cells in the uterine artery (see [1]). Large vesicles in vasoconstrictor neurons contain noradrenaline (NA), adenosine triphosphate (ATP) and neuropeptide Y (NPY), while small vesicles contain only NA and ATP. Transmitters released from small and large vesicles can act on the postjunctional receptors on the smooth muscle cells to produce vasoconstriction, as well as prejunctional receptors on the membrane of the varicosity where they usually inhibit transmitter release. Nearby varicosities of vasodilator neurons contain large vesicles with acetylcholine (ACh), vasoactive intestinal peptide (VIP), NPY and several other peptides [6]. Small vesicles contain ACh alone. Nitric oxide is synthesized in the cytoplasm by nitric oxide synthase conversion of L-arginine, before diffusing across the neuroeffector junction and into smooth muscle cells to activate cyclic GMP and relax the smooth muscle. VIP has a potent vasorelaxant action, while ACh only has a prejunctional effect to inhibit neurotransmitter release. The function of NPY released from the vasodilator neurons is not known, but it may produce relaxation of an already constricted vessel and is likely to have a prejunctional inhibitory effect on transmitter release. It is likely that postganglionic neurotransmitters also can affect neurotransmission from adjacent varicosities.

in postganglionic neurons contain noradrenaline, ATP or acetylcholine. Large vesicles often contain neuropeptides in addition to non-peptide transmitters. Nitric oxide is an unusual neurotransmitter – it is not stored in synaptic vesicles but synthesized on demand in the nerve terminals (Fig. 1).

## Lower Level Structures

The chemical structure of postganglionic neurotransmitters encompasses low molecular weight gases such as nitric oxide (and possibly carbon monoxide; [2] ), purine nucleotides like ATP, catecholamines and acetylcholine, and neuropeptides ranging in size from less than a dozen amino acids (e.g., enkephalin, substance P) to more than thirty amino acids (VIP, NPY, calcitonin gene-related peptide (CGRP; Table 1). Almost all of these substances also are neurotransmitters in the central nervous system. The nature and sequence of neurotransmitters has been remarkably conserved through evolution, so that only very small if any chemical differences occur between postganglionic neurotransmitters in different vertebrate classes.

## Higher Level Processes

As in all other neurons using chemical neurotransmission, synaptic vesicles in postganglionic neurons release their neurotransmitters by exocytosis, and vesicle membranes are recycled at the nerve terminal. Large vesicles are formed in the cell body where they are packaged with a variety of proteins (such as neurotransmitter synthesizing enzymes and transporters) and neuropeptides, then are transported down to the nerve terminal. In some neurons post-translational processing of peptides such as dynorphin can occur within large vesicles as they are transported down the axon. The non-peptide transmitters noradrenaline and acetylcholine are synthesized or taken up into vesicles in the cell body, axon and terminals. In contrast, neuropeptides cannot be taken up and repackaged into vesicles at the nerve terminal. This differential processing of peptide and non-peptide transmitters may

**Postganglionic Neurotransmitter. Table 1** Substances localized in postganglionic autonomic neurons of most vertebrates

| Neurotransmitter | Molecular weight | Postganglionic neurons with neurotransmitter | Common co-transmitters |
|---|---|---|---|
| Acetylcholine (ACh) | 146 | Parasympathetic neurons. | NO, VIP, Som |
| | | Enteric motor neurons, Enteric secretomotor neurons. | SP, NKA |
| | | | NPY, Som, Gal, CCK, CGRP |
| | | Subpopulation of sympathetic nerves e.g., sudomotor neurons | VIP |
| Adenosine triphosphate (ATP) | 507 | Sympathetic neurons. | NA, NPY |
| | | Pelvic nerves to the bladder. | Ach |
| | | Enteric inhibitory neurons. | NO, VIP |
| Adrenaline (Ad, epinephrine) | 183 | Sympathetic neurons in amphibians, fish. | NPY |
| Noradrenaline (NA, norepinephrine) | 169 | Most sympathetic neurons in mammals, birds, reptiles. | ATP, NPY |
| Calcitonin gene-related peptide (CGRP) | 3,807 | Parasympathetic neurons. | ACh, NO, VIP |
| | | Enteric secretomotor neurons. | ACh, NPY, Som, Gal, CCK, CGRP |
| Cholecystokinin (CCK8) | 1,142 | Enteric secretomotor neurons | ACh, NPY, Som, Gal, CGRP |
| Dynorphin (DynA1–17) | 2,148 | Sympathetic neurons. | NA, +/- NPY |
| | | Enteric neurons. | VIP, NO, GRP |
| Enkephalin (Enk) | | Some sympathetic neurons. | NA, +/- NPY |
| Met-Enk, Leu-Enk | 574, 556 | Enteric neurons. | Dyn, VIP, NO |
| Galanin (Gal) | 3,211 | Sympathetic neurons. | NA, +/- NPY |
| | | Intrinsic cardiac neurons. | ACh, Som |
| | | Enteric neurons. | |
| Gastrin releasing peptide (GRP) | 2,806 | Enteric neurons. | VIP, Dyn, Gal, NO |
| 5-Hydroxytryptamine (5-HT, serotonin) | 1,76 | Taken up into and released from some sympathetic and enteric neurons | NA, NPY |
| | | | Ach |
| Neurokinin A (NKA) | 1,133 | Enteric motor neurons. | SP, Ach |
| Neuropeptide Y (NPY) | 4,254 | Many sympathetic neurons. | NA, ATP |
| | | Some parasympathetic neurons. | ACh, +/- VIP |
| | | Enteric secretomotor neurons. | ACh, Som, CGRP, CCK |
| Nitric oxide (NO) | 30 | Parasympathetic neurons. | ACh, VIP |
| | | Enteric inhibitory neurons. | VIP, ATP |
| Peptide histidine isoleucine (PHI) | 2,996 | Most parasympathetic neurons. | ACh, VIP, PACAP |
| | | Enteric inhibitory neurons. | VIP, NO, ATP |
| Pituitary adenylate cyclase activating peptide (PACAP) 38 | 4,538 | Enteric neurons | VIP, GRP |
| | | Parasympathetic neurons. | ACh, VIP, PHI |
| Somatostatin (Som) | 1,638 | Intrinsic cardiac neurons. | ACh, +/- Gal |
| | | Enteric neurons. | ACh, NPY, CGRP, CCK |
| Substance P (SP) | 1,348 | Cranial parasympathetic neurons. | Ach |
| | | Enteric motor neurons. | ACh, NKA |
| Vasoactive intestinal peptide (VIP) | 3,326 | Most parasympathetic neurons. | ACh, PHI, PACAP |
| | | Enteric inhibitory neurons. | PHI, PACAP, NO, ATP |

Details of co-transmitters derived mostly from animal studies, concentrtial on guinea-pegs (see [1,4]). A definitive neurotransmitter role has been established for all substances in all locations listed. Many entric neurons do not receive direct inputs from the central nervous system but form part of intrinsic neural circuits.

contribute to selective depletion of co-transmitters after intense activation of autonomic neurons. Nitric oxide is synthesized in postganglionic nerve terminals by the calcium-dependent enzyme, nitric oxide synthase (NOS), located in the cytoplasm and not in vesicles (Fig. 1).

The action potential-dependent exocytosis of neurotransmitters from small vesicles in all neurons, including postganglionic autonomic neurons, occurs through specific interactions between proteins located on the vesicle membrane and proteins attached to the inner surface of the nerve terminal membrane, the ►SNARE proteins (soluble NSF attachment protein receptor proteins). Exocytosis is a multi-step process that is calcium-dependent. First, the vesicles are released from a framework of actin filaments and move close to the terminal membrane where they become docked. This is followed by fusion of the vesicle membrane with the nerve terminal membrane, allowing release of vesicle contents into the extracellular space of the neuroeffector junction. Exocytosis of transmitters from small vesicles can be inhibited by botulinum neurotoxins that act intracellularly to cleave the SNARE proteins. However, it is not clear whether exocytosis of neuropeptides from large vesicles uses the same SNARE proteins that mediate small vesicle exocytosis. Release of neuropeptides from postganglionic autonomic neurons certainly is less sensitive to blockade by botulinum toxin than release of non-peptides from small vesicles [6]. Nitric oxide release from postganglionic autonomic neurons is completely resistant to botulinum toxin, confirming that this transmitter is not associated with vesicular storage and exocytosis.

## Lower Level Processes

After release from the terminals of postganglionic neurons, noradrenaline, ATP and acetylcholine are rapidly removed from the neuroeffector junction by degradation or uptake by the nerve terminal and target tissue. These mechanisms limit the time course and distance over which the transmitters can act on prejunctional or postjunctional receptors. Nitric oxide acts on target tissues after diffusion across the membrane of both the nerve terminal and the postjunctional cell. This molecule diffuses rapidly from the neuroeffector junction and potentially can act outside the neuroeffector junction. However, superoxide radicals can rapidly inactivate nitric oxide, so diffusion of the transmitter away from the nerve terminal may be quite limited. Neuropeptides released from postganglionic neurons are not rapidly taken up across the pre- or postjunctional membrane and largely remain in the extracellular space until they are enzymatically degraded. This can result in neurally released neuropeptides interacting with receptors at considerable distances from the neuroeffector junction, a phenomenon called volume transmission. Nevertheless, neuropeptides bound to postjunctional receptors can be taken up into the target cell via ►endocytosis, thus contributing to ►receptor desensitisation.

## Process Regulation

The actions of postganglionic neurotransmitters can be regulated by altering synthesis, transport, release, breakdown or reuptake of the transmitter itself, by altering expression or availability of neurotransmitter receptors, or by altering intracellular messengers and ion channels mediating neurotransmitter actions in the target cell. The major regulator of postganglionic neurotransmitter release is the frequency and pattern of action potentials travelling down the postganglionic axon. This is determined primarily by the pattern of impulses leaving the central nervous system via preganglionic neurons. However, this pattern can be modulated by local and circulating hormones changing the excitability of postganglionic neurons in autonomic ganglia. The excitability of postganglionic neurons also can be changed by ongoing activation of sensory nerves passing through autonomic ganglia, such as happens in inflammation. The sensory neurotransmitter substance P, and the hormone angiotensin both increase the excitability of many postganglionic neurons so that they fire more often in response to the same pattern of preganglionic nerve activity. Many substances also can modulate the expression of neurotransmitters or their synthetic enzymes by altering gene transcription in the postganglionic nerve cell body, or affect the release of transmitter from the varicosities of postganglionic neurons.

Ultimately, the pattern of firing of postganglionic neurons determines which co-transmitters are released from the varicosities. With a low frequency of impulses, <2 pulses per second (Hz), the small vesicles preferentially release their transmitters, so catecholamines, ATP and acetylcholine are released without neuropeptides. NOS also can be activated by low impulse frequency, releasing nitric oxide. Generally, large vesicles containing neuropeptides are not released until impulse frequencies reach at least 5, and up to 20, per second. An irregular pattern of high frequency activation is more effective in releasing neuropeptides from large vesicles than is a continuous high frequency firing. This frequency-dependent release of co-transmitters allows postganglionic neurons to produce a wide range of actions on their target tissues.

## Function

Neurotransmitters released from postganglionic autonomic neurons have a wide range of functions. They activate or inhibit target cells such as smooth muscle cells of blood vessels, viscera, airways and skin, cardiac muscle, secretory cells in many glands, and other neurons in autonomic ganglia including enteric neurons. These actions regulate vital processes such as

heart rate and arterial blood pressure, control of regional blood flow, the gastrointestinal system, respiration, reproduction and thermoregulation.

Many neurotransmitters can act both on the target tissue (postjunctional action), and back on the nerve terminal that released them (prejunctional action) to regulate further release of neurotransmitter (Fig. 1). Postganglionic neurotransmitters typically act via receptors on the target cell membrane that in turn can switch on or off a large array of second messenger pathways that influence intracellular calcium levels and usually affect membrane potential. Some transmitters, for example ATP, also can act via receptors that are themselves ion channels, called ionotropic receptors. In contrast, nitric oxide does not use receptors on the target cell membrane but diffuses freely across the membrane of both the nerve terminal and target cell, where it stimulates production of cyclic GMP. The detailed actions of multiple co-transmitters released from the same nerve terminal are not fully known. However, it is clear that some co-transmitters may have only a postjunctional action and some only a prejunctional action [1,6]. Further research also is required to clarify the roles of co-transmitters that potentially can have opposite effects on the target cells (Fig. 1). Nevertheless, the very different molecular sizes of co-transmitters, their different post-junctional signalling systems together with their different methods of inactivation, results in wide variations in the time course of neurotransmitter action. While noradrenaline, ATP, acetylcholine and nitric oxide typically have post-junctional actions lasting seconds to minutes, neuropeptide effects are slow in onset and can last up to tens of minutes, if not hours. Thus, release of neuropeptide transmitters by higher levels of impulse activity provides an efficient way to produce long-lasting functional changes in the target tissues.

## Pathology

Pathological conditions involving dysfunction of the autonomic nervous system include those affecting post-ganglionic transmitter synthesis, release or post-junctional actions. Congenital deficiency in ►dopamine-ß-hydroxylase (DßH) has been demonstrated in a small number of patients with autonomic dysfunction restricted to sympathetic pathways. These patients fail to synthesize adequate noradrenaline, and noradrenaline and adrenaline are undetectable in the plasma while plasma dopamine is elevated. The most obvious symptom is severe postural hypotension from an early age [7]. Other symptoms include ptosis and retrograde ejaculation. In contrast, some forms of hypertension involve hyperactivity of cardiovascular sympathetic nerves that results in increased release of noradrenaline from postganglionic neurons. This increased sympathetic activity is thought to be involved in both the development and maintenance of arterial hypertension [7]. Autoimmune neuropathies affecting autonomic nerve function also can occur. Autoantibodies leading to autonomic dysfunction most often are directed at nicotinic receptors in autonomic ganglia. However, autoantibodies directed at muscarinic receptors on peripheral target tissues have been reported in Sjögren's syndrome and scleroderma. These antibodies prevent acetylcholine released from parasympathetic nerve terminals from producing secretion in the lacrimal and salivary glands via post-junctional muscarinic receptors, resulting in the characteristic sicca symptoms of the disease [8].

## Therapy

Therapeutic interventions for autonomic dysfunction include use of a wide variety of agents affecting post-ganglionic transmitters. DOPS (dihydroxyphenylserine) is useful in overcoming DßH deficiency, as it is converted directly to noradrenaline by dopa-decarboxylase, thus alleviating the requirement for DßH ([7]. Antagonists for post-junctional ß-adrenoceptors (beta blockers) are used widely to treat hypertension by reducing sympathetic cardio-excitation. In Sjögren's syndrome, agonists of M3 muscarinic receptors improve sicca symptoms, and use of antiidiotypic antibodies to neutralize autoantibodies has been proposed [8]. In conditions involving hyperactivity of postganglionic ►cholinergic nerves, such as hyperhidrosis, anticholinergic agents are sometimes used although surgical sympathectomy has long been the treatment of choice. Recently, botulinum neurotoxin treatment has been used to block exocytosis of acetylcholine from the sudomotor neurons. Botulinum toxin A (Botox) has been popular, but it has been suggested that botulinum toxin B (Neurobloc) might produce more prolonged therapy due to its decreased immunogenic nature [9]. Botox also is used increasingly to treat autonomic dysfunctions such as neurogenic urinary incontinence or oesophageal achalasia. Sildenafil (Viagra), an inhibitor of phosphodiesterase-5, is used for treatment of erectile dysfunction in males, although its benefit in females is more controversial. This agent enhances the action of nitric oxide released from pelvic autonomic nerves, by reducing breakdown of cyclic GMP in smooth muscle [10]. Thus, sildenafil is only beneficial if the pelvic nerve pathways are intact.

## Postherpetic Neuralgia (PHN)

### Definition

Postherpetic neuralgia (PHN) is a neuropathic pain syndrome and is the most common complication of herpes zoster (HZ, shingles). PHN occurs mainly in the 60 years plus age group and in individuals suffering more severe acute pain and rash with HZ. Herpes zoster (shingles, HZ) results from reactivation of varicella zoster virus (VZV), one of a family of human herpes viruses, which has remained latent in sensory ganglia following primary infection with varicella (chicken pox). The incidence of HZ increases with age reflecting an age related decline in cell mediated immunity (CMI).

►Neuropathic Pain

## Post-inhibitory Rebound

### Definition

The ability of a neuron to respond to a hyperpolarization with a depolarization of the membrane potential above the level of the normal resting membrane potential. This can either be due to the activation of a hyperpolarization- activated inward current, Ih, or the action of low-voltage activated inward current, ICa(T), that is inactivated at the normal resting membrane potential. In this case, hyperpolarization of the membrane potential removes the inactivation of the current, so that it can be activated when the membrane potential returns to its resting level at the end of the hyperpolarization. This activation causes a transient depolarization of the membrane potential, the post-inhibitory rebound, that can trigger action potentials.

## Post-junctional

### Definition

Post-junctional refers to the target cell distal to a neuroeffector junction, responding to neurotransmitters.

## Post-saccadic Drift

### Definition

In an ideal saccade, the eye rapidly accelerates and then abruptly stops so that gaze remains stationary during the subsequent period of fixation. In reality, many saccades are followed by continued eye movements that have sub-saccadic velocities (e.g., 2–30°/sec in primates) but sufficient durations to appreciably change the direction of gaze. These post-saccadic drifts may be onwards or backwards relative to the saccade, and have several origins. After undershooting saccades in cats, the superior colliculus may continue to fire at low rates and gaze may drift onward toward the target. It has been suggested that is one mechanism the saccadic system uses to correct the undershoot. Less pronounced drifts seen in humans may serve the same purpose. Short duration onward or backward post-saccadic drifts, often called glissades, are thought to be due to a mismatch between the neural signal that moves the eyes during a saccade (the saccadic burst) and that which holds the eyes in position after the saccade (the tonic signal). Small disconjugate glissades occur after saccades in normal subjects, but more prominent glissades can result from central (e.g., cerebellar or cortical) damage and from damage to the ocular motor nerves, muscles,

or orbital tissue. Finally, the recurring post-saccadic centripetal drift and inability to hold eccentric gaze (gaze-evoked nystagmus) that results from damage to the brainstem neural integrator is also a form of post-saccadic drift.

# Postsurgical Pain

►Incisional/Postoperative Pain

# Postsynaptic Currents (EPSCs and IPSCs) or Potentials (EPSPs and IPSPs)

## Definition

By the patch clamp method, it is possible to record the electrical events occurring in a postsynaptic cell as a result of neurotransmitters' release by the presynaptic terminal and the consecutive opening of ionotropic receptors. In the "voltage clamp" mode, the voltage is kept constant, so it is possible to record the current passing through the open ion channels, called "post-synaptic current" (PSC). In the "current clamp" mode, it is possible to record the changes in membrane potential induced by the opening of ion channels, called "postsynaptic potentials" (PSP).

For an excitatory synapse, the binding of neuro-trasmitters induces the opening of cationic channels, which is depolarizing the cell. The induced electrical events are called "excitatory postsynaptic currents" (EPSCs) and "excitatory postsynaptic potentials" (EPSPs). For an inhibitory synapse, the binding of neurotrasmitters induces the opening of chloride channels, which is hyperpolarizing the cell. The induced electrical events are called "inhibitory postsyn-aptic currents" (IPSCs), and "inhibitory postsynaptic potentials" (IPSPs).

## Definition

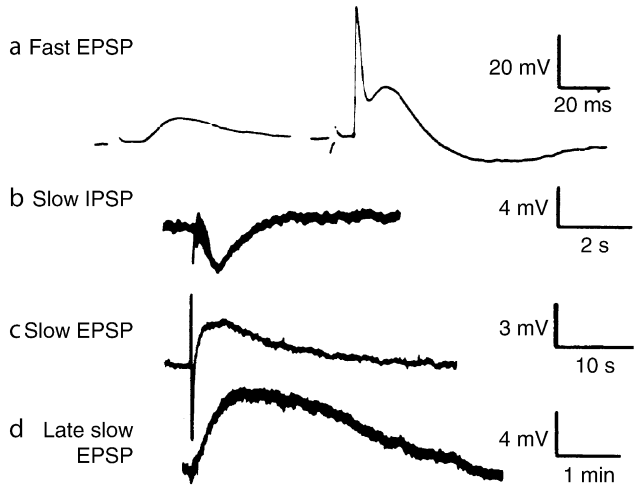
At chemical synapses, transmitter molecules are released from presynaptic terminals to the synaptic cleft or extra-cellular space as the mediator of transmission, and bind to receptors located on the membrane surface of postsynaptic cells. Binding of transmitters often give rise to transient change in the membrane potential of the postsynaptic cells, which is referred to as postsynap-tic potentials (Fig. 1) [1–5]. In the case of electrical synapses [6], electric current flows directly from one cell to the other as the mediator of transmission, and causes a change in membrane potential. Although this can also be referred to as postsynaptic potential, the term "postsynaptic" is conditional, because the electrical synapses are bidirectional. Hence, this term is used mostly for chemical synapses.

## Characteristics

### Mechanisms for Generating Postsynaptic Potentials

Some types of receptors are directly coupled with ion channels while others are either indirectly coupled to ion channels or not coupled at all. Activation of the receptors, either directly or indirectly coupled to ion channels, gives rise to changes in the open probabilities of ion channels, which can be detected as the change in the ion conductance of the membrane. Depending upon the ion selectivity, ion conductance, composition of the ion species, and the membrane potential, electric current flows through ion channels and charges the membrane capacitance to generate postsynaptic potentials. The direction of the postsynaptic currents depends on the ion-selectivity of the ion-channels coupled to the receptors, the composition of the ion species that permeate through the ion-channels, and the membrane potential. The direction of the current reverses at a certain potential, when the membrane potential of the postsynaptic cell is varied (Fig. 2). This potential is called the reversal potential. For instance, the reversal potential of the nicotinic acetylcholine receptor is around zero mV in physiological conditions, and the reversal potential of $GABA_A$ receptor is near the resting potential.

When the direction of the induced current is inward, and hence gives rise to depolarizing potential change, the current is referred to as excitatory postsynaptic current (EPSC), and the potential as excitatory post-synaptic potential (EPSP). When the direction of the



**Postsynaptic Potential. Figure 1** Various postsynaptic potentials generated in frog sympathetic ganglion neurons. a: fast EPSP induced by stimulating preganglionic fibers. This potential is mediated by nicotinic acetylcholine receptors, which is coupled directly with ion channels. A stronger stimulation induces larger depolarization, which triggers action potential (right). b,c: slow IPSP and slow EPSP induced by repetitive stimulations. The slow IPSP and the EPSP are mediated by muscarinic acetylcholine receptors. d: A late slow EPSP evoked by repetitively stimulating spinal nerves is mediated by LHRH-like peptide. (Adapted from reference [7]).

current is outward and gives rise to hyperpolarizing potential change, the current is referred to as inhibitory postsynaptic current (IPSC), and the potential as inhibitory postsynaptic potential (IPSP).

## Factors that Determine the Time Course of Postsynaptic Potentials

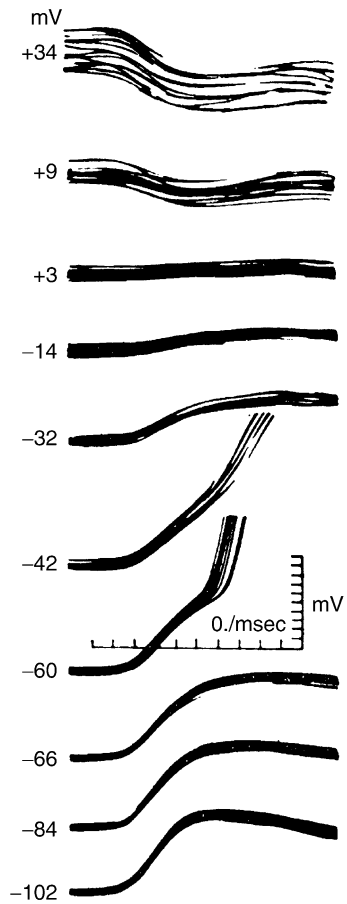
The time course of postsynaptic potentials range from a few milliseconds to a few minutes (Fig. 1). In general, fast postsynaptic potentials are mediated by ion-channel-coupled receptors (ionotropic receptors) for small molecule transmitters, and slow postsynaptic potentials are mediated by GTP-binding-protein-coupled receptors (metabotropic receptors). In the case of ion-channel-coupled receptors, channels open upon binding of transmitters, postsynaptic current flows through the channel, and the current charges the membrane to cause a change in the membrane potential (Fig. 3). Activation of GTP-binding-protein-coupled receptors usually generates second messengers in the cytoplasm, and the second messengers directly or indirectly regulate ion channels. Indirect regulation, in many cases, is by phosphorylation or dephosphorylation of ion channels.

In excitable cells, action potentials can be triggered when the summation of postsynaptic potential provides enough depolarization. The amplitude and the time course of postsynaptic potentials are important in triggering action potentials. Many factors are involved in determining the amplitude and the time course of postsynaptic potentials. Some of the factors are the amount and the time course of transmitter release, the structure of synapses, the lifetime of transmitters in the synaptic cleft, the properties of postsynaptic receptors, and the electrical properties of postsynaptic cells. The lifetime of transmitters in the synaptic cleft is determined by uptake mechanisms or degrading mechanisms, and estimated to be very short in the case of small molecule transmitters, such as glutamate and acetylcholine. The opening of channels indirectly linked to the receptors usually takes longer. The activation of ionotropic receptors is usually fast; hence, the rise time of postsynaptic currents is fast. The decay of postsynaptic currents also depends not only on the lifetime of transmitters in the cleft, but on the properties of receptors, channels, and the membrane as well. Some of the ligand-gated channels for small molecule transmitters show desensitization, and may be involved in determining the time course of postsynaptic potential. In the case of fast transmission, such as transmission at a neuromuscular junction, the decay time of postsynaptic potential is close to the time constant of the postsynaptic membrane, and is usually longer than that of the postsynaptic current (Fig. 3).

Dual whole cell recordings from neurons with long dendrites, such as neocortical pyramidal neurons, show that the postsynaptic potential measured from the cell body is slower compared to the potential measured near the input sites. This kind of distortion depends on the properties of the dendrites, and is important in determining cell response.

## Higher Level Processes

The process of postsynaptic potential generation is part of ►**synaptic transmission**. Processes involved in synaptic transmission are classified as ►**presynaptic processes**, ►**postsynaptic processes** and the rest. The



**Postsynaptic Potential. Figure 2** Reversal of Postsynaptic Potential. EPSP was measured from a cat motoneuron. The membrane potential was varied by injecting current through an intracellular electrode. The postsynaptic potential is depolarizing at potentials below 3 mV, and hyperpolarizing above 7 mV. Triggered action potentials are shown in the traces at −60 and −42 mV. (Adapted from reference [8]).

presynaptic processes are the processes concerning ►**transmitter release**, and the postsynaptic processes concerning ►**reception** of transmitters including the generation of postsynaptic potential. Upon reception of transmitters, the postsynaptic cells do not necessarily generate postsynaptic potential, but may activate intracellular signaling processes that include protein phosphorylation-dephosphorylation and protein synthesis through gene expression.

## Lower Level Processes

- Diffusion of transmitters.
  - Activation and desensitization of postsynaptic receptors.
  - Charging and discharging of membrane capacitance by postsynaptic currents.
  - Intracellular signaling.
  - Clearance of transmitters from synaptic cleft.

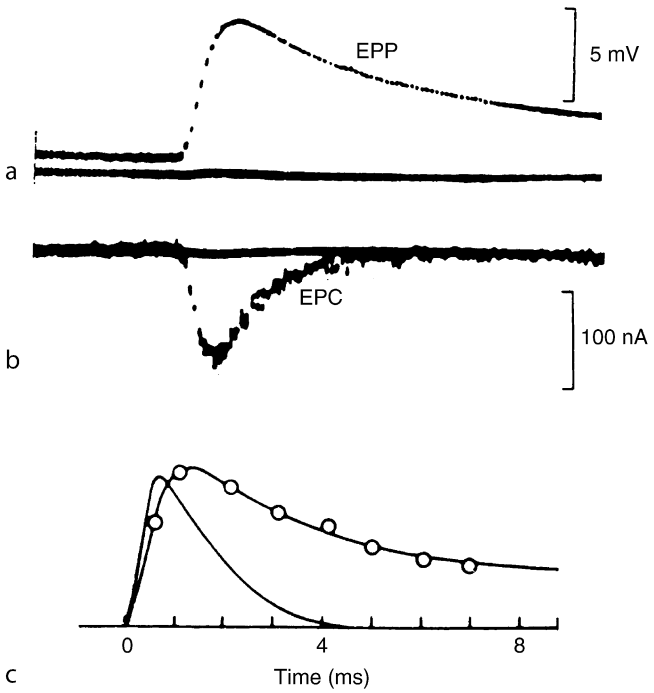
## Process Regulation

Generation of postsynaptic potential is regulated by various ligands including biogenic amines, neuropeptides, and hormones. This kind of regulation is referred to as neuromodulation. The important mechanisms for neuromodulation are phosphorylation-dephosphorylation of proteins and gene expression of proteins, which take part in the generation of postsynaptic potential. The activities of the cells themselves, which take part in generating postsynaptic potentials, also regulate the process of postsynaptic potential generation. This kind of regulation is referred to as ►**neuronal plasticity**. Neuronal plasticity shares common mechanisms with neuromodulations, and is described elsewhere.

## Function

To convey information for significant distance without decay, the neurons generate action potentials that propagate along the axonal processes. When the action potentials arrive at presynaptic terminals of chemical synapses, the information is converted into the form of chemical substances called transmitters. Upon reception of transmitters by the postsynaptic cells, the information is converted back to the form of electrical signal. The electrical signal can easily spread within the postsynaptic cell and can be summated and integrated to generate the output of the postsynaptic cells.

In the case of neuromuscular junctions, muscles receive a single presynaptic fiber. However, the amplitude of a postsynaptic potential (end-plate potential), induced by a single action potential in the presynaptic fiber, is large enough to trigger an action potential at the junction, which propagates along the entire length of the muscle fiber, and also into the transverse tubules, to induce a transient Ca rise and thereby generate a twitch response. The postsynaptic current generated by the activation of a postsynaptic receptor is greater than the current generated by the presynaptic action potential, and provide a current large enough to significantly depolarize the potential of the muscle membrane, the area of which is larger than that of the presynaptic membrane. Since the end-plate potential has large amplitude and a fast rate of rise, the muscle membrane can generate action potential. In contrast, most neurons in the central nervous system receive many thousands of inputs, and single synaptic inputs do not usually trigger action potentials in the postsynaptic cells because the amplitude of postsynaptic potentials is not large enough. Before an action potential is generated in the axons, many synaptic inputs need to be integrated. As synaptic inputs are converted into the form of an electrical signal, and electrical signals can quickly spread along the somato-dendritic axis, inputs



**Postsynaptic Potential. Figure 3** Postsynaptic potential and current. a: End-plate potential (EPP) in a curarized frog muscle fiber. b: End-plate current (EPC) measured from the same fiber voltage-clamped at the resting potential. c: The continuous lines show the actual EPP and EPC. The circles show the EPP calculated from the EPC, assuming the time constant of the membrane to be 25 ms (adapted from reference [9]).

that arrive at various locations at various times can easily be summated and integrated. Thus, the postsynaptic potentials serve as mediators of information integration, which can lead to generation of action potentials in the postsynaptic cells that travel down the axon, and eventually induce transient Ca rise in the presynaptic terminals to trigger transmitter release.

There are cases in which the generation of action potential is skipped and postsynaptic potentials directly trigger transmitter release. In those cases, the extent of transmitter release depends on the amplitude of the potentials, and the synaptic transmission can be graded.

# Postural Control

Fay B. Horak
Neurological Sciences Institute, Oregon Health and Science University, Portland, OR, USA

## Introduction

To inhabit the world, in all of its unpredictable, variable environments and situations, requires a powerful, yet flexible, system of postural control. For example, the ability to move from sitting to standing; to take a step; to respond to a slip or trip; to predict and avoid obstacles; to carry a glass of wine without spilling it, even when walking across a rolling boat; and to orient your body to a speeding soccer ball, all require excellent postural control. Although neural control of postural orientation and equilibrium involves most of the nervous system and all body segments, the postural system is often forgotten because it usually operates at an automatic, non-voluntary level. Only after an injury to the nervous system or musculo-skeletal system, when we have to really "think about" our balance and postural alignment or battle dizziness and spatial disorientation, do we begin to appreciate the complex systems involved in postural control.

## Biomechanical Goals of Postural Control

Postural control involves neural control of ►postural equilibrium and ►postural orientation [1]. Postural equilibrium involves coordination of sensory and motor ►strategies to maintain balance, that is, to stabilize the body's ►center of mass over its ►base of support. An important goal of postural equilibrium control is to prevent falls during both self-initiated and externally-triggered disturbances of stability. The postural equilibrium system controls stability during stance posture as well as during locomotion and performance of voluntary tasks. Postural orientation involves the positioning of body alignment with respect to gravity, the support surface, visual environment and other ►sensory reference frames. The goals of postural equilibrium and postural orientation are independently controlled and sometimes subjects give up one goal for another. For example, an athlete may give up the goal of postural equilibrium in order to achieve their goal to orient their body appropriately to a ball.

## Stance Posture

Although the musculoskeletal system affords some passive stability, humans and most animals require active postural muscle activation to maintain stance posture against gravity and to orient their body segments appropriately to their environment. To oppose the destabilizing effects of gravity, standing humnas are continuously making small correction to upright body position, called ►postural sway. ►Postural muscle tone provides antigravity support and flexibly adjusts to changes in support, alignment, and environmental conditions [2]. Besides postural tone, control of postural sway requires integration of sensory information to detect body motion with respect to the environment and the activation of muscles to maintain equilibrium and alignment of segments. Postural sway during stance can be measured with ►stabilometry; quantification of forces under the feet as continuous displacement of the ►center of pressure [3]. Displacement of the center of pressure represents the combination of motion of the center of body mass as well as the

►ground reaction forces used to control the body ►center of mass over the base of foot support.

Several different types of ►control theories have been used to describe how the nervous system maintains consistent reference values for posture. Because posture is so adaptable and flexible, depending on the situation, models of human posture control include ►optimal control and ►adaptive control, such as ►Kalman filers, of more than one variable, such as position of center of body mass, orientation of the trunk and head in space, energy efficiency, etc. Postural sway during human stance is often modeled as an ►inverted pendulum biomechanical system in which the center of mass of the body is situated at the upper end of a rigid link that pivots about a joint at the base (i.e., the ankle), although actual body sway includes control of multiple segments.

## Automatic Postural Responses

►Automatic postural responses counteract unexpected disturbances to equilibrium. In humans, postural responses are triggered at 100 ms in response to external perturbations. This latency of automatic postural responses is faster than the fastest voluntary postural reactions but slower than the fastest ►stretch reflexes. Stretch reflexes are triggered by muscle spindles and result in activation of the stretched muscles but these reflexes contribute little functional torque to correct postural equilibrium. Automatic postural responses include responses in muscles that are shortened, as well as stretched, as well as muscles far from the site of perturbation that can exert torque against surfaces to correct posture [4]. The recruitment of muscles in a postural response depends on the goal of maintaining equilibrium and not on stereotyped reflexes.

Automatic postural responses depend on ►central set so that they are specific to the conditions of support and adapt to prior experience. Central set is the readiness of the central nervous system for an upcoming event based on initial conditions, prior experience and expectations. For example, leg muscles are activated in response to surface perturbations during free stance but arm muscles are activated and leg muscles suppressed in response to surface perturbations when holding onto a stable support [5]. In addition, muscles on the back of the legs are activated in response to forward body sway while standing but muscles on the front of the legs and in the arms are active when supported on the hands and feet [6]. Postural responses change even in the first trial after a change in body configuration but continue to adapt with repeated trials to continue to optimize the response for the particular conditions. For example, a gradual adaptation of the postural response can be observed during repeated trials of surface rotation. In response to the first rotation, a destabilizing response may be seen in the stretched ankle extensor muscle but with repeated rotations this activation of the extensor is suppressed and activation of the stabilizing ankle flexor gradually increases.

Subjects can also influence which postural response is selected and the magnitude of their response based on experience, expectations, and intention [7]. For example, the stretched ankle extensor muscle responses are inhibited and the shortened tibialis muscles are triggered when subjects are instructed to step in response to a forward body perturbation [8]. Poor coordination of automatic postural responses can result in failure to return to equilibrium in response to external perturbations. Automatic postural responses can be defined by their ►postural strategies and ►postural synergies.

## Postural Strategies and Postural Synergies

Postural strategies can be defined by their functional goals and described based either on body kinematics (relationship of body segmental motion) or body kinetics (relationship of body segmental forces). Two main types of ►postural movement strategies can be used to return the human body to equilibrium when perturbed while standing: strategies that return the center of mass back over the ►base of foot support and strategies that change the base of support under the falling center of mass by stepping or reaching. The ►fixed-support strategies, that return the body center of mass over the base of foot support, form a continuum from the ankle strategy to the hip strategy. The ►ankle strategy, in which the body moves as a flexible inverted pendulum, is appropriate for small amounts of sway when standing on a firm surface [9]. ►The hip strategy, in which the body exerts torque at the hips to quickly move the body center of mass, is used when standing on surfaces not allowing adequate ankle torque or when the body center of mass must be moved more quickly such as for a faster, larger disturbance [9]. When subjects suddenly change from standing on a wide to a narrow surface, or vice versa, there is a gradual adaptation from an ankle to a hip strategy and vice versa with repeated perturbations. This gradual change in postural strategies suggest that they not only depend upon sensory feedback and current sensory conditions but also upon prior conditions based on central set.

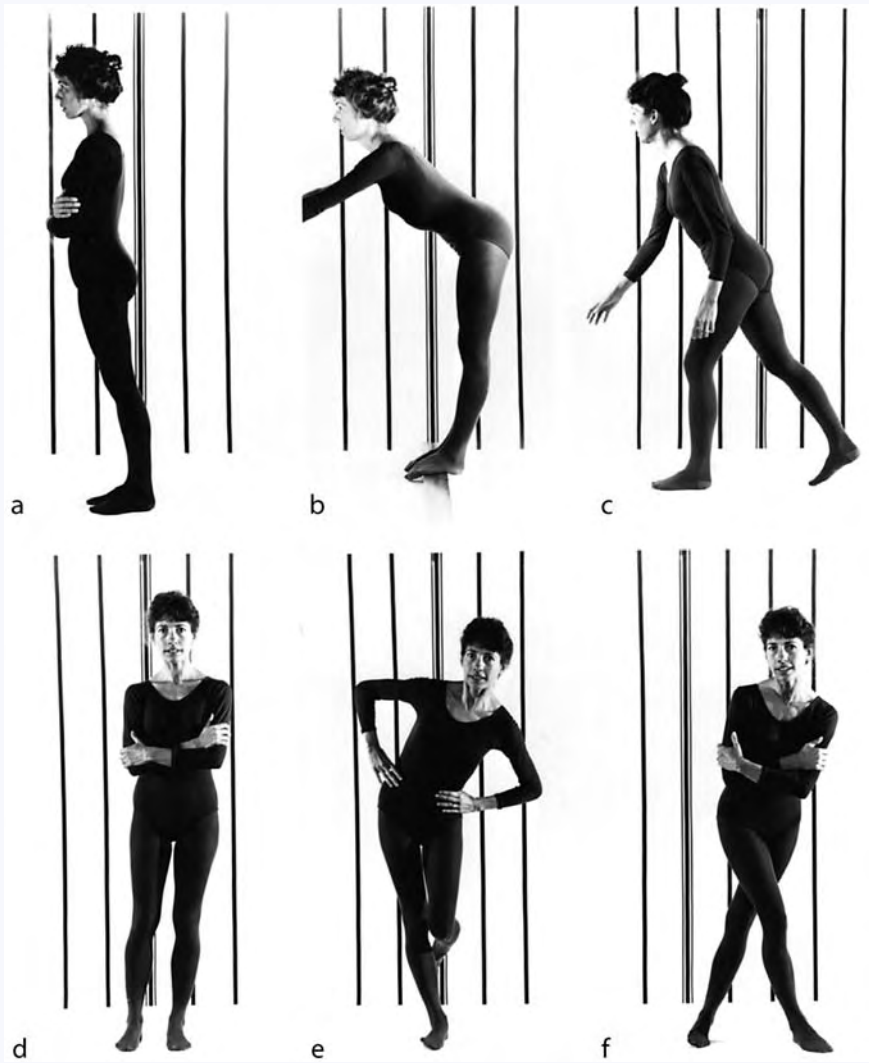
►Change-in-support strategies of stepping and/or reaching to recover equilibrium in response to perturbations are also common, especially during gait and when it is not important to keep the feet in place [10]. However, even when subjects step in response to an external perturbation, they first attempt to return the body center of mass to the initial position by exerting angle torque. If a railing or other stable surface is available, subjects forced to extend their base of support by external displacement will also use a ►reach-to-grasp strategy [11]. Reaching reactions are initiated even faster than stepping reactions. Change-in-support

strategies are often used even under conditions in which it is biomechanically possible for subjects to return to equilibrium using a fixed-support strategy. Figure 1 illustrates fixed-support and change-in-support strategies to correct forward and lateral postural displacements.

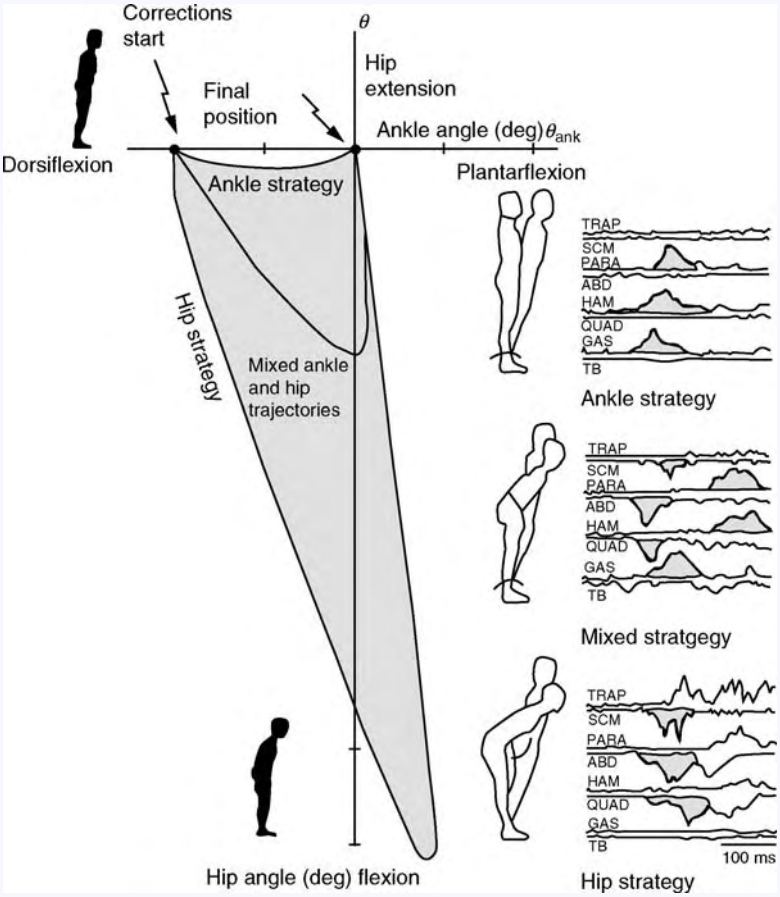
►Postural synergies are groups of muscles activated together by the nervous system to maintain equilibrium [4]. By eliminating the need to control each muscle independently, postural synergies are thought to simplify the neural control task of selecting and coordinating multiple muscles across the body. Postural synergies define the muscle activation patterns that are used by the nervous system to implement various postural strategies. For example, Fig. 2 shows several muscles activated in the ankle, hip and mixed ankle-hip postural muscle synergies in response to forward sway perturbations.

## Anticipatory Postural Adjustments

Voluntary movements are accompanied by ►anticipatory postural adjustments that act to counter, in a predictive manner, postural destabilization associated with a forthcoming movement [12]. Anticipatory postural adjustments are activated as ►feedforward postural control,



**Postural Control. Figure 1** Shows examples of feet-in-place and stepping strategies to correct forward and lateral postural displacements. In response to small CoM displacements, humans use a strategy that maintains upright trunk orientation. In response to more forceful displacements, humans add rapid trunk and hip movements to move the CoM over the base of foot support. Stepping and reaching strategies can also be used to recover equilibrium by moving the base of support under the falling CoM. Lateral stepping includes both a cross-over strategy, as shown, and a step by the loaded leg to widen the stance width.



**Postural Control. Figure 2** Plots the change in ankle and hip angles using the ankle and hip strategies and the continuum of mixed ankle-hip strategies used to return the body to upright stance equilibrium after a forward sway external perturbation.

prior to any sensory feedback indicating postural instability. For example, prior to taking a step, anticipatory postural adjustments move the body forward and onto the stance leg prior to lifting the stepping leg. In addition, when a standing subject rapidly moves their arms, leg and trunk muscles are activated more than 50 ms in advance of the prime mover arm muscles [13]. Anticipatory postural adjustments are specific to the biomechanical requirements of each specific movement and adapt when the biomechanical requirements change. For example, anticipatory postural adjustments in the legs associated with arm movements are reduced or disappear when subjects are supported at the trunk and no longer need the anticipatory postural muscle activity in the legs for stability [5]. These studies suggest that there is a preselection of an anticipatory postural muscle synergy associated with every voluntary movement requiring postural stability. This pre-selection or preparation of the sensorimotor nervous system in advance of movement has been called central set [14].

During locomotion, both anticipatory postural adjustments, via feedforward control, and automatic postural responses, via feedback control, contribute to postural stability. Unperturbed walking or running in healthy individuals consists of placing the feet under a falling center of body mass so the nervous system must anticipate where the feet need to be to maintain equilibrium during walking [15]. During bipedal locomotion, the trunk segment and thus, the body center of mass, is inherently unstable in the lateral direction and thus requires frequent corrections of lateral trunk orientation and/or lateral foot placement. When an individual slips or trips or makes voluntary movements while walking or running, the same automatic postural strategies observed during stance (See *Postural Strategies*) are added to the locomotor pattern [16]. Somatosensory feedback is also used to modify joint stiffness and quick responses to accommodate unanticipated changes in surface configuration.

## Sensory Integration

Sensory information from the ▶somatosensory, visual and vestibular systems must be integrated in order to interpret complex sensory environments because

sensory information from a single sensory channel can be ambiguous and misleading. Postural control depends on the central neural interpretation of convergent sensory information from somatosensory, vestibular, visual systems. Thus, the nervous system controls posture via estimates of position and motion of the body and the environment by combining sensory inputs from several modalities. In addition, ►kinematic and ►kinetic body information must be integrated for control of posture. Sensory systems that signal kinematic position and motion of the body provide ►negative feedback control to minimize postural motion whereas sensory systems that signal kinetic force input provide ►positive feedback control to maximize joint torque when tilting [17]. Interpretation of sensory information by integrating sensory information across modalities is also thought to involve internal models of the body's sensory and motor dynamics, also called the body schema, as well as internal models of the environment. These internal models are based on expected sensory inputs from prior experience and provide the basis for central set. Errors between expected and actual sensory information is thought to be the basis for disorientation, dizziness, and motion sickness in both pathology and challenging environments.

Somatosensory inputs for posture include pressure information from skin in contact with surfaces, limb segment orientation from muscle proprioceptors and joint receptors, as well as muscle length, velocity and force information. Somatosensory inputs from many different types of peripheral sensory receptors converge onto neurons in the spinal cord to encode intersegmental and limb orientation in space [18]. Somatosensory inputs are important for triggering the earliest automatic postural responses in response to external perturbations. Thus, people with neuropathies that slow conduction of somatosensory inputs such as from diabetes or multiple sclerosis have longer than normal latencies of automatic postural responses. Somatosensory inputs are also important for providing information about the direction of perturbation and about the texture and stability of the support surface so that appropriate postural strategies can be selected. Somatosensory inputs can provide confusing, ambiguous information about body center of mass motion because they cannot distinguish between body motion over a stable surface and surface motion under a stable body, such as when standing on a moving boat or pier.

Vestibular inputs for posture are important for orientation of the trunk and head to gravity, especially when the surface is unstable. The vestibular system consists of two types of structures located in the inner ear, the ►labyrinths that encode head rotational acceleration and the ►otoliths that encode head linear acceleration, including gravity. The labyrinth consists of three, fluid-filled, semicircular canals that each sense a different direction of head rotation via motion of hair cells imbedded in the ►cristae, the sensory tissue. Within the otoliths, the ►utricle senses horizontal linear acceleration such as during walking and the ►saccule senses vertical acceleration such as during falling. Vestibulospinal inputs are particularly important for controlling orientation of the head and trunk in space but are not necessary to trigger automatic postural responses to external perturbations [19]. Vestibular inputs can provide confusing, ambiguous information about body center of mass motion because they cannot distinguish, on their own, between head motion over a stable body and head motion accompanying body center of mass motion. Vestibular information is thought to help the somatosensory system distinguish a stable from an unstable surface and then become increasingly important for controlling postural orientation the more unstable is the surface (see ►sensory re-weighting, below). Thus, patients who have lost all vestibular function can still stand and walk and show normal latencies of automatic postural responses to a slip or trip although they will orient to moving surfaces and become unstable when vision is not available [20].

Vestibular inputs must be interpreted via somatosensory inputs for the nervous system to control posture. For example, ►galvanic vestibular stimulation from direct current behind the ears can activate or inhibit the vestibular nerve and result in ►vestibulospinal responses. Vestibulospinal responses consist of medium latency activation of a group of muscles that tilt the body toward the side of the inhibited vestibular nerve when standing. The direction of body tilt depends on the direction the head is facing with respect to the base of foot support [21]. The muscles activated depend on which muscles can exert forces against the surface such that leg muscles are activated in free stance but arm muscles are activated with holding onto a stable surface [22]. Vestibular control of head orientation in space also depends on the close interaction between the vestibular and somatosensory systems via the ►vestibulocollic and ►cervico-collic reflexes.

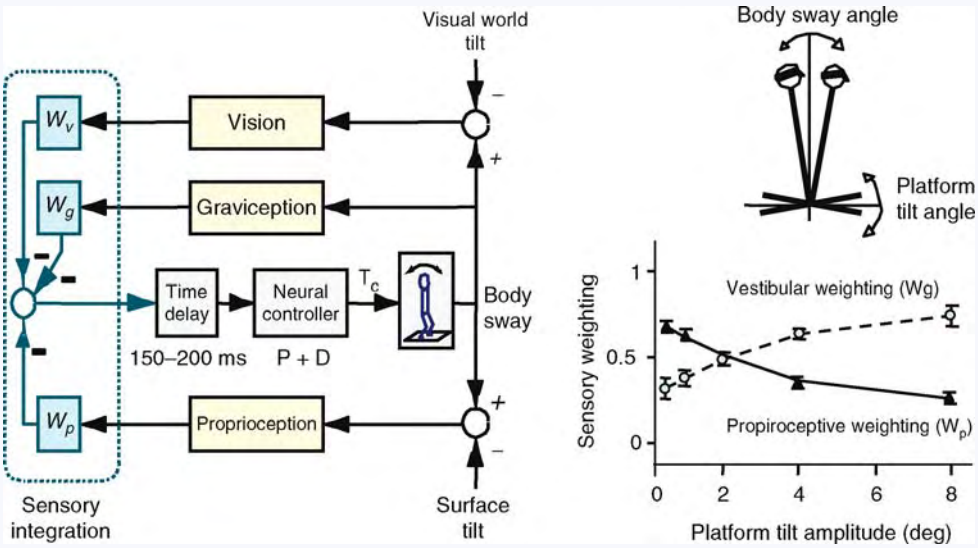
Visual information provides knowledge of body sway and orientation in the environment and provides advanced information about potentially destabilizing situations. Vision can provide information about the direction and speed of body sway. For example, forward body sway is signaled by the visual system as backward visual flow across the peripheral retina and looming across the central retina. Visual information also allows perception and body orientation with respect to the vertical and horizontal visual environment (see perception of visual vertical, below). Thus, standing subjects exposed to slowly moving visual surrounds will sway with reference to the visual motion, even when unaware of it. Visual inputs can provide confusing, ambiguous information about body center of mass motion because

they, alone, cannot distinguish between body motion with respect to a stable visual surround and visual surround motion with respect to a stable body. For example, when stationary subjects view large moving scenes, especially in their peripheral vision, they often momentarily perceive self-motion in the opposite direction. When actually moving the body through space, vision also provides advanced, or ►feedforward, information to position body parts to avoid obstacles, navigate complex terrain, and plan motor strategies. For example, subjects tend to view obstacles in order to plan foot placement and clearance about 3 steps before they reach the obstacles [23].

The ability to orient the body with respect to gravity, the support surface, visual surround and internal references and to automatically alter how the body is oriented in space, depending on the context and task requirements is an important attribute of postural control. For example, a subject may automatically orient their body perpendicular to the support surface unless the support surface becomes unstable, when they will orient themselves to gravity or to their visual surround.

►Sensory re-weighting is an important mechanism for changing the relative contributions made by different sensory systems for postural control. Figure 3 shows a model of sensory integration for postural control in which somatosensory, vestibular and visual inputs can change weighting depending on changes in the environment. Using this model, studies have shown that in a well-lit environment with a firm base of support, healthy subjects refy on somatosensory 70%, vision 10% and vestibular 20% [20]. However, when healthy subjects stand on an unstable surface, they increase sensory weighting to vestibular and vision as they decrease dependence on surface somatosensory inputs for postural orientation [24]. Ability to reweight sensory information depending on the sensory context is important for maintaining stability when moving from one sensory context to another, such as from a moving boat to firm ground. Individuals with loss of somatosensory, vestibular or visual input from pathology are limited in their ability to reweight postural sensory dependence and thus, are at risk of falls in particular sensory contexts. In addition, some central nervous system disorders may impair the ability to quickly reweight sensory dependence, even when the peripheral sensory systems are intact. Subjects can use ►sensory substitution to replace one sensory modality for another to help control posture. For example, light touch on a cane can be used to substitute haptic sensory cues for missing vestibular or somatosensory inputs dues to pathology and thereby reduce postural sway in stance [25,26]. Biofeedback systems that provide visual, auditory or somatosensory inputs to the nervous system correlated with body sway have also been shown to provide effective sensory substitution to improve postural stability in patients with loss of sensory information.

Healthy individuals also have a conscious perception of vertical spatial orientation. ►Perception of verticality, or upright, may have multiple neural representations [27]. In fact, ►perception of visual vertical, or ability to align a line in the dark with gravity, is independent of ►perception of postural (or proprioceptive) vertical, or ability to align the body in space without vision [28]. For example, the internal representation of visual, but not postural, vertical is tilted in subjects with unilateral vestibular loss, whereas the internal representation of



**Postural Control. Figure 3**

P

postural, but not visual vertical is tilted in some subjects with stroke. A tilted or inaccurate internal representation of vertical will result in automatic postural alignment that is not aligned with gravity.

## Neuroanatomy of Posture Control and Clinical Implications

Control of posture is distributed in the nervous system and the musculoskeletal system such that pathology almost anywhere in the nervous system or musculoskeletal system can impair postural equilibrium and/or postural orientation. The spinal cord is sufficient for maintaining antigravity support and locomotor patterns but not for maintaining balance [29]. Sensory pathways in the spinal cord carry somatosensory information about limb orientation as well as motor pathways such as the medially located vestibulospinal and reticulospinal pathways for activating postural muscle synergies. In the brainstem, the vestibular nuclei are important for integrating sensory information across modalities for postural orientation and the reticular formation is likely involved in organizing postural synergies. The important ►role of the cerebellum in posture can be seen by the severe problems with postural stability and postural orientation in patients with damage to the cerebellum. Damage to the spinocerebellum, specifically, impairs postural stability by causing larger than normal automatic and anticipatory postural adjustments and by impairing the ability to optimize postural strategies based on prior experience [30]. In contrast, damage to the vestibulocerebellum results in difficulty using vestibular or visual information to orient the body with reference to gravity or visual references. The basal ganglia's importance to postural control can be seen by the frequent falls in patients with pathology involving the basal ganglia, such as Parkinson's disease. The basal ganglia is important for quickly changing postural strategies when conditions change, for regulating postural muscle tone, for generating forceful anticipatory and reactive postural responses and for perception of postural orientation [31]. The cerebral cortex is involved in postural control in as many complex ways as voluntary movement [32]. The cortex is involved in changing postural responses with alterations in cognitive state, initial sensory-motor conditions, prior experience, and prior warning of a perturbation, all representing changes in central set. In addition, the supplementary motor cortex is involved in generating anticipatory postural adjustments and the primary motor cortex participates in longer latency postural responses to perturbations. Parietal and temporal association cortical areas are involved in perception of spatial orientation and in formulating the internal models of the body and the environment so important to postural control. Thus, damage to almost any part of the cortex from a cerebral vascular accident can impact postural stability or orientation.

## Postural Equilibrium

### Definition

A state in which the body is either at rest, moving at constant velocity or executing a repeatable (periodic) pattern of motion. A stable system is one that returns to a state of equilibrium after it has been perturbed.

►Postural Strategies

## Postural Instability

### Definition

Impairment of balance when standing, walking, or turning.

# Postural Muscle Tone

Victor S. Gurfinkel
Neurological Sciences Institute, Oregon Health & Science University, Portland, OR, USA

### Definition

Postural tone is the steady contraction of muscles that are necessary to hold different parts of the skeleton in proper relation to the various and constantly changing attitudes and postures of the body.

### Description of the Theory

#### Decerebrate Posture

Because postural muscle tone is completely suppressed by narcosis, postural tone has mainly been studied using an experimental model called the decerebrate animal [1]. In the decerebration of mammals, the cerebral cortex and thalamus are surgically inactivated by intercollicular cross-section of the brain stem under general anesthesia. Once the effects of the anesthesia have dissipated, the condition known as "decerebrate rigidity" can be seen. This condition is characterized by a strong extended neck, trunk, tail and limbs, which resist attempts to flex them. In decerebrate rigidity, there is no sensation of pain. Because of this rigidity, when the decerebrate cat is placed on its four limbs, tension in the limb muscles is enough to maintain its body posture. This muscle tone has been named "postural tone" [1]. In decerebrate animals, the neuronal structures of the brain stem and spinal cord are in an active condition. Therefore, this model is useful for studying many questions of neurophysiology. For example, on a background of high muscle tone, it is possible to study not only influences of excitation, leading to the enhancement of muscle tone, but also to study inhibition, which results in the suppression of muscle tone.

In the past, many researchers have been devoted to studying the nature of decerebrate rigidity. It was found that deafferentation (i.e., sectioning appropriate dorsal roots) abolishes decerebrate rigidity of limb muscles [1]. In addition, it was found that the tonus of the extensor muscles is autogenous, in that each muscle is dependent on afferent nerve fibers from the muscle itself ("myotatic component" in decerebrate rigidity). These findings were reproduced many times [2]. This showed that the origin of decerebrate rigidity cannot be completely explained by the myotatic component. The actual situation is more complex. In studies of decerebrate cats, it was shown that in addition to proprioception, there are other sources of postural tonic activity that are connected to the position of the head

in space and the position of the head relative to the trunk [3]. These neck and vestibular tonic reflexes strongly influence the level of decerebrate rigidity and cause a redistribution of muscle tension.

Another type of experiment elucidated mechanisms of decerebrate rigidity. This experiment involved, as described above, the cutting of the dorsal roots to the forelimbs in a decerebrate preparation to make forelimbs flaccid. When the spinal cord was transected below the level of origin of the brachial nerves (postbrachial transection), the forelegs became rigid, although still deafferented. This effect can be explained by the fact that post-brachial transection of the spinal cord cuts off the flow of inhibitory pulses to the motoneurons that ascend from tonically active propriospinal neurons located in L2–L3 segments (the "Schiff-Sherrington inhibition").

It is known that the cerebellum is involved in the control of muscle tone and that damage to the cerebellum is accompanied by a reduction in tone. However, it has been shown that the removal of the cerebellum in a cat that has undergone intercollicular brain stem transection increases decerebrate rigidity. This same effect can be caused by bilateral destruction of the fastigial nuclei. Here again, rigidity returns to the deafferented forelimbs of the decerebrate preparation.

Another model of decerebrate rigidity involves properties that are different from the intercollicular preparation and has extended our knowledge about the mechanisms involved in decerebrate rigidity. It is the so-called anemic decerebration (high ligation of the basilar artery and of both carotids) that functionally inactivates all the nervous structures that are supplied by blood vessels arising cephalad to the basilar ligature, including the anterior lobe of cerebellum. After anemic decerebration, strong tension in all extensor muscles also develops. However, decerebrate rigidity, after anemic decerebration, is not eliminated by transection of the dorsal roots. In the anemic preparation, rigidity is caused by the nonmyotatic component of muscle tension, represented mainly by the tonic labyrinthine influences on the spinal motoneurons. The nonmyotatic component of extensor rigidity is released by anemic damage to the anterior lobe of the cerebellum.

One cogent interpretation of the evolution of the cerebellar regulation of postural tone is that postural extensor mechanisms are tonically inhibited through bulbospinal relays by the paleocerebellum, whereas a tonic facilitating influence is exercised by the neocerebellum on the cerebral cortex [2]. After efferent innervation (γ innervation) of muscle spindles was established, intercollicular decerebrate rigidity was called "γ rigidity," and anemic rigidity was called "α rigidity" [4]. A comparison of these two kinds of decerebrate rigidity showed that they change differently under the influence of various factors, suggesting that both muscle and labyrinthine receptors tonically support extensor rigidity. The disappearance of decerebrate rigidity following deafferentation indicated that in the intercollicular animal, the vestibular component is tonically inhibited by cerebellar and spinal mechanisms (Schiff-Sherrington). However, in anemic decerebrate animals, the importance of the myotatic component of decerebrate rigidity is reduced by γ paralysis, while that of the vestibular component is increased through a release mechanism. It is possible that other brain structures also participate in the formation of decerebrate rigidity. The posture of the decerebrate animal may be the consequence of a disturbance in balance between different sources of tonic excitatory and inhibitory influences.

## Postural Adaptation

As mentioned above, a decerebrate cat can be stood on its legs and will maintain this position; a position that is a caricature not only because the cat's legs are hyper-extended but also because the body is absolutely motionless due to constant muscle tension. Such immobility can also be observed naturally in intact animals (e.g., a hunting dog becomes motionless when pointing to detected game, rabbits experience immobilization catatonia when faced with danger and many animals undergo hypnosis). However, immobilization, that is muscles in a state of constant tension, is the exception not the rule. Postural tone of muscles ranges from very high tension at exaggerated decerebrate rigidity, up to complete atonia in the vertebra prominens reflex. Although the decerebrate animal exhibits rigidity, it still has the capacity to adapt to experimental conditions. In 1909, it was shown for the first time that when a decerebrate animal's limb was flexed, the limb did not move back to its initial position; rather it adapted and maintained the new position [5]. This condition was explained as: "The forced stretch causes a relaxation of the tonic extensor, and this condition of relaxed tonus persists after the forced stretch itself has ceased. This reaction, may for brevity, be termed the 'lengthening reaction'" [5]. Similarly, when a decerebrate animal's limb is moved, the antagonist muscles shorten and adapt to their shorter length. In this shortening, the muscle insertion and origin are brought closer together, which appears to induce heightened tonus in the muscle—a reaction that has been termed the "shortening reaction" [5]. In other words, the limb that is brought by movement into a new posture remains in that new posture when released. This property is especially present in skeletal muscles when the nerve centers are operating to maintain posture [5]. Such behavior of tonically active muscles has been termed "plasticity." Skeletal muscles in this form of reflex contraction quite readily adapt themselves to different lengths while counteracting one and the same load [6].

The shortening reaction can be observed in humans. In some neurological diseases that are accompanied by tone abnormalities, passive movement of a joint results in the contraction of shortened muscles. This contraction is tonic, that is, it persists after the movement terminates.

Another form of postural tone adaptation in decerebrate animals deals with neck and vestibular tonic reflexes [3]. In decerebrate animals, neck reflexes result in a redistribution of tonic muscle tension that is dependent on the relative position of the head and trunk. Dorsiflexion of the neck produces extension of forelimbs and flexion of hind limbs, ventriflexion of the neck produces flexion of the forelimbs and extension of the hind limbs, lateral flexion of the neck (ear toward the shoulder) produces extension of the fore and hind limbs on the side toward which the head is turned and rotation of the head on the neck produces extension of both the fore and hind limbs on the side toward which the chin is turned. The changed distribution of muscle tonus in the limbs continues as long as the head retains a specific relationship to the trunk. Changes in head position in space when neck reflexes are inactivated, also result in a redistribution of postural tone of neck, trunk and legs muscles. There is one position of the head in space in which the extensor tone of the limbs is maximal and one position of the head in space in which it is minimal. The maximal and minimal positions differ from each other by 180°. When the position of the head in space is changed when the body is in different positions, tonic neck and labyrinth reflexes combine to modify postural tone in various ways.

Another factor that influences the distribution of postural tone is how the body or limbs contact the support surface. When a limb contacts the support surface, dorsiflexion occurs in the distal part of the limb (fingers and hands, toes and feet), which results in significant enhancement (strengthening) of tone in the extensor muscles of all joints in the limb (termed "the positive reaction of support"). The limb, in this enhanced tonic state, is capable of maintaining body weight. This reaction has been observed in animals without a cerebellum [7]. In decerebrate animals, this reaction is more difficult to observe because the limbs are in an initial state of high tonic tension. This type of reaction has also been observed in humans with brain pathology. In the examples discussed above, the adaptive changes of postural tone were tonic in character, but in natural conditions, adaptive changes are also phasic in character. In natural conditions, such reactions are mainly directed to preserving balance and maintaining the stability of body parts during movement. Almost all movements of the hands and legs in natural conditions inevitably require a redistribution of postural tone. For example, when a human moves the arms to catch a falling object, contact with the object is preceded by the contraction of appropriate hand muscles. Similarly, when a human moves a leg when taking a step, this movement is preceded by a change in muscle tone distribution in the trunk and in the opposite leg. Adaptation of muscle tonic activity maintains harmony between mobility and stability.

# Postural Orientation

## Definition

Postural orientation refers to the positioning of the body or body segments with respect to some reference frame.

The selection of the reference frame is arbitrary and there are many choices. A commonly used and often implicit reference is a global or earth fixed reference frame. Other common reference frames include clinical joint based frames where joint motions can be described, for example in terms of extension or flexion and local reference frames which might move with the body or be affixed to a particular body segment.

## Synonyms

Balance-recovery reactions; Postural reactions; Postural synergies

## Definition

Postural strategies are specific patterns of muscle activation, joint torque, joint rotation and/or limb movement that are evoked by balance perturbation. These reactions serve to prevent the body from falling and act to re-establish a state of ►postural equilibrium. Triggered by multiple sensory inputs, they involve polysynaptic spinal and supraspinal neural pathways and are highly adaptable to meet functional demands. Strategy selection and modulation are dependent on: (i) the features of the perturbation (timing, direction, magnitude, predictability), (ii) the "►central set" of the individual (affect, arousal, attention, expectations, prior experience), (iii) ongoing activity (cognitive or motor) and (iv) environmental constraints (on reaction force generation and limb movement).

## Description of the Theory

### Biomechanical Requirements for Postural Equilibrium

The mechanics of the upright human body can be modeled as a multi-link ►inverted pendulum, with each link corresponding to a body segment (e.g., foot, shank, thigh, trunk) [1]. Static postural equilibrium requires the ►center of mass (COM) of this linkage to be positioned over the ►base of support (BOS); however, the linkage is inherently unstable, due to the force of gravity. Additional destabilizing forces arise due to movement of the body and interaction with the environment. The BOS is usually defined by the position of the feet, but may include the arms when grasping or touching an object for support. In the absence of arm support, static equilibrium requires the COM to be positioned over the feet and the perimeter of this foot area can be considered to represent the static stability limits associated with the BOS. Dynamic equilibrium takes into account the additional requirement of controlling the momentum associated with movement of the COM [2]. If the COM is moving with sufficient horizontal velocity, it is possible for the body to be dynamically unstable, even when the COM is positioned over the BOS. Conversely, it is possible for the body to be dynamically stable even though the COM is located outside the static stability limits of the BOS, provided that the COM is moving toward the BOS with sufficient velocity that it can eventually be repositioned over the BOS.

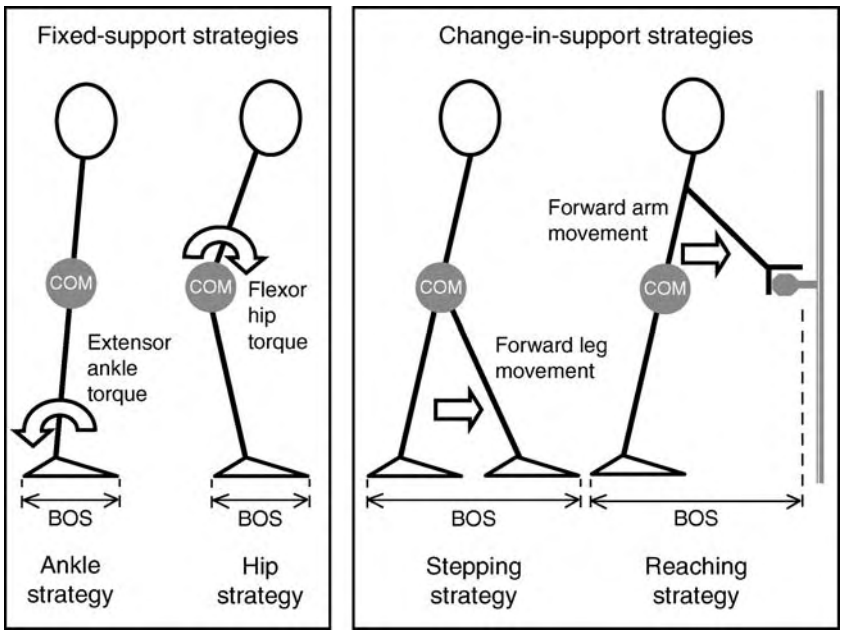
### Postural Strategies for Responding to Perturbation

Passive muscle stiffness could, in theory, be sufficient to maintain a stable upright posture under static conditions; however, the reality is that coordinated muscle activation is required to keep the body upright in the activities of daily life. To maintain upright stance, the central nervous system (CNS) must actively regulate the static and dynamic relationship between the COM and the BOS [2]. Responses to perturbations must involve deceleration of the COM, but can also involve changes in the BOS. Accordingly there are two distinct classes of postural strategies: (i) "►fixed-support" ("feet-in-place") strategies, in which the BOS is not altered and (ii) "►change-in-support" reactions, where the BOS is altered via rapid ►stepping or reaching movements of the limbs [3]. See Fig. 1.

Although the focus here is on reactions to perturbation of stance, it should be noted that fixed support and change-in-support reactions are also used to respond to perturbations experienced during gait. However, the gait responses may show some differences, e.g., bilateral asymmetries in muscle activation, phase dependent gating of sensory inflow and triggering of additional strategies (e.g., elevation of the swing foot in response to a trip perturbation). In addition, stepping reactions during gait may involve modulation of an ongoing step, while arm reactions may be affected by gait-related arm swing.

Postural reactions can be controlled, to some extent, in a predictive manner provided that the characteristics of the destabilization are known in advance (e.g., the "►anticipatory postural adjustments" that normally precede preplanned volitional movement or the reactions evoked by a periodic sinusoidal perturbation). In general, however, sensory information about the body orientation and motion is also required, particularly when balance is disturbed unexpectedly by a sudden perturbation (e.g., due to a force applied to the body or motion of the support surface). This sensory information is used to detect instability and to generate appropriate stabilizing responses, either by triggering and scaling preprogrammed "feedforward" reactions or by continuously updating ongoing "feedback" corrections. The initial phases of the reactions to sudden, transient perturbation are thought to be triggered feedforward corrections, whereas the later phases may also involve ongoing feedback control.

Postural strategies involve multiple sensory inputs (somatosensory, vestibular, visual) and highly adaptable triggered reactions, rather than stereotyped short-latency reflexive responses arising primarily from a single source of afferent drive (e.g., vestibulo-spinal reflex, myogenic stretch reflex). The triggering afferent signals depend on the nature of the perturbation, e.g., whether the



**Postural Strategies. Figure 1** Postural strategies. Static postural equilibrium requires the body center of mass (*COM*) to be positioned over the base of support (*BOS*). The *stick figures* illustrate potential responses evoked by a perturbation that induces forward falling motion of the COM. Note the large increase in BOS associated with the change-in-support strategies.

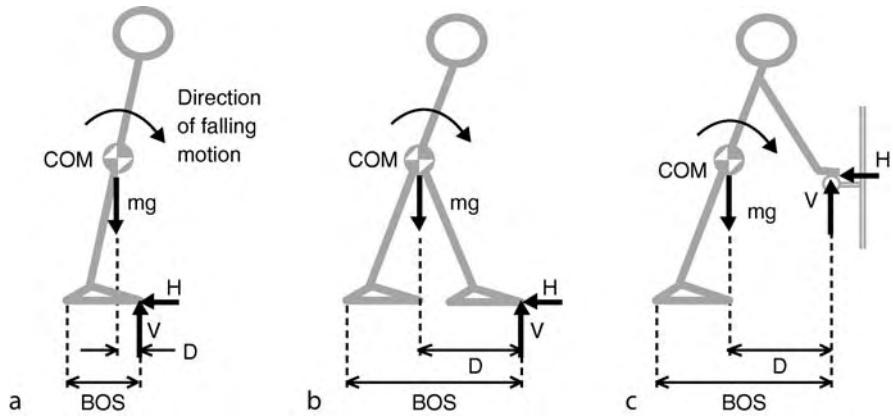
perturbation involves the movement of the support surface or a force applied to the upper body. Responses to support surface perturbations may involve ankle muscle spindles (Ia afferents); however, the role of the vestibular system and/or somatosensory inputs from other joints cannot be ruled out [4] and it appears that even visual inputs (which are generally thought to require much longer processing times) can modulate the earliest postural muscle activation in some situations. The earliest muscle activation associated with the postural reaction typically occurs at a latency of about 80 to 140 ms after perturbation onset.

The control of these reactions is mediated via polysynaptic spinal and supraspinal neural pathways [5]. Furthermore, although balance reactions are often considered to be "automatic," it appears that control of later phases of the response (e.g., 200 to 500 ms after perturbation onset) may involve transcortical pathways and high-level cognitive and attentional systems [6]. This is supported by evidence from dual-task studies, where later phases of the balance response can be affected by performance of a concurrent cognitive task. Measurements of perturbation-evoked cortical potentials also support cognitive involvement. Thus, it appears that reactions to perturbation are not as stereotyped as once believed, but are in fact highly adaptable to the functional demands of maintaining stability, i.e., regulating the relationship between COM and BOS. Although some researchers have speculated that critical afferent information for determining the state of the COM may arise from load receptors such as Golgi tendon organs, maintaining stability also requires information about the state of the BOS and the direction of a gravitational reference vector. In contrast to the traditional view that the vestibular otoliths provide the reference vector, some researchers have suggested a construct based on multiple sensory modalities. Determination of the BOS state is also probably dependent on multiple sensory inputs, although it appears that the plantar cutaneous mechanoreceptors may play a particularly critical role in providing information pertaining to BOS stability limits and the state of contact between foot and ground [1].

## Fixed-Support (Feet-in-Place) Strategies

In ►fixed-support strategies, the COM motion that is induced by the postural perturbation is decelerated via generation of active muscle torques at the joints of the supporting leg or legs, as well as the trunk and upper limbs. These joint torques create antero-posterior "environment reaction" forces (i.e., shear force at the foot ground interface, as well as forces occurring at the hand if it is in contact with a stable object or surface) and it is these forces that act to decelerate and arrest the horizontal COM motion (Fig. 2). Fixed-support reactions occur very rapidly (e.g., onset latency of 80 to 140 ms in ankle muscles) and are essentially the first line of defense against postural perturbation.

Biomechanically, the upright human body has redundant degrees of freedom. This means that there are potentially many different combinations of muscle



**Postural Strategies. Figure 2** Biomechanical advantages of change-in-support strategies (*panels* b and c) in comparison to fixed-support strategies (*panel* a). The postural reaction must generate a horizontal ground-reaction shear force (*H*) in order to decelerate the horizontal motion of the center of mass (*COM*). Note that the stepping (b) and grasping (c) reactions can greatly amplify the moment arm (D) between the COM and the contact force (*V*), which allows greater shear force to be generated (H is approximately proportional to D). In addition, the increase in base of support (*BOS*) allows a larger range of COM motion to be accommodated without loss of stability. Adapted from [1].

torques at the various joints that could be used to re-establish postural equilibrium, in responding to a given postural perturbation. It has been proposed that the CNS deals with this redundancy, and simplifies the control problem, by restricting the response to a finite number of specific response patterns (often referred to as synergies as well as strategies) or weighted combinations of these patterns.

Early research identified two major strategies for responding to antero-posterior perturbations: (i) the ►ankle strategy and (ii) the ►hip strategy [7]. Although not included in the original definitions of these strategies, activation of knee muscles can also play an important role in both ankle and hip strategies, particular for perturbations that induce a backward falling motion and hence tend to cause the knee to "collapse" in flexion [4].

In the ankle strategy, the predominant stabilizing action involves active generation of ankle torque. This strategy is characterized by activation of ventral muscles (i.e., ankle dorsiflexors, hip flexors, abdominals) in response to backward falling motion and activation of dorsal muscles (i.e., ankle plantarflexors, hip extensors, paraspinals) in response to forward falling motion. In essence, the body is controlled to behave predominantly in the manner of a single-link inverted pendulum, with joint rotation primarily occurring at the ankle. For responses to support-surface perturbations, the involved muscles fire in a distal to proximal sequence.

In the hip strategy, the predominant stabilizing action involves active generation of hip torque. This strategy is characterized by activation of muscles on the opposite side of the thigh and trunk in comparison to the ankle strategy, i.e., dorsal muscles in response to backward falling motion and ventral muscles in response to forward falling motion. There is relatively little activation at the ankle. The main effect biomechanically is to generate stabilizing shear force (at the foot ground interface) that is larger than the shear force that can be generated using the ankle strategy.

The ankle strategy predominates at small levels of perturbation, whereas increasing levels of hip activation are added as the postural challenge increases [8]. These latter "mixed strategy" responses were originally thought to involve a weighted combination of the ankle and hip strategies; however, the "pure" hip strategy is seldom if ever observed during natural behavior (in experiments, it was learned over the course of repeated trials that involved standing on a shortened support surface, which limited ability to generate stabilizing ankle torque) [3]. This suggests that there is actually a continuum of postural responses formed by the addition of hip torque to the ankle strategy, rather than two distinct strategies.

Feet-in-place strategies for responding to medio-lateral perturbation primarily involve the hip abductors and adductors, due to the limited capacity at the ankle and knee for motion and torque generation in the frontal plane. Although one might expect responses to perturbations in "off axis" or "diagonal" directions to involve a weighted combination of the medio-lateral hip strategy and the antero-posterior ankle strategy, it appears that this construct is inadequate to explain the complex muscle responses that are evoked by multi-directional perturbations. Rather, there appears to be a continuum of strategies that are modifiable in a task-dependent manner [9]. Thus, for example, there may be co-contraction of agonist and antagonist ankle muscles

(which serves to stiffen the ankle joint) and latencies for some muscles may differ according to the perturbation direction.

Although the feet in place strategies described above primarily involve activation of the lower limb and axial (trunk and neck) musculature, postural reactions involving the upper limbs often occur in parallel. In fact, activation of the arm muscles can occur as rapidly as the earliest activation at the ankle (80 ms after perturbation onset). The functional role of these arm-reaction strategies appears to vary, depending on task conditions. In situations where the hand is in contact with a supporting object or surface at time of perturbation onset, the arm reaction can rapidly generate stabilizing "environment reaction" forces at the hand. In situations where the arms are free to move, the arm movements may serve to augment the stabilization achieved by the lower limb reactions. For example, raising the arms can help to stabilize the body by acting as a counterweight, by inducing inertial joint torques at the shoulder (due to the acceleration and/or deceleration of the arm segments) or by increasing the rotational inertia of the body. In some situations, it appears that the raising of the arms may also serve a protective function, to absorb energy and reduce the risk of injury in the event that a fall does occur. It is also possible that the arm activation is related to an aborted ►reach-to-grasp ►change-in-support strategy (see below).

## Change-in-Support Strategies

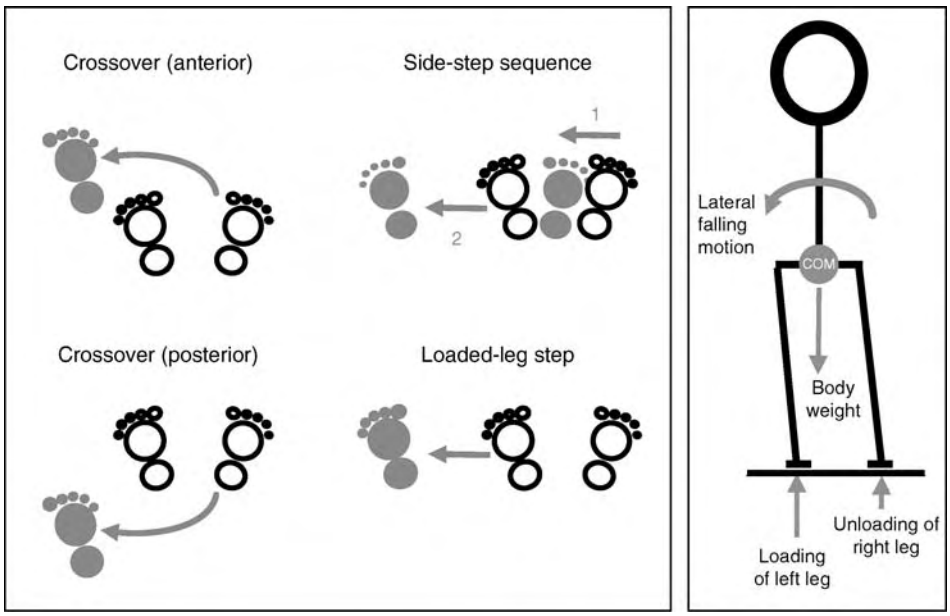
In change-in-support reactions, the BOS is altered via rapid stepping or reaching movements of the limbs. Increase in the BOS allows: (i) a larger range of perturbation-induced COM motion to be tolerated without loss of equilibrium, (ii) more time for this COM motion to be decelerated (via "environment reaction" forces generated at the foot and/or hand) and (iii) larger decelerating "environment reaction" forces to be generated (Fig. 2). Reach to grasp reactions provide a further biomechanical advantage in that they allow the body to be anchored with respect to the grasped object, provided that a sufficiently strong grip can be maintained. Change-in-support reactions can provide a much larger degree of stabilization, in comparison to fixed support reactions and are the only recourse in responding to large perturbations [1,3].

The neural control of change-in-support (compensatory) and volitional limb movements appear to differ in some fundamental ways. First, the compensatory postural movements are much more rapid. A compensatory stepping movement is typically completed in about 500 ms, approximately half the time required to step as fast as possible in reaction to a visual cue. Similarly, compensatory reaching reactions are more rapid than volitional arm movements. For example, compensatory arm activation typically begins at a latency of 80 to 140 ms after perturbation onset, whereas the most rapid latency for volitional arm activation (single-choice reaction-time task) is about 150–200 ms (and is slower when the task involves multiple choices).

Another fundamental distinction between compensatory stepping and volitional stepping pertains to the presence or absence of an "anticipatory postural adjustment" (APA), prior to the lifting of the swing leg. Volitional movements that involve stepping or raising a leg are invariably preceded by an APA which acts to propel the COM toward the stance limb and thereby serves to reduce the tendency of the COM to fall laterally toward the unsupported side during the subsequent foot movement. The APA is typically either absent or severely truncated during compensatory stepping reactions. This allows more rapid step execution; however, the consequence is that the lateral COM motion arising during the swing phase must be arrested after the swing foot lands. A large APA does occur when task demands require a prolonged swing phase (e.g., when the compensatory step must clear an obstacle). Presumably, the APA is required in such situations because the COM has much greater opportunity to fall laterally.

Whereas antero-posterior perturbations typically (in healthy young adults) evoke a single step that is predominantly directed forward or backward, perturbations in other directions evoke a wider variety of stepping patterns. If the perturbation-includes a mediolateral component, then the perturbation induced COM motion will cause an increase in loading of one leg and a decrease in loading of the contralateral leg. Typically, when the perturbation is unpredictable, the unloaded leg is used to execute the stepping reaction. This has the advantage of allowing a more rapid foot lift, as less time is required to complete the unloading of the swing foot; however, the consequence is that a more complex stepping movement is required. This may involve a crossover step, in which the swing foot is moved across the body (either in front of or behind the stance leg). Alternatively, the unloaded leg may be used to execute a small initial medial step, which is then followed by a large lateral step with the contralateral leg (a "side-step sequence"). See Fig. 3.

The direction of perturbation-evoked reach-to-grasp reactions is highly dependent on both the direction of the perturbation and the location of potential handholds that can be grasped or touched for support. Remarkably, even the earliest portion of the arm trajectory (at a latency as early as 80 ms) is directed toward the nearest available handhold. Such a rapid response does not permit visual scanning of the environment; hence, it appears that the initial arm trajectory must either involve peripheral vision or "remembered" visuospatial information. In order to use "remembered" information,



**Postural Strategies. Figure 3** ▶Stepping strategies evoked when the postural perturbation includes a lateral component. The footprint drawings illustrate responses evoked by a perturbation that induces leftward falling motion of the center of mass (*COM*). The *unshaded* footprints indicate the starting position at time of perturbation onset, and the *shaded* footprints indicate the landing position of each step. The *stick figure* illustrates how the initial COM motion induced by this perturbation creates increased loading of the left leg. As a consequence of this loading, the stepping responses are most commonly initiated with the unloaded (right) leg, and involve either a crossover movement or a side step sequence (a small medial step followed by a large lateral step). Reactions where the initial step is taken with the loaded foot have been observed to occur very rarely in some studies, but more commonly in others. The "loaded leg" steps seem more likely to occur when the individual can preplan to step with a specific leg (e.g., if the direction of the perturbation is known in advance).

the CNS would need to maintain and automatically update an egocentric spatial map of the immediate surroundings as the person moves about in daily life. This would then allow the hand to be directed very rapidly toward the nearest available handhold, if and when sudden unexpected loss of balance occurs. A similar control mechanism would allow rapid perturbation-evoked stepping reactions to be directed appropriately, so as to avoid obstacles and accommodate other constraints on foot movement.

Although the neural pathways involved in the control of change-in-support reactions are not well established, it seems likely that the planning of the limb trajectory makes use of the same neural pathways as those thought to be involved in planning volitional limb movements, i.e., spinal pattern generators in the case of stepping reactions and cortical pathways in the case of reaching reactions. The very rapid initiation and scaling of the trajectory could then be triggered by subcortical pathways similar to those thought to be involved in triggering the early fixed-support postural reactions.

## Strategy Selection

A traditional view has been that change-in-support reactions are only used as a last resort when earlier fixed-support reactions fail to keep the COM within the stability limits of the BOS. The basic idea is that the ankle strategy is used to respond to antero-posterior perturbation when the induced COM motion is small in relation to the BOS stability limits, the hip strategy comes into play when the COM motion is larger, and stepping and reaching emerge only when the COM motion exceeds the stability limits of the BOS. This may be true when individuals are instructed to try not to step or move the arms; however, this is clearly not the case when the person is allowed to respond naturally. It is now clear that compensatory stepping and reaching are commonly initiated very early, with the COM well within the stability limits and in fact often seem to be the preferred response. For example, individuals will almost always step and begin to move the arms when the perturbation is unexpected or novel (e.g., the very first trial in an experiment), even if the perturbation is relatively small.

It appears that initiation of reach-to-grasp reactions occurs in parallel with the earliest fixed-support reaction, as evidenced by the similarity in timing of the arm and ankle activation (latency of ~100 ms). Typically, the initiation of compensatory stepping is not quite as rapid; however, the onset of the stepping

reaction (i.e., active changes in leg loading) can occur as early as 130 ms after perturbation onset. Interestingly, the early fixed-support reaction is not eliminated, even when a rapid reach-to-grasp or stepping reaction is initiated. Presumably, the fixed-support reaction persists as an important safeguard against instability. Early initiation of the change-in-support response, regardless of perturbation magnitude, may also reflect the high priority given by the CNS to the task of safeguarding stability.

Ultimately, strategy selection can be influenced by a number of factors, including (i) the features of the perturbation (timing, direction, magnitude, predictability), (ii) the "►central set" of the individual (affect, arousal, attention, expectations, prior experience), (iii) ongoing activity (cognitive or motor) and (iv) environmental constraints (e.g., slippery surfaces that limit reaction-force generation, obstacles that constrain limb movement) [1,7,10].

### Modulation of Strategies

Both fixed-support and change-in-support reactions are highly modifiable and adaptations to meet task demands can be learned rapidly (e.g., over the course of one to five experimental trials). The same factors that affect strategy selection listed above can also modulate many of the features of the reactions *per se*.

One of the features that is not highly modifiable is the timing of the early activation of the ankle muscles in the ankle strategy. This early activation typically persists, at a similar latency, even when the individual preplans to use a stepping reaction to recover balance, despite the fact that the ankle activation may interfere with the execution of the step. In keeping with the persistent and apparently automatic nature of this response, the early ankle activation is commonly referred to as the early "automatic postural response" (APR). Nonetheless, the APR is not a stereotyped response. The magnitude of the activation is scaled according to the direction and magnitude of the perturbation and is influenced by the predictability of the perturbation, the "central set" of the individual and the instructions given (e.g., whether or not to step). The functional task demands can also have a profound effect. For example, backward horizontal support surface movements evoke activation in the ankle plantarflexors, which serves to stabilize the body. When similar ankle rotation is evoked by toes-up tilt of the support-surface, the evoked plantarflexor activation acts to amplify the destabilization, but this non-functional response quickly habituates over the course of repeated trials in healthy individuals [10].

Change-in-support reactions exhibit an even greater degree of modifiability, in both magnitude and timing [1,3]. For example, initiation of stepping reactions can be delayed substantially by instructions to try not to step. Conversely, stepping and reaching reactions can be initiated more quickly when the person is given prior instruction to step or reach in response to the perturbation. Furthermore, the limb movements are heavily dependent on environmental constraints (i.e., location of obstacles and potential handholds). There also appears to be capacity for online modulation. For example, the limb trajectory can be altered (to at least some degree) to deal with additional perturbations or changes in environmental constraints arising after initiation of the reaction and reactions that are initiated can be aborted prior to completion.

## Postural Sway

### Definition

In stance, a process of continuous, small corrections of the upright body position takes place to oppose the destabilizing effect of gravity. This creates a pattern known as spontaneous sway, or postural sway.

## Definition

A ►postural synergy is a preferred pattern of muscle co-activation that is used by the nervous system to maintain standing balance. Each postural synergy specifies a pattern of muscle activation across many muscles. Through flexible combinations of postural synergies, a repertoire of postural behaviors is produced. By eliminating the need to control each muscle independently, postural synergies are thought to simplify the neural control task of selecting and coordinating multiple muscles across the body. A postural strategy defines the overall goals involved in the maintenance of balance; these can vary depending on the particular postural task, the context in which the task is performed and the postural configuration. Postural synergies define the muscle activation patterns that are used by the nervous system to implement various postural strategies.

## Description of the Theory

### Introduction

The theory of postural synergies address the basic question of whether the nervous system activates each muscle independently when it performs a task or whether the multiple muscles are activated together, thus reducing the total number of neural command signals necessary. Currently, postural synergies are thought to represent neural "building blocks" for generating a wide range of postural behaviors. Each postural synergy specifies a pattern of muscle activation across many muscles and is purportedly controlled by one neural command signal. By combining muscle synergies in various proportions, a continuum of muscle activation patterns for postural control can be generated using just a few neural command signals.

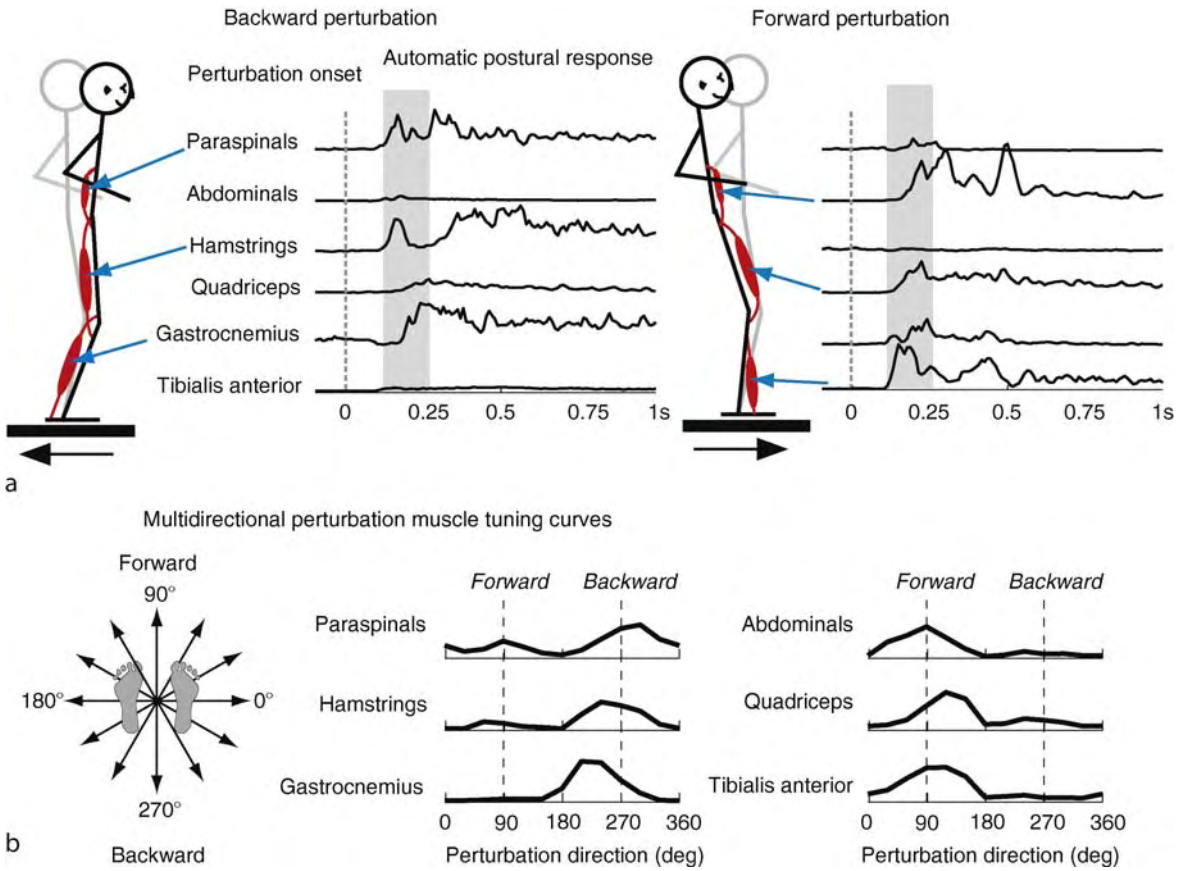
The long-standing debate within the general motor control field over the concept of muscle synergies is exemplified by the specific debate over the existence of postural synergies. Nashner first described "fixed" postural synergies in subjects standing on a moving perturbation platform [1]. Distinct patterns of muscle activation across the ankle, knee, hip and trunk were reliably observed when the platform was moved either forwards or backwards (Fig. 1a) and were thought to represent two different postural synergies [2]. Originally, it was thought that postural synergies were activated in a mutually exclusive fashion and that each muscle was activated by only one postural synergy (Fig. 2a).

These conclusions were challenged by later studies that showed flexibility in patterns of muscle activation in response to a backward perturbation. Depending on the perturbation amplitude and prior experience of the subject, two types of responses were observed, the "ankle strategy" and the "hip strategy," so named for the major joint motions involved. Each strategy elicits a very different pattern of muscle activation, demonstrating that postural synergies to a particular direction of perturbation are not fixed. Moreover, when perturbations were given in many directions in the horizontal plane, even more complex patterns of muscle activation emerged in both humans and cats [2]. Each different perturbation direction elicited a unique pattern of muscle activation (Fig. 1b), suggesting that muscles must be controlled independently to perform multidirectional balance control. It was for this reason that the notion of muscle synergies was then rejected as being too constraining and inflexible for the production of natural movements [3].

Recently, new computational techniques have helped to demonstrate that a motor control architecture based on muscle synergies can both simplify neural control as well as provide flexibility in motor output. In the new framework, more than one muscle synergy can be activated during a postural response and each muscle can also be activated by more than one synergy. By varying the magnitude of the neural command signals to just a few muscle synergies, many different muscle activation patterns can be generated (Fig. 2b), including the responses to multidirectional postural responses describe above [4]. The neural substrates of muscle synergies for postural control remain unknown. Where muscle synergies are encoded within the neural control hierarchy is a complex topic and may also be task dependent. It is hypothesized that postural synergies are formed in the brainstem, based on observations of postural control following neural impairment.

### Degrees of Freedom Problem

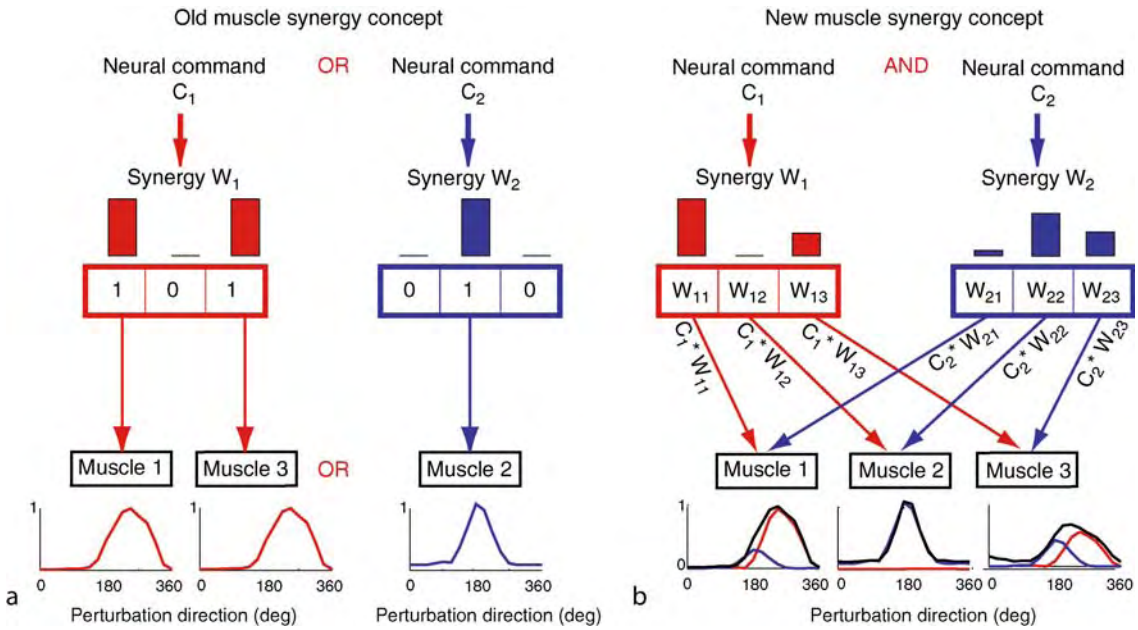
To maintain standing balance, the nervous system must confront the classic "degrees of freedom" problem posed by Nikolai Bernstein [5], where many different solutions are available due to the large number of elements or degrees of freedom involved. In postural control, a large number of muscles and joints across the limbs, trunk and neck must be coordinated to maintain the body's ►center of mass (CoM) over the base of support, typically formed by the feet. The large



**Postural Synergies. Figure 1** Muscle activity evoked following perturbations to the support-surface. (a) Backward perturbations elicit activity in muscles on the posterior side of the body. (b) Forward perturbations elicit activity in muscles on the anterior side of the body. The gray area represents the initial muscular response to perturbation, called the automatic postural response (APR). (c) The magnitude of the response during the APR varies as a function of direction and can be plotted as a tuning curve. Each muscle has a unique tuning curve, suggesting that each muscle is activated by a separate neural command signal.

number of degrees of freedom afforded by the multiple joints and muscles in the body thus allow for many solutions that can accomplish the task goals equally well. This multiplicity or redundancy of solutions allows flexibility in performing the postural task; it also poses the problem that the nervous system must choose from a large set of possible solutions. In contrast, if the body were a simple rigid stick balanced on one end, then the angle of the stick in space would completely determine the location of the center of mass with respect to the base of support. Moreover, if only one muscle is available, there is no ambiguity as to how to activate the muscle in order to move the center of mass. Thus, the "degrees of freedom problem" occurs only when overall task requirements are not sufficient to specify multiple output variables controlled by the nervous system.

Bernstein proposed the existence of synergies as a neural strategy for simplifying the control of multiple degrees of freedom by coupling or grouping output variables [5]. This scheme was based on experimental observations that many joint angles appear to be controlled together rather than independently during motor tasks. For example, during locomotor tasks such as running, the hip, knee and ankle joints all flex and extend at the same time, suggesting that they are not controlled independently. However, such observations only identify correlations between the joint motions. A variety of muscle activation patterns can produce similar joint movements. Therefore, joint angle changes do not necessarily have a direct relationship to neural command signals activating muscles. Since muscle activation is directly caused by motoneuron firing, correlations between muscle activation patterns can be more plausibly derived from a single neural command that is distributed across the various motoneuron pools. Thus, muscle synergies may represent a mechanism by which the nervous system can achieve repeatable multijoint coordination.



**Postural Synergies. Figure 2** Illustrations of two different muscle synergy concepts. (a) In the original muscle synergy concept, only one muscle synergy was elicited at a time, and muscles could only be activated by one synergy. Therefore, all muscles activated by the same synergy would have the same directional tuning curve, determined by the neural command c that activated it. (b) In the new concept, more than one synergy can be activated at a time. Further, muscles can participate in multiple synergies, and have different weightings in each synergy. Therefore, each muscle's tuning curve is a weighted average of the two tuning curves of each muscle synergy.

## Computational Methods for Identifying Postural Synergies

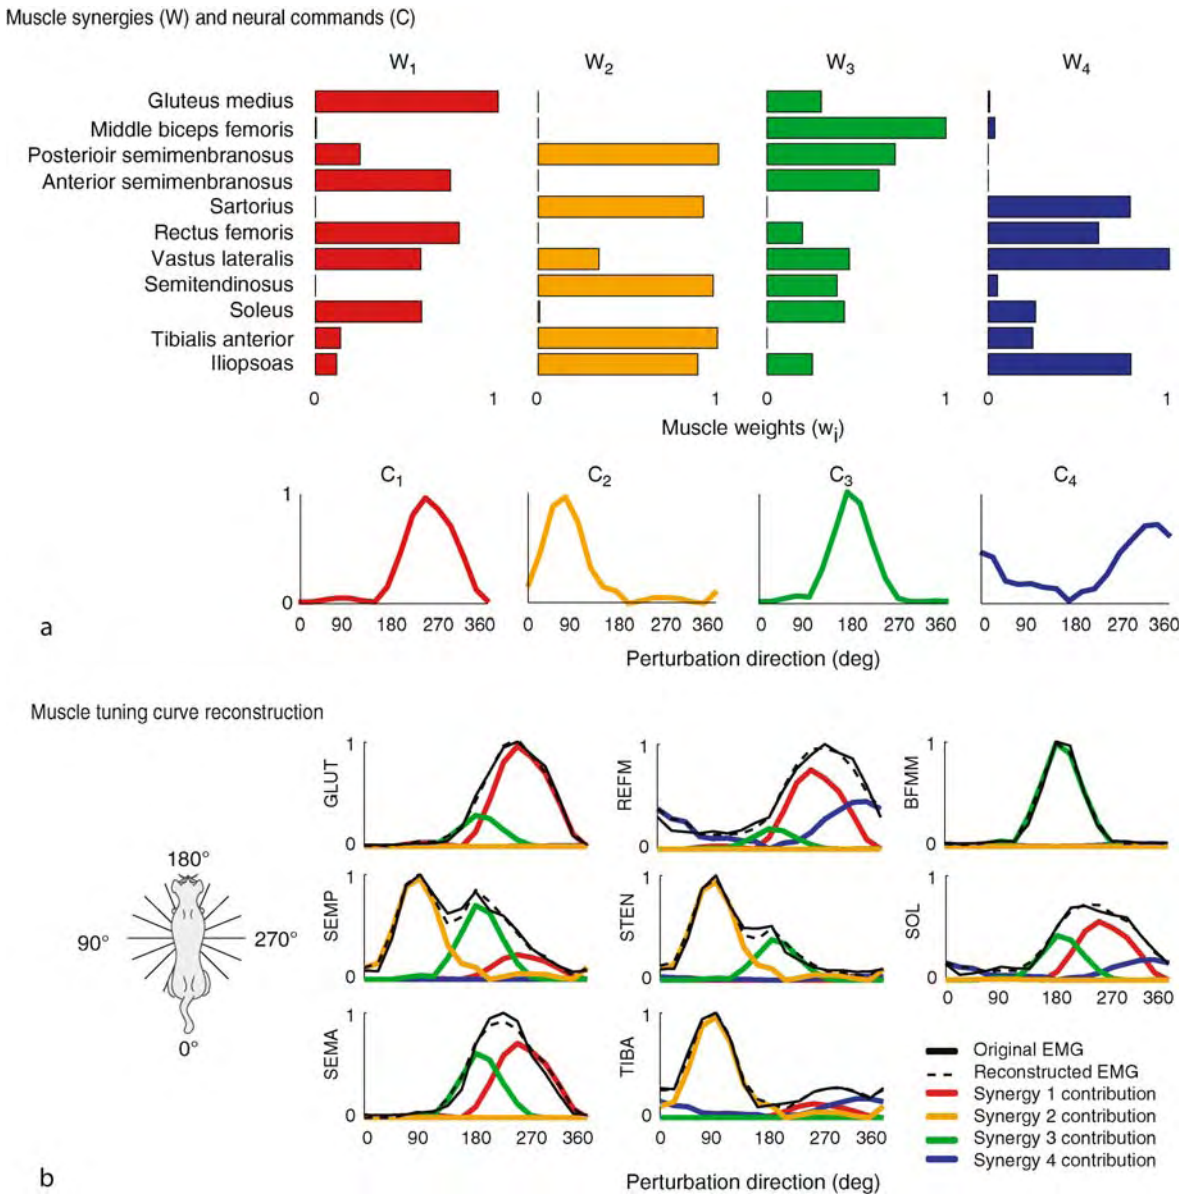
Recent computational techniques have redefined the working hypothesis of how muscle synergies can allow for flexible motor coordination while also simplifying the degrees of freedom problem. In this new formulation, a single synergy specifies a fixed muscle activation pattern that is modulated by a single neural command signal, but multiple muscle synergies can be activated at one time [4,6,7]. Mathematically, each muscle activation pattern is thus composed of a linear combination of a few (n) muscle synergies $\mathbf{W}_i$, each activated by one neural command $c_i$. The net muscle activation pattern vector $\mathbf{M}$ is therefore hypothesized to take the form:

$$\mathbf{M} = c_1\mathbf{W_1} + c_2\mathbf{W_2} + \ldots + c_n\mathbf{W}_n$$

$\mathbf{M}$ is a vector where each element is the resulting level of activation in each muscle (Fig. 3a). $\mathbf{W}_i$ is a vector that specifies the pattern of muscle activity defined by that muscle synergy. Each element of $\mathbf{W}_i$ takes a value between 0 and 1, representing the relative contribution of each muscle to that muscle synergy. Each muscle synergy is then activated by a single, scalar neural command signal $c_i$, which determines the relative contribution of the muscle synergy $\mathbf{W_i}$ to the overall muscle activation pattern, $\mathbf{M}$.

The above formulation allows for flexible "mixing" of a set of muscle synergies to produce the final output muscle activation pattern. Therefore, if two muscle synergies are present, rather than defining just two output muscle activation patterns, as in previous definitions (Fig. 2a), an entire continuum of output muscle activation patterns can be generated by varying the commands $c_1$ and $c_2$. Within this continuum, individual muscle activations are not strictly correlated to each other because most muscles belong to more than one muscle synergy and are thus activated independently by two different neural commands (Fig. 2b).

Linear decomposition techniques can be used to identify muscle synergies from experimentally measured muscle activation patterns. Because the number of muscle synergies is smaller than the number of muscles for any given task, the spectrum of muscle activation patterns that can be generated using muscle synergies is more limited than the case where muscles are controlled independently. However over the entire behavioral repertoire the number of muscle synergies could exceed the number of muscles. This dimensional reduction, which simplifies the degrees of freedom problem, can be identified using several mathematical analysis techniques such as principal components analysis (PCA), independent components analysis (ICA) and factor analysis (FA) [6]. Another such technique, non-negative matrix factorization (NMF),



**Postural Synergies. Figure 3** Muscle synergies and neural commands used to generate muscle tuning curves during postural responses in cats. (a) Each muscle can participate in each muscle synergy with a different weight, indicated by the bars. (b) Neural commands to each muscle synergy can also be illustrated as tuning curves. Each muscle synergy therefore has preferred direction of activation. (c) EMG tuning curves can be reconstructed using muscle synergies. Each muscle's tuning curve is found by summing the product of each tuning curve, $c_i$ and the weighting of each muscle within the synergy $W_i$. All muscle tuning curves are thus constrained to be weighted averages of the synergy tuning curves. Therefore, the muscle tuning curves have more varied and complex shapes than the synergy tuning curves.

allows complex data sets to be more successfully partitioned into meaningful parts [4,6,8]. NMF is particularly useful for data that are inherently positive valued, such as neural spike trains or muscle activations. The extracted elements are based on the components forming the data set rather than on more holistic features. For example, when applied to images of faces, a non-negative extraction routine generates vectors representing noses, ears and eyes, whereas PCA generates components that all tend to look roughly like an entire face [8].

## Muscle Synergies in Postural Control

During postural responses to perturbations in different directions, multiple muscles across the body are activated and for each different direction of the perturbation, a different pattern of muscle activation is

P

elicited (Fig. 1b). In both humans and in cats, a stereotyped, directionally specific pattern of muscle activity called ►automatic postural response (APR) is evoked after perturbations to the support surface. The muscle activation occurs after the platform motion begins, but before the center of mass moves appreciably, with a latency of around 50 ms in the cat and 100 ms in humans. In both cases, this latency is about twice the ►stretch reflex latency for distal muscles and evokes a much larger response than the stretch reflex [2]. Each muscle's activation level can be expressed in terms of a muscle tuning curve, which shows the variation of the muscle activation with perturbation direction (Fig. 1b – human, Fig. 3b – cat). Thus, for some directions, a muscle may have high activation and for others it may not be active at all. These muscle tuning curves define the complex patterns of muscle activation evoked across many perturbation directions [2,4,9].

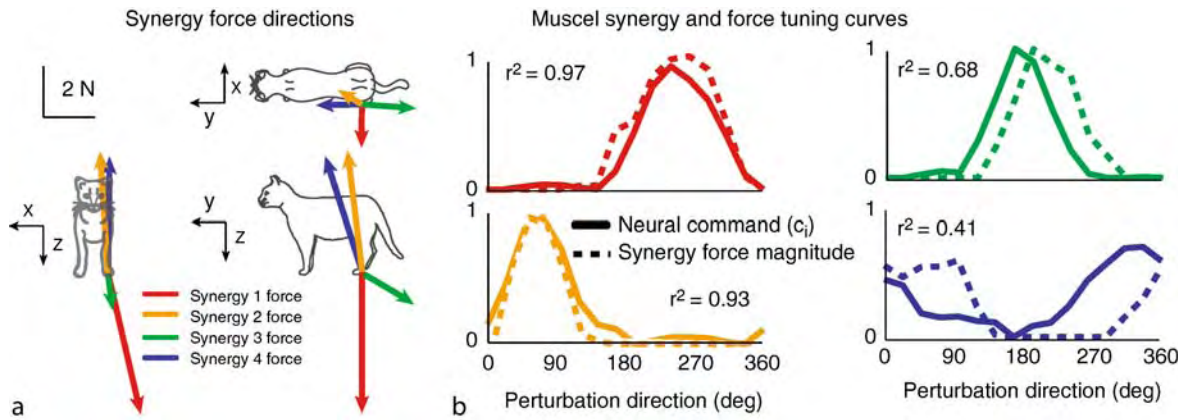
Although each direction of perturbation evokes a slightly different pattern of muscle activation over all muscles, these variations can be explained by a combination of just a few muscle synergies in the cat [4]. Over 95% of the variability in as many as fourteen muscle tuning curves can be explained by combining just four muscle synergies (Fig. 3b). Instead of activating each muscle independently for each perturbation direction, only four neural commands, each activating a synergy $\mathbf{W_i}$, need to be specified with amplitude $\mathbf{c}_i$ for any perturbation direction. The net muscle activation pattern is thus found by adding up the contributions of each muscle synergy to each muscle's activation level.

Muscle synergies may coordinate the limb to produce a specific biomechanical function for stabilizing the body. In the cat, it has been suggested that each muscle synergy allows the leg to produce a force in a particular direction in order to stabilize the leg (Fig. 4a). Variations in the components of active force generated by each leg are correlated to the variations in the neural commands of each muscle synergy (Fig. 4b). Each muscle synergy can generate a specific direction of force; the forces are distributed so that upward, downward, anterior, posterior and lateral force direction can be produced. Thus, muscle synergies may be organized to produce specific task-level biomechanical functions [4].

Even for postural perturbations of the same direction, multiple muscle synergies may exist. In backward perturbations of the support surface in humans, two types of responses can be elicited. One is called the "ankle strategy" where the body remains upright and most of the motion occurs around the ankle joint. The other is called the "hip strategy," where the trunk tilts forwards and the hip angle motion is most predominant. Each strategy can be defined by a specific pattern of joint torques. Because joint torques directly relate to the force generation of the musculature, this suggests that there are muscle synergies underlying these two strategies. While these two strategies were initially thought to be mutually exclusive, they in fact represent two different postural synergies that can be combined to produce a whole continuum of intermediate responses [2,11]. Therefore, rather than having a simple repertoire of just two response patterns, the flexible combination of these postural synergies allows the APR to be tuned and varied with perturbation amplitude, prior experience and anticipation.

## Encoding of Muscle Synergies in the CNS

If muscle synergies reflect neural control mechanisms, then what are the neural substrates that generate muscle synergies? It is now understood that postural synergies



**Postural Synergies. Figure 4** Forces produced during the automatic postural response correlate with muscle synergy activations. (a) Forces produced during postural responses can be decomposed into four force vectors. (b) During postural response, the magnitude of each force vector required to reproduce the total force varies as a function of direction and can be illustrated as a tuning curve. The tuning curves of force magnitude are highly correlated with the tuning curves of the neural commands $c_i$ activated the muscle synergies. Thus, each force vector may represent the functional output of the muscle synergy.

cannot be explained just by reflexes acting in response to muscle stretch. In both humans and cats, it has been shown that perturbations that stretch the muscles differently can activate the same muscle synergies. For example, Nashner originally demonstrated that for a backward translation of the support surface, the calf muscle is stretched as the subject falls forward and that the same muscle is subsequently activated to maintain balance, consistent with a stretch reflex. In contrast, if a toes up rotation of the support surface is given, the calf muscle is stretched but the subject falls backwards, so that the antagonist muscle is activated to restore balance, in direct opposition to the stretch reflex [1]. This same principle has been demonstrated in multidirectional perturbations in both cats and humans [9]. Moreover, the loss of a single sensory modality, such as proprioceptive, vestibular or visual loss, does not appear to significantly affect muscle activation patterns, only their activation levels. Therefore muscle synergies are not a direct response to local sensory input, but appear to be related to more global variables, such as the direction of CoM displacement caused by the perturbation, that require multisensory integration [2,9].

How postural synergies are encoded in the nervous system is not known. For locomotor tasks, the encoding of muscle synergies appear to be located within the neural circuitry of the spinal cord [7], as animals can produce locomotor activity from a spinal cord that is isolated from the brain following spinal cord transection. These same animals can support their own weight while standing, but direction specific responses to postural perturbations are lost. This suggests that postural synergies are generated within the spinal cord [10]. It is known that the brainstem is essential to the maintenance of postural orientation and equilibrium and it is possible that neural mechanisms producing postural synergies reside there. Moreover, postural synergies appear intact in patients with postural impairments due to lesions in higher brain centers. For example, Parkinson's disease is characterized by pathology of the basal ganglia, which project to brainstem areas that are important for postural control. Individuals with Parkinson's disease have the aility to generate postural synergies that are similar to control subjects, but have difficulty changing the muscle synergy that is activated when perturbation conditions change. Similarly, in individuals with cerebellar dysfunction, postural synergies are similar to control subjects, but their activation levels do not decrease with repeated perturbations as in control subjects. Therefore, the muscle synergy structure appears intact, but the ability to correctly activate the neural commands to those muscle synergies is compromised, which impairs the postural stability in these individuals [2]. The theory of postural synergies therefore contributes to our understanding of the role of various nervous system structures in postural control and can guide experimental investigations that may further the validity of the theory.

# Postural Tone

## Definition

Background tension developed by the antigravity muscles. It represents a prerequisite for the maintenance of posture. The postural tone is regulated by intrinsic properties of spinal motoneurons, by the tonic activity of the corresponding muscle spindle afferents and by signals arising from brainstem systems projecting to the spinal cord, including the vestibular nuclei and the reticular formation.

## Synonyms

Sensor fusion

## Definition

Sensory integration, as it pertains to posture, refers to the process by which ►kinematic (orientation and motion) and ►kinetic (force related) information from multiple sensory sources is combined in the nervous system for the purpose of generating motor action to compensate for the destabilizing effect of gravity and to resist external perturbations.

## Description of the Theory

### The Task of Sensory Integration

Sensory information that is relevant to postural control is available from various sensory systems. These include the visual system, vestibular system, various aspects of somatosensation (proprioception signaling muscle stretch and joint angle, tendon force sensors, pressure sensors in the feet and other parts of the body signaling contact with the ground or the environment and tactile sensors in the skin around the joints) and the auditory system. Within each system, different subsystems encode physical variables related to different aspect of motion and orientation and related to forces applied to the body and within the body. Furthermore, within each subsystem, the individual sensory receptors typically have a variety of static and dynamic response characteristics. The monumental task of the sensory integration process is to somehow combine this information and make it available to the motor control system so that the organism generates coordinated motor actions that maintain stability, respond appropriately to external perturbations and permit the expression of voluntary actions.

### Benefits of Sensory Integration

In many situations the orientation cues provided by different sensory systems are redundant. Consider the simplest possible case where the legs, trunk and head of a human subject move together as a single mechanical unit with body sway consisting of a rotation about the ankle joints. In this case, during stance on a level surface while viewing an earth fixed visual scene, body sway relative to earth vertical is accurately sensed by the visual system, which signals body motion relative to the visual scene, by the vestibular system, which signals body motion in space and by proprioceptors, which signal ankle joint angle. However, there is variability and therefore uncertainty associated with orientation estimates derived from each of these sensory systems. In this common situation with redundant sensory information, an orientation estimate with reduced overall variability can be obtained by appropriately combining the redundant sensory information.

What is the appropriate way to combine redundant sensory information? Previous theoretical and experimental work suggests that the nervous system may employ the principle of maximum likelihood estimation to combine sensory inputs [1]. For the case of two sensory sources, $S_a$ and $S_b$, the combined maximum likelihood estimate, $\hat{S}$,is given by a weighted combination of the individual sensory estimates

$$\hat{S} = w_a \cdot S_a + w_b \cdot S_b$$

where the sensory weights $w_a$ and $w_b$ are equal to

$$w_a = \frac{\sigma_b^2}{\sigma_a^2 + \sigma_b^2}, \quad w_b = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_b^2}$$

with $\sigma_a^2$ being the variance of $S_a$, and $\sigma_b^2$the variance of $S_b$. In words, the sensory source with the smaller variance will have the larger weight and will make a larger contribution to the overall sensory estimate $\hat{S}$. Although an intuitive method for combining sensory information might be to ignore information from the more variable source, the maximum likelihood principle shows that the best (lowest variance) estimate is obtained by a weighted combination, even though one source may be considerably less reliable (i.e., large noise or variance) than the other source.

It is not currently known if the maximum likelihood principle strictly applies to sensory integration for postural control. However, it is known that a sensory weighting mechanism can account for experimental results in humans where body sway was provoked by tilts of the support surface or visual surround [2].

## Constraints on Sensory Integration

Because postural control involves motor action as well as sensory integration, there are additional constraints on the sensory integration process as well as opportunities for the sensory integration process to facilitate postural control. Consider a simplified representation (Fig. 1) of a ►postural control system where orientation information is provided by proprioceptors and ►graviceptors.

Graviceptors yield the sensory signal $S_{bs}$ that encodes the physical variable, *BS* (i.e., body in space angular orientation). Proprioceptors yield the sensory signal $S_{bf}$ that encodes the physical variable *BF* (i.e., body orientation relative to the feet). It can be hypothesized that a weighted combination of these sensory sources contributes to an overall estimate of orientation, $\hat{S}$,and this overall estimate is compared to an internal reference orientation, $S_{ref}$, that represents the desired body orientation. Without loss of generality, it can be assumed that $S_{ref} = 0$ to symbolize the desired goal of remaining in an upright orientation. The difference between the orientation estimate and the reference orientation gives a sensory "error" signal, *e*. This process is represented by the equation

$$e = \hat{S} - S_{ref} = w_p \cdot S_{bf} + w_g \cdot S_{bs} \ (\text{for } S_{ref} = 0)$$

where $w_p$ is the proprioceptive weighting factor and $w_g$ the graviceptive weighting factor. Then, through a sensory to motor transformation, a corrective torque, $T_c$, is generated as a function of *e*, $T_c = f(e)$, and $T_c$ is applied to the body to control body orientation in space.

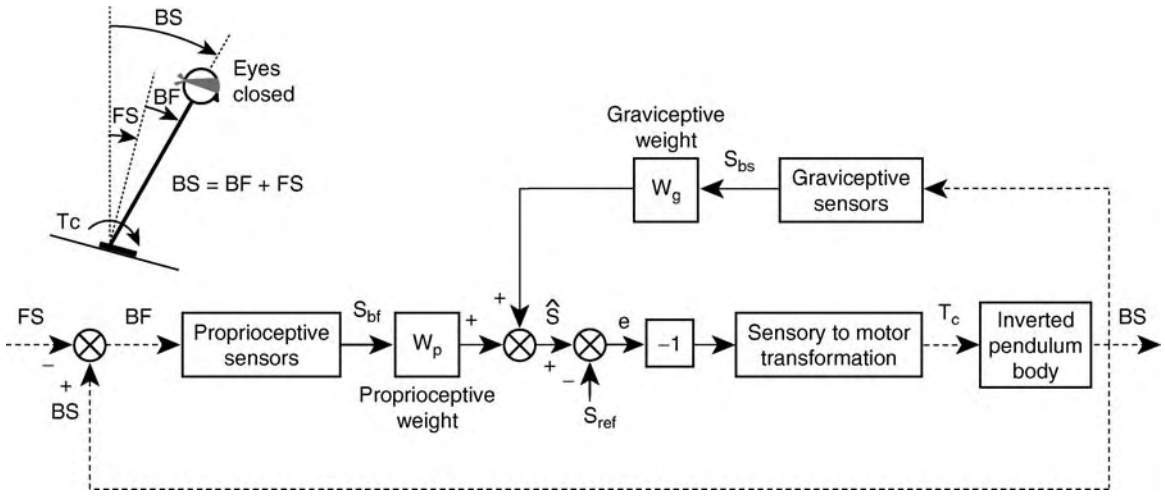
The net result of the process of sensory encoding, sensory integration and sensory to motor transformation is that $T_c$ is generated as a function of a weighted combination of the physical variables *BF* and *BS*

$$T_c = f\left(w_p \cdot BF + w_g \cdot BS\right)$$

During stance on a level surface, the physical variables *BF* and *BS* are equal and the torque generated in relation to both proprioceptive and graviceptive cues facilitates maintenance of a stable vertical body orientation. However, on a tilting surface, *BF* is equal to *BS-FS*, where *FS* is the orientation of the feet in space (and equal to the tilted surface orientation assuming that the feet remain in contact with the surface). Therefore the above equation can be rewritten as

$$T_c = f\left(w_p \cdot (-FS) + \left(w_p + w_g\right) \cdot BS\right)$$

This equation shows that there are two components to $T_c$ and these components have opposite signs. One



**Posture – Sensory Integration. Figure 1** A block diagram representation of a sensory integration scheme for postural control based on a weighted combination of sensory orientation signals. In this example, proprioceptors are assumed to encode body orientation relative to the feet (*BF*) and graviceptors encode body in space orientation (*BS*). A weighted combination of these sensory signals is compared to an internal reference orientation ($S_{ref}$) and the resulting error, *e*, is used to generate a corrective torque, $T_c$, via a sensory to motor transformation process. The corrective torque acts on the body to change body orientation in space and relative to the feet. The block with –1 indicates a sign inversion such that a positive value of *e* produces a negative $T_c$ that tends to drive the body back toward an upright orientation. The *dashed lines* connecting boxes indicate physical variables, and the *solid line* represents neural signals. The *inset stick figure* defines the positive direction of the physical variables.

P

component is related to *FS*. This component can be considered to be an undesirable disturbance torque that causes the body to align with the tilted surface and therefore would be destabilizing. The other component is related to *BS*. This component can be considered to be a desirable, stabilizing torque that causes the body to remain oriented with respect to earth vertical.

Now it is clear that an adjustment in the sensory weights can have an influence that goes beyond the consideration of optimal maximum likelihood estimation. Specifically, a reduction of $w_p$ reduces the disturbance torque produced by surface tilt. A reduction in the disturbance torque would seem to be a desirable effect, except that a reduction in $w_p$ also reduces the magnitude of the stabilizing torque related to *BS*. The magnitude of this stabilizing torque must be maintained above the level needed to counteract torque due to gravity. Furthermore, analysis of the postural control system in Fig. 1 indicates that the overall stabilizing torque level must be closely regulated in order to maintain stable, non-resonant behavior [3]. The dual task of reducing the destabilizing torque associated with surface tilt and maintaining adequate stabilizing torque can be accomplished by increasing $w_g$ in equal proportion to the reduction in $w_p$ [4]. This reciprocal adjustment of sensory weights is termed a ►sensory re-weighting strategy and is also related to the concept of ►sensory substitution. Therefore, a sensory integration mechanism that uses a weighted combination of sensory orientation sources can facilitate postural control by selecting weights to provide a low variance estimate of orientation in conditions where sensory systems provide redundant information and by adjusting weights to limit the effects of external disturbances while simultaneously maintaining stability.

The sensory integration mechanism shown in Fig. 1 is easily extended to include sensory information from vision [2] and other sensory systems by adding additional feedback loops, each with its own sensory weighting factor.

## Combining Kinematic and Kinetic Information

The above discussion focused on combining information from kinematic sensors signaling body motion relative to the surface and relative to earth vertical. Integrating kinetic (force related) sensory information with kinematic information affords a further opportunity to enhance the capabilities of the postural control system. Fig. 2a shows a sensory integration scheme that includes a feedback path whereby a sensory signal encoding corrective torque contributes to the sensory error signal *e*.

Note that for the kinematic sensors, a forward (positive sign) body sway on a level surface produces a negative corrective torque that tends to restore body orientation to the upright position. That is, the kinematic sensors are organized within the postural control system to provide ►negative feedback control. However, a negative corrective torque sensed by the kinetic sensors produces an even larger negative torque. That is, the kinetic sensors are organized to provide ►positive feedback control.

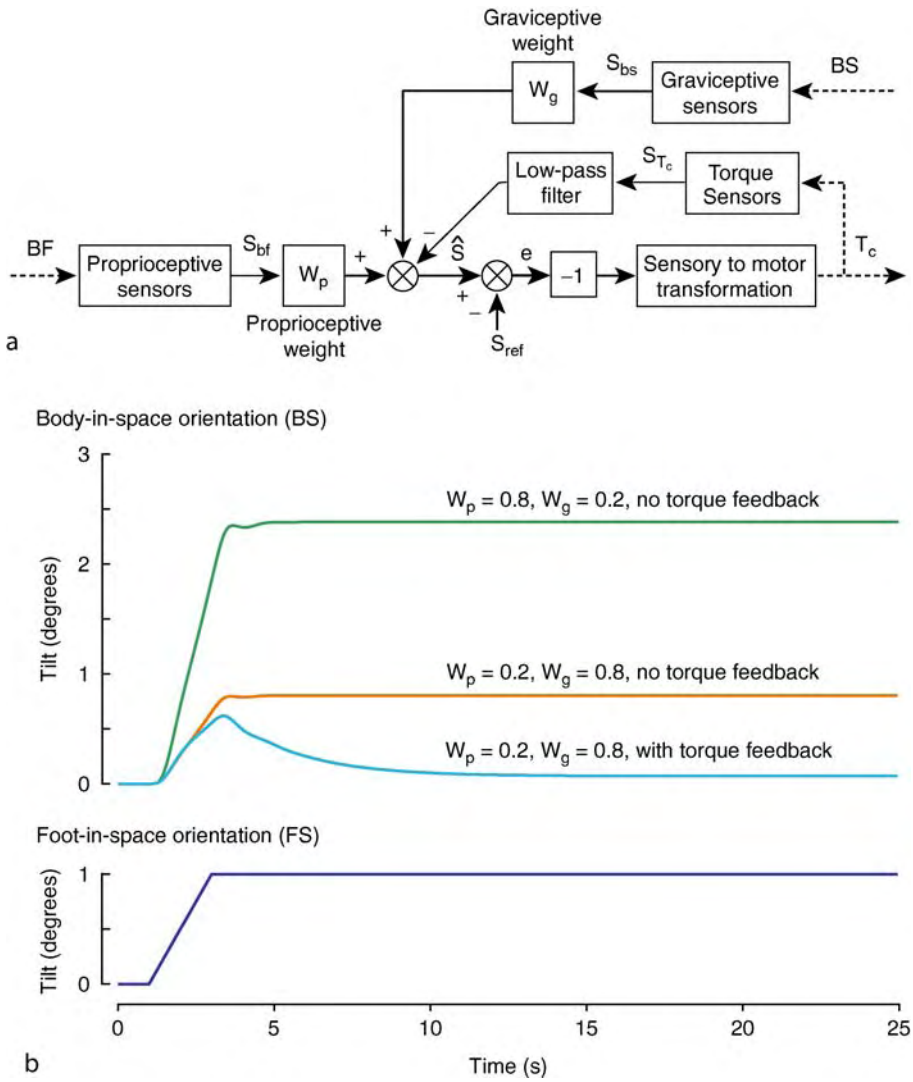
The benefit of integrating a kinetic contribution with kinematic sensory sources is illustrated in Fig. 2b. With only kinematic control, the Fig. 1 model predicts that a surface tilt of 1° produces a large body tilt of about 2.4° if the sensory integration relies primarily on proprioception ($w_p$ = 0.8, $w_g$ = 0.2). Body tilt is reduced to about 0.8° if a sensory re-weighting occurs that shifts toward increased reliance on ►graviception ($w_p$ = 0.2, $w_g$ = 0.8). When kinetic sensory information is integrated with the kinematic information using the positive feedback mechanism shown in Fig. 2a, the surface tilt induces only a transient body tilt. Note that the time course of responses to surface tilt depends on the sensory integration mechanism, the properties of the sensory to motor transformation and body mechanics. For the results shown in Fig. 2b, the sensory to motor transformation generated $T_c$ in proportion to *e* and to the rate of change of *e*, and included a time delay representing the combined delays attributable to sensory transduction, neural transmission, central processing and muscle activation. The torque feedback loop included a low pass filter, which implies that torque feedback mainly influences tonic or low frequency behavior of the postural control system [4].

## Alternative Mechanisms for Sensory Integration

Although sensory integration can be modeled as a sensory weighting process, there are alternative representations that may correspond more closely to actual central nervous system processes. One idea is that the nervous system uses sensory information to reconstruct an internal representation of the external physical reality. As an example, Fig. 3 shows a sensory integration mechanism whereby proprioceptive and graviceptive sensory signals are used to reconstruct an internal representation of foot in space orientation.

Even though there are no direct sensors of foot in space orientation, the nervous system now has access to a derived representation of this important physical variable that encodes the surface orientation (assuming the feet are in contact with the surface). This internal representation of surface orientation provides an internal base upon which the nervous system can apply a hierarchical set of transformations that can be used to encode the orientation of various body segments relative to the surface [6].

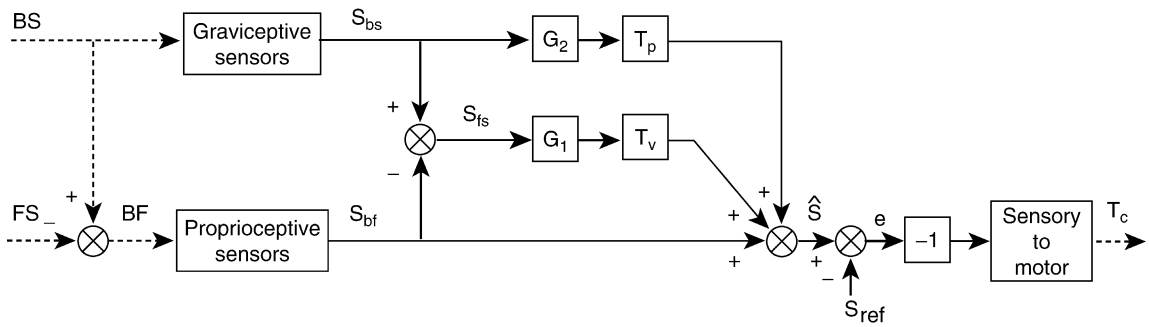
Figure 3 also shows a scheme for combining the various internal representations of body orientation for the purpose of generating an overall error signal, *e*, which is the basis for generating the corrective torque



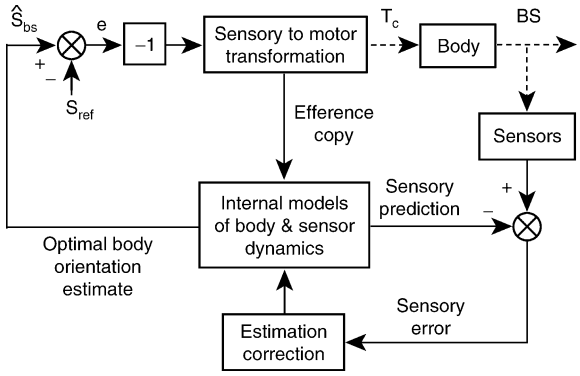
**Posture – Sensory Integration. Figure 2** a Representation of a sensory integration scheme that includes a torque feedback contribution in addition to the weighted combination of proprioceptive and graviceptive cues shown in Fig. 1. The corrective torque, $T_c$, is assumed to be encoded, low pass filtered and then combined with other sensory signals via a summation with a sign opposite to those of the other sensory signals. Thus a positive value of $T_c$ produces an even larger positive value of $T_c$, which facilitates the return of the body toward an upright position. b Examples of body sway responses evoked by a 1° tilt of the surface orientation (*lower blue trace*) for different sensory integration configurations. The predicted body sway is shown for different combinations of weighted sensory feedback both with and without torque feedback. See [4] for details regarding the postural control model and model parameters.

required for balance control as shown in Fig. 1. This sensory integration process includes gain factors and thresholds that effectively perform a sensory re-weighting as a function of the amplitude of the internal sensory related signals [5].

A final sensory integration scheme that has been applied to postural control is based on the engineering concepts of optimal estimation and control [7,8,9] (Fig. 4). This scheme assumes that the nervous system possesses internal models of the body and sensor dynamics. An efference copy of the motor command generated by the postural control system is also applied to the internal model. The internal model is used to estimate body orientation and to predict the expected sensory signals associated with motor commands applied to the body. The predicted sensory signals are compared to the actual sensory signals and any sensory error is used to improve the estimate of body orientation. This improved orientation estimate is used to generate corrective motor responses via feedback control. Furthermore, this optimal estimation and control scheme is able to account for the noise



**Posture – Sensory Integration. Figure 3** A sensory integration scheme based on a internal reconstruction of external physical variables. In this example, a neural representation of foot in space orientation, $S_{fs}$, is formed by combining graviceptive sensory information signaling body in space orientation, $S_{bs}$, and proprioceptive sensory information signaling body orientation relative to the feet, $S_{bf}$. These three sensory signals are combined to form an overall orientation signal, $\hat{S}$, which is used to generate corrective torque, $T_c$. The boxes labeled $G_1$ and $G_2$ are multiplying factors, $T_p$ is a position related threshold, and $T_v$ is a velocity related threshold. These multiplying factors and thresholds produce a change in $\hat{S}$ as a function of the amplitude and frequency of the sensory signals and effectively perform a re-weighting of these signals. See [5] for details.



**Posture – Sensory Integration. Figure 4** A block diagram representation of a sensory integration scheme for postural control based on optimal estimation of sensory orientation information. An optimal estimate of body orientation in space, $\hat{S}_{bs}$, is used to generate a corrective torque, $T_c$, via a sensory to motor transformation process. The block with –1 indicates a sign inversion such that a positive value of $e$ produces a negative $T_c$, which tends to drive the body back toward an upright orientation. The optimal orientation estimate is derived via a process that accounts for the dynamic characteristics of the body and the various sensory systems that contribute information related to body in space orientation, *BS*. The *dashed lines* connecting boxes indicate physical variables and the *solid line* represents neural signals.

properties and dynamic characteristics of sensory and motor systems. Modifications of this scheme can also be used to generate internal estimates of external perturbations [9]. These optimal estimation and control models have been successful in predicting a variety of experimentally observed phenomena including the apparent sensory re-weighting that occurs in response to external perturbations of varying amplitude [9] and changes in the statistical properties of spontaneous sway caused by exposure to environments which limit access to accurate sensory orientation information [8].

## Summary

The maximum likelihood principle provides an excellent foundation for understanding why the nervous system would benefit from using a weighted combination of sensory information when more than one sensory source is available. However, when sensory information is used for motor action, the physics of the body and its interaction with the environment place additional constraints on the sensory integration process. Sensory re-weighting and combined use of kinematic and kinetic sensory information provide a flexible mechanism for minimizing the effects of external disturbances while maintaining stability. Relatively simple models based on sensory reconstruction and re-weighting via threshold operations account for a wide variety of experimental data. Optimal estimation methods, developed for engineering applications and applied to postural control, also account for many experimentally observed features of sensory integration. The actual neural mechanisms for sensory integration remain to be determined.

# Posture-Movement Problem

## Definition

The problem of how the nervous system prevents the posture-stabilizing mechanisms from generating resistive forces when an active movement from an initial to a final posture is produced.

►Equilibrium Point Control

# Posture Role of Cerebellum

Dagmar Timmann

## Definition

The cerebellum is critical for motor coordination and motor learning. The cerebellum is involved both in voluntary movement control, for example upper limb coordination, and postural control.

►Ataxia of stance and gait are characteristic signs of cerebellar disease. Cerebellar disorders result in enhanced postural sway. As a compensatory response, the stance is overly wide based. If the subject attempts to stand on a narrow base, there is increase in postural sway and a tendency to fall (Fig. 1).

Many features of cerebellar gait are related to balance disorders and ways to compensate for them. For example, step length is decreased and step width is increased. Furthermore, the coordination between posture and rhythmic movements of locomotion is impaired. Likewise, postural adjustments are disordered prior to voluntary limb movements.

This chapter focuses on findings of disordered postural control during quiet stance and in response to balance disturbances in subjects with cerebellar lesions. Localizing signs of postural disturbances in cerebellar disease are reviewed first. Next, physiology and pathophysiology of cerebellar postural control is discussed.

## Description of the Theory

The structure of the cerebellar cortex is the same all over the cerebellum. Various parts of the cerebellum differ in function because of differences in fiber connections. The cerebellar cortex receives afferent input from many parts of the peripheral and central nervous system. Proprioceptive and vestibular afferents are of particular importance in cerebellar control of posture. These sensory informations are relayed to differents parts of the cerebellum and probably related to different aspects of postural control.

The relative simplicity and quasicrystalline microstructure of the cerebellar cortex suggests a common computational function of this structure. As yet there is no unifying theory for cerebellar function. A number of theories and models have been proposed, including the coordination of movement across different joints, timing, an internal model for sensorimotor control or the cerebellum as a motor learning machine. These possibilities are not mutually exclusive. In the following, references to current theories of cerebellar function are made where applicable.

### Functional Compartimentalization

Gross subdivision of the cerebellum into the lateral hemispheres and medial vermis gives a first idea of functional localisation within the cerebellum. The vermis is involved in the control of posture and equilibrium as well as eye movements. The hemispheres are involved in motor execution and planning of voluntary movements. Lesions of the vermis result in disturbances of stance, gait, and ocular movements, whereas lesions of the cerebellar hemispheres primarily affect limb movements.

On the basis of the efferent projections from the cerebellar cortex to the cerebellar nuclei the cerebellum has been subdivided into a medial zone (that is the vermis) projecting to the fastigial nuclei, an intermediate zone projecting to the interposed nuclei and a lateral zone projecting to the dentate nucleus. Animal lesion studies show that lesions of the fastigial nuclei are followed by impaired or prevented sitting,

**Posture Role of Cerebellum. Figure 1** Ataxia of stance in a cerebellar subject suffering from spinocerebellar type 6 (SCA6). a Stance is wide-based. b If the subject attempts to stand on a narrow base, balance is lost (c) and subject has to make use of the wall to prevent a fall (d).

standing and walking, because of falls to the side of the lesion. This was interpreted as a deficit in equilibrium [1]. Efferents from the fastigial nuclei project to the brain stem and modify vestibular and reticular influences on posture.

The flocculonodular lobe and adjoining parts of the caudal vermis have been named the ►vestibulocerebellum because of heavily projecting vestibular afferents. Lesions of the vestibulocerebellum cause postural ataxia of head and trunk during sitting, standing and walking. Patients frequently fall while sitting. The classic example is medulloblastoma, which occurs most often in the cerebellum in children between 5 and 10 years of age. In subjects with such lesions, visual stabilization of posture, as evaluated by comparing sway with eyes closed and sway with eyes open, is impaired (absence of ►Romberg's sign). Severe postural sway is present with eyes open and is essentially unchanged with eyes closed. Intersegmental movements are diminished.

The anterior and posterior parts of the vermis and paravermal parts of the cerebellar hemispheres are called the ►spinocerebellum because of their spinal afferents. Damage to the spinocerebellar parts of the ►anterior lobe is characterized by ataxia of stance and gait. The classic example is alcoholic cerebellar degeneration. Visual stabilization of posture is relatively preserved and the tremor is provoked by eye closure (presence of Romberg's sign). Patients rarely fall because the body tremor is opposite in phase in head, trunk, and legs, resulting in a minimal shift of the center of gravity.

Chronic damage to the lateral cerebellar hemispheres that is the cerebro- or pontocerebellum, does not result in significant postural disorders. The lateral hemispheres receive the main input from the cerebral cortex, synaptically interrupted in the pontine nuclei.

Diener and coworkers [2] measured body sway by means of a force-measuring platform in human subjects with lesions of the ponto-, vestibulo- or spinocerebellum (Fig. 2).

Postural sway was basically unaffected in subjects with lesions of the lateral cerebellar hemispheres. Lesions of the lower vermis caused omnidirectional postural sway with frequency components below 1 Hz. Lesions of the anterior lobe led to anterior-posterior body sway with a frequency of about 3 Hz. A more recent human lesion study questioned if 3 Hz body oscillations occur exclusively in lesions of the anterior lobe. Likewise, assessement of trunk sway in patients with spinocerebellar ataxias showed that postural instability was generally more pronounced in the pitch than in the roll plane, corresponding with predominant involvement of the spinocerebellum [3].

## Posture Role of the Spinocerebellum

Postural muscle tone is a primary contributor to the maintenance of upright stance. Damage to the anterior lobe in experimental animals primarily produces a change of muscle tone. In decerebrate animals, the decerebrate rigidity increases, as do the postural reflexes. In humans it is doubtful whether lesions of the anterior lobe produce increased muscle tone. Postural sway following lesions of the anterior lobe has been explained by an increased gain of posturally stabilizing (long loop) reflexes [4].

Sway can be provoked by platform perturbations or electrical stimulation of the tibial nerve. Subjects with anterior lobe atrophy show hypermetric postural responses and overshooting of the initial posture, with larger than normal surface reactive torque responses and exaggerated and prolonged muscle activity (Fig. 3; [5]).

Latencies of postural responses provoked by platform perturbations are normal in patients with cerebellar disorders. Increased gain and prolonged duration of ►long loop reflexes result in an overcompensation of the postural tasks and are believed to evoke (exaggerated) postural responses of the corresponding antagonists. The postural tremor supposedly continues by the same mechanism.

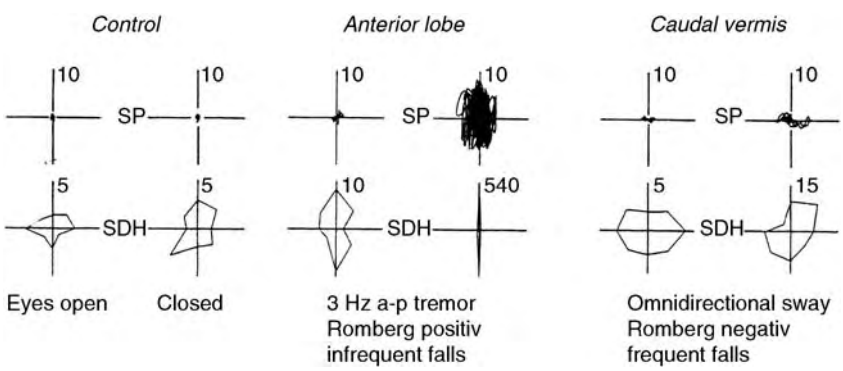
A more recent model of the (spino-) cerebellum supports the notion that the cerebellum may contribute to balance by long loop feedback with scheduling of linear gains at the same joint and interjoint responses between ankle, knee, and hip [6]. Explicit internal dynamics models within the cerebellum, which have been hypothesized to control voluntary limb movements, do not necessarily contribute to spinocerebellar balance control.

## Posture Role of the Vestibulocerebellum

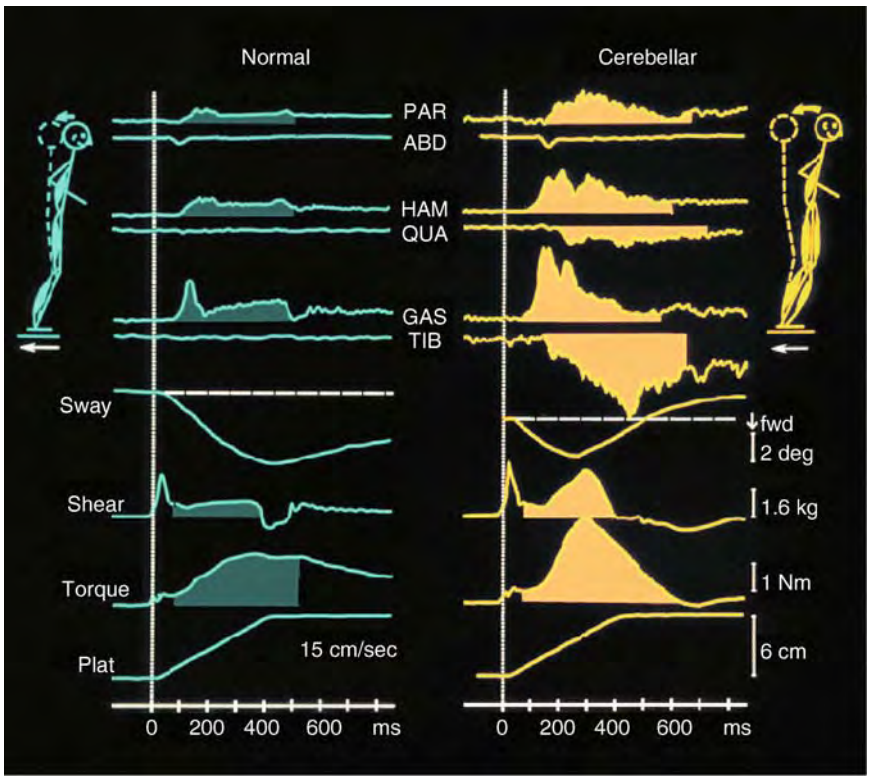
Studies in primates have helped to understand the specific contributions of the vestibulocerebellum to postural control. Knowledge based on human studies is more limited.

The dominant afferent inputs to the vestibulocerebellum come from the semicircular canals, which signal changes in head position, and the otolith organs, which signal the orientation of the head with respect to gravity. Semicircular canal information is relayed to the flocculus and otolith information to the caudal cerebellar vermis (►nodulus and ►uvula).

Sensory input from the otoliths evoke vestibulocollic and vestibulospinal reflexes that maintain the head vertical with respect to gravity. Vestibulocollic and vestibulospinal reflexes are primarily static. The semicircular canals, however, have weaker influences on spinal



**Posture Role of Cerebellum. Figure 2** Sway path (*SP*) and sway direction histograms (*SDH*) in a control, a patient with anterior lobe atrophy and a patient with a vestibulocerebellar lesion. Note the strong preference of anterior-posterior sway in the patient with anterior lobe atrophy. (Adapted from [2]; with permission).



**Posture Role of Cerebellum. Figure 3** Mean postural responses evoked by a backward translation of the supportive platform in a control group and a cerebellar group with anterior lobe atrophy. Cerebellar subjects show hypermetric postural responses, exaggerated and prolonged muscle activity and larger than normal surface reactive torque responses. Latencies of postural responses are normal. Traces show (*top to bottom*): electromyographic (*EMG*) recordings from paraspinal (*PAR*), rectus abdominis (*ABD*), biceps femoris (*HAM*), rectus femoris (*QUA*), gastrocnemius (*GAS*), and anterior tibial (*TIB*) muscles; sway, shear forces, surface torque and platform displacement. (Adapted from [5]; with permission).

circuits and serve predominantly to control extraocular muscles and coordinate head and eye movements.

It has been assumed that a lesion of the vestibulocerebellum leads to disturbed gravitational set values and therefore to a loss of spatial orientation vs. gravity. The set value of determining the upright is lost.

More recent single cell recording studies in the primate provide evidence that the rostral fastigial nucleus represents a main processing center of otolith driven information for inertial motion detection and spatial orientation. Angelaki and coworkers [7] showed that cerebellar and brainstem motion sensitive neurons encode dynamically processed otholith signals appropriate to construct an internal model of inertial motion detection.

A study in children and adolescents with chronic surgical cerebellar lesions underscores the importance of the fastigial nuclei in human postural control. High-resolution magnetic resonance imaging allowed detailed analysis of the lesion side. The ability to control upright stance based on vestibular information alone (that is without visual information and unreliable proprioceptive information) was only impaired in subjects with cerebellar lesions that included the fastigial nuclei (Fig. 4; [8]).

Findings further showed that the lesion site was critical for the motor recovery. Lesions affecting the cerebellar nuclei (but not the cerebellar cortex) were not compensated at any developmental age.

Interestingly, otolith dysfunction has been demonstrated in patients with spinocerebellar ataxia type 6 (SCA6). SCA6 is a hereditary disorder, which affects the vestibulocerebellum early in the disease.

## Role of Cerebellum in Postural Adaptation

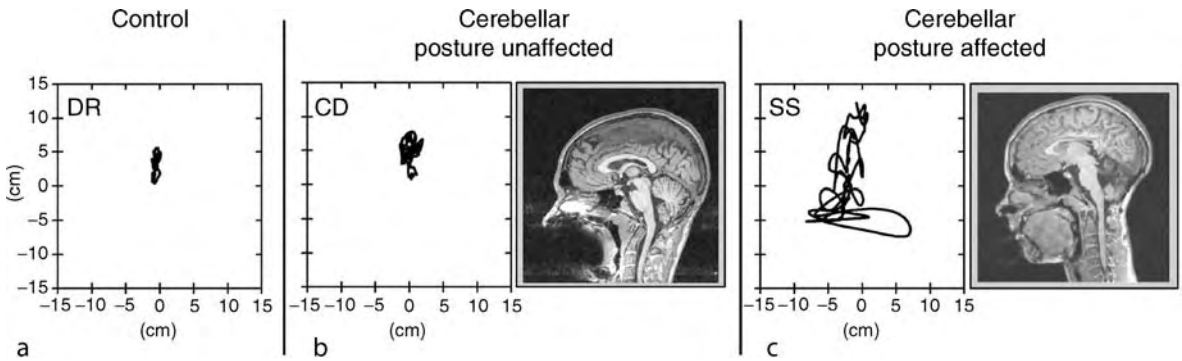
Many studies show that the cerebellum plays an important role in motor learning, in particular in adaptation and automatization of movement. Disordered adaptation probably contributes to ataxia of stance, but has been assessed by few studies only.

Most studies investigated adaptation of early automated postural responses to changes in surface perturbations. Because the contribution of the somatosensory system is much greater than that of the vestibular system when compensating for transient surface

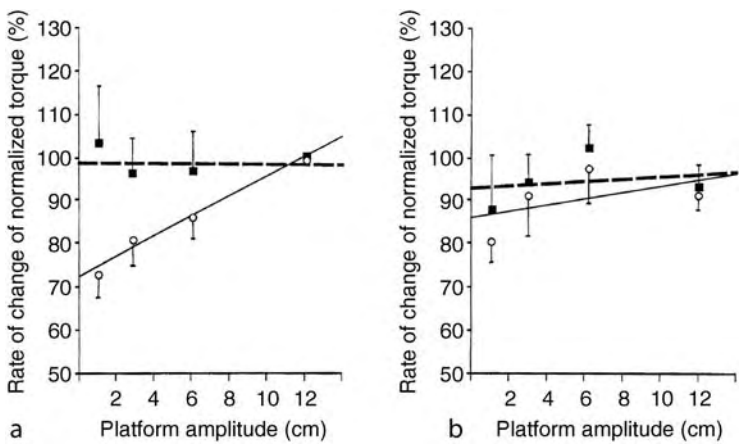
perturbations, contributions of the spinocerebellum are assessed. Initial findings of Nashner [9] showed that healthy subjects but not cerebellar patients adapt automated postural responses depending on context. Nashner compared postural responses to backward translations and upward rotations. Both lead to the same ankle rotation. Upright stance however, is maintained by contraction of the anterior tibial muscle in upward rotations, but of the gastrocnemius muscle in backward translations. In controls, but not cerebellar subjects, responses that stabilize posture were facilitated progressively with repeated trials, whereas responses that destabilize posture were diminished. These findings were, however, challenged in later studies. When the type of perturbation changed from translation to rotation and vice versa both controls and cerebellar subjects showed an immediate change in the response amplitudes of the gastrocnemius and anterior tibial muscles.

Horak and Diener [5] studied whether cerebellar subjects could learn to adjust for predictable postural perturbations during standing (Fig. 5).

When different displacement amplitudes were presented in a serial (predictable) format, healthy subjects were able to appropriately scale their initial postural responses. In contrast, cerebellar subjects were unable to learn to use predictive feedforward control (in other words central set from prior experience) to scale their early automated postural responses



**Posture Role of Cerebellum. Figure 4** Effects of fastigii lesions on postural sway. Postural sway is increased in patient *SS*, but not in patient *CD* compared to the control subject *DR*. In both patients an astrocytoma had been surgically removed. The sagittal MRI images reveal that area above the 4th ventricle, that is the location of the fastigial nuclei, was affected in SS but not in CD. Shown are the center of gravity sway paths over 20 s in a condition that is dependent on vestibular function (that is eyes closed and surface sway referenced). (Adapted from [8]; with permission).



**Posture Role of Cerebellum. Figure 5** Scaling of torque responses to platform displacement amplitude in controls (*continuous line*) and cerebellar subjects (*broken line*). The mean ±SE of normalized torque responses are indicated for serial (predictable) (a) and random (b) amplitude presentation. Control subjects scale to predictable but not random presentation of displacement amplitudes, whereas the cerebellar group scaled neither to predictable or random presentation. (Adapted from [10]; with permission).

to expected perturbation amplitudes. A subsequent study showed that cerebellar patients could predict perturbation amplitudes based on prior experience, but they could not use this prediction to modify precisely the gain of early automated postural responses [10]. The spinocerebellum may be important for accurate tuning of response gain based on prediction.

Cerebellar contribution to adaptation of vestibular reflexes is likely. Cerebellar contributions have been investigated in great detail for adaptation of the vestibulo-ocular reflex (VOR). The function of the VOR is to stabilize retinal images by generating smooth eye movements that are equal and opposite to each head movement. Learning occurs whenever image motion occurs persistently during head turns; as a result image stability is gradually restored. The cerebellar role in retention is disputed, but there is a consensus on the need of an intact cerebellum (that is flocculus) for acquisition.

The role of the caudal cerebellar vermis (nodulus and uvula) for adaptation of the "static" vestibulocollic and vestibulospinal reflexes has not been assessed in detail.

### Summary

The medial cerebellum (that is vermis) is of particular importance in postural control. The contribution of the cerebellum is two-fold. Vermal parts of the anterior lobe (that is spinocerebellum) are involved in control of automated postural reflexes evoked by proprioceptive feedback. Hypermetric postural responses and disordered adaptation can be explained by inaccurate tuning of reflex gain. Disordered coordination between head, trunk and legs (asynergia) probably contributes but is less well understood. Caudal parts of the vermis (that is the vestibulocerebellum) play an important role in spatial orientation of the body against gravity and detection of inertial body motion evoked by otolith feedback. The vestibulocerebellum appears to be important in building an internal model of inertial body motion.

## Posturography

### Definition

Analysis of body posture, and postural control, typically using computerized image analysis of the position and movement of body segments over time.

## Potential Energy

### Definition

Certain systems of forces (called conservative systems) are such that the forces can be obtained as (minus) the spatial derivatives of a single scalar function of position. This function, if it exists, is called the potential energy of the system. It is of paramount importance in analytical mechanics.

►Mechanics

## Potentiation

### Definition

Potentiation refers to the combination of two stimuli resulting in a larger response than the sum of responses to each stimulus alone.

## Potentiometer

### Definition

A variable resistor used to control an electronic device.

## Pre-Bötzinger Complex

### Definition

A physiologically defined region within the ventrolateral medulla of mammals that is critical for the

generation of inspiratory activity. The pre-Bötzinger complex can be functionally isolated in brainstem slice preparations, and is still capable of generating three specific rhythmic activities that have many characteristics of normal respiratory activity (eupnea), gasping and sighing.

►PreBötzinger Complex Inspiratory Neurons and Rhythm Generation

# Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation

Christopher A. Del Negro, John A. Hayes, Ryland W. Pace
The Department of Applied Science, The College of William and Mary, Williamsburg, VA, USA

## Definition

The ensemble of neurons in the ventral medulla that plays an important role in generating breathing behavior in mammals by synchronously producing large-magnitude bursts that drive the inspiratory phase of the respiratory cycle.

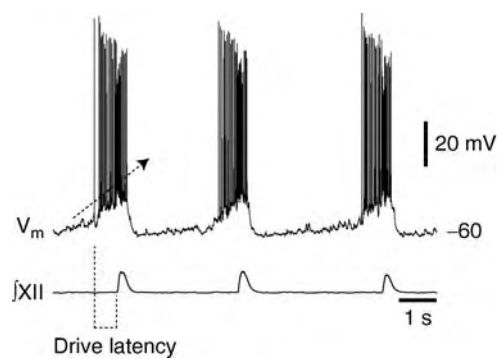
## Characteristics

The ►preBötzinger Complex (preBötC) of the ventral medulla plays an important role in generating breathing behavior in mammals. Anatomical studies have demarcated the borders of the preBötC and experiments in vivo have defined its functional purview. However an unsolved problem pertains to which neurons – and which intrinsic and synaptic properties – make up the rhythmogenic kernel? In vitro models of respiration, particularly slice preparations from neonatal rodents, make experimental tests possible. Transverse slices isolate the preBötC and provide unprecedented access to preBötC neurons for electrophysiology and imaging while maintaining spontaneous inspiratory motor activity, which can be monitored via the ►hypoglossal (XII) cranial nerve root. A diverse array of intrinsic and synaptic properties have been found, which subsequently motivated numerous attempts to subdivide preBötC neurons into various 'types' to assign roles in respiratory rhythm generation. Here we review and critique these classification schemes and proffer objective criteria to distinguish rhythmogenic neural properties.

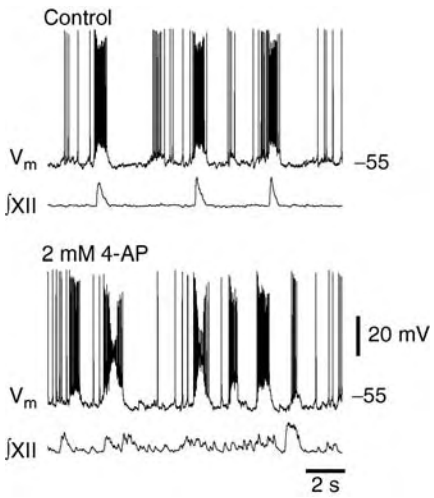
## Inspiratory Drive Latency and Peptide Receptors

Rekling and colleagues [1] proposed a classification scheme that considered sensitivity to ►neuropeptides and ►inspiratory drive latency, defined as the time interval consisting of a crescendo of EPSPs and spiking activity preceding XII motor output (Fig 1). They argued that inspiratory neurons with the earliest drive latency and highest levels of excitability, which also responded to inspiratory drive latency that modulate respiratory rhythm, were most likely to be rhythmogenic. Earliest to activate were type 1 neurons with ~400 ms drive latency and highly excitable membrane properties. Type 2 neurons also exhibited high excitability with ~170 ms drive latency. The least excitable were type 3 neurons with drive latency of ~100 ms. Type 1 neurons were proposed to be rhythmogenic and to activate type 2 neurons downstream, followed by type 3, which were postulated to have a motor or premotor function.

Transient $K^+$ current, i.e., A-current ($I_A$), was expressed exclusively in type 1 neurons whereas the hyperpolarization-activated mixed cation current ($I_h$) was associated only with type 2 neurons. These data suggested a genuine disparity that could distinguish a hierarchy of rhythmogenic subtypes. We measured $I_A$ in ~60% of preBötC inspiratory neurons and found that its selective blocker, 4-aminopyridine (2 mM), caused profound disruptions in the respiratory rhythm (Fig. 2), consistent with the proposal that $I_A$ expression is a hallmark of rhythmogenic neurons (i.e., type 1-like). $I_h$ is present in ~15% of preBötC inspiratory neurons and blocking it with $Cs^+$ or organic agents speeds up the rhythm, which is consistent with $I_h$ expression



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 1** A typical voltage trajectory for a preBötC neuron putatively involved in rhythm generation shown with respiratory-related XII motor output. Inspiratory drive latency is illustrated with *dotted lines* to mark the onset of inspiratory drive and the XII motor discharge. A *dotted-line arrow* emphasizes the incremental depolarization and spike discharge pattern that distinguish relatively small neurons with early drive latency.



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 2** Pharmacological blockade of $I_A$ disrupts respiratory rhythm *in vitro*. The preBötC neuron in control showed early inspiratory drive latency and spike discharge as well as robust inspiratory bursts. After 2 mM 4-AP application the respiratory rhythm was erratic and noisy, and the inspiratory neuron generated bursts that were not necessarily associated with a collective inspiratory burst at the XII motor output level. Blockade of $I_A$ furthermore increased inspiratory burst amplitude to such an extent that spiking activity inactivated transiently.

in neurons that may also be rhythmogenic, but not preeminent (i.e., type 2-like).

Whether $I_A$ and $I_h$ expression maps one-to-one with differences in drive latency, thus validating the type 1 versus 2 classification scheme, has not yet been resolved. Our measurements revealed a continuous drive latency distribution with a mean of ~300 ms (Fig. 3a), rather than bimodal with peaks at ~200 and ~400 ms, as originally suggested. Therefore, types 1 and 2 could reflect the same underlying population of rhythmogenic neurons, but neurons with $I_A$ may be more important for rhythmogenesis simply because $I_A$ plays a more important role than $I_h$ in rhythmogenesis (Fig. 2).

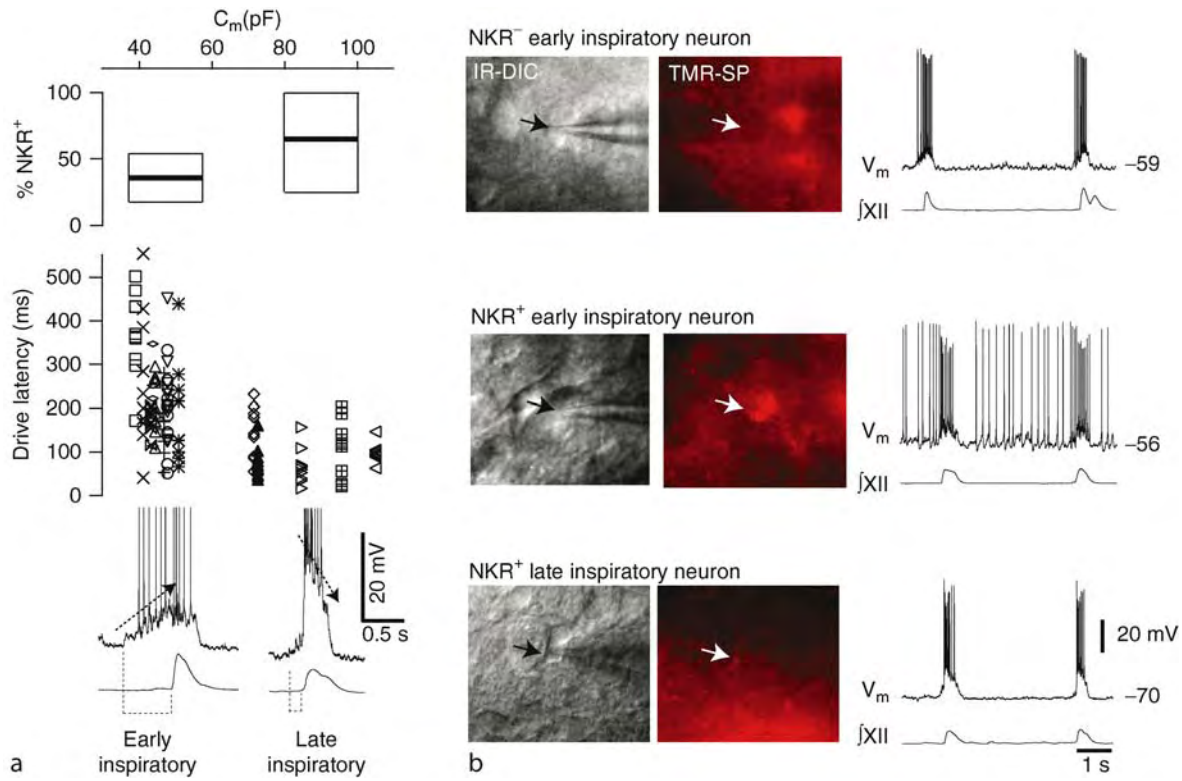
Rekling's classification scheme recognized peptide sensitivity as a criterion to distinguish rhythmogenic neurons. In a watershed study, Gray *et al.* showed that ►neurokinin-1 receptor (NK1R) expression demarcated the borders of the preBötC and that ►substance P (SP), the endogenous ligand for NK1Rs, directly excited rhythmogenic neurons, i.e., with properties consistent with types 1 and/or 2, and also profoundly excited respiratory rhythm [1]. These results led to the hypothesis that NK1R-expressing ($NK1R^+$) neurons, distinct by anatomical and physiological criteria, comprised the rhythmogenic kernel in the preBötC. In support of this hypothesis, ablation of $NK1R^+$ neurons in awake intact adult rats abolishes normal breathing behavior [3].

Guyenet and colleagues used in vivo electrophysiology and neuroanatomy to show $NK1R^+$ neurons concentrated in a region coextensive with the preBötC, where there was an abundance of inspiratory neurons and few ►expiratory neurons [4]. Inspiratory neurons with early drive latency in vivo could be antidromically activated from the contralateral medulla 70% of the time, consistent with interneurons in a local circuit. 34% of these early inspiratory neurons were $NK1R^+$, whereas expiratory or phase-spanning neurons did not appear to have the NK1R (i.e., $NK1R^-$). These data are consistent with the idea that drive latency and peptide receptor expression might specify rhythmogenic neurons in the preBötC.

$NK1R^+$ neurons in the preBötC showed no immunoreactivity for tyrosine hydroxylase (TH) nor choline acetyl-transferase (ChAT) [4]. Therefore, these neurons were unlikely to be catecholaminergic or cholinergic (motoneurons). As a control against these negative findings in $NK1R^+$ neurons of the preBötC, co-labeled $NK1R^+/TH^+$ neurons were found in the noradrenergic A5 and C1 regions outside the preBötC and $NK1R^+/ChAT^+$ motoneurons were profusely labeled in the ►nucleus ambiguous [1,4]. The $NK1R^+$ neurons in the preBötC area rarely showed immunoreactivity to GAD67 or GlyT2, which would have distinguished them as GABAergic or glycinergic inhibitory neurons, and were later shown to contain vesicular glutamate transporter mRNA. In sum, $NK1R^+$ neurons concentrated in the preBötC are locally interconnected excitatory interneurons that discharge prior to the onset of the inspiratory phase, hallmark properties for a role in rhythmogenesis (Fig. 3b).

But the hypothesis that $NK1R^+$ neurons define the kernel needs to be reevaluated because the $NK1R^+$ population can be subdivided. The smallest $NK1R^+$ neurons express preprosomatostatin mRNA, do not project to the spinal cord, nor express preproenkephalin (PPE) mRNA, and are rostrally sited in the preBötC area [5]. 75% of these $NK1R^+$ neurons project contralaterally and may be co-extensive with the $NK1R^+$ cells whose destruction abolishes normal breathing [3]. However, much larger $NK1R^+$ neurons found in the caudal preBötC area express PPE mRNA and project to the spinal cord, consistent with a premotor role, not rhythmogenesis [5].

Combining whole-cell patch clamp with a fluorescent labeling technique that tags all SP-sensitive $NK1R^+$ neurons, we found rhythmogenic properties, e.g., early drive latency, small size, in $NK1R^-$ neurons (Fig. 3b). Early drive latency (~300 ms, type 1- or type 2-like) was associated with small preBötC inspiratory neurons ($C_M \sim 45$ pF) of which 36% were $NK1R^+$. In contrast, larger preBötC inspiratory neurons ($C_M \sim 86$ pF)



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 3** Criteria to distinguish inspiratory preBötC neurons that are involved in rhythm generation. (a), Inspiratory drive latency (lower ordinate) and neurokinin receptor (NKR) expression (upper ordinate) are plotted as a function of whole-cell capacitance $C_M$. Box plots show mean and 95/5% credible interval range. Typical examples of early as well as late inspiratory phenotypes are shown beneath their characteristic $C_M$ range. (b), NKR expression is shown for three typical inspiratory preBötC neurons. Two early inspiratory neurons, which are hypothesized to be rhythmogenic on the basis of membrane properties, are shown with NKR expression ($NKR^+$) and without ($NKR^-$). An $NKR^+$ late expiratory neuron, hypothesized to have motor or premotor function, is also illustrated. Modified from [2].

showed drive latency of ~100 ms and were $NKR^+$ 67% of the time (Fig. 3). The majority of the preBötC neurons we recorded were small with early inspiratory activity. The early latency, small size, and incremental discharge trajectory are characteristic of glutamatergic interneurons, and resemble types 1 and 2 [1] and therefore are probably glutamatergic, not GABA- or glycinergic neurons [4]. The fraction of $NK1R^+$ neurons with early drive latency in adult rats in vivo is also near 36%, so the fraction of $NKR^+$ neurons in the preBötC appears consistent in neonate and adult rodents.

Large preBötC inspiratory neurons that activate latest in the respiratory cycle (Fig. 3a) may be premotor neurons [5]. A large fraction of these cells were $NKR^+$ (Fig. 3b) thus sensitive to saporin lesions [3]. However, because the small neurons with early drive latency are more numerous saporin lesions will probably cause a greater total reduction in $NKR^+$ rhythmogenic-like neurons. However, the destruction of a large fraction of $NKR^+$ respiratory premotoneurons must be considered as a factor in explaining apneas resulting from saporin lesions [3].

Finally, we showed that peptide sensitivity and receptor expression were not necessarily synonymous. Even though only 36% of the putatively rhythmogenic neurons were $NKR^+$, a much larger fraction (87%) showed a SP-evoked inward current ($I_{SP}$) in voltage clamp, which suggests that ►gap junctions may provide a means for NKRs to evoke inward current in both $NKR^+$ as well as $NKR^-$ preBötC inspiratory neurons [2]. This suggests that most of the putatively rhythmogenic neurons still satisfy the three objective criteria: small size, early inspiratory drive latency, and peptide sensitivity.

## Pacemaker Properties: Not Specialized Phenotypes, Cannot Explain Rhythmogenesis

Evidence for a ►pacemaker cell-type accompanied the discovery of the preBötC [6]. In the absence of synaptic transmission, some neurons with a baseline

membrane potential between −57 and −45 mV spontaneously depolarize and generate rhythmic bursts, dubbed ►conditional pacemaker properties. Voltage-dependent pacemaker properties were attractive from the standpoint of rhythmogenesis because conditional bursting in isolated cells had the same duty cycle as the network-intact XII rhythm. Pacemaker neurons were postulated to form a specialized phenotype that periodically excites so-called follower neurons and synchronizes both sets of neurons through excitatory synaptic interconnections.

PreBötC inspiratory neurons have been classified as either pacemakers or followers, yet this binary classification is more apparent than real. Voltage-dependent bursting depends on a requisite region of negative slope in the current-voltage relationship endowed by ►persistent $Na^+$ current ($I_{NaP}$). We now know that $I_{NaP}$ is a generic property, ubiquitously expressed throughout the preBötC and ventral medulla. Since baseline membrane potential must be within a specific voltage window, ►leakage potassium current ($I_{K\text{-}Leak}$) also becomes important to maintain voltage-dependent bursting. $I_{NaP}$ and $I_{K\text{-}Leak}$ are distributed continuously among preBötC inspiratory neurons, thus a small subset with conditional bursting properties arises naturally for neurons with the proper $I_{NaP}/I_K$ ratio and is a byproduct of heterogeneity in membrane properties.

The real question is whether $I_{NaP}$ is important for rhythmogenesis. To avoid caveats associated with bath-applications [7], we performed micropressure injections to apply riluzole – and low doses of TTX (20 nM) that preferentially block $I_{NaP}$ – directly into the preBötC without affecting premotor or XII motoneurons (Fig. 4). Riluzole and 20 nM TTX microinjections did not stop the rhythm nor affect XII motor output, indicating that $I_{NaP}$ is not obligatory for rhythmogenesis [8].

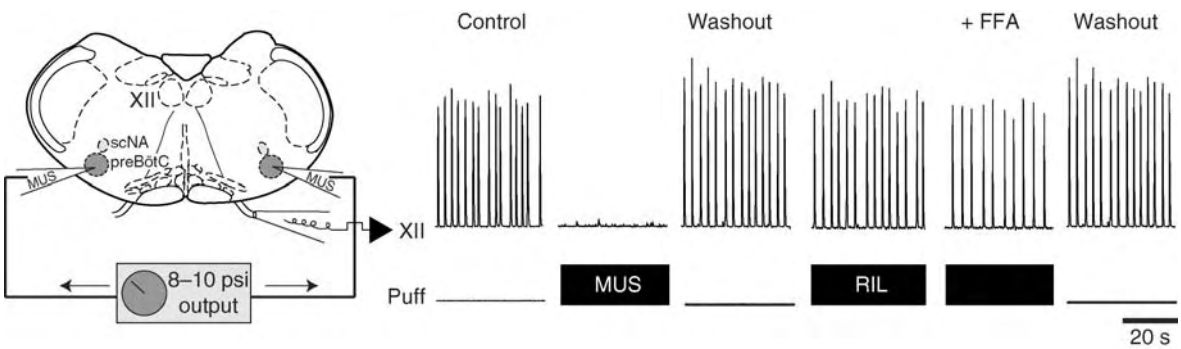
Voltage-dependent pacemaker properties do not constitute a specialized phenotype in the preBötC because $I_{NaP}$ is commonplace and nonessential for rhythmic function. Nevertheless, $I_{NaP}$ contributes to baseline membrane potential and facilitates high-frequency spiking, and thus helps maintain neural excitability [7,8].

Pacemaker properties unrelated to $I_{NaP}$ were documented in 2001. Bursting was sensitive to blockade by $Cd^{2+}$, indicating dependence on intrinsic $Ca^{2+}$ currents; later a ►$Ca^{2+}$-activated nonspecific cation current ($I_{CAN}$) was shown to be involved [17,20]. $Cd^{2+}$-sensitive bursting neurons were posited to form an additional rhythmogenic subpopulation that could drive rhythmogenesis in combination with, or in lieu of, $I_{NaP}$ pacemaker neurons [9]. However, two key facts falsify this hypothesis: first, $Cd^{2+}$-sensitive pacemaker properties are sparse or nonexistent in early in post-natal development [9], yet riluzole does not stop the rhythm. Second, doses of flufenamic acid (FFA, 10–100 μM) that attenuate $I_{CAN}$ to an extent that precludes $Cd^{2+}$-sensitive bursting – but do not completely block $I_{CAN}$ – do not stop rhythmogenesis in the presence of riluzole or TTX at any post-natal age [8].

Unless a miniscule number of pacemaker neurons that are insensitive to $I_{NaP}$ and $I_{CAN}$ antagonists can drive the rhythm – or a heretofore undiscovered pacemaker phenotype exists – these observations invalidate the hypothesis that pacemaker neurons are the basis for rhythmogenesis.

## $I_{CAN}$ Activates Synaptically and Generates Rhythmic Inspiratory Bursts in Prebötc Neurons

►AMPA receptors (AMPARs) are necessary for rhythmogenesis. Moreover, group I ►metabotropic glutamate receptors (mGluRs) and ►NMDA receptors



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 4** Sequential drug application experiments using local microinjection of 10 μM riluzole (RIL). Top traces show XII motor output, lower traces labeled "puff" reflect TTL pulses at 3 Hz that gate micropressure drug-delivery injections. Bilateral injection of 15 μM muscimol (MUS) is used to verify the effective microinjection pipette locations. After recovering from MUS, RIL is microinjected for >20 min, followed by bath application of 100 μM flufenamic acid (FFA). The rhythm did not stop, nor became perturbed in any noticeable form, after >20 min of bath-applied FFA (cumulative RIL exposure >40 min). Recovery from all drugs occurred within 1–2 h and is shown as washout. Modified from [8].

P

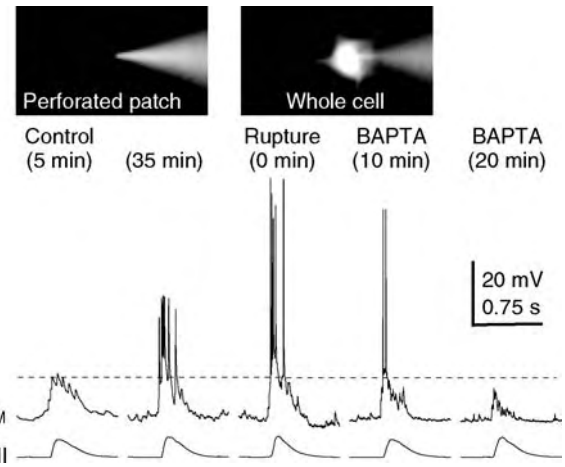
(NMDARs) provide a substantial – yet heretofore unrecognized – contribution to generating inspiratory bursts and rhythm. Both ionotropic, and metabotropic glutamate receptors activate $I_{CAN}$ via voltage-gated $Ca^{2+}$ channels and inositol (1,4,5)-triphosphate ($IP_3$)-mediated intracellular $Ca^{2+}$ release. Additionally, $I_{CAN}$ serves to generate robust inspiratory drive potentials in all preBötC inspiratory neurons [10].

Group I mGluRs consist of subtypes mGluR1 and mGluR5. While mGluR5 triggers $I_{CAN}$ activation, via $IP_3$-mediated intracellular $Ca^{2+}$ release, mGluR1 appears to promote inspiratory drive potentials by transiently closing $K^+$ channels. In contrast, group II mGluRs modulate interburst period but do not contribute to inspiratory burst generation.

$Ca^{2+}$ influx via NMDARs may also contribute to $I_{CAN}$ activation. AMPAR-mediated depolarization recruits ►voltage-gated $Ca^{2+}$ channels and may partially relieve the voltage-dependent $Mg^{2+}$ block of NMDARs and thus indirectly activate $I_{CAN}$ in the preBötC. This is the first example of a convergent activation of $I_{CAN}$ involving NMDARs, $Ca^{2+}$ channels and intracellular $Ca^{2+}$ release to serve burst generation in a ►central pattern generator.

How important is $I_{CAN}$? We used two strategies to test its role. In the first, intracellular drug application was employed to test the role of $I_{CAN}$ in drive potential generation in a single preBötC neuron without disrupting respiratory rhythm in the rest of the network. We recorded inspiratory drive in control using ►perforated patches (Fig. 5), which does not modify the intracellular milieu. Then we ruptured the patch and dialyzed the cytosol with patch solution containing 30 mM BAPTA, a high-affinity $Ca^{2+}$ chelator. BAPTA abolishes the ability to activate $I_{CAN}$ and reduced drive potentials by 70% after ≥20 min suggesting $I_{CAN}$ that $I_{CAN}$ is the major charge carrier underlying inspiratory drive potentials [10].

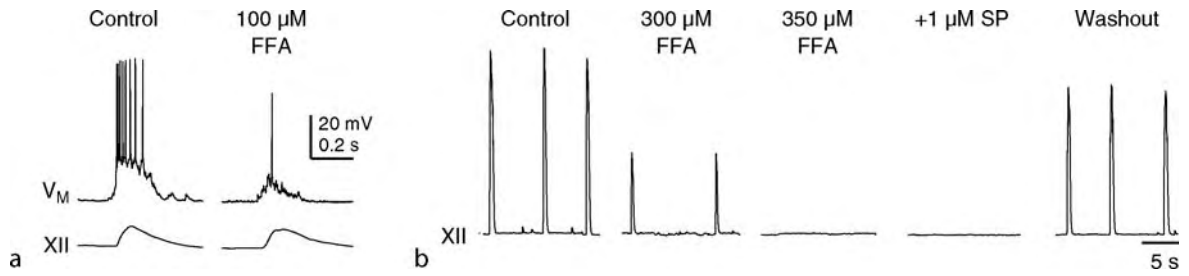
We examined whether $I_{CAN}$ (Fig. 6) was crucial for rhythmogenesis in the network as a whole using bath application of the selective antagonist flufenamic acid (FFA). Dose is a critical issue: 100 μM FFA incompletely blocks $I_{CAN}$ and does not stop the network rhythm, but nonetheless reduces inspiratory drive potentials by ~40% [10]. Higher concentrations of FFA (300–350 μM) stop respiratory rhythmogenesis. While an attractive conclusion is that FFA at ≥300 μM stops rhythmogenesis by fully and selectively blocking $I_{CAN}$, FFA doses exceeding 100 μM exert numerous side effects [10], and thus confound such a straightforward interpretation. Nevertheless, we can conclude that $I_{CAN}$ contributes enormously to inspiratory drive on a cycle-to-cycle basis by transforming synaptic input into long-lasting membrane depolarization, and thus plays an important role in inspiratory burst generation.



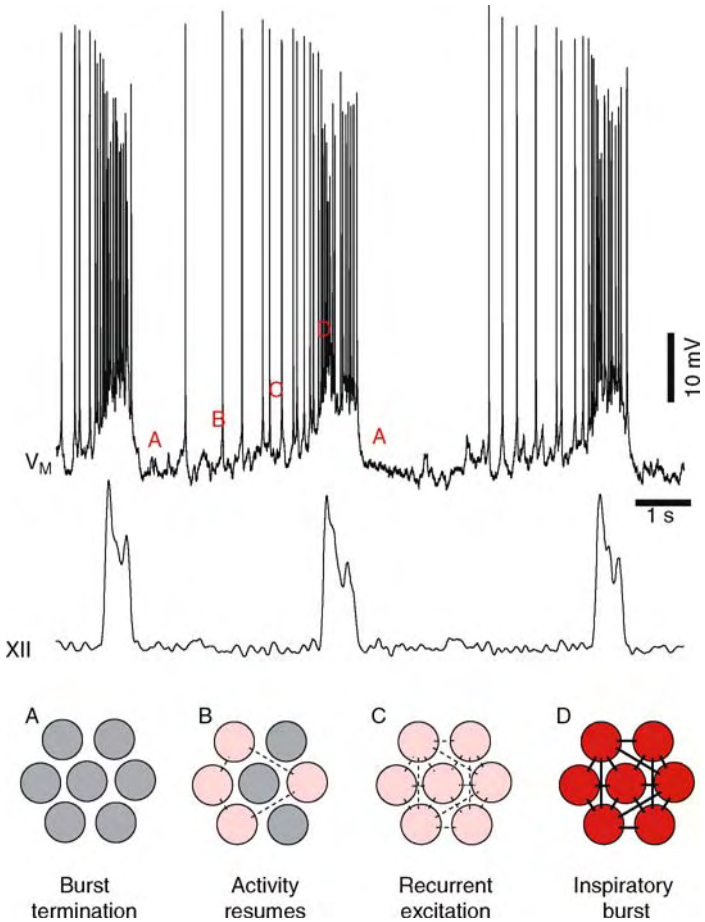
**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 5** Perforated-patch control recordings and subsequent intracellular dialysis with 30 mM BAPTA patch solution demonstrate the importance of $Ca^{2+}$ transients and $I_{CAN}$. Control conditions were recorded in the perforated-patch configuration (5 and 35 min shown). BAPTA was introduced into the cytosol via patch rupture (0 min) and caused a progressive attenuation of the drive potential. Baseline membrane potential was −60 mV throughout the experiment. The perforated-patch configuration (PP; *left* picture) is confirmed by the failure of the Lucifer yellow in the patch-pipette solution to dialyze the cell. The whole-cell configuration (WC; *right* picture) allows Lucifer yellow to fill the cell. The $V_M$ traces verify that the underlying inspiratory dive potential can be accurately measured in PP mode as compared to the first minute of WC mode. In WC, the spikes are less truncated because the access impedance decreases. Modified from [10].

## The Group-Pacemaker Hypothesis of Respiratory Rhythm Generation

$I_{CAN}$ activation depends on AMPA, NMDA, and metabotropic glutamate receptors during endogenous respiratory behavior, and thus is properly considered a network property. The group-pacemaker hypothesis (Fig. 7) postulates a mechanism for rhythmogenesis wherein recurrent synaptic excitation linked to postsynaptic intrinsic currents plays a special role. In the group pacemaker, a fraction of neurons in the preBötC are spontaneously firing; baseline voltage during the expiratory phase exceeds spike threshold. In the waning expiratory phase, active neurons excite silent neurons, which in turn excite additional silent neurons and also provide positive feedback to re-excite the neurons already spiking. $I_{CAN}$ is normally latent and unavailable except when recruited by synaptic excitation. Glutamatergic input sufficient to evoke $I_{CAN}$ is ultimately achieved a few hundred milliseconds prior to inspiratory burst discharge. The negative feedback process that causes burst termination remains unknown. After burst termination, neurons



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 6** Effects of $I_{CAN}$ antagonist flufenamic acid (FFA) on inspiratory bursts and rhythmogenesis. (a), Typical inspiratory bursts recorded in whole-cell conditions for control and 100 μM FFA, respectively. (b), An experiment showing that 300 μM FFA severely perturbed the respiratory rhythm (monitored via XII discharge) and 350 μM FFA stopped it altogether. In the presence of 350 μM FFA, even the excitatory peptide substance P (which normally stimulates rhythmogenesis profoundly) fails to revive rhythm generation. The effects of FFA were reversible, as shown by the full recovery in washout conditions. Modified from [10].



**Pre-Bötzinger Complex Inspiratory Neurons and Rhythm Generation. Figure 7** Group-pacemaker hypothesis of rhythm generation. The membrane potential of an inspiratory preBötC neuron is shown ($V_M$) with XII motor output. Images at the bottom depict neuronal activity at different stages of the cycle. (a), the refractory state following the inspiratory burst. (b), some preBötC neurons recover their excitability and begin to spike low rates. (c), Spiking preBötC neurons begin to synaptically activate other silent preBötC neurons, leading to aggregation of network activity via recurrent synaptic excitation, which is positive feedback. (d), the inspiratory burst occurs when recurrent synaptic activity is sufficiently strong to recruit postsynaptic inward currents such as $I_{CAN}$. Inspiratory bursts terminate due to intrinsic properties that remain unknown. Modified from: Feldman and Del Negro, *Nat Rev Neurosci* 7: 232–242, 2006.

P

undergo a recovery phase in which they gradually approach a baseline membrane potential largely determined by $I_{K\text{-}Leak}$ and the by tonic inputs. The most excitable neurons spontaneously cross threshold and begin the next positive feedback cycle.

Given the diminishing evidence in support of the obligatory role of pacemaker properties in respiratory rhythm generation [8], a framework in which recurrent synaptic excitation evokes postsynaptic burst-generating membrane properties available to all pre-BötC inspiratory neurons, such as the group pacemaker hypothesis, is a viable mechanism that can explain key aspects of respiratory rhythmogenesis.

# Precentral Gyrus

### Definition

The precentral gyrus is the cerebral gyrus immediately anterior and parallel to the central sulcus. It is part of the frontal lobe and is the primary motor cortex.

►Primary Motor Cortex
►Gyrus precentralls

# Precerebellar Long-Lead Burst Neurons

Charles Scudder
Portland, OR, USA

### Definition

Precerebellar neurons, in general, are neurons that have their somata in the brainstem or spinal cord and send their axons to the cerebellum. Precerebellar ►long-lead burst neurons (PCbLLBNs) (►burst cells – long lead (LLBNs)) are precerebellar neurons that have long-lead burst discharges during saccades. They comprise the major route for the transmission of saccadic commands to the cerebellum. All PCbLLBNs that have been identified to date have their somata in the pontine reticular formation or the pontine nuclei.

### Characteristics

#### Higher Order Processes

PCbLLBNs receive information from higher order saccadic command centers and relay this information to the ►oculomotor vermis and the ►floccular lobe of the cerebellum (see ►Cerebellum – Role in Eye Movements). Projections to the oculomotor vermis comprise the first leg of a trans-cerebellar route by which saccadic commands are processed in the cerebellum and then conveyed to the saccadic burst generator. At the burst generator, these processed commands are combined with a raw command conveyed directly from the same higher command centers, and are thought to provide the detail needed for generating accurate saccadic eye movements (see cerebellum – role in eye movements). PCbLLBNs provide the major, but not the only, input to the oculomotor vermis, and provide a minor input to the floccular lobe.

Command centers that provide the major input to PCbLLBNs are the deep and intermediate layers of

the ►superior colliculus, the ►frontal eye fields (FEF), the ►supplementary eye fields (SEF), and the ►lateral intraparietal area (LIP). The superior colliculus collects information from the above three cortical areas (FEF, SEF, LIP), the ►basal ganglia, the superficial layers of the superior colliculus, and other smaller projections, and is considered the final common path for the saccadic command.

## Parts of the LLBN Pathway to the Cerebellum

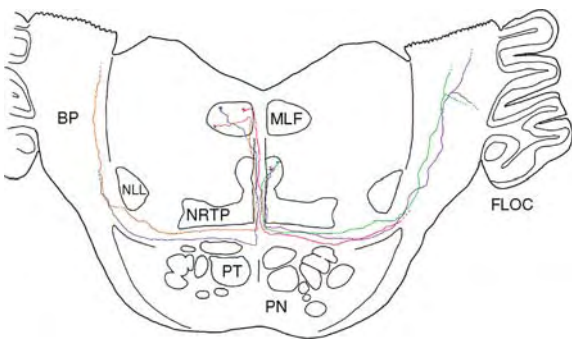
### *Groups of PCbLLBNs*

Somata of PCbLLBNs reside in four principal areas within the pons, and each area receives somewhat different information. By far the largest population is in the caudal ►nucleus reticularis tegmenti pontis (NRTP), both in the medial group of cells that extends dorsally from the main body of NRTP (Fig. 1), and to a lesser extent, in the medial part of the body of NRTP. The major input to this part of NRTP is from the superior colliculus, with a smaller input from the FEF and SEF. NRTP also receives a major feedback signal from the output of the midline cerebellum, namely, the fastigial nucleus.

A second group of PCbLLBNs resides in a diffuse collection of somata amid the fascicles of the medial longitudinal fasciculus (the intrafascicular nucleus of the MLF, or IFN) just rostral to the abducens nucleus (Fig. 1). The third group resides in raphe pontis, which is located below the MLF immediately rostral to the abducens nucleus (not illustrated). The known inputs to these areas based on anatomical data arise from the superior colliculus and from the ►inhibitory burst neurons (IBNs) of the saccadic burst generator (see ►brainstem burst generator), but there may be other sources of input.

Locations of cell bodies and axonal projections for two of these three groups are illustrated in Fig. 1, which was derived from intraaxonally labeled neurons [1]. Axons of all NRTP, IFN, and raphe pontis PCbLLBNs course to the midline where they travel ventrally with other fiber bundles. Just above the pontine nuclei, they sharply turn either ipsilaterally or contralaterally and travel laterally in a well defined band of fibers between NRTP and the pontine nuclei. Subsequently, they enter the brachium pontis and travel dorsally to the cerebellum without ever branching in the brainstem. Several neurons originating in NRTP were observed to send collaterals to the floccular lobe, while none originating in the IFN or raphe pontis were so observed.

One group of investigators has found a fourth group of PCbLLBNs in the dorsolateral pontine nuclei [2]. The principal input to this group is from LIP, with a smaller input from the FEF. The dorsolateral pontine nuclei also receive heavy input from visual-motion sensitive cortical areas MST and MT, but PCbLLBNs presumably receive little of this input. This latter input goes mainly to neurons discharging during ►smooth pursuit eye movements, which are intermixed with PCbLLBNs in this region.



**Precerebellar Long-Lead Burst Neurons.**
**Figure 1** Transverse section of the monkey brainstem at a level just rostral to the abducens nucleus is illustrated along with the somata and axons of five precerebellar LLBNs. Neurons were visualized using intraaxonal staining and were reconstructed using a camera lucida. Three somata are located in a fasciculated portion of the medial longitudinal fasciculus (MLF), and two others are located in a dorsomedial extension of nucleus reticularis tegmenti pontis (NRTP). Axons course to the midline and then ventrally to a lateral fiber tract just ventral to NRTP, where some cross and some do not (follow axon colors). Axons course laterally and then back dorsally in brachium pontis (BP). Staining faded before reaching the cerebellum (dotted lines). The NRTP neurons sent collaterals toward the floccular lobe (FLOC). NLL, nucleus of the lateral lemniscus; PN, pontine nuclei; PT, pyramidal tract.

### *Discharges of PCbLLBNs*

Discharges of PCbLLBNs with somata in the reticular formation have been recorded extracellularly in medial NRTP, intra-axonally along their projection route, and extracellularly in the white matter of the oculomotor vermis and floccular lobe [1,3–5]. Like other LLBNs, they are mostly silent during fixations between saccades, but have a presaccadic firing that begins 21–300 ms before saccades in a preferred direction. Firing rate usually builds up towards a peak that usually also occurs before saccade onset. Firing ends near the time of saccade end.

PCbLLBNs in the reticular formation exhibit spatial properties that are intermediate between those of two common classes, namely ►directional and ►vectorial LLBNs. Like vectorial neurons, the range of directions for which a PCbLLBN may fire is less than a full hemifield, but it is usually larger than that of the superior-colliculus neurons that provide its major input. Unlike vectorial neurons, only a few PCbLLBNs

P

have closed ►movement fields. That is, the discharge rate and number of spikes of typical PCbLLBNs first increase as saccade size increases but then might plateau with further increases in size. A few act like directional neurons, in that discharge parameters continually increase as saccade size increases. For neurons that do not have vertical preferred directions, all have an ipsilateral component to their preferred direction and none have a ►contraversive component. PCbLLBN responses have also been shown to depend on the torsional component of the saccade, making movement fields three dimensional [6]. These spatial characteristics are probably produced by convergent input from appropriately selected superior-colliculus efferents.

In the dorsolateral pontine nuclei, LLBNs are one population within a range of burst neurons [2]. Discharges of some burst neurons lag saccade onset, and some burst neurons also exhibit responses during smooth pursuit eye movements. All possible preferred directions for bursts are present in the population.

### Lower Level Processes

The major targets of PCbLLBNs originating in the NRTP, IFN, and raphe pontis are the "oculomotor vermis" (lobules VIc and VII) [7] and the ►fastigial oculomotor region (FOR; see cerebellum – role in eye movements). The fastigial nucleus is presumably innervated by collaterals of ►mossy fibers projecting to the vermis, but retrograde tracing data suggests that not all PCbLLBNs issue these collaterals [8,9]. PCbLLBN signals are used in the cerebellum to produce a burst in FOR neurons, whose timing and amplitude affect the duration and amplitude of the discharges of burst neurons in the saccadic burst generator. The cerebellum thus provides fine control of the size and direction of saccades (see brainstem burst generator).

Some PCbLLBNs with somata in NRTP project to the ►flocculus and paraflocculus as collaterals of axons projecting to the oculomotor vermis [1]. It is uncertain whether all LLBN input to the floccular lobe arises in this fashion. IFN and raphe pontis neurons also project to the floccular lobe, but these may be the burst-tonic neurons that are also found in these nuclei. There is no firm data about how PCbLLBN signals are used in the floccular lobe, but one possibility is that they are used to help remove saccade-related signals from the many inputs with mixed saccade and smooth eye-movement signals, leaving mainly the latter in the output pathway.

### Pathology

There have only been preliminary studies using experimental lesions of NRTP at the location of PCbLLBNs. Temporary inactivation of caudal NRTP with lidocaine or muscimol in monkeys has produced hypometric saccades, deficits in convergence and accommodation to a near target after a saccade, and aberrant torsional eye-position after a saccade [6,10]. Experimental lesions of the dorsolateral pontine nuclei produced deficits in smooth pursuit with no observable deficits in saccades. Specific lesions of raphe pontis have not been performed.

## Precocial

### Definition

Young born with hair or feathers, eyes open, the ability to move about immediately after birth and capable of leaving the nest within a few days.

►Neural Correlates of Imprinting

## Precocious Puberty

### Definition

The appearance of any sign of secondary sexual maturation, such as pubic hair, before the age of 8 years (or menarche before the age of 9 years) in girls and 9 years in boys.

►Neuroendocrinology of Tumors

## Precuneus

### Definition

Part of the parietal lobe visible in a median section. Has a virtually square shape (hence also called quadrate lobe). The precuneus appears to be implicated in complex, sensory evaluation processes, language processing as well as spatial and temporal orientation.

►Telencephalon

## Precursor Cells

### Definition

(Neural) precursor cells occur in both fetal and adult brains and are partially specialized; they undergo cell division and give rise to differentiated cells in a site-specific manner. In their normal states, adult precursor cells do not generate a wide variety of neurons. In the injured brain, adult precursor cells can partially replace neurons that are damaged or dead.

►Adult Neurogenesis

## Predicate (Attribute)

### Definition

A predicate is what can be said of something, truly or falsely. The linguistic predicate "is red" can truly be applied to red things. The relational predicate "is larger than" can be used to state a relation between two things.

An attribute is a feature, like being red, for which a linguistic predicate stands. Realists claim, while nominalists deny, that an attribute is a special entity (universal) that can be exemplified by several particular things.

►Argument
►Logic

## Prediction Error

### Definition

A discrepancy between the expected and the experienced outcome of a behavioral situation. The prediction error is a relevant variable determining recruitment of dopaminergic action in the brain and formation of associations between events (stimuli and or behaviors).

►Dopamine
►Neuroethological Aspects of Learning

## Predictive Eye Movements

### Definition

Predictive eye movements occur whenever the motion of a target exhibits regular temporal features. Particularly with periodic movements, they compensate for the lag of the eye on the target implied by the reaction time, achieving either a nearly perfect synchronisation with the target (smooth pursuit of sinusoids at $< 0.5$ Hz) or even a lead (saccades tracking a target stepping back and forth at regular pace).

►Oculomotor Control
►Saccade, Saccadic Eye Movement

## Preferential Motor Reinnervaton (PMR)

### Definition

The bias and modest selectivity that motor axons exhibit in choosing motor endoneurial pathways and

end-organs over sensory pathways and end-organs during reinnervation.

►Peripheral Nerve Regeneration and Nerve Repair

# Preferred Direction (of a Neuron)

## Definition

Neurons that respond to motion of either discrete visual stimulus or of a structured background modulate the strength of their response as function of the direction of motion. Plots of the strength of the response, e.g., mean firing rate, against the angle of stimulus trajectory are called tuning curves. The angle corresponding to the peak of the curve defines the preferred direction of the neuron. Visuomotor neurons, such as tectoreticulospinal neurons (TRSNs) have a directional tuning for visual stimulus, as well as to the direction of orienting movement associated to motor components of their bursts. Preferred movement direction of a given neuron is determined from the tuning curves, in the same way as for visual or, more generally, sensory preferred directions.

►Reaching Movements
►SC-Tectoreticulospinal neurons (TRSNs)

# Prefrontal Cortex

Susan R. Sesack
Departments of Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

## Synonyms

Frontal cortex; Dorsolateral cortex; Orbitofrontal cortex

## Definition

The prefrontal cortex was so named because it was discovered in electrical stimulation studies to be a "silent" region in front of the motor areas of the frontal lobe. It appears to have increased in size and complexity in the course of evolution, culminating in the human brain as approximately 30% of the cortical mantle and at least 11 different cytoarchitectonically defined areas according to Brodmann's nomenclature. It is involved in many of the cognitive and ►executive control functions necessary for goal directed behavior, including ►working memory, shifting of ►selective attention, decision-making and ►response inhibition. Disturbances in function are thought to contribute to the pathophysiology of several mental conditions, including ►schizophrenia, major ►depression, ►post-traumatic stress disorder (PTSD), ►attention deficit hyperactivity disorder (ADHD) and susceptibility to ►addiction.

## Characteristics

### Anatomy

In common with all cortical areas, the PFC is a layered structure, with six layers in this case, and has the same major cellular constituents [1–5]. These include spiny ►pyramidal neurons with an excitatory glutamate phenotype whose axons ramify locally in addition to entering the white matter and projecting to other cortical and subcortical regions. The second major cell class consists of relatively aspiny, non-pyramidal ►interneurons whose inhibitory phenotype is GABAergic and whose axonal connections are strictly local. Several major subclasses of these local circuit neurons are distinguished by their content of calcium binding proteins or ►neuroactive peptides and by differences in their axonal targets, providing the necessary circuitry for feedback and feedforward inhibition within the cortex. Subsets of interneurons are also thought to entrain pyramidal cells to fire in ►oscillations, at frequencies deemed essential for specific forms of information processing [4].

In the past, cortical territories were defined by their inputs from specific nuclei of the ►thalamus, and this still constitutes a reasonable starting point for identifying cortical regions across species [3]. For the PFC, the principal thalamic division is the mediodorsal nucleus (MDTN). The MDTN is itself divided into three main subregions, each of which maintains reciprocal connections with portions of the PFC. (i) The paralamellar division is the most lateral part of the MDTN and innervates the cortical territory around the arcuate sulcus corresponding to Brodmann's area 8, also known as the ►frontal eye fields. This serves as the motor command region for voluntary (►saccadic) eye movements. (ii) Medial to the paralamellar division is the parvocellular region of the MDTN, which connects to the cortex along the dorsolateral convexity (DLPFC), including Brodmann's areas 9, 10 and 46, the latter lying within and along the banks of the principal sulcus. (iii) The most medial portion of the MDTN is the magnocellular division, which is interconnected to orbital regions of the cortex (named for their position above the eye socket) and to other ventral and medial surfaces of the frontal lobe, Brodmann's areas 11, 13, 14, 24, 25, 32 and 47/12. Collectively, these are termed the orbitomedial PFC (OMPFC). Areas 24, 25 and 32

lie within the ►cingulate gyrus and so are also considered parts of the ►anterior cingulate cortex.

In addition to specific inputs from the MDTN, the PFC is also innervated by other thalamic nuclei within the anterior, ventral, medial and midline divisions as well as the pulvinar nucleus. As an association cortex, the PFC receives extensive inputs from other cortical regions organized in a hierarchical fashion [3]. Major afferents arise from other association areas, including those in the posterior parietal and inferior temporal regions. The sensory streams innervating the PFC appear to involve mainly visual, auditory and somatosensory projections to the DLPFC and primarily olfactory, gustatory and viscerosensory projections to the OMPFC. The OMPFC is also innervated by important structures within the ►limbic system, the ►hypothalamus, ►hippocampus and ►amygdala [1,3,5]. The amygdala is a quasi-cortical structure that regulates behavior by conditioned associations and its reciprocal connections with the PFC are important for facilitating appropriate emotional behaviors. It has been argued that within the OMPFC, orbital divisions are the main sites of sensory termination, whereas medial regions are the main origin of descending projections to autonomic regions [5]. Hence, these two subdivisions may function as viscerosensory and visceromotor regions, respectively.

The PFC, like most cortical structures, is extensively innervated by ►ascending neuromodulatory projection systems (see Essay of same name) arising in the brainstem and basal forebrain, including pathways conveying ►acetylcholine, ►dopamine, ►norepinephrine and ►serotonin inputs [3,6,7]. These projections provide essential modulation of cortical firing patterns and many studies demonstrate that either decreases or increases in critical levels of monoamines are sufficient to disrupt PFC function [6,7]. Conversely, pharmacological therapies for mental disorders (e.g., antipsychotic, antidepressant and anxiolytic medications) are often designed to alter monoamine transmission in an effort to restore more balanced activity in this region.

Many of the efferent projections of the PFC reciprocate the afferent inputs [1,3], including those to association cortices and to thalamic nuclei. Another major output of the PFC, as with many cortical regions, is to the ►basal ganglia. Cortical projections to the ►striatopallidum (see Essay of same name) are relayed back to the cortex via the thalamus, forming functional "loops" for the selection of appropriate actions and suppression of maladaptive responses. The DLPFC targets mainly the head of the ►caudate nucleus, forming a major associative loop that supports cognitive and executive functions, whereas the OMPFC projects to more ventral parts of the striatal complex, including the ►nucleus accumbens and participates in limbic circuitry for motivated behaviors. The brainstem projections of the PFC include the ►superior colliculus for saccadic eye movement control and the pontine nucleus, which relays executive commands to the ►cerebellum for controlling the timing and coordination of movement and cognition. Interestingly, the OMPFC is the source of extensive projections to diencephalic and brainstem structures that are important regulators of autonomic output, including the amygdala, hypothalamus, ►periaqueductal gray, ►parabrachial nucleus and ►nucleus of the solitary tract [3,5] Moreover, portions of the OMPFC are among the only cortical regions that project directly to brainstem monoamine neurons [3], placing this division of the PFC in a position to regulate the level of modulatory drive to the cortex generally. The latter connections are no doubt important for understanding the pathophysiology of mood disorders, in which brainstem monoamines are implicated in both cause and treatment.

On the basis of these differential inputs and outputs, the DLPFC is considered to be the main region within which spatial and object working memory and other executive functions are carried out [1–4,8]. The OMPFC has been deemed a viscerosensory and visceromotor network that guides behavior based on emotional experience [1,3,5,9]. Of course, the major subdivisions of the PFC are interconnected, so that goal directed behavior is accomplished by consideration of both external and internal perceptions [3].

## Function

The PFC performs many essential cognitive functions whose complexity increases in the course of evolutionary development. The PFC guides behavior particularly when situations are novel or complex and is probably not involved in functions that are routine or well learned [1]. There is considerable consensus that the PFC is a major contributor to the processes underlying ►working memory, a short form of memory in which information is held temporarily in mind until it can be used to guide immediate behavior [1,2,4]. Such information is also available for mental manipulation and the PFC has sometimes been described as the brain's "scratch pad." The PFC provides a mechanism for bridging time between the near past and the actions that proceed from keeping this information "in mind." In this way, the PFC is essential for preparing the motor systems for action and hence for future planning and logical sequences of action and thought [1].

Behavioral tasks in which a delay is interposed between cue and choice (►delayed–response tasks) are important tools for evaluating working memory performance in experimental animals and humans. Such tasks assess the ability to maintain a representation of spatial location, object identity or stimulus associations in the absence of the original cue and performance of these tasks is highly sensitive to PFC damage [1,2]. The

oculomotor variant of this test, the ►delayed saccade task was created to minimize movement in behaving animals and so to facilitate electrophysiological recording of neuronal activity during working memory. The resultant studies have depicted cells that respond to the presentation of the cue or to the go signal for the motor response. More importantly, many of these studies have described neurons that increase their activity during the delay period between the cue and the go signal. These "delay" cells appear to represent the maintenance of critical information obtained from the cue in order to guide future responding and so are widely considered as a neural correlate of working memory. Many studies report that delay period cells are spatially tuned, responding best to cues that dictate subsequent motor responses into specific regions of space [2]. The exact cellular mechanisms that underlie delay period activity are not yet known. Collateral synapses between pyramidal cells may form local reverberatory connections that could sustain such firing. Alternatively or in addition, delay period activity probably reflects long-range interconnections between the PFC and posterior association areas where similar firing patterns have been described [1,2,4,8]. Other electrophysiological recording studies, particularly those in the OMPFC, have described neurons that appear to encode the salience or reward value of stimuli, which is likely to subsequently influence motivation in motor responses [1].

Many of these observations from animal physiology have been verified to the extent possible in humans using variants of working memory or decision making tasks and functional imaging methods [1,8,9]. Functional magnetic resonance imaging (►fMRI) and positron emission tomography (►PET) monitor signals that reflect altered blood flow as indirect measures of activation in brain regions. Performance of tasks for which working memory is an essential component produce signals consistent with an increase in blood flow to the PFC. Moreover, many studies using this methodology have produced findings that extend theories regarding the cognitive functions of this region to include stimulus ►encoding, sustained attention, decision making and motor preparation.

## Disorders

Although lesions caused by stroke, tumor or accidental damage are rarely circumscribed within subdivisions of the PFC, some relatively distinct syndromes have been characterized [1]. Lesions that are centered in orbital regions of the OMPFC tend to cause loss of ►response inhibition [9], with changes in personality that include impulsiveness and recklessness. Patients have problems with selective attention and exhibit inappropriate decision making to the point of self-destructive and sociopathic behavior. Attentional problems are also seen with damage to medial portions of the OMPFC that include the anterior cingulate cortex, in this case accompanied by affective blunting, apathy and withdrawal [1]. Lesions of the DLPFC produce a "dysexecutive syndrome" characterized by deficits in working memory and related cognitive functions, poor planning capability, difficulty in the execution of logically ordered sequences of behavior or language and attention deficits [1]. The consistent observation of attentional problems with damage to the PFC suggests that this cortical territory is important for regulating the attentional processes necessary for goal directed behavior [1]. Functional imaging studies of the anterior cingulate cortex in particular support a major role for this region in attentional mechanisms. Partly as a result of these observations, the PFC is considered a principal site of pathophysiology in ADHD [6].

There is ample evidence from functional imaging, postmortem and neuropsychological analyses for a significant malfunction of the PFC in ►schizophrenia [2,4]. Schizophrenic patients show deficits in working memory and other cognitive skills, consistent with reduced blood flow to the PFC during performance of tasks designed to test these functions. These and other "negative" symptoms form the core features of the illness; they are the most predictive of long-term prognosis and are the least susceptible to pharmacological intervention. Postmortem studies show structural alterations in both pyramidal and non-pyramidal neurons and reductions in markers of synaptic communication. Some of these deficits are specific to the PFC, while others are observed throughout the cortex. Most appear to be associated with the illness and not with treatment with antipsychotic medications [4].

Functional imaging and postmortem studies also report changes in the PFC in major ►depressive disorders, including ►bipolar depression [5]. Altered metabolism/blood flow is particularly observed in the medial portions of the OMPFC and such changes are consistent with the symptom complex that accompanies lesions to this region. The earliest studies reported increased blood flow in the OMPFC with major depression, although later investigations have also shown decreased blood flow in this region. Some postmortem analyses have also reported reduced tissue volume in portions of the midline frontal cortex, primarily due to loss of glia and neuropil as opposed to a loss of neurons.

The PFC is highly susceptible to the impact of acute and chronic ►stress and it is well known that stress can exacerbate the symptoms of mental disorders [6,7,10]. Behavioral studies indicate that working memory performance is degraded in animals subjected to stress and several investigations report structural alterations in pyramidal neurons following exposure to chronically stressful conditions. Theories regarding the likely pathophysiology of PTSD often focus on the amygdala as a probable site of dysfunction, but these models also

suggest loss of inhibitory regulation of the amygdala by the OMPFC in this condition [10]. Stress is also a known contributor to recidivism in addiction disorders. Loss of inhibitory control of behavior by a weakened PFC system has been implicated in susceptibility to addiction and the impact of acutely stressful events on PFC activity may further destabilize individuals toward relapse [7].

# Preganglionic Neuron

## Definition

Within the autonomic nervous system – which is the set of central and peripheral nerve structures that control the activity of viscera (such as bladder, heart, intestines, trachea, glands) and of blood vessels – there are large arrays of neurons located in the spinal cord and the brain stem, arranged in columns and nuclei, that project their axons outside the central nervous system (CNS) and are part of the efferent (motor) pathways leading from brain centers to peripheral organs. They are known as preganglionic neurons because their axons gather into small nerves that reach autonomic ganglia (sympathetic and parasympathetic) and terminate with innumerable nerve endings synapsing on ganglion neurons.

In the brain stem the main bilateral groups of preganglionic neurons are the accessory oculomotor nuclei of Edinger-Westphal projecting to the ciliary ganglia, the superior salivatory nuclei projecting to the pterygo-palatine and submandibular ganglia, the inferior salivatory nuclei projecting to the otic ganglia, the dorsal vagal nuclei projecting to ganglia in the trachea, oesophagus and gastro-intestinal tract, and part of the nucleus ambiguus projecting to cardiac ganglia.

In the spinal cord, autonomic neurons are grouped into bilateral columns in the ventral horn; the largest ones are part of the sympathetic pathways extending from the last cervical level (C8) to the second lumbar level (L2). Other columns, which are part of the parasympathetic pathways, occupy sacral levels (between S2 and S4).The preganglionic neurons, which are all cholinergic, receive two main inputs: from higher centers, for example the pontine micturition centre, the cardiovascular centers, several autonomic nuclei in the hypothalamus, and from the periphery via afferent (sensory) autonomic neurons, directly or through an interneuron.

# Preganglionic Neurotransmitters

## Definition

Neurotransmitters released from preganglionic neurons to influence the activity of postganglionic neurons within autonomic ganglia. Acetylcholine is the primary neurotransmitter used by probably all preganglionic neurons. Co-transmitters in preganglionic neurons modulate the excitability of postganglionic neurons, or have presynaptic actions to affect further release of preganglionic neurotransmitters.

## Prenatal Brain Injury by Chronic Endotoxin Exposure

Sandra Rees
Department of Anatomy and Cell Biology, University of Melbourne, Melbourne, Australia

### Synonyms

Fetal brain injury; Brain inflammation

### Definition

Many factors contribute to perinatal brain injury, with the major causes likely to be hypoxia-ischemia/reperfusion [1] and infection of the fetus and/or mother [2]. Clinical studies have indicated that there are significant associations between maternal infection, preterm birth, neonatal brain damage and increased levels of ►proinflammatory cytokines in the amniotic fluid and umbilical cord; the strength of specific correlations are still being deduced. Fetal inflammatory responses can occur in the absence of overt signs of infection or fetal compromise and it is possible that subclinical inflammation underlies otherwise unexplained brain injury. Preterm birth occurs in 7–10% of pregnancies; advances in perinatal care have led to a significant improvement in the survival of very premature (less than 30 weeks) and very low birth weight (less than 1,500 g) infants. However up to 10% of these infants develop spastic motor deficits and 20–50% suffer developmental and behavioral disabilities. The most common cerebral neuropathology observed in premature infants is white matter injury, referred to as periventricular leukomalacia. This includes diffuse gliosis (►microgliosis and astrogliosis) extending throughout the white matter and also focal cystic infarction adjacent to the lateral ventricles in about 5% of cases. It is now increasingly recognized that the cerebral cortex and deep grey matter are also likely to be affected.

Invading microorganisms are thought to gain access to the amniotic cavity and fetus, most commonly, by ascending through the vagina and cervix [3]. This induces an innate immune response with inflammation of the chorioamniotic membranes and the production of proinflammatory cytokines. The cytokines and/or other inflammatory mediators then gain access to the fetus via swallowed amniotic fluid or fetal lungs, eyes or nasal membranes. It has been suggested that these agents increase the permeability of the blood–brain barrier with enhanced leucocyte infiltration of the brain mediated by brain chemokines; brain microglia and astrocytes will be stimulated to upregulate the production of cytokines and alterations to brain structures and/or overt injury will ensue depending on the severity of the inflammatory response.

### Characteristics

#### Description of the Process

##### *Lipopolysaccharide and the Inflammatory Response*

In order to more fully understand the mechanisms involved in inflammatory-induced brain damage animal models are required with one of the specific goals being the development of therapeutic strategies. The bacterial endotoxin, lipopolysaccharide (LPS) is most commonly used to model the systemic inflammatory response induced by infection, although live bacteria have also been used. LPS is a major component of the outer membrane of gram negative bacteria. Since fetal inflammation associated with maternal infection is likely to be chronic in nature [3] models involving repeated exposure to LPS are most likely to mimic the human situation [4,5] although other models stand to contribute to an understanding of the inflammatory process. LPS has been administered to fetal rodents and sheep and neonatal rats, kittens and monkeys at a developmental age which equates to 25–30 weeks in the human fetus, a period of high vulnerability for white matter damage.

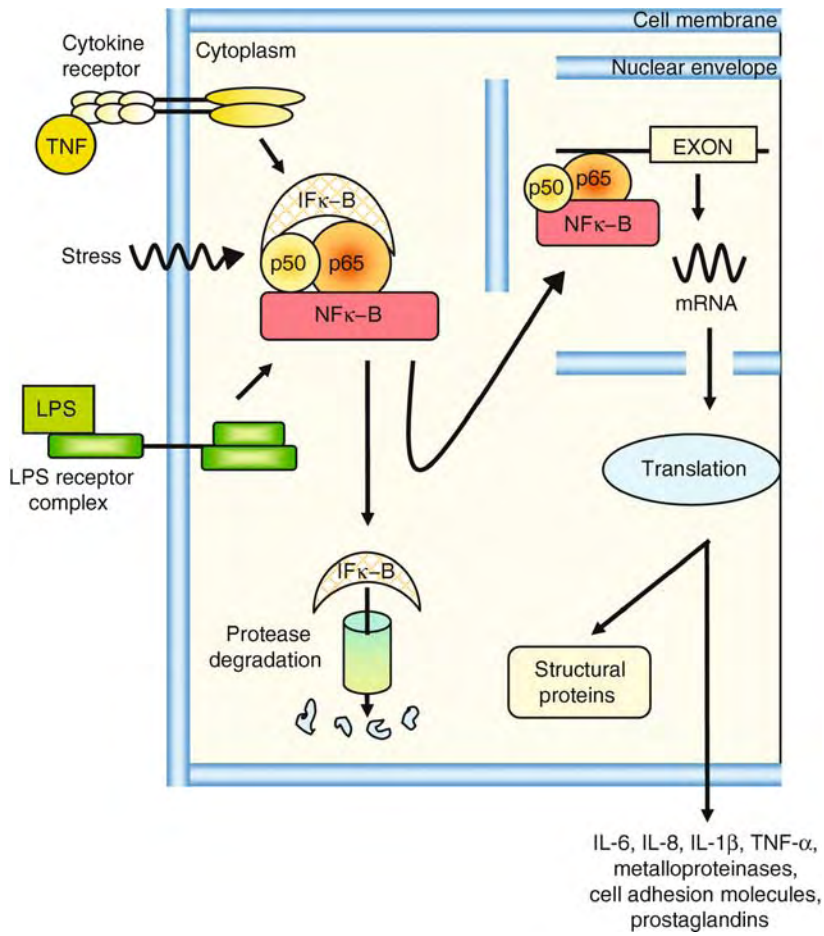
##### *Cytokines*

To contend with invading organisms, as typified by lipopolysaccharide, the innate immune response includes the generation of reactive oxygen species, phagocytosis and the production and release of cytokines and chemokines. LPS binds initially to LPS-binding protein (LBP), an acute phase protein released into the bloodstream from the liver [6]. LBP then appears to aid LPS in docking with the LPS receptor complex by forming a ternary complex with CD14 thus enabling LPS to be

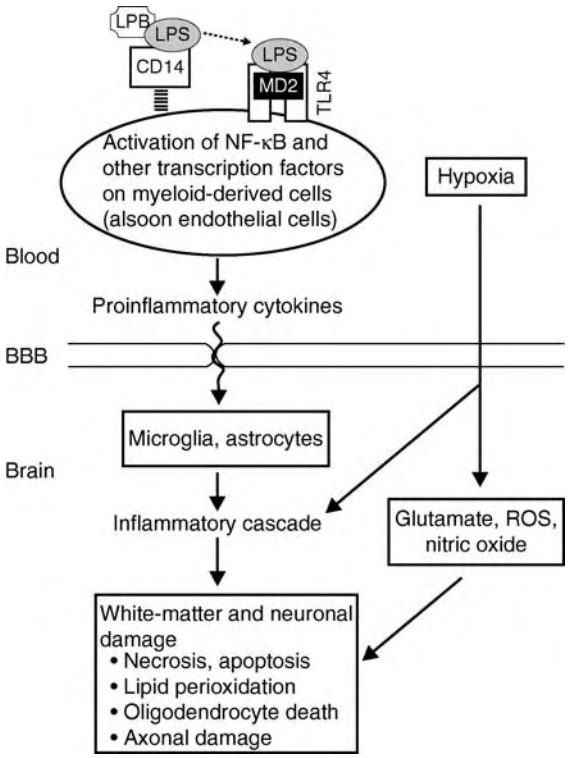
presented to the LPS receptor complex consisting of Toll-like receptor-4 (TLR4) and MD-2 an extracellular adaptor protein, on the surface of myeloid and other cells. Binding to the complex activates transmembrane signaling pathways (Fig. 1) which result in the activation of the transcription factor nuclear factor (NF)-κB, containing subunits p50 and p65 as homo-or heterodimers. NF-κB binding activity can be induced by changes in the intracellular redox status and LPS is known to be one of the most potent activators of this pathway. NF-κB is normally present in the cell cytoplasm forming an inactive complex with an inhibitor I-κBα. Following cellular activation, I-κBα is phosphorylated by I-κB kinase; its subsequent degradation by cytoplasmic proteases releases NF-κB which is translocated to the nucleus where it regulates transcription of several genes including cell adhesion molecules, metalloproteinases and the pro-inflammatory cytokines, IL-1β, IL-6 and TNF-α. For example TNF-α is elevated within 2 h of LPS exposure in the preterm ovine fetus (Fig. 2).

### Blood–Brain Barrier

Systemic cytokines (and LPS) can then bind to receptors on cerebral endothelial cells or periventricular cells initiating downstream signaling events which include an increase in prostaglandin synthesis and altered cGMP and nitric oxide levels. This results in increased blood–brain barrier (BBB) permeability for at least 24 h after LPS exposure particularly in white matter tracts; the exact molecular site within the blood vessels at which the leak to proteins occurs is not yet clear. Cytokines and proinflammatory substances can then pass into the brain activating microglia and



**Prenatal Brain Injury by Chronic Endotoxin Exposure. Figure 1** In response to proinflammatory cytokines, endotoxins or environmental stress, the nuclear factor (NF) -kB pathway is activated. NF-kB (containing subunits p50 and p 65) is normally present in the cytoplasm forming an inactive complex with inhibitory factor (IF-kB). Following cellular activation, IF-kB is phosphorylated and subsequently degraded by cytoplasmic proteases. This releases NF-kB which is translocated to the nucleus where it regulates the transcription of several genes including proinflammatory cytokines.

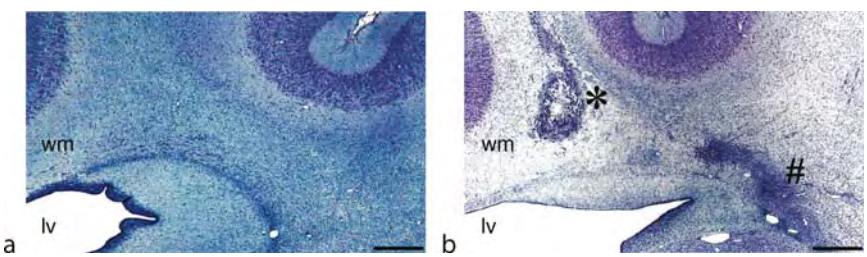


**Prenatal Brain Injury by Chronic Endotoxin Exposure. Figure 2** Possible activation of the inflammatory cascade by endotoxin (lipopolysaccharide, LPS). LPS binds to LPS binding protein (LBP) which then forms a ternary complex with CD14, enabling LPS to be presented to the LPS receptor complex consisting of Toll-like receptor 4 (TLR4) and MD-2. This activates NF-κB and other signaling pathways. Proinflammatory and other proteins are transcribed; they affect the permeability of the blood–brain barrier, perhaps via the up-regulation of prostaglandins, and allow the entry of proinflammatory substances and circulating leukocytes into the brain. Here there is activation of microglia and astrocytes to up-regulate cytokine production; this ultimately leads to white-matter and neuronal damage. If hypoxia is also involved, excess extracellular glutamate will result in further nitrosative and oxidative stress, exacerbating neuronal and axonal damage.

astrocytes to release cytokines, oxygen free radicals and other factors which will have multiple effects on the brain ranging from altered neuronal development to overt injury (Fig. 3). A recent microarray study in the LPS-exposed neonatal rat demonstrated altered gene expression of hundreds of inflammatory molecules and also cell-death associated molecules in the brain. In the adult brain, TLR4 receptors are found in regions devoid of the BBB namely the circumventricular organs (CVOs) and also the choroid plexus, meninges and scattered cells within the brain parenchyma. It has been postulated that LPS binds to TLR4 in the CVOs inducing an inflammatory reaction which is then disseminated throughout the brain. In the neonatal brain mRNA for CD14 receptors has been identified although their cellular distribution is not known.

### *Oxidative and Nitrosative Stress*

Reactive oxygen species (ROS) are toxic oxygen metabolites produced in small quantities during the normal cellular metabolic processes in mitochondria via univalent reduction of molecular oxygen. In response to stimuli, including an imbalance in the cellular redox status, the formation of ROS increases dramatically. ROS interact with the lipid components of cell membranes, initiating lipid peroxidation resulting in the breakdown of lipid constituents into highly reactive by-products including lipid aldehydes, for example 4-hydroxynonenal (4-HNE). These reactive aldehydes then bind to and modify protein creating protein adducts. In addition to oxidative stress, nitrosative stress results from nitric oxide (NO) released from reactive microglia reacting with superoxide anions to form peroxynitrite which targets tyrosine residues of proteins to form nitrotyrosine residues. Both of these processes are highly damaging to cell membranes. Lipid peroxidation of membranes can occur in the cerebral hemispheres within 6 h of LPS exposure in the ovine fetus [7]. The major antioxidant defence system that prevents the intracellular accumulation of ROS is the glutathione system. Reduced glutathione (GSH) acts as both a free radical scavenger and as a substrate in the GSH redox cycle. During late



**Prenatal Brain Injury by Chronic Endotoxin Exposure. Figure 3** Section of the cerebral hemispheres from control (a) and LPS-exposed (b) fetal sheep at 70% of gestation (term ~147 days). P

gestation, there are marked increases in the antioxidant protective capacity. The combination of an immature defence system, LPS challenge and localized oxidative and nitrosative stress exposes the fetal brain to a high risk of ROS-mediated tissue injury.

### Glial Response

Within the preterm ovine and rat brain activation of microglia is the most prominent glial response after LPS exposure; there is a significant correlation between the intensity of microglial/macrophage invasion and the extent of white matter injury indicating a substantial role for microglial activation in the manifestation of and/or response to injury [4,5]. Currently it is not certain whether these cells are mainly microglia already resident in the brain or macrophages invading from the circulation. Of interest is the recent suggestion that the high density of activated microglia in the white matter during normal fetal human brain development might potentially prime this area for diverse brain insults characterized by the activation of microglia; this also appears to be the case in the ovine and rodent fetus.

### Axonal Injury

This could occur as a result of increased glutamate levels in the extracellular space induced by cytokine activation of glutamate–containing astrocytes and the subsequent activation of glutamate receptors on oligodendrocytes or the myelin sheath itself causing a toxic influx of $Ca^{2+}$. Excess $Ca^{2+}$ will likely cause disruption to mitochondrial function and damage to the structural integrity of the axon. During the peak gestational age for white matter damage, developing oligodendrocytes (preoligodendrocytes) predominate [8]. The basis for this maturational susceptibility could be related to preferential vulnerability to free radicals, cytokines, glutamate toxicity or a mismatch of antioxidant enzymes and a subsequent imbalance of oxidative metabolism.

### NF-kB Activation in the Brain

Within the brain the role of NF-κB in neuronal survival is controversial with studies supporting both a neurodestructive or neuroprotective role, the latter possibly by upregulation of anti-apoptotic genes [9]. Perhaps this dichotomy is due to differences in stages of neuronal development, different monomeric composition, degrees of NF-κB activation or different combinations of cellular stimuli. It has been suggested that activation of NF-κB in neurons might protect them against degeneration whereas activation in microglia promotes neuronal degeneration via cytokine production [9]. Chronic systemic administration of LPS in the ovine fetus leads to increased binding activity of NF-kB subunits in specific regions of the fetal brain and placenta within 6 h of exposure [7]. There was no clear-cut relationship however between alterations in levels of NF-kB and the vulnerability to endotoxic damage. In the cerebral hemispheres where damage occurs NF-κB was not upregulated whereas in the hippocampus where damage does not occur NF-kB was elevated. Clearly the activation of NF-κB can result in several downstream signaling pathways and an upregulation does not necessarily signal that brain damage will ensue. Therefore blocking NF-κB transcription might not be a means of protecting against brain injury.

## Higher Level Processes

Cerebral white matter injury resulting from ►chronic endotoxin exposure in the prenatal brain (►prenatal brain injury (PBI)) is likely to have consequences on the overlying cortex; the cell bodies associated with damaged cortical efferent axons are likely to die. Cortical neurons in layers 5 and 6 demonstrate an upregulation of beta amyloid precursor protein (a marker of cellular stress) after chronic LPS exposure not only in regions of overt white matter damage as might be expected, but also in adjacent gyri. This suggests that chronic endotoxin exposure also induces damage to cortical neurons either directly or secondarily to sensory deafferentation. Progressive post-injury reorganization of the undamaged cerebral cortex will play a role in the underlying mechanisms of ensuing neurological sequelae. It is becoming increasingly recognized in human MRI studies of premature infants that subtle alterations in cerebral structure are common, particularly in the extremely immature infant. Effects of LPS on other aspects of development such as neurogenesis remains to be elucidated.

### Interaction Between Inflammation and Hypoxemia

Elucidating the mechanisms involved in inflammatory–induced brain injury is made more complex by the observation that inflammation can interrupt hemodynamic stability and that activation of inflammatory pathways is involved in the neural responses to hypoxia/ischemia. In animal models the inflammatory cascade and associated brain damage appears to be exacerbated if cerebral oxygen delivery is also reduced. LPS administered in repeat bolus doses at 70% of gestation results in fetal hypoxemia, hypotension, acidemia and associated brain damage in the ovine fetus [4]. A chronic infusion of the same or higher total dose of LPS does not result in significant alterations in fetal physiology but does cause brain injury, which is not as severe as when accompanied by hypoxemia [5]. Furthermore, endotoxin has been shown to sensitize the immature brain to hypoxic-ischemic injury [10]. In human pregnancies where intrauterine inflammation is accompanied by fetal asphyxia, there appears to be a significant increase in the risk of cerebral palsy.

Thus there are likely to be synergistic pathways between hypoxia and infection/inflammation which potentiate the evolution of brain damage although it is evident that inflammation alone can indeed cause fetal brain injury. It is possible that infection could impair oxygen delivery to the fetal brain via effects on gas exchange in the placenta. Histologic chorioamnionitis when compounded with a placental perfusion defect has been shown to enhance the risk of abnormal neurologic outcome in extremely low birth weight infants.

### Function

It is likely that altered brain structure and white matter lesions resulting from ►brain inflammation will have long term consequences for brain development and function, including cognition, behavioral and motor abilities. Inflammation might also have long term effects on autonomic and neuroendocrine responses, including the manifestation of fever. It has recently been shown that neonatal exposure to LPS attenuates the febrile and CNS neurochemical responses to an LPS challenge in later life; this might equate to an altered ability to combat diseases after birth.

## Presynaptic Inhibition

Jorge N. Quevedo
Department of Physiology, Biophysics and Neuroscience, Centro de Investigación y de Estudios Avanzados del I.P.N, Mexico City, Mexico

### Synonyms

Decrease of synaptic effectiveness

### Definition

Presynaptic inhibition (PSI) refers to a decrease of transmitter release at central synapses. Five decades ago, it was reported that activation of afferent fibers originating in flexors led to depression of monosynaptic group Ia ►excitatory postsynaptic potentials (EPSPs) evoked on extensor motoneurones in the cat spinal cord [1]. This depression occurred with no detectable changes in the time course of monosynaptic EPSPs, membrane potential or motoneurone excitability [1,2]. It is now known that PSI occurs broadly within the central nervous system of both vertebrates and invertebrates, and that synaptic efficacy at axon terminals from sensory afferents, descending systems or interneurones [3] can be subject to an inhibitory control by a number of neurotransmitters and presynaptic receptors [4].

### Characteristics

#### PSI Associated with Primary Afferent Depolarization (PAD)

##### *PAD as a Measure of PSI in the Spinal Cord*

Stimulation of sensory nerves produces a slow negative potential recorded in dorsal roots via depolarization of intraspinal terminals of afferent fibers. This depolarization, termed ►primary afferent depolarization (PAD), is electrotonically propagated to the dorsal roots and can be recorded as a ►dorsal root potential (DRP). It can also be recorded intra-axonally in the dorsal horn. When the intra-axonal membrane potential produced by PAD reaches firing threshold, back-propagating action potentials are seen, and are called ►dorsal root reflexes (DRRs). Owing to the parallel time course of PSI and PAD, it has been assumed that PAD is responsible for PSI and that both phenomena are mediated by the same mechanisms [2,3].

##### *Mechanisms Involved in the Generation of PAD*

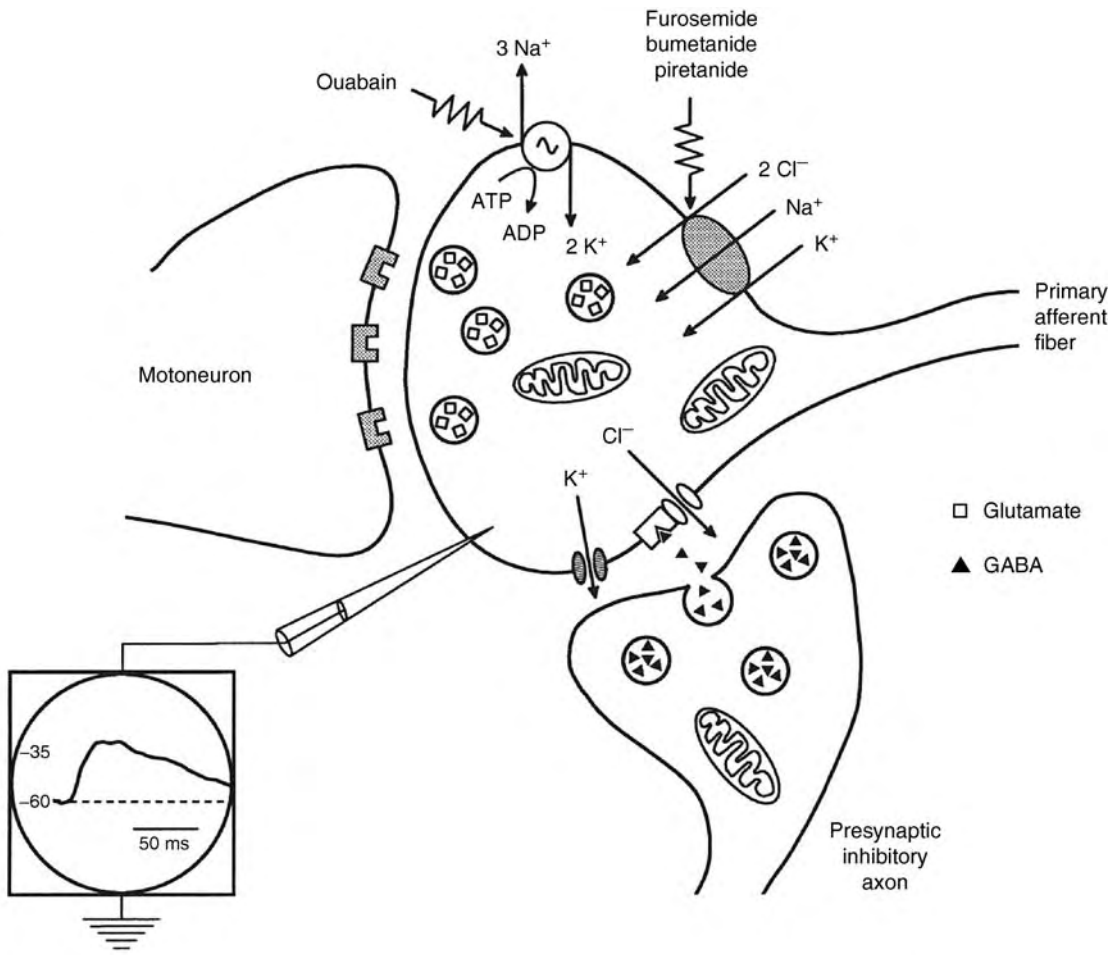
Pharmacological and electrophysiological studies have lead to the conclusion that PAD is primarily mediated by last-order GABAergic interneurones, and generated by the activation of presynaptic ionotropic $GABA_A$ receptors [2,3]. $GABA_A$ receptors are $Cl^-$-permeable, and their activation drives the membrane potential towards the $Cl^-$ reversal potential. Because a $Na^+$, $K^+$, 2-$Cl^-$ cotransporter (NKCC1) maintains the $Cl^-$ reversal

potential less negative than the membrane potential, $GABA_A$ receptor activation leads to an efflux of $Cl^-$ ions and consequent depolarization of afferent terminals, i.e. PAD (Fig. 1) [4]. The increase in $Cl^-$ conductance reduces transmitter release by inactivation of voltage-gated $Na^+$ and $Ca^{2+}$ channels, or by shunting the membrane current to prevent spike invasion into the axon terminals [3]. The depolarization produced by activation of $GABA_A$ receptors can also enhance spontaneous transmitter release in the dorsal horn neurons by activating voltage-gated $Ca^{2+}$ channels [5].

### Interneurones Mediating PAD

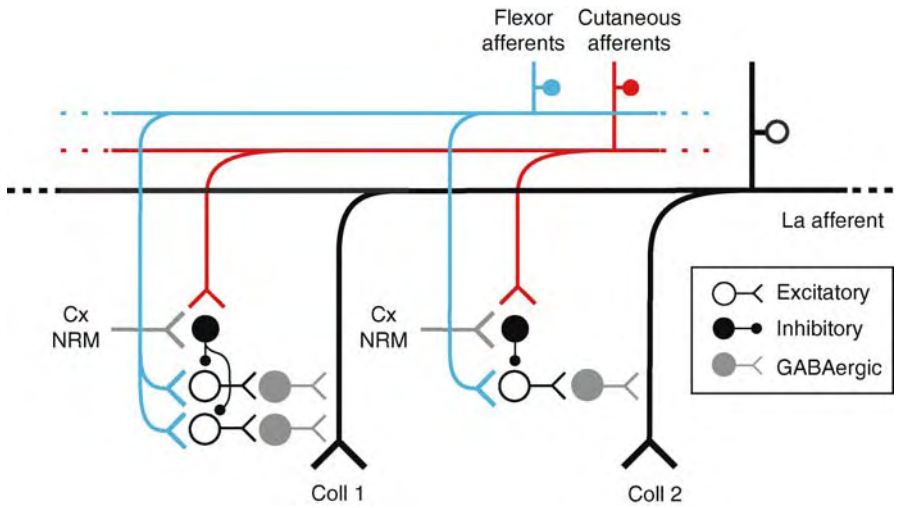
There is clear anatomical evidence for the existence of GABAergic axo-axonic synapses on ►muscle spindle group Ia and II, muscle ►Golgi tendon organ group Ib, and large diameter cutaneous afferents. However, a direct identification of interneurones mediating PAD is still lacking [3]. In addition to activation of conventional interneuronal circuits, PAD on myelinated and unmyelinated cutaneous afferents may be also accounted for by non-spiking microcircuits that involve dendroaxonic GABAergic contacts or GABA spill-over [6].

The shortest pathway mediating PAD of group I, group II and large diameter cutaneous afferents fibers is thought to be trisynaptic (Fig. 2), including first order excitatory and last-order GABAergic interneurones interposed [2,3]. The long duration of PAD (Fig. 1), suggests that last-order interneurones mediating PAD produce a prolonged burst of spikes following a brief afferent input. However, since a single interneurone spike is able to generate a similarly long-lasting DRP,



**Presynaptic Inhibition. Figure 1** Schematic representation of a presynaptic inhibitory axon from a GABAergic interneurone contacting a primary afferent fiber. The activation of $GABA_A$ receptors present on afferent terminals drives the membrane potential towards the $Cl^-$ reversal potential. Because a $Na^+$, $K^+$, 2-$Cl^-$ cotransporter maintains the $Cl^-$ reversal potential less negative than the membrane potential, $GABA_A$ receptor activation leads to an efflux of $Cl^-$ ions and consequent depolarization of afferent terminals (i.e. PAD). This depolarization could be recorded theoretically by a microelectrode inserted in the terminal of the primary afferent. $Na^+$ concentration inside the terminal is regulated by the $Na^+$-$K^+$-ATPase pump. Several drugs that can inhibit the cotransporter are indicated. (From [4]).

P



**Presynaptic Inhibition. Figure 2** Schematic diagram illustrating the local character of primary afferent depolarization (PAD) in collaterals of a single muscle spindle (Ia) afferent (*black lines*) ending at two different spinal levels. PAD produced by stimulation of flexor afferents (*blue lines*) is mediated by at least two interneurones interposed. First-order and last-order interneurones are excitatory (*open circles*) and GABAergic (*gray circles*), respectively. PAD evoked in collateral 1 (Coll 1) and collateral 2 (Coll 2) is mediated by separate sets and number of interneurones. PAD evoked by stimulation of flexor afferents in each collateral is reduced by stimulation of cutaneous (*red lines*), and the corticospinal (Cx) and raphespinal (NRM) (*gray lines*) systems via different sets of inhibitory interneurones (*black circles*). From [7].

PAD may be due to slow kinetics of GABA release, action, or uptake [3].

Interneurones mediating PAD are spatially segregated in the spinal cord, generally located in regions corresponding to the termination sites of the various afferent modalities. PAD of cutaneous and group I muscle afferent fibers is mediated by interneurones located in the middle and lateral parts of Rexed laminae III-IV, and medial Rexed laminae V-VI, respectively. PAD of group II afferents is produced by separated sets of interneurones into dorsal horn and intermediate zone, and the PAD of group II afferents seen in mid-lumbar and sacral spinal segments is also mediated by distinct populations of interneurones [3,8].

## Organization of Pathways Mediating PAD

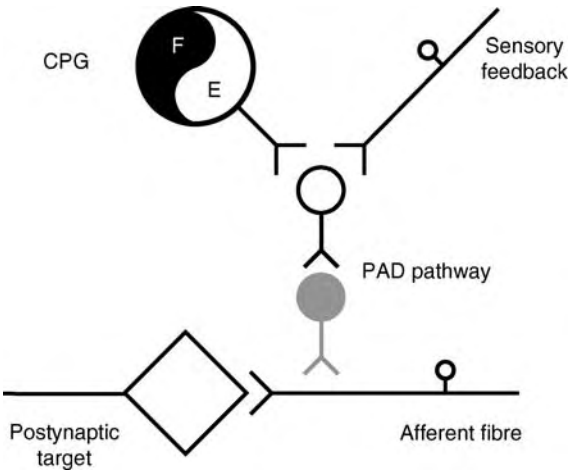
The patterns of PAD evoked by stimulation of sensory and supraspinal inputs differ for each afferent modality, suggesting that interneuronal pathways mediating PAD are modulated in a rather selective and complex manner. However, a primary mechanism of recruitment of PAD appears associated with a negative feedback control of their activated afferents.

### Muscle Afferents

PAD of Ia afferents is most effectively produced by stimulation of group Ia and group Ib flexor afferents, and vestibulospinal inputs; it is also inhibited by stimulation of various supraspinal (corticospinal, rubrospinal, reticulospinal and raphespinal serotonergic systems) and peripheral systems (large cutaneous and joint afferents) (Fig. 2). PAD of group Ib afferents occurs predominantly following activation of group Ib afferents from flexors and extensors, joint, and large cutaneous afferents (but may also be inhibited by these cutaneous afferents). In contrast to PAD of group Ia afferents, PAD of group Ib afferents is evoked by corticospinal, reticulospinal and raphespinal serotonergic systems, and also by the noradrenergic nucleus locus coeruleus, cerebellum and the vestibulospinal tract [3].

The different patterns of PAD of group Ia and group Ib afferent fibers produced by segmental and supraspinal inputs suggest that PAD is mediated by different sets of last-order GABAergic interneurones. Yet PAD of group I muscle afferents can be modulated differentially in afferent fibers ending at two separate spinal levels, or even in proximal collaterals of the same afferent fiber (Fig. 3). This local character of PAD is likely due to the activation of different sets of interneurons mediating PAD [3,7].

PAD of group II afferents is generally evoked by stimulation of group II, cutaneous, joint and pudendal afferents, as well as by the noradrenergic locus coeruleus and serotonergic raphespinal systems. It is most effectively evoked by group II afferents ending at the same spinal sacral or midlumbar segment. This implies that separate populations of interneurones mediate PAD of group II affetents projecting to these segments. PAD of group II afferents is generally stronger than PAD of group I afferents, indicating that PAD of group I and group II afferents is mediated by different sets of interneurons [3,8].



**Presynaptic Inhibition. Figure 3** Diagram of systems modulating presynaptic inhibitory pathways during locomotion. Synaptic transmission from afferent fibers to postsynaptic targets (open diamond) is modulated by PAD-related PSI mechanisms. Inputs from the locomotor pattern generator (CPG) circuitry and the sensory feedback from limbs in movement modulate PAD pathways, which are mediated by first-order excitatory (open circles) and last-order GABAergic (gray circles) interneurones. PAD-related PSI mechanisms participate in shaping motor pattern activity to adapt movement limbs to the environment. Adapted from [9].

### *Cutaneous Afferents*

PAD of low threshold cutaneous afferents is produced by stimulation of low threshold cutaneous, group Ib, group II, and high threshold muscle afferents, as well as by stimulation of corticospinal, reticulospinal, rubrospinal and the raphespinal serotonergic system. PAD of low threshold cutaneous afferents is larger in response to activation of their specific afferent modality (e.g. rapidly-adapting vs. slowly adapting). Therefore, PAD of low threshold cutaneous afferents plays an important role in sensory discrimination by enhancing contrast and eliminating surplus excitation. High threshold cutaneous afferents (Aδ and C) are more effectively depolarized by noxious stimulation, as well as by stimulation of reticulospinal and raphespinal serotonergic systems [3]. However, because of the scarcity of axo-axonic GABAergic contacts on Aδ and C fibers, spillover mechanisms may be involved in the generation of PAD in these fibers [3,6].

## PAD Evoked by Non-GABAergic Mechanisms

The accumulation of $K^+$ ions in the extracellular space following activation of spinal interneurones was proposed as a mechanism to explain PAD. However, changes in extracellular $K^+$ cannot account for all of the characteristics of PAD associated with stimulation of peripheral nerves or supraspinal pathways [3].

In addition to $GABA_A$ receptors, primary afferents contain a diversity of receptors whose activation can evoke depolarization of terminals and in consequence PSI. Stimulation of high threshold afferent fibers evokes DRPs including a large component evoked by activation of NMDA and AMPA/kainate ionotropic glutamate receptors [6]. Activation of presynaptic AMPA and kainate receptors depresses excitatory transmission in dorsal horn neurons, but increases spontaneous transmitter release, both kinds of effects being apparently produced by PAD [5]. Capsaicin depresses excitatory synaptic transmission evoked by stimulation of C afferent fibers and this depression is also related to PAD [5].

The spinal cord receives diffuse projections from several descending monoaminergic nuclei that modulate PAD pathways. For instance, stimulation of the serotonergic nucleus raphe magnus produces PAD on group Ib afferent fibers [3]. However, because iontophoretic application of serotonin and noradrenaline produces no change in the intraspinal threshold of group I afferents, it is unlikely that PAD occurs by a direct effect of these monoamines on afferent fibers [3].

Stimulation of the noradrenergic locus coeruleus and the serotonergic raphe nucleus produces PAD on group II afferent fibers associated with a concomitant depression of synaptic transmission of the same afferents, suggesting participation of a presynaptic inhibitory mechanism. Nevertheless, the decrease in transmitter release appears not to be mediated by direct actions of monoamines on group II afferents, but indirectly via modulation of the interneuronal pathways mediating PAD [3,8].

Localization of serotonin and noradrenaline receptor subtypes is apparently restricted to high threshold cutaneous afferents [3,8]. Indeed, Aδ and C fibers are depolarized by direct application of serotonin, yet there is no clear association between PAD and decrease in synaptic effectiveness of these afferents [3].

## PSI not Associated with PAD

While PAD is generated predominantly by the activation of $GABA_A$ receptors, it is well known that activation of presynaptic G-protein coupled receptors, such as $GABA_B$, can lead to PSI. This type of PSI is linked to intracellular signaling pathways that inhibit voltage-gated $Ca^{2+}$ channels, with no associated presynaptic depolarization. Moreover, in contrast to the activation of $GABA_A$ receptors, activation of $GABA_B$ receptors produces a longer-lasting component of inhibition of the monosynaptic EPSPs [3].

Activation of metabotropic adenosine and cannabinoid receptors also inhibits transmitter release by inhibition of voltage-gated $Ca^{2+}$ channels coupled to G-protein receptors [5]. The inhibitory effects of monoamines on the synaptic efficacy of high threshold cutaneous afferents may be also produced by activation

of metabotropic receptor subtypes coupled to signal transduction pathways [3,8].

A long-lasting inhibition of the monosynaptic reflex has been associated with a ►homosynaptic depression of the synapse between group Ia afferents and motoneurones. This depression also occurs in the absence of changes in motoneurone excitability and results from postactivation transmitter depletion [3].

### PSI and Function

PSI pathways are modulated during real and fictive motor behaviors. During ►fictive locomotion (i.e. in the absence of sensory information), there is a tonic PAD accompanied by an overall synaptic depression of group I, group II and cutaneous afferents. Depression of group I afferent transmission is associated with the reductions in gain of stretch reflexes and the H-reflex observed at the onset of locomotion in humans. Superimposed on the tonic PAD, there are phase-dependent fluctuations of the membrane potential in group I, group II and cutaneous afferents, with more depolarization during the flexion phase. Synaptic transmission from group I, group II and cutaneous afferents also displays a phase-dependent modulation during fictive locomotion. However, unlike the synaptic depression observed during tonic PAD, phase-dependent PAD is not correlated with a depression of synaptic transition from Ia afferents onto motoneurones. Both tonic and phase-dependent oscillations of PAD are mediated by as yet unknown mechanisms [9].

PAD evoked by stimulation of sensory afferents is also rhythmically modulated during fictive locomotion, suggesting that the locomotors central pattern generator (CPG) circuitry has access to the pathways mediating PAD (Fig. 3). The pattern of modulation of sensory evoked-PAD is complex and appears to depend more on the specific postsynaptic targets than on the peripheral origin of the afferents. During real as opposed to fictive locomotion, the patterns of PAD depend on interactions between supraspinal, sensory feedback and CPG inputs on pathways mediating PAD. PAD-related PSI mechanisms play an important role during patterning generation and contribute in shaping motor pattern activity to adapt limb movements to the environment [9].

During voluntary muscle contractions in humans there is a decrease of PSI of afferent terminals contacting the active motoneurone pools and a concomitant enhancement of PSI of afferent terminals ending on inactive motoneurone pools. These observations indicate that corticospinal control of PSI selectively "opens" transmission in group Ia afferents to voluntarily activated motoneurones, while "closing" transmission to motoneurones of relaxed muscles [10]. Findings in humans are supported by studies in the cat showing that different collaterals of the same afferent fiber are selectively controlled by separate sets of last-order interneurones mediating PAD (Fig. 2) [8]. The differential PAD-related PSI of individual collaterals of muscle afferents allows a selective control of sensory information according to the neuronal targets and to the motor task to be performed [8,10].

## Presynaptic Proteins

Michael Seagar
INSERM/Université de la Méditerranée, UMR641, Faculté de Médecine Nord, Marseille, France

### Definition

Proteins that participate in neurotransmission by ensuring functions specific to the presynaptic compartment (i.e., nerve terminals). Typically, these proteins control the progression of synaptic vesicles through the steps (docking, priming, vesicle fusion) that lead up to the release of neurotransmitters into the synaptic cleft.

## Characteristics

Nerve terminals concentrate neurotransmitters in synaptic vesicles. Neurotransmitter release into the synaptic cleft then occurs when $Ca^{2+}$ influx triggers the fusion of these vesicles with the presynaptic plasma membrane. However, only a small fraction of the total vesicle population within a nerve terminal is available to respond to the $Ca^{2+}$ signal [1]. The presynaptic proteins described in this section, control transmitter release by holding vesicles in reserve or alternatively preparing and then accomplishing fusion.

### Synaptic SNARE Proteins and SNARE Complexes

Vesicle fusion involves assembly of *trans* ►SNARE complexes at the interface between a docked synaptic vesicle and the plasma membrane, a process that pulls the opposing membranes together. These *trans* complexes contain three proteins: one vesicle protein, the vesicular- or v-SNARE VAMP 2 (also known as ►synaptobrevin) and two plasma membrane proteins, the target- or t-SNAREs: ►syntaxin 1 and ►SNAP-25 [1,2]. VAMP and syntaxin have a similar topology with membrane anchors at their C-terminal extremities and the N-termini orientated towards the cytoplasm. SNAP-25 is attached to the membrane via palmitoylation of amino acids located in the middle of the sequence, thus both its N- and C-termini are cytoplasmic. SNARE proteins carry a characteristic 70 amino acid sequence, the SNARE motif. This sequence mediates the interactions with partner SNAREs to form complexes [3]. SNAP-25 has two SNARE motifs while VAMP and syntaxin have only one each.

The N-terminal portion of syntaxin constitutes an auto-inhibitory domain, which folds back to interact with and mask the membrane-proximal helical (H3) domain containing the SNARE motif. In this "closed" conformation, syntaxin cannot bind to SNAP-25 and VAMP. When syntaxin "opens," four SNARE motifs (1 from VAMP, 1 from syntaxin, 2 from SNAP-25) can assemble into a four-helical bundle forming the SNARE complex. In this bundle, the alpha helices are in a parallel orientation with all the N-termini at one end and all the C-termini at the other. Zipping-up of the complex, starting at the N-termini and progressing towards the C-termini pulls the C-terminal membrane anchors of v- and t-SNAREs, and consequently the vesicular and plasma membranes, towards each other. This leads to mixing of the outer lipid leaflet of the vesicle with the inner leaflet of the plasma membrane, and can then progress to full fusion upon $Ca^{2+}$ influx. However, the SNARE proteins themselves do not directly bind $Ca^{2+}$. The fusion machine probably comprises of a radial array of SNARE complexes at the synaptic vesicle/plasma membrane interface, associated with $Ca^{2+}$-sensor proteins such as the synaptotagmins that confer $Ca^{2+}$-dependency on the release process.

The synaptic SNARE proteins are the targets of botulinum neurotoxins (of which there are seven distinct types: BoNT/A to G) and tetanus neurotoxin (TeNT) [4]. These extremely potent toxins inhibit transmitter release by introducing their light chains into the nerve terminal cytoplasm. The light chains are metalloproteases that specifically cleave synaptic SNAREs at defined peptide bonds (e.g., BoNT/B & TeNT - VAMP2, BoNT/A & E - SNAP-25, BoNT/C - syntaxin 1). BoNTs and TeNT do not affect vesicle docking but block synaptic vesicle fusion by a selective proteolytic attack on the fusion machine.

In addition to driving membrane fusion, *trans* v-SNARE/t-SNARE pairing may also contribute to proofreading, ensuring that vesicles can only fuse with the appropriate target membrane. Families of SNAREs have been identified in many other subcellular compartments in a variety of eukaryotic cells. Vesicular transport thus uses the same basic fusion machinery, conserved through evolution from yeast to human nerve terminals.

Presynaptic proteins include several molecules that bind to SNARE proteins and regulate the assembly of SNARE complexes.

#### *Munc-18*

►Munc-18 (also called nsec1 or rbsec1 in mammals) is a 67 kDa hydrophilic protein, which associates with nerve terminal membranes via it's interaction with syntaxin 1. Munc-18 genes are the mouse members of the SM (Sec1/Munc-18) gene family, which includes yeast Sec1 and the nematode and drosophila orthologues Unc-18 and Rop [5]. The precise mode of action of Munc18 is unknown. Munc-18 binds tightly to the "closed" conformation of syntaxin 1 preventing SNARE complex assembly in vitro, but it is not simply a negative regulator of vesicle fusion. Genetic manipulations that decrease SM protein levels generally diminish secretion, consistent with the notion that these proteins are required for fusion. Yeast *SEC1* was initially identified as a gene required for exocytosis. However, in contrast to Munc-18, sec1p does not bind to monomeric yeast syntaxins but only to assembled SNARE complexes. SM proteins may act as chaperones to favor SNARE complex formation. Thus, although Munc-18 binds to "closed" syntaxin, it might, in concert with additional factors, be involved in opening it and thus participate in priming. Munc-18 binds to additional presynaptic proteins including the Munc interacting proteins (Mint 1 and 2). Mints link the vesicle fusion apparatus to adhesive proteins in the presynaptic plasma membrane that are involved in establishing synaptic connections.

#### *Munc-13*

►Munc-13 proteins constitute a family of three high molecular weight (200 kDa) molecules. Munc13–1 and

Munc13–3 are brain specific, while Munc13–2 is ubiquitous. At the N-terminal extremity, Munc-13 contains a conserved $Ca^{2+}$-dependent calmodulin binding site followed by a C1 motif, which binds the lipid messenger diacylglycerol, and two C2 domains [6,7]. Munc-13 (Unc-13 in the nematode) is involved in synaptic vesicle priming. Gene deletions in both mice and nematodes principally affect the readily releasable pool of synaptic vesicles. Munc-13 probably acts by binding to the auto-inhibitory N-terminal domain of syntaxin 1. In the nematode Unc13 displaces Unc-18, which is bound to the closed state of syntaxin. Furthermore, expression of mutant syntaxin, frozen in a permanently open conformation, rescues worms with an Unc-13 mutation. Thus, munc-13 appears to act downstream of munc-18 by driving syntaxin from a closed to an open conformation. Regulation of Munc-13 action via $Ca^{2+}$/calmodulin or diacylglycerol binding has been implicated in presynaptic plasticity.

### Synaptophysin

►Synaptophysin was the first synaptic vesicle membrane protein to be isolated and cloned [8]. It is a major component of synaptic vesicles, thus anti-synaptophysin antibodies are widely used in immunocytochemistry to identify nerve terminals, and to evaluate diagnostically the neuroendocrine phenotype of a variety of tumors. Synaptophysin is an N-glycosylated 38 kDa protein. Like its homologue physins, synaptoporin, pantophysin and mitsugumin 29, it contains four membrane-spanning segments with N- and C-termini orientated towards the cytoplasm. It is the major cholesterol-binding protein in synaptic vesicles, and may contribute to the induction of vesicle curvature during vesicle biogenesis. Synaptophysin forms a complex in the vesicle membrane with the v-SNARE VAMP and subunits of the vacuolar proton pump (V-ATPase). The synaptophysin – VAMP2 complex prevents VAMP from entering into SNARE complex assembly. It thus constitutes an additional molecular mechanism for regulating transmitter release by determining v-SNARE availability. The amount of VAMP sequestered by synaptophysin is modulated by neuronal activity, indicating that it is functionally implicated in plasticity. However, deletion of the synaptophysin gene in mice does not result in a significant phenotype, which may reflect compensation by other members of the physin family. Mice that lack both synaptophysin and the structurally related tetraspan vesicle protein synaptogyrin do display defects in synaptic plasticity.

Additional presynaptic proteins mediate interactions of synaptic vesicles with the cytoskeletal elements. In this way, they seem to retain vesicles in a reserve pool that does not participate in regular vesicle exo-endocytotic recycling, unless mobilized by intense stimulation.

### Synapsins
