# Preface

Neuroscience is a rapidly expanding endeavor devoted to unraveling the structure and function of the nervous system. It relies on, and keeps close relations to, a number of other disciplines, such as mathematics, physics, chemistry, engineering, computer science, genetics, molecular biology, biochemistry, medicine and philosophy. Indeed, many of its recent successes result from the application of ideas, concepts and methods borrowed from these fields. Thus, neuroscience has become the archetype for interdisciplinary undertakings. This convergence of influences accounts for part of its enormous attractiveness and fascination to students, researchers and lay persons from various walks of life or science. Many of neuroscience's most creative and productive investigators have been lured into the field not only by the excitement inherent in the possibility of uncovering the secrets of the human mind, but by the appeal of venturing into a vast unknown land, requiring the development of new tools for its effective cultivation. Far from simply satisfying our intellectual curiosity, however, neuroscience has become ever more important as a theoretical ground for practical applications in medicine, in particular neurology, and other disciplines.

The explosion of neuroscience has made it virtually impossible for individuals to follow all the ramifications and fast developments in the many corners and branches of this science. This *Encyclopedia* has therefore been designed for a wide variety of readers, from members of the lay public to students, practitioners and researchers in biology, medicine, psychology, sociology, philosophy and their associated auxiliary fields. Moreover, it should also prove useful to advanced researchers of biology and neuroscience who wish to stay abreast of current developments outside their immediate areas of expertise.

In the interest of rapid and convenient access to information, this *Encyclopedia* has adopted a new format. The entire complex of neuroscience has been divided into 38 subject fields organized and surveyed by associated Field Editors. Entries, which are in alphabetical order for rapid localization, are of three type: (1) simple and relatively brief definitions and explanations (glossary entries), (2) structured "essays" of a few pages to provide coherent treatments of particularly important topics, and (3) synopses written by the Field Editors as larger overviews of their fields with links to the essays in their field. Extensive cross-references to definitions and essays serve to lead the reader to additional sources of information.

This *Encyclopedia* is available as a print version (5 volumes, more than 4,500 pages, 6,500 entries and 1,000 illustrations), an eReference version (online version), and as a bundle (print plus online) version.

Thanks are due to a vast number of people who have made this ambitious endeavor possible. First and foremost, we are extremely grateful to our 46 Field Editors who accepted the arduous challenge of organizing their fields, soliciting essays and glossary terms from expert authors, editing the submitted texts, and finally writing their own synopses. Second, many thanks also go to our nearly 1,000 authors who wrote essays and glossary terms. Third, Drs. Thomas Mager, Natasja Sheriff, Michaela Bilic and Jana Simniok of Springer-Verlag investigated much effort, initiative, patience and enthusiasm (at times interrupted by outbursts of frustration) into initiating, administering, pushing ahead and keeping alive this project. Many thanks are due to the numerous unnamed support staff in the background: secretaries, copy editors, computer and graphics specialists at *Springer*.

Marc D. Binder (Seattle)
Nobutaka Hirokawa (Tokyo)
Uwe Windhorst (Göttingen)

## Editor-in-Chief

Marc D. Binder
Department of Physiology & Biophysics
University of Washington School of Medicine
Seattle, Washington, USA
mdbinder@u.washington.edu

Nobutaka Hirokawa
Department of Cell Biology and Anatomy
Graduate School of Medicine
University of Tokyo
Hongo, Bunkyo-ku, Tokyo, Japan
hirokawa@m.u-tokyo.ac.jp

Uwe Windhorst
Göttingen, Germany
siggi.uwe@t-online.de

## Conceptual Editor

Martin C. Hirsch
iAS interActive Systems,
Marburg, Germany
martin.hirsch@brainmedia.de

## Section Editors

### Autonomic and Enteric Nervous System

Akio Sato
(deceased)
University of Human Arts and Sciences
Saitama, Japan

Brian Budgell
Departement de Chiropratique
Universite du Quebec a Trois-Rivieres
Quebec, Canada
budgell@uqtr.ca

Sae Uchida
Department of the Autonomic Nervous System
Tokyo Metropolitan Institute of Gerontology
Tokyo, Japan
suchida@tmig.or.jp

### Behavior

Hermann Wagner
Institut für Biologie II
RWTH Aachen
Aachen, Germany
wagner@bio2.rwth-aachen.de

### Biological Rhythms and Sleep

Martha U. Gillette
Molecular and Integrative Physiology, and
Neuroscience Program
Institute for Genomic Biology University of Illinois at
Urbana-Champaign
Urbana, IL, USA
mgillett@uiuc.edu

### Biomechanics

Walter Herzog
Faculty of Kinesiology
Human Performance Lab University of Calgary
Calgary, AB, Canada
walter@kin.ucalgary.ca

### Central Vision

Uwe Windhorst
Göttingen, Germany

## 3 Splice

**Definition**
One edge of the splicing reaction.

►Alternative Splicing and Glial Maturation

## 5 Untranslated Region (5 UTR)

**Definition**
The 5 region of the mRNA that is not translated into protein. It extends from the transcription start site to the translation ATG start site, and contains regulatory sequences that control mRNA stability and translation efficiency.

## 14-3-3

**Definition**
A large family of acidic adaptor proteins of ~30 kDa that mainly (but not solely) interact with phosphoserine or -threonine sites on target proteins to facilitate their activity. 14-3-3 proteins have 9–10 alpha helices, generally form homo- or heterodimers, and contain a number of common modification sites (e.g. phosphorylation, divalent cation binding, and so forth) to regulate their activities, interactions, and localizations.

►Synaptic Proteins and Regulated Exocytosis

## 65-kDa Synaptic Vesicle Protein

►Calcium Binding Proteins

## 2074v Alpha1-Beta1 and Alpha6-Beta1-Integrin

**Definition**
Integrins are a family of alpha-beta-heterodimers, comprising of different beta chains that associate with different alpha chains. Integrins primarily mediate cell adhesion and recognize a variety of ligands including extracellular matrix proteins, cell surface proteins and plasma proteins.

## A1-A7 Cell Groups (Noradrenergic Cell Groups)

**Definition**
A1-A7 is the original designation for separate catecholamine cell groups located in the brainstem by the use of fluorescent histochemical methods. The numbering began in the medulla and continued into the forebrain. Groups A1-A7 are located only in the medulla, and are noradrenergic.

►Cellulae noradrenergicae/A1 – A7

## A8-A17 Cell Groups (Dopaminergic Cell Groups)

### Definition

A1-A17 is the original designation for separate catecholamine cell groups located in the brain by the use of fluorescent histochemical methods. The numbering began in the medulla and continued into the forebrain. Groups A8-A16 are dopaminergic, and reside primarily in the midbrain and hypothalamus. Another dopaminergic cell type, A17, appears in the retina.

## Abducens Nucleus

### Definition

A nucleus which contains both motoneurons and interneurons. The motoneurons send direct projections to the lateral rectus muscles. The interneurons send projections via the medial longitudinal fasiculus to the contralateral medial rectus motoneurons neurons.

## Aδ-, C-Fibers

### Definition

Small-diameter myelinated (conduction velocity 2–30 m/s, diameter below ≤4 μm) or unmyelinated (conduction velocity λτ;2 m/s, diameter λτ1–2 μm) afferent nerve fibers.

►Complex Regional Pain Syndromes: Pathophysiological Mechanisms

## Abducens Internuclear Neuron

### Definition

Neurons located within the abducens nucleus which project to the contralateral medial rectus motoneurons to produce conjugate eye movements.

►Accommodation–vergence Interactions
►Near Response Neuron
►Saccade-Vergence Interactions

## Abducens Nerve (VI)

### Synonyms

►N. abducens (N. VI); ►Abducent Nerve (VI)

### Definition

Abducens nerve (VI) has a purely motor function and innervates the lateral rectus muscle of the eyeball, generating an abduction movement of the eyeball (hence the name) Nucleus: nucleus of abducens nerve.

Skull: superior orbital fissure.

Damage to the nerve causes inversion of the ipsilateral eyeball towards the nose. This produces diplopia (double vision), increasingly so the more the two visual axes deviate from each other. Looking in the direction of the respective eye reduces the severity of the diplopia.

►Nerves

## Absence Epilepsy

### Definition

Absence (petit mal) seizures are a group of epileptic syndromes typically starting in childhood or adolescence and characterized by a sudden brief lack of attention (indicated by a stare or cessation of behavior) and mild automatic movements (fluttering of eyelids or facial twitches) for some seconds to minutes. The ►electroencephalogram shows typical three-per-second spikes and waves. Absence ►epilepsies are generalized, i.e. the whole ►neocortex shifts into a state of sleep-like oscillations.

►Electroencephalography

## Absolute Temperature

### Definition

A (positive) temperature scale postulated by the second law of thermodynamics. It is physically related to the laws of ideal gases.

►Mechanics

## Absolute Threshold

### Definition

The lowest intensity of sensory stimulation that can be detected.

►Sensory Systems

## Absolute Threshold in Acoustics

### Definition

This characterizes the lowest level of sound that a listener can reliably detect and is sometimes referred to as threshold of audibility. The units are typically reported in dB sound pressure level (SPL).

►Psychoacoustics

## Absorption (Sound Absorption)

### Definition

Change in sound energy into some other form, usually heat, in passing through a medium or striking a surface.

►Acoustics

## Abstinence Syndrome

### Definition

The abstinence syndrome (synonym: withdrawal symptom) is observed after withdrawal of a drug to which a person is addicted. For example, the abstinence syndrome after alcohol withdrawal is characterized by ►tremor, nausea, tachycardia, sweating and sometimes ►hallucinations.

## Abstract Entity

### Definition

Something that exists but is not spatiotemporally located, e.g. universals (whiteness, horseness), numbers or states of affairs.

►Possible World
►Property

## Abundance of Degrees of Freedom

### Definition

An apparent excess of elemental variables (cf. redundancy); the term assumes that elemental variables (degrees-of-freedom) are not eliminated in voluntary movements, but they are all used to stabilize important task-related performance variables (principle of abundance).

►Coordination
►Redundancy

## Abventricular Division

### Definition

Any cell divisions that occur outside the ventricular and subventricular zones.

## ACC

### Definition

Anterior cingulate cortex.

## Acceleration

### Definition

The time-derivative of the velocity vector of a specific particle. For a material body, at each instant of time there exists an acceleration field, namely an acceleration vector assigned to each particle of the body.

►Mechanics
►Measurement Techniques

## Accessory Nerve (XI)

### Synonyms

►N. accessorius (N.XI)

### Definition

The accessory nerve has two parts:

- Accessory nerve (XI), cranial roots: these fibers arise from nucleus ambiguus and innervate the pharynx and larynx muscles and course together with the vagus nerve (X). Skull: Foramen jugulare.
- Accessory nerve (XI), spinal root: it arises from a nuclear column in the cervical cord (spinal root nucleus of accessory nerve) and innervate the sternocleidomastoid muscle and the trapezius muscle.

  Skull: Foramen magnum.

Dysfunction of the accessory nerve (XI) results in accessory paralysis rendering it more difficult to lift the arm above shoulder level (trapezius muscle), and turning the head to the unimpaired side is possible only after having successfully contended with resistance (sternocleidomastoid muscle).

►Nerves

## Accessory Nucleus of Oculomotor Nerve

### Synonyms

►Accessorius n. Oculomotorii

### Definition

The accessory nucleus (Edinger-Westphal) is the parasympathetic nuclear component of the oculomotor nucleus.

It contains the somas of the preganglionic parasympathetic fibers and innervates the sphincter muscle of pupil as well as the ciliary muscle. It receives its afferents from the pretectal area of the ipsi- and contralateral side. Its efferents course in the ipsilateral oculomotor nerve to the second neuron in the ciliary ganglion.

►Mesencephalon

## Accessory Neuromast

### Definition

Supernumary neuromasts found only in teleosts. Most likely sensitive to fluid velocity and may mediate rheotaxis in teleosts.

►Evolution of the Mechanosensory and Electrosensory Lateral Line Systems

## Accessory Olfactory Bulb

### Definition

Specialized region adjacent to the dorsocaudal main olfactory bulb receiving input from the vomeronasal organ. Axons of vomeronasal sensory neurons are bundled in the vomeronasal nerve and terminate in accessory olfactory bulb glomeruli where they form synapses with the dendrites of mitral cells, the first-order relay neurons in the accessory olfactory system.

Axons from vomeronasal sensory neurons expressing the same vomeronasal receptor converge onto a small number of glomeruli in the accessory olfactory bulb.

►Accessory Olfactory System
►Evolution of Olfactory and Vomeronasal Systems
►Vomeronasal Organ (Jacobson's Organ)

A

# Accessory Olfactory System

Ulrich Boehm
Center for Molecular Neurobiology, Institute for Neural Signal Transduction, Hamburg, Germany

## Synonyms

Vomeronasal system; Vomeronasal pathway

## Definition

Second olfactory pathway found in addition to the ►main olfactory system in terrestrial vertebrates. Initiating in the neuroepithelium of the vomeronasal organ, the ►accessory olfactory system is specialized in the detection of pheromones. The accessory olfactory system converges and synergizes with the main olfactory system to control behaviors and hormonal changes triggered by chemosensory cues.

## Characteristics

### Vomeronasal Organ

In addition to the main ►olfactory epithelium (OE), a second chemoreceptive structure can be found at the base of the nasal septum in most terrestrial vertebrates. This structure is called ►vomeronasal (or Jacobson's) ►organ (VNO) and is specialized in the detection of ►pheromones [1]. Pheromones are chemical cues that are released by animals and act on members of the same species to regulate populations of animals and their social interactions by eliciting stereotyped behaviors and neuroendocrine alterations.

Pheromonal effects in mammals range from intermale aggression to reproductive behaviors and endocrine changes [1]. In rodents, pheromones can influence the onset of puberty as well as the length of the estrus cycle in females, and cause a surge in serum testosterone levels in males. In the ►Bruce effect, implantation failure results from exposure of a female mouse to the urine of a male genetically different from the inseminating male, coupling a pheromone effect with the detection of "individuality cues." Male pheromones can also stimulate female courtship behaviors, as well as receptive posturing (lordosis). Vice versa, female pheromones can act on males to stimulate mounting behavior, increased intromission attempts, and ultrasonic vocalizations associated with courtship. Experimental ablation of the VNO has shown that it contributes to most if not all of these pheromone effects [1].

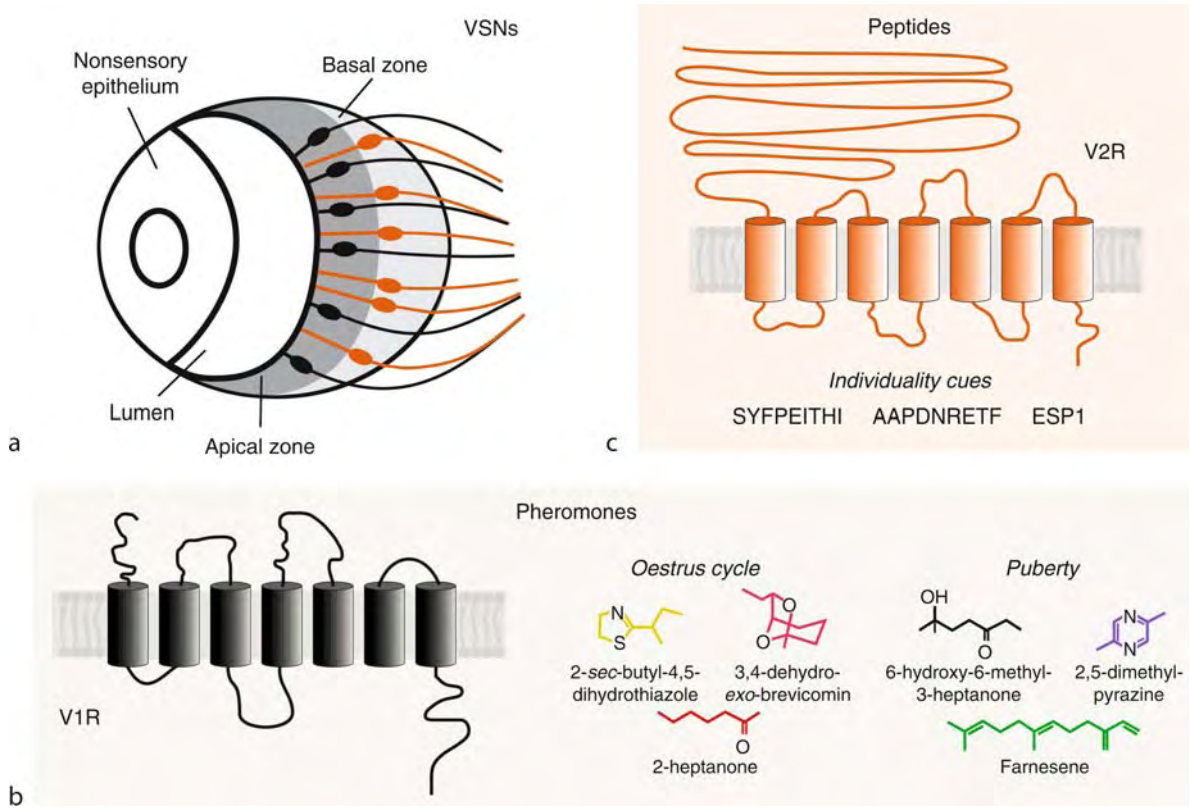
Due to advances in molecular biology and genetic engineering of mice, the molecular architecture of the mouse VNO in particular has emerged in great detail [2]. The mouse VNO is a bilateral tubular structure contained in a cartilaginous capsule, which is connected to the nasal cavity via a narrow duct [1] (Figs. 1a and 2b). Stimulus access to the VNO depends on a vascular pumping mechanism that is activated in situations of novelty.

The VNO contains two populations of bipolar ►vomeronasal sensory neurons (►VSNs), which appear to be specialized in responding to different types of ►ligands (Fig. 1) [2]. Each VSN expresses members of two large families of ►vomeronasal receptors (VRs), the V1Rs and V2Rs (Figs. 1b and c). VRs are seven-transmembrane-domain ►G-protein-coupled receptors (►GPCRs) and members of each family are diverse in amino acid sequence, suggesting that they may recognize a variety of different sensory ligands [3]. It appears that each VSN may express only one V1R or V2R gene and that ~500–1000 VSNs express the same VR [2].

Expression of V1Rs and V2Rs is anatomically confined to specific zones in the VNO ►neuroepithelium (Fig. 1a). Members of the V1R family are exclusively expressed by VSNs located in the apical zone (Figs. 1a and b) and appear to be specialized in the detection of pheromones [4]. Each of the few mouse pheromones identified so far (Fig. 1b) is detected with high specificity by a unique small subset of VSNs in the apical V1R positive zone (Figs. 3a and b), suggesting that VSNs are very narrowly tuned. However, it is not known whether a given pheromone is recognized by one or multiple VRs, and only one VR-ligand pair has been identified so far [2]. A mouse line lacking a cluster of V1R genes has clearly established their contribution in the detection of some pheromones [5].

In contrast, members of the V2R family are specifically expressed by VSNs located in the basal zone of the epithelium and appear to be specialized in the detection of individuality cues such as peptides (Figs. 1c and 3d, e) [2]. A small number of VSNs respond to two different ►major histocompatibility complex (MHC) class I peptides [6] as well as to a sex-specific peptide secreted from exocrine glands [2] (Figs. 1c and 3e) and all of them are located in the basal V2R positive zone (Fig. 3d). MHC class I peptides are fragments of intracellular proteins which are presented on the cell surface by MHC class I molecules. This process is called ►antigen presentation and enables cytotoxic T cells to identify and selectively eliminate those cells that are synthesizing foreign or abnormal proteins. MHC-peptide complexes can be shed from the cell surface and their fragments appear in urine and other body fluids, which can get access to the VNO [6]. It has been shown, that MHC peptides can function as individuality signals during social recognition offering a molecular basis to explain the pregnancy block in the Bruce effect [6].

Chemosensory signal transduction in VSNs is distinct from that in ►olfactory sensory neurons



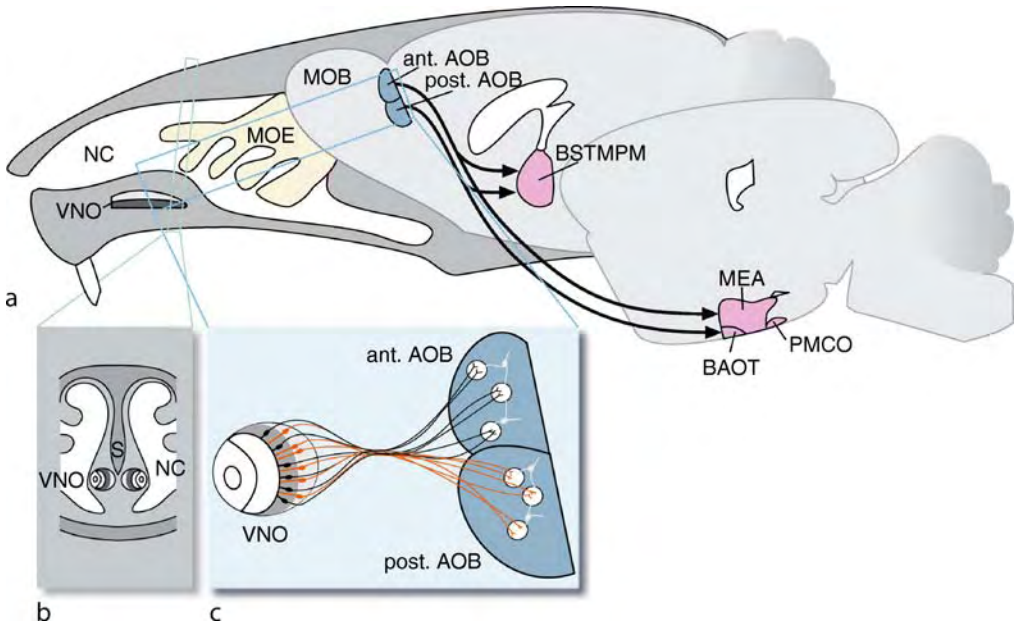
**Accessory Olfactory System. Figure 1** Molecular architecture of the vomeronasal organ. (a) Schematic representation of a rodent vomeronasal organ (coronal view). Vomeronasal receptors of the V1R family (Fig. 1b) are expressed by sensory neurons in the apical zone (black) whereas V2R family members (Fig. 1c) are expressed by sensory neurons in the basal zone of the epithelium (orange). (b) V1Rs are seven-transmembrane-domain GPCRs that appear to be specialized in detecting pheromones (pheromone colors correspond to Fig. 3a and b). (c) V2R GPCRs contain a long N-terminal extracellular domain and appear to be specialized in the detection of peptides such as the mouse strain specific MHC class I peptides SYFPEITHI and AAPDNRETF (see Figs. 3d and e) and exocrine-gland secreting peptide 1 (ESP1).

(►OSNs), but poorly understood. V1R and V2R positive VSNs express different G proteins, $G_{\alpha i2}$ and $G_{ao}$, respectively, however a direct role in VSN ►sensory transduction still needs to be demonstrated. Signal transduction in VSNs involves a diacylglycerol-activated cation channel, which partially depends on TRPC2, a VNO-specific member of the Trp family of ►calcium channels [7].

## From Vomeronasal Organ to Accessory Olfactory Bulb: Segregation and Convergence

Each VSN projects one single ►axon to the ►accessory olfactory bulb (►AOB), which is a specialized region adjacent to the dorsocaudal main ►olfactory bulb (MOB). VSN axons are bundled in the vomeronasal nerve and terminate in anatomically discrete synaptic units called ►glomeruli where they form synapses with the ►dendrites of AOB ►mitral cells, the first-order relay neurons in the accessory olfactory system [1]. Neurons that express V1R/$G_{\alpha i2}$ or V2R/$G_{\alpha o}$ synapse in the anterior or posterior part of the AOB, respectively, maintaining the anatomical segregation observed in the VNO [1] (Fig. 2c). This raises the possibility that signals generated by the V1R and V2R families are eventually targeted to brain regions that mediate different behavioral and physiological effects.

Axons from ~500–1000 VSNs expressing the same VR converge onto a small number (6–30) of glomeruli in the AOB [7] (Fig. 2c). This wiring pattern is similar but not identical compared to that in the MOB where axons of olfactory sensory neurons (OSNs) expressing the same ►odorant receptor (OR) converge onto 1 or 2 glomeruli at two specific locations in the MOB [3]. AOB mitral cells can have from one up to six dendrites contacting multiple glomeruli innervated by neurons expressing the same V1R or V2R [2]. Therefore convergence in the AOB is achieved by dendritic convergence of mitral cells.



**Accessory Olfactory System. Figure 2** The rodent accessory olfactory system. (a) Schematic representation of a rodent nasal cavity and brain (lateral view). AOB mitral cells project to vomeronasal and extended amygdala. For abbreviations, see text. (b) Schematic representation of a coronal section through a rodent nose. The VNO is a bilateral tubular structure located at the base of the nasal septum. (c) VSNs that express the same V1R or V2R converge on a small number of glomeruli in the accessory olfactory bulb (AOB). The apical layer of the epithelium projects to the anterior part of the AOB whereas the basal layer projects to the posterior part. Adapted from [2].

## Accessory Olfactory System Signaling Beyond the Bulb

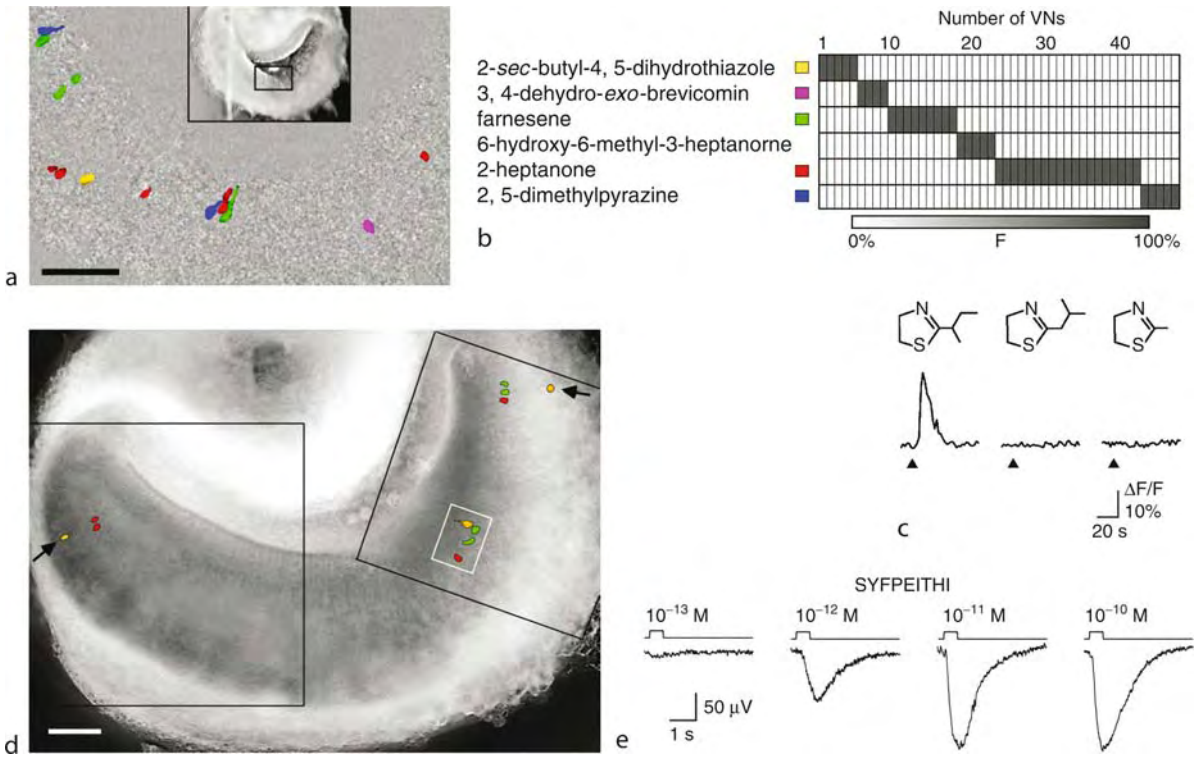
Sensory signals generated in the VNO follow neural pathways separate from those that carry odor signals from the OE [1]. OE signals are transmitted to the MOB, and then relayed through the primary ►olfactory cortex to higher cortical areas involved in conscious ►perception as well as ►limbic areas controlling basic drives and ►emotions [3]. In contrast, VNO signals are relayed through the AOB to regions of the ►amygdala and ►hypothalamus implicated in behavioral and physiological effects of pheromones. Although the general projections of the accessory olfactory system are known, the individual cells and neural circuits that mediate pheromonal effects on behavior and physiology have not been identified. Only recently some new techniques using genetically engineered mouse models have started to reveal individual neurons in the hypothalamus that appear to integrate ►chemosensory information.

How are signals generated by VSNs relayed beyond the bulb? AOB mitral cells project to the medial amygdaloid nucleus (MEA) and posteromedial cortical amygdaloid area (PMCO; which taken together are referred to as the vomeronasal amygdala), as well as to the bed nucleus of the accessory olfactory tract (BAOT) and the posteromedial bed nucleus of the stria terminalis (BSTMPM, also called "extended amygdala") (Fig. 2a). All of these connections are bidirectional suggesting ►feedback loops [2].

It is not known whether the V1R/V2R segregation observed in VNO and AOB is preserved in connections beyond the bulb. Although differential projections from the distinct AOB zones to the vomeronasal amygdala were observed in some species, this segregation could not be confirmed in the mouse [1]. Several studies of neural activation in rodents, however, suggest some functional segregation within the vomeronasal amygdala itself [1].

Information from the vomeronasal amygdala to the medial hypothalamus is sent both by direct projections and via a relay in the BSTMPM [1]. Therefore the BSTMPM receives vomeronasal information both by direct innervation from AOB ►mitral cells and via a relay in the vomeronasal amygdala, suggesting a prominent role in the integration of accessory olfactory signaling [2]. It is not known whether accessory olfactory signaling involving a particular chemosensory stimulus can bypass any of these relay nodes. The BSTMPM is also a prominent part of a sexually dimorphic forebrain circuit including the MEA and several nuclei in the hypothalamus [2].

It is not yet known if signals relayed by AOB mitral cells representing two different VRs converge onto the same neuron(s) in the vomeronasal amygdala or



**Accessory Olfactory System. Figure 3** Chemoselectivity of vomeronasal sensory neurons. (a) VSN activation map produced by successive stimulation with each of the six ligands listed in B (each at $10^{-6}$ M). Each ligand activated a unique, nonoverlapping subset of VSNs. Inset, low-power transmitted light image of the VNO slice; black box, imaged area. Scale bar, 50 µm. (b) Summary of the tuning profiles of 47 VSNs responding to the six ligands. For each VSN, the magnitude of the $Ca^{2+}$ response was plotted as a percentage of the maximal response to a given chemical. Dark grey, 100%; white 0%. Without exception, VSNs responded to only one of the pheromones tested. Thus, computed tuning curves were identical for all VSNs that responded to the same pheromone. (c) Two structural analogues of 2-*sec*-butyl-4,5-dihydrothiazole, isobutyl-4,5-dihydrothiazole and methyl-4,5-dihydrothiazole, were unable to evoke a $Ca^{2+}$ response in VSNs (each tested at $10^{-6}$ M). Adapted from [4]. (d) Spatial representation of peptide-induced activity in VNO sensory epithelium using an acute slice preparation. Shown are reconstructed VSN response maps for the MHC class I ligands AAPDNRETF ($10^{-12}$ M, green) and SYFPEITHI ($10^{-12}$ M, red). Cells responding to both peptides are shown in yellow. Black arrows indicate peptide-sensitive neurons that are localized at the base of the epithelium. Black boxes: imaged areas. Scale bar, 100 µm. (e). Ultrasensitive detection of the MHC class I ligand SYFPEITHI by VSNs. Traces are summed field potentials evoked by brief pulses of increasing concentrations of ligand. Adapted from [6].

BSTMPM or if a stereotyped map represents vomeronasal input in the amygdala.

Ultimately, VNO signals are relayed to specific neurons in the hypothalamus, which initiate and control the behavioral and hormonal responses triggered by pheromones. At the center of hypothalamic control of reproduction are ►GnRH neurons, which regulate the reproductive endocrine status in mammals. Recent studies using ►transneuronal tracers have shown, that GnRH neurons appear to integrate both vomeronasal [8] and main olfactory signals [8,9]. In addition, these studies have revealed feedback loops between the neuroendocrine hypothalamus and both the main and accessory olfactory systems [8], suggesting that the animal's neuroendocrine status might modulate its susceptibility to chemosensory cues.

## Multiple Level Convergence and Synergism of the Main and Accessory Olfactory Systems

Because the main and accessory olfactory systems consist of anatomically separated chemosensory epithelia (Fig. 2a) with different molecular profiles and parallel largely non-overlapping projections, strict functional dichotomy was postulated with each olfactory system specialized in distinct behavioral domains [1]. However, experimental evidence is accumulating that hints at complementary roles of the two olfactory systems and it is important to point out that accessory

olfactory signaling is not functionally equivalent to pheromone signaling [2].

Several experiments across species have shown that pheromone signals are not exclusively perceived by the VNO, but can also be processed by the main olfactory system [2]. Consistent with this, 2-heptanone (Fig. 1b), the only ligand matched to a particular VR (V1Rb2) so far, is also recognized by an olfactory receptor (mOR912–93; [2]). Vive versa, some odorants can also stimulate VSNs [2]. In addition, both the main and the accessory olfactory bulbs are stimulated by both pheromones and general odorants in mice [2]. Furthermore, the two MHC class I peptides recognized by VSNs were recently shown to stimulate OSNs at equally low concentrations, consistent with numerous studies demonstrating participation of the main olfactory system in MHC-related behaviors [2]). Thus, both OE and VNO can contribute to olfactory recognition of pheromones, odorants and peptides.

Convergence of the main and accessory olfactory systems could potentially also occur at different levels in the brain [1,2]. For example, the MEA in hamster has been shown to share extensive bidirectional connections with the cortical nucleus of the amygdala (ACO), which receives information from the MOB but not AOB [1]. In addition, convergence could occur in the hypothalamus, for example in GnRH neurons, which apparently receive information from both olfactory systems [8].

Potential synergism of both olfactory systems is evident in the analysis of reproductive behavior in hamster where complete removal of the olfactory bulbs (bulbectomy) in hamsters completely eliminates mating whereas VNO or OE ablation alone have more subtle effects [1]. Therefore it appears that both olfactory systems can converge and synergize to express reproductive behaviors and hormonal changes triggered by chemosensory cues in rodents.

### Do Humans Have a Functional Accessory Olfactory System?

Fueled by significant public interest, pheromonal communication in humans is controversially debated [7]. Both anatomical and molecular evidence clearly speaks against the existence of a functional human accessory olfactory system. Although an embryonic structure resembling a VNO and a fetal AOB have been identified, they degenerate before birth [1]. A ►vomeronasal pit has been described in some adults, however this structure is not connected to the brain. In addition, no AOB has been found in adults. On the molecular level, hallmarks of the rodent accessory olfactory system are missing in humans. The V2R family is not found in the ►human genome, the V1R repertoire is reduced from 150 functional genes in mice to five in humans and the gene encoding the human TRPC2 channel is a ►pseudogene [7].

The apparent absence of a functional accessory olfactory system in humans does however not imply that humans do not have pheromonal communication. Some chemosensory effects like synchronized estrus in women living in close proximity are well documented [7]. Presumably these more subtle pheromonal effects in humans are mediated by the main olfactory epithelium. Consistent with this, a family of putative pheromone receptors expressed in the main olfactory epithelium has recently been identified [10].

# Accommodation of the Lens

## Definition

Increase in the refractive power of the lens of the eye.

# Accommodation–Vergence Interactions

Lawrence Mays
University of North Carolina at Charlotte, NC, USA

## Definition

In this context, accommodation refers to the change in the refractive power of the crystalline lens of the eye. A unit of refractive power is the Diopter, which is the reciprocal of the focal length measured in meters. Positive accommodation decreases the focal length of the lens, allowing near objects to be seen clearly, while negative accommodation or relaxation of accommodation increases the focal length for viewing more distant objects. Vergence, or vergence angle, refers to the angle between the lines of sight of the two eyes in the horizontal plane. Clinically, vergence angle is usually expressed in terms of prism diopters. A prism diopter is the deviation of light by one cm at a distance of one meter, and is ~0.57°. Convergence (►Convergent eye movement) is an increase in vergence angle, and occurs when viewing a near object with both eyes. Divergence (►Divergent eye movement) is a decrease in vergence angle. Accommodative convergence (AC) is the increase in vergence angle which occurs when the lens accommodates to view a nearer object. The AC/A ratio is the change in vergence angle for each Diopter of accommodative demand. Convergence accommodation (CA) is the increase in lens accommodation which occurs when the eyes converge. The CA/C ratio is the amount of accommodation (in Diopters) associated with a given change in convergence (usually measured in prism diopters).

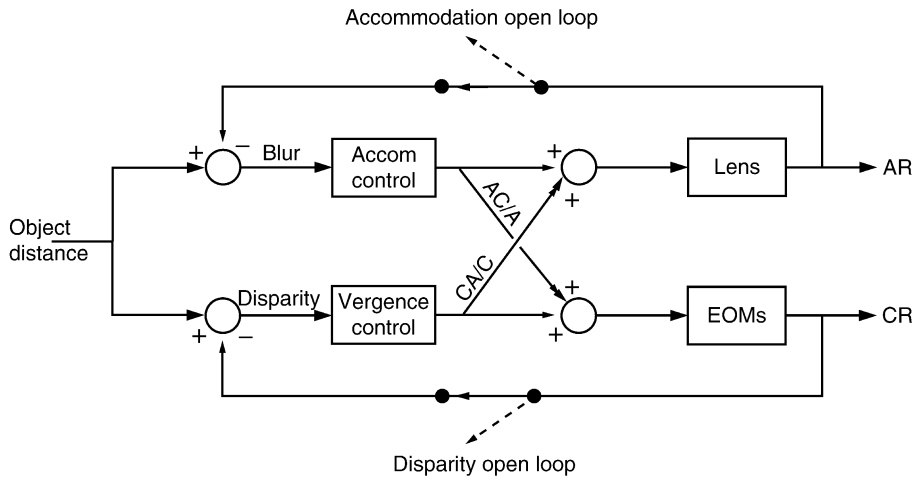
## Characteristics

### Upstream Events/Conditions

The primary stimulus for ►accommodation of the lens is optical blur caused by a mismatch between the distance to the object of regard and the refractive power of the lens. Since blur decreases the spatial frequencies of the image, any element in the visual system which is tuned to spatial frequency can be used to detect blur. Indeed, many neurons in the visual cortices show such sensitivity. In operation, accommodation is modeled as a negative feedback system (top half of Fig. 1) the goal of which is to minimize blur [1]. The primary stimulus for horizontal ocular vergence is binocular disparity, which is the difference between the locations of an image on the two retinas. Many neurons in the primary visual cortex, the first point in the geniculo-striate system at which inputs from the two eyes are combined [2], are sensitive to absolute horizontal binocular disparity, and so could provide a useful disparity error signal. Single binocular vision requires that binocular disparity be reduced to a fraction of a degree. Like the accommodative system, the vergence system is modeled as a negative feedback system (bottom half of Fig. 1). It is important to note that for both the accommodation and vergence systems, the subtraction of the accommodative or vergence response from the demands imposed by the visual stimulus is geometric and not neural.

### Interactions Between Systems

The observations that accommodation by itself drives vergence and vergence responses drive accommodation suggest a simple cross linking of these systems, as indicated by the crossed arrows in the Fig. 1. The strengths of these cross-links are given by the AC/A (accommodation to vergence drive) and CA/C (vergence to accommodation drive) ratios. Control system analysis indicates that as long as the product of AC/A and CA/C, measured in equivalent units (Diopters for accommodation and Meter Angles for vergence) is less than unity, the system is stable. Indeed, the accommodative and vergence systems work in a synergistic manner via these cross-links to facilitate responses to changes in the distance of visual objects. Both psychophysical [1] and neurophysiological studies [3] have supported this model.



**Accommodation–Vergence Interactions. Figure 1** Representation of the dual-interaction model of accommodation and vergence. Both the accommodation (upper half of figure) and the disparity vergence (lower half) systems are controlled by negative feedback. The input to both controllers is Object Distance. For the accommodative controller, the error signal is optical blur, arises from the mismatch (difference) between Object Distance and the Accommodative Response (AR). The blur-driven accommodative controller (Accom Control) produces an output proportion to this error to drive the neurons controlling the crystalline lens (Lens) and thus changes the AR. The accommodative system can be made open loop by placing pinholes in the optical path which eliminates blur, regardless of the relationship between the Object Distance and the AR. This is shown schematically by a switch represented by the dashed arrow at top. A similar system is used for the disparity vergence system; except that the error signal for the controller (Vergence Control) is binocular disparity, which is the difference between the vergence demand imposed by Object Distance and the Convergence Response (CR). The output of the vergence controller goes to the extraocular muscles (EOMs) which adjust vergence angle. This feedback loop can be opened (dashed arrow at bottom) by any manipulation which eliminates binocular viewing of the target, such as occluding one eye. The accommodation-vergence interaction is due to cross-links by which some fraction of the output of the accommodative controller is added to output of the vergence controller (accommodative convergence, downward angled arrow), and some fraction of the output of the vergence controller is added to the output of the accommodative controller (convergence accommodation, upward angled arrow). The strengths of these cross-links is assessed by the AC/A and CA/C ratios. In order to measure the AC/A ratio, the disparity feedback system must be open loop, and measurement of the CA/C ratio requires that the accommodative feedback system be open loop.

Although not indicated by the Fig. 1, there is some flexibility associated with these cross-links. For example, if a subject is required to binocularly view a target at a given distance through base-out prisms, a greater demand is placed upon the systems to converge than to accommodate. Subjects have some limited ability to dissociate the convergence and accommodative responses. However, if the convergence demand imposed by the prisms is too great, the subjects will experience blurring of the target, caused by the excessive driving of the accommodative system by the vergence systems via the AC/A cross-link. If the change in vergence demand by the prisms is gradual and takes place over a time course of minutes, prism adaptation may occur. Prism adaptation may be considered as a change in the vergence offset or bias in the relationship between accommodation and vergence [4]. Adaptation with base-out prisms causes the eyes to be more converged for a given level of accommodative demand. Prism adaptation is also called phoria adaptation, because it is measured as a change in the phoria. There is some evidence for adaptation of accommodation when accommodative and vergence demands are mismatched, but the degree of adaptation appears to be modest.

In addition to the changes in bias or offsets, the AC/A and CA/C ratios can be modified. Prolonged viewing of targets using periscopic spectacles which simulate a larger inter-ocular distance results in an increase in the AC/A ratio and a corresponding decrease in the CA/C ratio [5]. Optical manipulations which effectively decrease the inter-ocular distance decrease the AC/A ratio and increase the CA/C ratio, although the observed changes are more modest. For adults, the inter-ocular distance is constant, and so are the AC/A and CA/C ratios for a given individual, although there are differences in the ratios among people. The capacity to increase the AC/A ratio with increasing inter-ocular separation is probably important during childhood growth.

### Downstream Events/Conditions

Although both the vergence and accommodative control systems strive to minimize error, this is rarely realized. Error within the vergence systems is termed binocular disparity. If it is small enough to permit single vision (i.e. less than about 0.25°) this error is termed "fixation disparity." Larger binocular disparities lead to double vision, or ►diplopia, which generally results in the suppression of one eye's image by the nervous system. Errors in accommodation seem to be more readily tolerated, and the mismatch between the accommodative demand and the eye's response is termed "accommodative lag." With aging, there is a progressive loss of the ability to accommodate (presbyopia), which is believed to be due to the gradual loss of elasticity of the crystalline lens.

### Involved Structures

The neuronal circuits for both accommodation and vergence are believed to be located in the midbrain. Although it seems likely that visual cortical inputs provide the sensory inputs to this mechanism, the pathways are not known. Neuronal signals related to accommodation and vergence are found on midbrain near response cells (►Near response neurons). Most near response cells have a firing rate which is proportional to both accommodation and vergence. Many also have a signal related to vergence velocity, and presumably, to accommodation velocity as well. A subset of near response cells has been shown to project to the ►medial rectus subdivisions of the oculomotor nucleus, the site of medial rectus motoneurons, which are needed to generate convergence of the eyes [3]. Near response cells may also project to the Edinger-Westphal nucleus to control accommodation, but this has not been demonstrated. Neurons in the abducens nucleus are also involved in ocular vergence, but neither direct nor indirect projections from near response neurons to the abducens nucleus have been shown. Lens accommodation is effected by the action of the ciliary muscle of the eye, which has both parasympathetic and sympathetic inputs. Parasympathetic input, which appears to be more important for accommodation, is relayed from the midbrain Edinger-Westphal nucleus via the ciliary ganglion.

### Methods to Measure This Event/Condition

The most commonly used measure of the interaction between accommodation and vergence is the AC/A ratio. This is measured by first opening the vergence feedback loop (see dashed arrow in lower half of Fig. 1). This is done by dissociating vision in the two eyes, often with a hand-held occluder, so that they do not see the same object at the same time. Typically, a clinician will measure the subject's phoria while viewing a distant target. The phoria is the deviation of the non-viewing eye from the target. The phoria will then be re-measured while the subject views a near target. The AC/A is calculated as the ratio of the change in phoria to the change in accommodative demand. A typical AC/A ratio value is 4 prism diopters per Diopter, or about 0.6 Meter Angles (MA) per Diopter. Note that this describes a stimulus AC/A ratio; in that the subject's accommodative response is not measured. The accommodative response can be measured, but this is rarely done in clinical settings. The CA/C ratio must be determined independently, since it cannot be calculated from the AC/A ratio. To measure the CA/C ratio, it is necessary to open the accommodative feedback loop (dashed arrow on top half of Fig. 1), which can be done by having the subject view a target through optical pinholes. Convergence can be elicited by placing base-out prisms in the optical path as the subject views a target binocularly. The associated change in accommodation, which can be measured using retinoscopy or by means of an optometer, is expressed as a ratio of accommodative change per unit of vergence change. When expressed in equivalent units, the CA/C ratio is usually around 0.7 D/MA. This corresponds to about 0.1 Diopters per prism diopter. Due to the specialized optical equipment needed to measure the CA/C ratio, it is rarely done in clinical settings.

## Acetylcholine (ACh)

### Definition

Acetylcholine (ACh) is a classical neurotransmitter found both in the central nervous system (CNS) and the peripheral nervous system (PNS). Cells that produce acetylcholine are referred to as cholinergic. Acetylcholine formed the basis for early studies of synaptic transmission which led to the formation of key principles of chemical neurotransmission. The transfer of the acetyl group from acetyl-coenzyme A to choline is a single step process that forms acetylcholine and is dependent on the enzyme choline acetyltransferase (ChAT). Acetylcholine is inactivated by the enzyme acetylcholinesterase, which converts acetylcholine to choline and acetic acid. Choline is transported back into the presynaptic terminal where it is used to synthesize acetylcholine. Acetylcholine is released from both somatic motor nerve terminals (at the neuromuscular junction) and autonomic preganglionic terminals, as well as at synapses in enteric ganglia and some central synapses. In the central nervous system, cholinergic neurons are primarily located in the basal forebrain and brainstem. Acetylcholine acts at nicotinic and muscarinic acetylcholine receptors.

## Acoustic Neurinoma

### Definition

Tumor arising from the nerve sheath cells. Other terms to describe this entity include acoustic schwannoma, neurilemoma, acoustic neuroma. This tumor arises on the cranial nerve VIII (acoustic). It is presumably formed by Schwann cells (or their progenitors).

Schwannoma arises eccentrically within the nerve, displacing the axons and sparing the nerve. This feature makes nerve-sparing surgery possible in some cases.

Tissue architecture of the tumor is characterized by dense or loose structures named Antoni A or B respectively. Acoustic schwannoma corresponds histologically to WHO grade I. Maligant progression of acoustic schwannoma is extremely rare. Clinical presentation typically includes tinnitus (ringing in the ear) and hearing loss. Magnetic resonance imaging (MRI) is the study of choice for detection of this tumor and usually reveals well-circumscribed, sometimes cystic and enhancing mass. Treatment modalities employed include observation, surgical resection and/or radiotherapy. Bilateral acoustic schwannomas are the hallmark of a neurogenetic disease Neurofibromatosis type 2.

# Acoustics

William A. Yost
Speech and Hearing Science, Arizona State University, Tempe, AZ, USA

## Definition

►Acoustics is the study of ►sound [1,2]. Sound is produced when an object vibrates causing a pressure wave to propagate through a medium (e.g., air) to a receiver.

## Characteristics

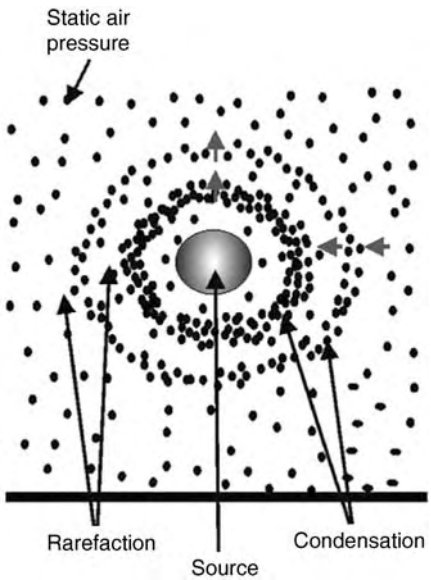
As acoustics is the study of sound [1,2], it is the study of how objects produce sound through vibration. An object must have mass and inertia in order to vibrate. A spring attached to a weight may serve as a model for a vibrating object, with the weight representing the properties of mass and the spring the properties of inertia. When the weight is pulled away from or pushed past its resting point, the spring will cause the weight to vibrate. A force moves the object and the spring applies a restoring force. These forces can be expressed as the moving force, $F = ma$, and the restoring force, $F = -sx$, where $m$ is mass, $s$ is stiffness, and $a$ and $x$ are acceleration terms. In a frictionless world with no ►resistance, the two forces offset each other when the weight vibrates resulting in $ma + sx = 0$. This equation has as one of its solutions $a(t) = A\ Sin[/(s/m)t + \theta]$, where $s$, $m$ are defined as above, $a(t)$ is the instantaneous displacement of the weight as a function of time, $t$ is the time in seconds, $A$ is the peak distance that the weight moves, and $\theta$ is the ►starting phase (in radians) that describes the position of the start of the vibration relative to the weight's resting position.

Hence, a sinusoidal (sin) function describes the motion of the free vibration of the weight and spring. The formula $a(t)$ can be rewritten as $a(t) = A\ Sin(2\pi ft + \theta)$, where $A$ is the peak amplitude, $f$ is ►frequency (for the mass and spring $f = /[s/m]$), $t$ is the time, and $\theta$ is the starting phase. Such a sinusoidal vibration produces a ►simple or pure-tone sound. The frequency of vibration ($f$) is expressed in ►Hertz (►Hz), in which "n" Hz means that the object has gone through "n" vibratory ►cycles in one second. When friction is included, the sinusoidal pattern of vibration becomes a damped pattern in which the amplitude of vibration decreases over time, at a rate that is proportional to the amount of resistance.

Vibrating objects then impart their pattern of vibration to the molecules within a medium (e.g., air). As air is the medium for sound transmission for most animals, we will consider the transmission of sound through air. Air consists of molecules in constant random motion. When a vibrating object moves in one direction, air molecules are pushed in the same direction (assuming no frictional forces). The molecules next to the vibrating object are compressed together as the object moves outward from its resting state, creating an area of greater air-molecule density. As the density of air molecules increases, the pressure increases creating an area of ►condensation. As the vibrating object moves in the opposite direction (back toward its resting state), the air molecules fill the space vacated by the vibrating object moving in the opposite direction. As the vibrating object moves back past its resting state, an even larger vacated area is generated for the air molecules to fill. Now the density of air molecules has decreased, lowering the pressure, and generating an area of ►rarefaction.

The mere presence of molecules in air creates ►static air pressure, which is proportional to the density of molecules. The changes in pressure due to the vibrating object are changes in this existing static air pressure. Imagine a photograph of the air molecules taken when the object was vibrating, freezing the density pattern at a moment in time (Fig. 1).

The molecules appear to cluster at some points in space (condensation) and spread farther apart at other places (rarefaction). The molecular motion at a condensation tends to be away from the source, and the motion at a rarefaction tends to be toward the source. As an object vibrates, it causes a sound pressure wave with alternating areas of condensation and rarefactions to radiate out from the source in a spherical



**Acoustics. Figure 1** A depiction of a sound wave and areas of condensation and rarefaction of increased and decreased pressure (above and below the static air pressure) as the wave motion forces the air molecules to move away from and toward the vibrating source.

manner. The distance between successive condensations or rarefactions is the ►*wavelength* (λ) of sound; $\lambda = c/f$, where $c$ is the speed of sound in meters/second, $f$ is the frequency, and λ is expressed in units of distance (e.g., meters). The speed of sound in air is approximately 345 m $s^{-1}$, although it can vary as a function of temperature, density, and humidity.

A propagating wave produces instantaneous changes in pressure $p(t) = mv / tAr$, where $m$ is the mass, $v$ is the velocity, $t$ is the time, and $Ar$ is the area. The root-mean-square (rms) pressure ($p$) describes an average pressure. Since force, $F = mv / t$, then, $p = F / Ar$. As a vibrating object exerts a force, this means that the force moves an object through some distance. This is a definition of work. Energy ($E$) is the ability to do work. Power ($P$) is the rate at which work is done. Therefore $P = E/T$, where $T$ is the time in seconds over which the work is done. ►Sound intensity (►$I$) is a measure of sound power, $I = p^2/p_o c$, $p$ is the rms pressure, $p_o$ is the density of the medium, and $c$ is the speed of sound in the medium. Sound pressure is usually expressed in units of micropascal (μPa) and sound intensity in units of watt/$cm^2$.

Given the very large range over which sound intensity can vary (especially in terms of the range for hearing), a logarithmic relationship is often used to measure sound ►level in terms of sound intensity and sound pressure. The ratio of two sound intensities ($I_1$ and $I_2$) expressed in ►decibels (►dB) is 10 log $I_1 / I_2$. As $I = p^2 / p_o c$, then the formula for decibels in terms of pressure ($p$) is decibel (dB) = 10 log $I_1 / I_2$ = 20 log ($p_1 / p_2$). The decibel (dB), therefore, is 10 times the log of the ratio of two intensities, two powers, or two energies and 20 times the log of the ratio of two pressures. Two conventions are commonly used to define decibels in relative terms. Experiments conducted in the 1930s determined that a pressure of 20 μPa was the smallest sound pressure required for the average young adult to detect the presence of a mid-frequency pure tone. When decibels are expressed relative to 20 μPa (i.e., $p_2$ = 20 μPa), they are expressed as decibels of ►Sound Pressure Level (dB SPL), and they indicate the decibel level relative to the softest sound that humans can detect. ►Sensation Level (dB SL) is referenced to the least intense sound a particular subject can detect in a particular experimental situation (for example, at a particular frequency). Decibels of ►Hearing Loss (dB HL) is a measure like dB SL, in that dB HL is expressed relative to standardized levels required for listeners with normal hearing to detect tones of different frequencies.

The sound wave propagates out from the source in a spherical manner. Since sound intensity is inversely proportional to area, and the area of a sphere is proportional to its radius squared, sound intensity decreases as function of the square of the distance from the source. This inverse relationship between sound intensity and distance is referred to as the ►inverse-square law. Thus, for each doubling of the distance from the sound source, sound intensity decreases by a factor of 4, or about 6 dB (10 log4 = 6.02 dB) assuming the sound wave does not encounter any obstacles as it radiates out from the vibrating source.

The sound pressure wave can encounter objects as it travels from its source. The sound wave can be reflected from the object, absorbed at the boundary of the object, transmitted through the medium of the object, or ►diffracted around the object. The amount of reflection depends on the difference between the characteristic ►impedance of the original medium in which the sound wave is traveling and that of the object the sound wave encounters. ►Characteristic impedance (►$Zc$) is defined as $Zc = p_o c$, where $p_o$ is the density of the medium and $c$ is the speed of the sound in the medium. Notice that $Zc$ is the same as the denominator of the definition of sound intensity, i.e., $I = p^2 / Zc$. The greater the characteristic impedance of the object, the greater the magnitude of the sound wave that is reflected from the surface of the object.

Sound is diffracted around objects whose diameters are approximately equal to or less than the wavelength of the sound wave. The level of sound on the side of an object opposite the direction in which the sound travels may be less than that on the side that the sound wave encounters first. That is, objects can produce a sound shadow. Since wavelength is inversely proportional to frequency, the higher the frequency of the sound wave, the greater the amount of attenuation due to the sound shadow.

The reflections of sound waves traveling in enclosed spaces (e.g., in a tube) can produce a pattern of reflections that can both reinforce and cancel the pressure waveform. Under appropriate conditions, a ►standing wave can be created. A standing wave creates areas of increased pressure within the enclosed spaces (►antinodes), interspaced with areas of decreased pressure (►nodes). The fundamental frequency ($f_o$) of the standing wave is related to the length of the enclosed space (e.g., $f_0 = c / (2L)$, where c is speed of sound, $L$ is length of enclosed space, when the enclosed space is closed or opened at both ends).

The reflections from surfaces in enclosed spaces like rooms can reinforce each other and the combined reflected sound wave can last a long time after the originating sound has ceased. In this case, ►reverberation is produced and the time it takes the reverberant sound level to decrease 60 dB from the original sound level is the ►reverberation time of the room. Reverberation time is proportional to the size of the room and inversely proportional to the amount of sound that is absorbed by the surfaces of the room.

Sound may be analyzed in several ways. The time waveform representing the relationship between sound pressure or intensity and time may be converted into a frequency-domain representation using a mathematical procedure known as the ▶Fourier transform. Using the Fourier transform, any ▶time-domain waveform can be represented by the sum (or integral) of a set of simple sinusoidal time-domain components.

For ▶periodic time-domain waveforms, the discrete Fourier transform is

$$f(t) = 1/2\mathrm{A}_o + \sum [a_n \cos(n\omega_o t) + b_n \sin(n\omega_o t)] \quad \text{for} \quad n = 0 \text{ to } \infty,$$

where $f(t)$ is the time-domain waveform, $\mathrm{A}_o$ is a DC shift in the baseline of the time-domain waveform, $\omega_o = 2\pi f_o$, $f_o$ is the fundamental frequency of the periodic complex time-domain waveform, and $a_n$ and $b_n$ are magnitude constants expressed in terms of amplitude or power.

For non-periodic waveforms the Fourier transform is $f(t) = 1/2\pi \int f(\omega) e^{j\omega t} d\omega$, over the integral from $-\infty$ to $+\infty$, where $f(t)$ is the time-domain waveform, $f(\omega)$ is ▶frequency domain transform, j is complex number ($\sqrt{-1}$), and $\omega = 2\pi f$. The exponential ($e^{j\omega t}$) is related to a complex form of the trigonometric sinusoidal function.

Thus, either the time-domain or the frequency domain description of the sound waveform provides a unique and complete characterization of the waveform. In the frequency domain, the sinusoidal components are described by ▶spectra. The ▶magnitude spectrum indicates the magnitude (pressure or intensity) of each sinusoidal component as a function of its frequency (e.g., for discrete Fourier transforms of "n" components, the magnitude spectrum is the relationship between $Cn = \sqrt{(a_n^2 + b_n^2)}$ and $n\omega_o$). The ▶phase spectrum indicates the starting phase of each sinusoidal component as a function of its frequency (e.g., for discrete Fourier transforms of "n" components, the phase spectrum is the relationship between the arctangent ($a_n/b_n$) and $n\omega_o$). Thus, the magnitude and phase spectra completely and uniquely describe the waveform. If sound is to be described in terms of pressure variations over time, then the time-domain waveform is used. If it is important to know the frequency components of the sound, then the frequency-domain description is used.

Any system that analyzes sound can be described as linear or nonlinear. A ▶linear analysis system means that the spectrum of the sound would only change in the sense that the amplitudes and starting phase of the input spectrum might change, but the frequency components at the output of the analysis system are the same as those of the input spectrum. In a ▶nonlinear system, there may be frequency components at the output of the analysis system that were not present in the input. For instance, if the input to a nonlinear analysis system was a spectrum of two sinusoidal components with frequencies f1 and f2 (f1 > f2), then a nonlinear system of the form $y = x^n$, where x is the sum of the components with frequencies f1 and f2, can produce nonlinear ▶distortion components at mf1, mf2, (m−1)f1 + (p−1)f2, and (m−1)f1 − (p−1)f2, where m = p = 1 to n, m ≠ p. If n = 2, then the output spectrum would contain frequency components at f1 and f2 (the input components), 2f1, 2f2 (▶harmonics), f1 + f2 (▶summation tones), and f1−f2 (▶difference tones). Since the additional sinusoidal components would be added to the input components, the time-domain description of the output of a nonlinear system is distorted relative to the input.

Filtering may be used to estimate the magnitude spectrum of a complex time-domain waveform. A ▶filter is a device or function that passes the frequency components of a sound within the ▶passband of the filter without altering their magnitude. The magnitudes of frequency components with frequencies that lie outside of the passband are attenuated. For instance, a bandpass filter with a 500-Hz to 1,000-Hz passband and a 6-dB/octave ▶roll off would not change the magnitude of the frequency components with frequencies between 500 and 1,000 Hz. The magnitude of components with frequencies greater than 1,000 Hz, or less than 500 Hz, would be reduced by 6 dB for each ▶octave (doubling) of the component's frequency away from 500 or 1,000 Hz (e.g., components at two octaves below 500 Hz, 125 Hz, and two octaves above 1,000 Hz, 4,000 Hz, will have magnitudes at the output of the filter that are 12 dB less than they were at the input to the filter).

In the example above, if a ▶complex sound input to the filter had frequency components in the range of 500–1,000 Hz, the filter output would be greater in level than if the complex sound only had frequencies above 4,000 Hz. Thus, the output of each filter in a bank of bandpass filters can estimate the relative magnitudes of the frequency components in a complex sound. The accuracy of the estimate depends on the density of filters, the width of the passbands of each filter (the width of the passband is related to the ▶Q of the filter, where Q is the ratio of the filter's center frequency and its bandwidth), and steepness of the roll offs of each filter. Thus, a bank of bandpass filters may be used to estimate the magnitude spectrum of a sound.

The description of sound and its analysis provided above covers the major aspects of sound that affect auditory processing. The auditory system is sensitive to the pressure wave and how any objects that it encounters as it travels from its source to the ears of a listener affect it. Both the time and frequency domain descriptions of sound are coded by the auditory periphery. A filter bank is often used to model the frequency analysis performed by the biomechanics of the inner

ear. The auditory system is nonlinear at almost every stage of processing and is remarkably sensitive to the acoustic properties of vibrating objects.

## Acquisition in Classical Conditioning

### Definition

Learning about the predictive relation between a conditioned stimulus (CS) and an unconditioned stimulus (US) follows a negatively accelerated acquisition curve. A common index of acquisition is the ability of the CS to elicit a conditioned response. Control procedures are used to ensure that the change in behavior to the CS is due to learning about the CS-US relation and not to experience with the events per se. In the unpaired control procedure, the same number of CSs and USs is presented as in the paired condition but they are never contiguous in time; in the random control procedure, the probability of an US is unchanged by the presence or absence of the CS.

## Actin

### Definition

Actin filaments (microfilament) are a major structural component of the cellular cytoskeleton. The monomeric globular form (G-actin) polymerizes to form long helical filaments (F-actin), 7–9 nm in diameter. All subunits are oriented in the same direction resulting in a structural polarity where the ends of the filament are different. The structural polarity has important functional implications where the barbed end (+ end) of the filament has a faster rate of growth than the pointed (-) end. Actin is also the name of one of the two contractile proteins implicated in muscle contraction. Actin (sometimes also referred to as the thin filament) consists of two chains of serially linked actin globules that are wrapped around each other in a helical fashion. Actin also contains tropomyosin, a long fibrous protein that lies in the groove formed by the actin chains and three sub-units of troponin, troponin T, I and C. Tropomyosin and troponin are regulatory proteins associated with controlling cross-bridge binding to actin.

# Action, Action-Theory

Ralf Stoecker
Institut für Philosophie, Kollegium LER, Universität Potsdam, Potsdam, Germany

## Synonyms

Action; Behavior; Doing; Action-theory; Philosophy of action

## Definition

Usually an action is defined as something which is done by an agent for a reason, where the reason explains the action. But here, at the latest, agreement comes to an end and various action-theories start.

## Description of the Theory

There is no single action-theory but a variety of theories which address a number of closely interrelated topics that shape what is usually called ►philosophy of action. Although many of these topics had already been discussed in traditional philosophy (notably by Aristotle, Hume, Kant), these discussions were then usually regarded as part of moral philosophy. Philosophy of action as a discipline of its own came up in the middle of the twentieth century (helpful collections of classical papers in action theory are [1,2]).

### The Central Question: What are Actions?

The main target of any action-theory is to give an adequate account of ►what actions are. An action is something we do, not something that merely happens to us, like rotating with the earth or catching a cold. Yet, not everything done is properly called an action. Warming the seat of a chair or outwearing one's shoes are things we do, but they are not actions. Neither is it an action if someone trembles when he is scared or blinks when something is approaching his eyes. Hence, actions are to be distinguished from things that happen to us and also from mere behavior, particularly reflexive behavior.

In order to account for the difference, actions are usually regarded as events each of one of which is a person's doing something for a reason, where the person's having the reason explains why they did the thing. In ordinary language the term "reason" is used in two different ways to explain actions: reasons are either states of affairs that speak in favor of the action (The reason I phone you is that your uncle died) or reasons are mental states that motivate the action (The reason I phone you is that I want to invite you for dinner). Both kinds of reasons (so called ►external and ►internal reasons) have been used to specify what actions are.

The idea that reasons basically are external reasons, i.e. states of affairs in the environment of the agent, and that actions are the agent's ►response to them was proposed, among others, by Georg Henrik von Wright [3]. But this view faces a number of serious problems: First, usually we would only regard such responses as actions if the agent also realizes the specific features of the environment, i.e. if she has the respective internal reason as well. Secondly, we would still take them to be actions even if the features do not in fact obtain, as long as the agent mistakenly assumes that they do. And thirdly, it is not quite clear how an adherent of this approach could account for the explanatory power of reasons.

Because of these problems and because it is initially so plausible that we are agents because we have minds, the received understanding of action in modern action theory is ►mentalistic, which means that the specific difference between actions and other doings is located in the mental attitudes the agent has towards her doings. Actions are done, because the agent wants, wills or intends them to occur. Mentalistic proposals differ with respect to the mental attitudes they take to be crucial and/or with respect to what they regard as the proper relationship between these attitudes and the respective actions.

The classical mentalistic view is ►volitionalism, according to which actions have to be preceded by volitions or ►acts of will that trigger the action. Volitionalism arguably originates in the early Christian adaptation of antique concepts of agency, particularly in the writings of Augustine. However, in recent philosophy of action volitionalism met at least two serious problems: first, there are many everyday, routine actions, which we seem to perform without a preceding act of will, and secondly volitionalism seems to imply that volitions are actions too, which would presuppose that they in turn are preceded by another act of will, and so on, ad infinitum. Despite these difficulties there are still defenders of volitionalism.

The dominant mentalistic alternative to volitionalism is the so-called ►belief-desire thesis. According to this view it is characteristic of actions that they are

performed because the agent has a desire (or more generally: a pro-attitude) towards doing something and believes that what she does is of the desired kind. The agent might e.g. phone her friend because she wants to invite him for dinner and believes that phoning him is a way to invite him. In the terminology of the leading proponent of this view, Donald Davidson, the belief-desire pair is called the action's ►primary reason [4]. Actions are things done for primary reasons.

However, the belief-desire thesis, too, faces an obvious problem: it seems to account merely for ►intentional actions, leaving all kinds of unintentional, involuntary, inadvertent actions unexplained. If the agent phones her friend because she mistook his number for the number of her parents, she does not act on a primary reason for phoning him, yet her phoning him is neither just something that happened to her nor a mere behavior, it is a mistaken, misguided action. What is therefore needed is a two-step account of actions: they are either intentional (i.e. done for a primary reason) or they are performed by doing something else intentionally.

For some time, roughly between 1970 and 1990, the metaphysical question of how to understand this by-locution played an important role in action theory (for an overview see [5]). According to Davidson and others "by" only relates different descriptions of the same, numerically identical action. Hence, in their terminology, actions are intentional only under a certain description (►coarse grained account). According to authors like Alvin Goldman and Jaegwon Kim on the other hand "by" always or at least sometimes relates different, numerically distinct actions (►fine-grained accounts). These views were usually combined with ontological claims as to whether actions are events at all, whether they are restricted to bodily movements or could also comprise some other events, or whether actions should in the last analysis be seen as internal, mental phenomena: e.g. strivings, tryings or decisions.

The ontological debate in action theory also focused on the problem of how to account for so called ►negative actions, i.e. omitting something or letting something happen. On the one hand it seems to be beyond doubt that part of what we intentionally do belongs to this negative kind (e.g. if we abstain from smoking because it is unhealthy), on the other hand negative actions seem to be ontologically unreal, because in a sense the agent is not doing anything at all.

The intentionality of actions also gave rise to the question, whether a pair of beliefs and desires is really sufficient for an action to occur or whether it is necessary to have an ►intention in advance of one's action. The proposal to augment the belief-desire thesis by an additional mental component, the agent's intention or choice, has the advantage to preserve the initial plausibility of volitionalism with a good chance for avoiding some of its difficulties. However, the proposal it is still faced with the problem that particularly routine acts seem not to be preceded by such an attitude. Yet in any case, even if not all actions presuppose intentions separate from the agent's primary reasons, it is an important task in action theory to account for the role an agent's intentions play, since intentions are crucial for understanding ►planned, ►complex and ►joint actions [6]. Authors disagree though on what intentions are and particularly whether they could be reduced to other kinds of intentional attitudes.

Other mental phenomena also play an important role for agency. Actions are not only performed for reasons or intentions, we also act on e.g. fury, love, fear, or shame. Sometimes we even act just for fun or "for nothing." What this shows is that, at least, action theory has to take into account other mental antecedents of actions that add to action explanations, although some authors go further and regard the existence of such ►arational actions as a refutation of the belief-desire thesis and of its too rationalistic view of actions.

Despite their differences all mentalistic approaches agree in the idea that for a doing to be an action it is not sufficient that the agent has the respective mental antecedents, the doing must also be explained by them. This leads to a second major topic in the philosophy of action, the character of action explanations.

## Action Explanations

Action explanations combine two ideas: first the action is described as, in a sense, being ►adequate (or fitting) to the explanantia, and secondly it is described as happening because of its adequacy.

The first idea is easily illustrated by explanations based on the agent's acts of will, volitions, intentions or decisions. The action fulfils what is expressed in the content of the respective attitude. The agent's phoning her friend fits to her preliminary intention, because phoning him is what she intended to do.

Primary reasons fit the action in showing it as being reasonable, in the sense that the agent could have concluded from the reasons she has that it is somehow favorable to perform the action. The agent's desire to invite her friend together with her belief that this could be done by phoning him speak in favor of phoning him. The idea that reasons allow for a special sort of inference to the respective action goes back to Aristotle who called inferences like these ►practical syllogisms. Obviously there is something to the idea that action explanations have such a quasi-logical structure, but there is widespread disagreement as to whether practical inferences could be valid at all, whether they follow a special kind of (deontic) logic and which form a conclusion of a practical syllogism has. Is it, e.g. a value judgement, an expression of intention or perhaps the action itself?

Moreover, pointing out the primary reason of an action seems to be quite a feeble kind of explanation. Since agents usually have many competing desires which they cannot fulfill simultaneously, simply saying that there was a reason in favor for the agent's action doesn't explain why it was just this desire she satisfied and not any other. So one might wonder why we are at all interested in an agent's reasons.

One way to cope with this question is to regard the agent's intentional states as constituting something like a ►hierarchical structure, ordered according to the strength of her desires and the subjective probability of her beliefs. Reason explanations would then carry an implicit presumption that the reasons mentioned were on top of this hierarchy. Seen in this light the agent is a perfectly ►rational being and reasons explain an action because from the agent's perspective every action is displayed as the very rational thing to do.

Obviously, this view has difficulties in coping with familiar cases of ►irrationality, e.g. instances of weakness of will, and also with agency in dilemmatic cases. Moreover, as Rational Choice Theory and Game Theory have made vivid, it is sometimes awfully complicated to figure out how to behave rationally, hence it would be surprising if every human agent could be regarded as a perfectly rational being.

But besides these difficulties there is the second idea that for an occurrence's being an action it may not be sufficient that it is rational in the light of the agent, but that it also has to be caused by the agent's intention.

When this topic was discussed in the mid twentieth century by, among others, Ludwig Wittgenstein, Gilbert Ryle and G.E.M. Anscombe there was widespread agreement that because reason explanations aim at an ►interpretation (or an understanding) of the action they could not at the same time be causal explanations. The most prominent argument for this view was the so called logical connection argument, according to which the connection between a reason for doing something and the resultant action is incompatible with the logical independence requisite for cause and effect.

During the sixties these arguments were criticized very effectively, most prominently by Davidson. Since then it is the received view that reason explanations are a special kind of causal explanations. This causalistic view fits well with different approaches to the mind body problem that were developed in these days in the ►philosophy of mind, e.g. identity theory and functionalism. But there are still authors who doubt that reason explanations are causal and defend alternative views (►interpretative or ►teleological approaches).

One reason for being skeptical about the causalistic approach is that there are cases where although intentional attitudes rationalize as well as cause something the agent does, what she does isn't an action. A student, e.g. who wants to avoid an examination may try so hard to find a way of getting around it that she absentmindedly runs into a car on the street and spends her time in the hospital instead of being examined. Although the student certainly knows that having a car accident is a suitable means for avoiding an examination, and although her want to avoid the examination also has caused the accident, the accident still was not an intentional act of her. Some authors regard such cases of so called ►wayward causal chains as evidence against causalism. What they show in any case is that there is more to the explanatory value of reason explanations than just rationalization and causation. Speaking metaphorically, the causation has to take the right route, and it is a widely discussed topic in today's action theory how to unwrap this metaphor.

## Agents

Another reason for being reluctant to accept the standard causal account of action explanations is that it may threaten our ►freedom and responsibility (►Will, freedom of). The suspicion that taking reasons to be causes of actions would leave us no real freedom of choice has led some authors (most prominently Roderick Chisholm) to the view (foreshadowed in ancient conceptions of causality) that instead of the agent's intentional attitudes the agent herself should be regarded as the cause of the action.

But although most action theorists are reluctant with regard to such a special kind of ►agent causality, many agree that the standard belief-desire thesis underestimates the role of the agent, as far as full-fledged human agency is concerned. What is usually assumed to be missing is some sort of complexity that distinguishes agents like us from simpler (e.g. animal) agents. Moreover most authors agree that the crucial difference is to be found in features that are usually associated with concepts like ►personality and ►autonomy (►personal autonomy). These features in turn are either located in the reflective structure of the intentionality of persons (e.g. Harry Frankfurt's conception of second order volitions in [7]), or in a special capability of valuing (e.g. Charles Taylor's distinction between weak and strong evaluations in [8]).

Parallel to this debate about the characteristics of paradigmatic full-fledged human agents there is also a discussion about borderline cases of ►non-human agency. In accordance with common sense most authors agree that at least higher mammals are agents, but some authors are willing to concede agency to lower animals, plants and perhaps even artifacts as well. A rather different and also widely discussed question is concerned with corporate agency. While animals typically raise worries whether they are sophisticated enough for being agents, corporations, in a sense, are obviously very smart, but on the other hand they seem to be too lofty entities for counting them as true agents.

### Why Action Theory?

There are several good reasons for being interested in the results of action theory. Action theory is part of ►anthropology i.e. the study of human nature. In particular, there are strong connections with the philosophy of mind. On the one hand actions are typically characterized by their mental antecedents, therefore most problems in action theory can only be solved by taking into account the nature of these antecedents. On the other hand, many influential characterizations of mental states in the philosophy of mind refer to their behavioral output (e.g. behaviorism, functionalism), so that presumably any plausible theory of the mind has to offer an account of actions as well (for an overview see [9]).

The findings of action theory also have strong bearings on ►ethical issues. For one thing ethics is obviously interested in the problem of freedom of the will since free will is usually regarded as a prerequisite of moral responsibility, and for another there are some important distinctions in moral theory that rely on corresponding differences in action theory, most prominently the difference between actively doing something and letting something happen or omitting something, which e.g. is at the basis of the distinction in medical ethics between killing a patient and letting him die. Another distinction that is relevant for applied ethics is the one between causing something and merely accepting it as a side effect, which, e.g. is sometimes employed for drawing the line between permitted and forbidden killings of civilians in warfare. Both distinctions have to be elucidated in action theory in order to estimate their ethical impact in moral philosophy [10].

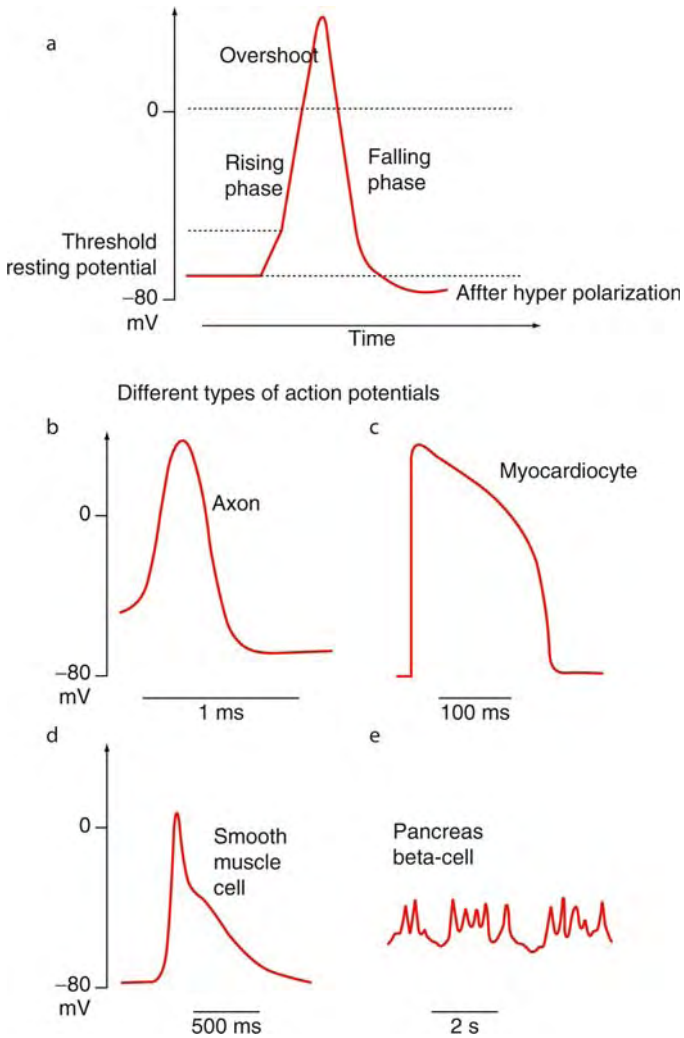
### Definition

The action potential is the active electrical response of an excitable cell membrane to a stimulus, reflected in a fairly stereotyped change in membrane potential from a resting value (negative inside) to a depolarized (either positive or less negative inside) value and back. The durations of action potentials range from a few milliseconds in neurons to hundreds of milliseconds in cardiac, gastric and intestinal cells. The underlying mechanism consists of voltage-dependent opening of $Na^+$, $Ca^{2+}$ and $K^+$ channels. The response is initially depolarizing due to opening of $Na^+$ and/or $Ca^{2+}$ channels, and subsequently repolarizing due to delayed opening of $K^+$ channels.

### Characteristics

The action potential represents membrane mechanisms, that yield an electrical signal, which propagates over long distances. The signal originates from an encoding process that converts graded, non-propagating ►receptor potentials or synaptic potentials into action potentials (►Sensory Systems).

Various examples of action potentials (red lines) in different cells are displayed in Fig. 1. Most of them are pulses (also called “impulses” or “spikes”) of fairly short duration, on the order of 1–3 ms (Fig. 1a, b) except for those in heart or smooth muscle cells (Fig. 1c, d). A spike (Fig. 1a) evolves from a ►resting membrane potential of about −50 to −90 mV, (►Membrane Potential – Basics), depolarizes at a steep rate and reaches a peak which, depending on the resting potential from which it arises, ranges from a much less negative value than at rest (typically −10 mV to −5 mV) to a positive voltage (►overshoot). In cardiac Purkinje fibers, myocytes and some cells of the gastro intestinal tract. the action potential has a prolonged plateau phase (Fig. 1c), while in neurons and skeletal muscle cells, rapid repolarization brings the action potential back close to the resting potential, where a ►delayed depolarization or protracted ►afterhyperpolarization (AHP) may follow (Fig. 1a, b). Some neurons, such as



**Action Potential. Figure 1** (a–e) Intracellular records of membrane and action potentials (red lines). (a) Schematic representation of an action potential with its phases. (b) The action potential measured in a squid axon is a prototype of the fast action potential produced by nerve or muscle fibers. It is about 100 times faster than the action potentials of heart muscle cells. In heart and smooth muscle cells (c,d), the rising phase of the action potential is carried by $Na^+$ currents through $Na^+$ channels, while the prolonged plateau phase is mediated by $Ca^{2+}$ currents through $Ca^{2+}$ channels. E: Endocrine cells such as the pancreatic β-cells also produce action potentials, which are mediated by $Ca^{2+}$ and trigger exocytosis of the hormone (in this case insulin) (Adapted from ref. [1]).

the ►motoneurons innervating skeletal muscle fibers, may have pronounced (several mV deep) and long-lasting (50–200 ms) afterhyperpolarizations.

## The Squid Giant Axon

The basic processes underlying the generation of the axon action potential were studied and described by Hodgkin, Huxley (A.L. Hodgkin, A.F. Huxley, Nobel Prize of Physiology or Medicine 1963) and coworkers, including B. Katz (Nobel Prize of Physiology and Medicine (1970). The giant axon of the squid turned out to be a favourable structure because its size (diameter 0.5–1 mm) and robustness allowed it to be removed from the animal, placed in a bath and subjected to varying extracellular compositions. Its size allowed insertion of relatively bulky longitudinal electrodes, and because of membrane durability it was possible to squeeze out the intracellular content and replace it with solutions of varying composition (►Intracellular Recording).

## Processes Underlying the Squid-Axon Action Potential

### *Need for Extracellular $Na^+$*

The squid-axon experiments showed that the depolarization (rising phase) of the action potential results from a regenerative increase in $Na^+$ conductance, beginning

with the observation that reducing extracellular $Na^+$ concentration diminished the amplitude and rate of depolarization. Subsequently, current measurements were made with the ►voltage-clamp technique, which identified voltage- and time-dependent properties associated with the action potential.

### Voltage-Dependent Currents

Voltage changes during the action potential are associated with several different currents:

- $Na^+$ and $K^+$ conductances and the ensuing currents show complicated dependencies on both time t and time-varying membrane potential V(t):

$$I_{Na}(V,t) = g_{Na}(V,t)\,[V(t) - E_{Na}], \qquad (1a)$$

$$I_K(V,t) = g_K(V,t)\,[V(t) - E_k], \qquad (1b)$$

These dependencies lead to a fast ionic current $I_{ion}(V,t)$ through the membrane, composed of $Na^+$ and $K^+$ currents:

$$I_{ion}(V,t) = I_{Na}(V,t) + I_K(V,t) \qquad (2)$$

- Although small and relatively insignificant in the squid axon, a so-called leakage or ►leak current through other ion channels must be taken into account, if only for corrective purposes [2]:

$$I_L(V,t) = g_L(V,t)\,[V(t) - E_L]. \qquad (3)$$

- Fast voltage changes during the action potential generate ►capacitative currents $I_C$ due to charging and discharging the membrane capacitance $C_m$:

$$I_C(t) = C_m.dV(t)/dt \qquad (4)$$

- The total current during the action potential would thus be:

$$I_{tot}(t) = I_{Na}(V,t) + I_K(V,t) + I_L(V,t) + I_C(t) \qquad (5)$$

The superposition of various time-and voltage-varying currents was difficult to disentangle using the more conventional methods of the time. The invention of the voltage-clamp technique (►Intracellular recording) made it possible to separate and analyze voltage- and time-dependent properties of the action potential.

### Voltage Clamp

The basic idea of the voltage-clamp technique is as follows. Rather than studying the naturally occurring action potential with its complicated time- and voltage-dependent currents, abrupt step-like changes in membrane potential from an initial "holding" potential $V_h$ to a final test potential $V_f$ are utilized. The fundamental principle is to keep the membrane potential constant before and after the step by injecting, via a second intra-axonal electrode, currents into the axon. These currents would, of necessity, have the same magnitude, but the opposite polarity of those elicited by the voltage step.

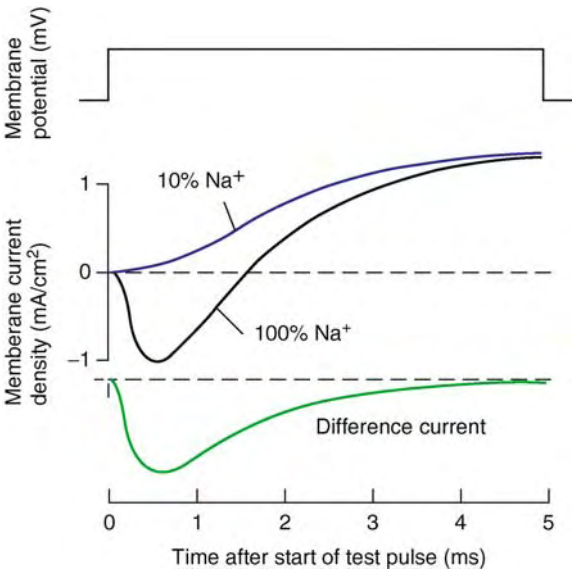
The method was revolutionary for its time, introducing a number of advantages:

1. The transient capacitative current $I_C$ (Eq. 4) is isolated because it only occurs during a very brief time (order of microseconds), whereas the slower ionic currents persist and can be measured independently of $I_C$.
2. The membrane potential can be "clamped" at various, constant test levels, at which the time course of the voltage-dependent net current [$I_{net}$ (t)] can be followed.
3. Varying the voltage-step size reveals the dependency of ion conductances on membrane potential.
4. Conditioning voltage steps and holding potentials permit measurements of time- and voltage-dependent properties of ion channel activation and inactivation.
5. Changes in extra- and intracellular ion concentrations, and/or elimination of specific ion conductances with ion channel neurotoxins, can be used in conjunction with voltage-clamp protocols to elucidate the relative contributions of $I_{Na}(t)$ and $I_K(t)$ to $I_{net}(t)$.
6. The experimental arrangement for voltage-clamping the squid axon has the further advantage of producing a uniform space clamp, because an identical transmembrane potential change is impressed across the entire length of the membrane. The result is that current changes due to longitudinal current spread between regions of different membrane voltage cannot contaminate transmembrane current flow through voltage-gated ion channels.

### $Na^+$ and $K^+$ Currents Elicited by Depolarization

An example of a voltage-clamp experiment is shown in Fig. 2. The membrane is abruptly depolarized from an initial holding potential of −65 mV by 56 mV to −9 mV (upper trace). This evokes an initial capacitative current (not shown) that is very brief and precedes an inward-outward sequence of slower currents (middle panel, lower trace). Provided this latter sequence is ionic, various manipulations should demonstrate its nature and composition.

Replacing about 90% of the external $Na^+$ with choline, an impermeant ion, renders the $Na^+$ concentrations inside and outside the axon approximately equal and, according to the Nernst equation (►Membrane Potential – Basics), brings $E_{Na}$ to about zero. If, after the step, the membrane potential is then held at 0 mV, no net $Na^+$ current should flow, and the remaining current should be due to $K^+$ (Fig. 2, middle panel, blue line labelled "10% $Na^+$"), as verified by the observation that its magnitude is altered by varying extracellular $K^+$



**Action Potential. Figure 2** Classical ion substitution method for studying the ionic basis of voltage-clamp currents. The axon is depolarized from −65 mV by 56 mV to −9 mV (top trace). With normal seawater (100% $Na^+$), the typical curve (black line in the middle panel) results. Reducing the external $Na^+$ concentration to 10% of normal results in the blue line (labeled "10% $Na^+$") in the middle panel. The difference between these two curves (green line in lower panel) corresponds to the current carried by $Na^+$. T = 8.5°C (Adapted from ref. [3]).

concentration (not shown). The $K^+$ current is slowly activated by depolarization, directed outward, has a slow time course, and remains activated throughout the depolarization. The difference between the $K^+$ current (blue line) and the mixed current (Fig. 2, middle panel, black line labelled "100% $Na^+$") is plotted in the bottom trace (green line labelled "Difference current") and corresponds to the current carried by $Na^+$ (►Intracellular Recording). It is an inward current that peaks within 1 ms and then decays over a few milliseconds despite continued depolarization. Hence, the $Na^+$ current is quickly activated, but subsequently ►inactivates automatically (see below).

## Dependence of $Na^+$ and $K^+$ Currents and Conductances on Depolarization Amplitude

The precise dependence of these currents on the amplitude of the voltage steps and, hence, the steady state potential, can be established [4] by stepping the membrane from a holding potential (say −65 mV) to various end-potentials. The late $K^+$ current increases as the depolarizing steps increase. By contrast, the early $Na^+$ current first increases, but subsequently decreases with increasing depolarization, is absent at +52 mV (corresponding approximately to the $Na^+$ equilibrium potential), and is reversed in sign (directed outward) at +65 mV. The $Na^+$ and $K^+$ currents can be transformed into the underlying conductance changes by using Eqs. 1a, b. Like the currents, these conductance changes depend on the amplitude of the voltage step. While the $K^+$ conductance remains elevated with continuing depolarization, the $Na^+$ decays on its own. This process is due to ion channel inactivation (see below).

## Pharmacological Identification of $Na^+$ and $K^+$ Conductances

The above results indicate that the squid giant axon must possess (at least) two voltage-dependent conductances with different, very specific properties. Indeed, voltage-clamp experiments have shown that they also have very different pharmacological sensitivities. The neurotoxins ►tetrodotoxin (TTX) or ►saxitoxin (STX) and local anaesthetics such as procaine, cocaine and tetracaine block voltage-gated $Na^+$ current but leave the $K^+$ current intact. On the other hand, ►tetraethylammonium (TEA) as well as cesium ions block $K^+$ currents but not sodium currents [5].

## Ion channels that carry $Na^+$ Current Inactivate during the Time Course of the Action Potential

Voltage-clamp experiments such as those described above pointed to two processes that bring about the fall of the action potential from its peak: inactivation of the $Na^+$ conductance and late development of the $K^+$ conductance. If both $Na^+$ activation and inactivation during an action potential are triggered by depolarization, the two processes must be timed in such a manner as not to cancel each other. Inactivation should have a slower time course that allows it to follow activation. By the same token, any degree of antecedent inactivation should suppress a second activation (see below), and preceding membrane potential changes should influence the amount of $Na^+$ activation. These predictions have been confirmed in pulse-conditioning experiments and have functional consequences on discharge properties during bursts of action potentials (see below).

In voltage-clamp experiments on squid giant axons, depolarization from −65 mV to −21 mV elicits the usual inward-outward sequence of currents. However, when the voltage step to −21 mV is preceded by a short-lasting, smaller depolarization of 14 mV (conditioning pre-pulse), the inward current is much reduced. Conversely, when a hyperpolarizing pre-pulse of 31 mV is applied, the step depolarization elicits a much stronger inward current. A plot of normalized inward current vs. amount of conditioning potential change shows that at the normal resting potential, about one-third of the $Na^+$ current is inactivated. The functional consequence is that antecedent membrane hyperpolarization decreases the degree of inactivation and therefore

increases action potential amplitude, while residual membrane depolarization has the opposite effect.

The time course of recovery from $Na^+$ inactivation has been worked out in paired depolarizing pulse paradigms, where the pulses are delivered at varied intervals. They show that the $Na^+$ system recovers from inactivation with an approximately exponential time course and a time constant on the order of 5 ms, with the time constant depending on the holding potentials [5].

At the peak of an action potential and during the subsequent decline toward resting potential the $Na^+$ channels exhibit reduced depolarization-dependent permeability, from which recovery occurs gradually over several milliseconds. This period of reduced channel reactivity characterizes the ►refractory period. At peak membrane depolarization and shortly thereafter, $Na^+$ permeability cannot be activated at all, however strong the depolarization. This is called the absolute refractory period. During the subsequent relative refractory period, $Na^+$ permeability can be increased by relatively large degrees of membrane depolarization.

Proteolytic enzymes such as pronase or papain applied intracellularly impair or remove $Na^+$ inactivation, leading to long-lasting $Na^+$ activation during prolonged depolarization [5].

## Consequences of $Na^+$ Inactivation

The impact of membrane depolarization on both activation and inactivation of $Na^+$ conductance has profound functional consequences. The sequence of $Na^+$ activation and inactivation:

1. Limits action potential frequency. Since an action potential is followed by an absolute refractory period, there is a minimal interval at which one action potential can follow the preceding one. This minimal interval defines the maximal rate of occurrence of action potentials.
2. Leads to accommodation. When a nerve fiber is slowly depolarized by a ramp-like rather than a step-like waveform, the $Na^+$ inactivation may have time enough to develop in step with $Na^+$ activation. Slow depolarization – even to very high levels – may thus not elicit action potentials, but rather completely prevent their generation.
3. Has clinical implications. Nerve, muscle and gut paralysis can result from long-lasting depolarization (►depolarization block).

## The Hodgkin–Huxley Model of the Action Potential

Voltage-clamp experiments revealed that the $Na^+$ and $K^+$ conductances that give rise to the action potential vary with membrane potential and time. A successful attempt at quantitatively describing these dependencies and mathematically model the squid-axon action potential was made by Hodgkin and Huxley [6]. They were able to reconstruct the shape of the action potential and its underlying ion conductance changes, as shown in Fig. 3. The "HH equations" and variations thereof are still used to model neuron bioelectrical properties.

## Channel Gating Currents

Hodgkin and Huxley [6] suggested that channel opening should be associated with the movement of charged particles within the membrane. This was subsequently demonstrated in voltage-clamp experiments with computer averaging and subtraction techniques [7].

## Single-Channel Currents

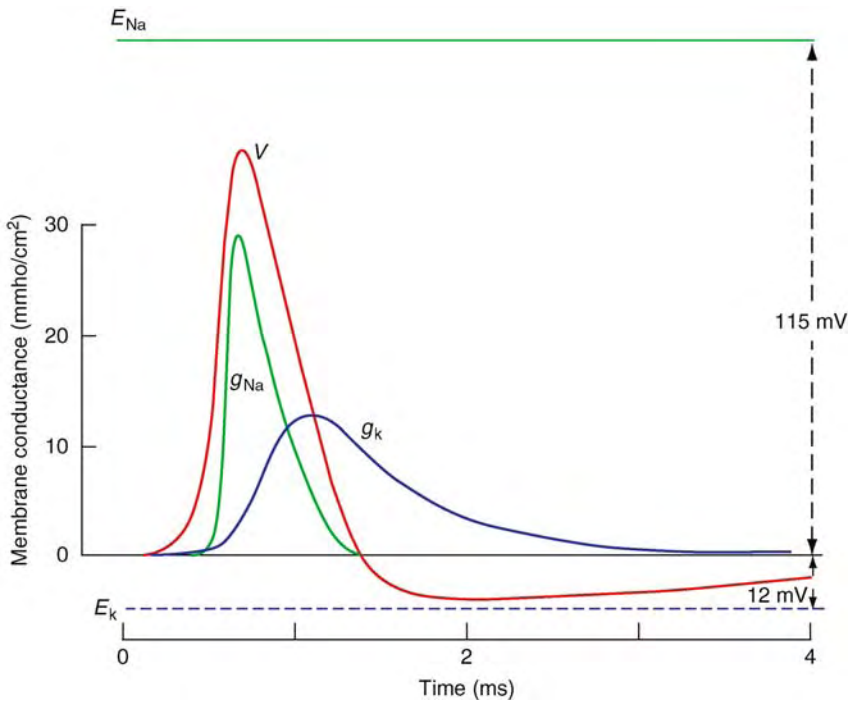
Within the last 25 years, it has become possible to voltage-clamp small patches of cell membrane and record single-channel currents with the ►patch-clamp technique (►Intracellular Recording). Single-channel inward currents appear at varying times after step depolarization, but most often close to the beginning. When hundreds of individual recordings are averaged, the average inward current has a time course comparable with that of the inward $Na^+$ current shown in Fig. 2 (green line in lower panel: "Difference curve"). Experiments such as these have revealed some interesting properties of single ion channels. They indicate that channel behavior is probabilistic; the current reflects the probability of being open. The $Na^+$ current recorded with gross electrodes (Fig. 2) results from the superimposed activity of many $Na^+$ channels.

## Action Potentials in Central Neurons

The squid axon is a relatively simple system devoted to conducting action potentials along the axon (►Action Potential Propagation), and probably for this reason can be content with two major ion conductances. Central neurons, however, have much more varied signal-processing functions and therefore express complex repertoires of ion channels, endowing them with a plethora of firing behaviors. Thus, individual neurons in the mammalian brain typically express several subtypes of ►voltage-dependent $Na^+$ channels, ►voltage-dependent $Ca^{2+}$ channels, ►voltage-dependent $K^+$ channels, ►$Ca^{2+}$-activated $K^+$ channels (►Neuronal potassium channels), ►hyperpolarization-activated, ►non-selective cation channels, and more. The different combinations of channels enable diverse action potential shapes and firing patterns. Action potential amplitude, shape and firing rate are particularly important at presynaptic axon terminals, where they co-determine – via the amount of presynaptic $Ca^{2+}$ influx – the amount of released ►neurotransmitter [8].

## Contribution of $Na^+$ Currents to Action Potentials

In central neurons, very much like in the squid axon, the rising phase of the action potential is generated by very fast activation and inactivation of voltage-dependent



**Action Potential. Figure 3** Reconstruction of the action potential. The time courses of the propagated action potential and underlying ionic conductance changes computed by Hodgkin and Huxley [5] from their voltage-clamp data. The constants used were appropriate to a temperature of 18.5°C. The calculated net entry of $Na^+$ was 4.33 pmole/cm$^2$, and the net exit of $K^+$ was 4.26 pmole/cm$^2$. The calculated conduction velocity was 18.8 m/s (Adapted from ref. [6]).

$Na^+$ channels, although the detailed kinetics may vary between different types of neuron and even between different parts of a neuron [8].

### Contribution of $Ca^{2+}$ Current to Action Potentials

Although individual mammalian neurons typically express at least four or five types of voltage-dependent $Ca^{2+}$ channels, inward $Ca^{2+}$ currents contribute little to the action potential upstroke because of their slow activation kinetics, whereby they start to be activated near the peak of the action potential and are maximal during the repolarization phase. In addition to initiating intracellular signalling pathways, the action potential-evoked $Ca^{2+}$ influx influences action-potential shape and firing pattern. Conversely, since the activation and inactivation kinetics of the $Ca^{2+}$ channels are strongly voltage-dependent, the shape and width of the action potential determines the amount of evoked $Ca^{2+}$ influx and thereby, at presynaptic terminals, the amount of neurotransmitter released [8].

Among the $Ca^{2+}$ channels expressed are low-voltage-activated T-type channels (Cav3 family channels) and high-voltage-activated channels including L-type (Cav1.2 and Cav1.3), P/Q-type channels (Cav2.1), N-type (Cav2.2) and R-type (Cav2.3) channels.

Pharmacological blockade of $Ca^{2+}$ channels often broadens the action potential and lengthens dischage duration, because $Ca^{2+}$ influx leads to opening of large-conductance ►$Ca^{2+}$-activated $K^+$ channels (►BK channels) that promote membrane repolarization. Small-conductance $Ca^{2+}$-activated $K^+$ channels (SK channels) are also coupled to $Ca^{2+}$ influx. They activate too slowly to affect action-potential repolarization, but they do contribute to the following afterhyperpolarization (AHP; below) [8].

### Contribution of $K^+$ Current to Action Potentials

Central neurons express a huge variety of voltage-gated $K^+$ channels, only a fraction of which activate appreciably during the action potential. Significant contributions to action potential repolarization are commonly made by Kv3 family and Kv4 family channels mediating the A-type current ($I_A$.) In some ►fast-spiking neurons (below), Kv3-mediated current appears to be the major current flowing during repolarization. In glutamatergic neurons of hippocampus and cortex, repolarization is mediated by at least three types of $K^+$ currents: the BK $Ca^{2+}$-activated $K^+$ current (above), and two purely voltage-dependent currents, $I_A$ and $I_D$. $I_A$ shows relatively rapid inactivation

and is, in cell bodies and dendrites, mostly mediated by the Kv4 family channels. $I_D$ is activated by sub-threshold depolarizations, inactivates slowly and is blocked by ►4-aminopyridine, which broadens action potentials. In some neurons, high rates of firing lead to broadening of action potentials that probably results from cumulative inactivation of $K^+$ channels, and may facilitate synaptic transmission by increasing $Ca^{2+}$ influx in presynaptic terminals [8].

### Afterdepolarization

In many neurons (e.g., pyramidal cells of hippocampus and cortex), the fast phase of action potential repolarization is followed by a delayed depolarization, either attached to the fast phase as a slow phase or as a hump intercalated between a fast transient and a subsequent afterhyperpolarization. The origins of ►afterdepolarization may be passive and/or active. That is, an action potential in the cell soma may recharge the dendritic tree with its large surface area and ►capacitance (electrical), which takes time. This electrotonic mechanism may be amplified by active dendritic conductances, whose activation is often delayed and slower than that of the somatic conductances. Active ionic currents contributing to afterdepolarization include ►persistent $Na^+$ currents, ►resurgent $Na^+$ currents, R-type and T-type $Ca^{2+}$ currents, and currents due to ►non-selective cation currents [8].

### Afterhyperpolarization (AHP)

While in the squid axon, the afterhyperpolarization (Fig. 3) is generated by the merely slowly inactivating voltage-dependent $K^+$ conductance activated during the action potential, afterhyperpolarizations in mammalian central neurons are more complex. First, they may show different phases: fast, medium and slow. Second, the contributing $K^+$ channels include BK and SK channels and Kv7 channels mediating the ►M-current. BK-channel-mediated afterhyperpolarizations are usually brief, while SK-channel-mediated ones can last up to seconds [8].

### Repetitive Firing

Many central neurons discharge action potential over a wide range of frequencies and with various patterns, to which many factors already discussed may contribute. For example, if the hump-like intermittent afterdepolarization is fast and large enough, it may elicit new spikes and thus burst firing [8]. On the other hand, the depth and duration of afterhyperpolarization (reduced excitability) co-determines the firing pattern, e.g., in skeletomotoneurons [9].

The rates and patterns of repetitive firing are also influenced by several sub-threshold currents that flow between action potentials and accelerate or slow the approach to threshold. Such currents include the steady-state "persistent" $Na^+$ current, $I_A$ and $I_D$ $K^+$ currents, the $I_h$ current carried by ►hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, and currents carried by low-voltage-activated (T-type) $Ca^{2+}$ channels [8].

The ►A-type $K^+$ current ($I_A$) activates and inactivates at sub-threshold voltages. During the post-spike hyperpolarization, $I_A$ inactivation is partially removed; during the subsequent depolarization, $I_A$ first activates and slows the approach to threshold, and then inactivates enabling threshold crossing. The $I_D$ current plays a similar role but inactivates more slowly [8].

Most central neurons possess TTX-sensitive and insensitive, voltage-dependent, steady-state "persistent" inward $Na^+$ current flowing at voltages between −65 and −40 mV, which significantly influences sub-threshold membrane potential changes and thus the firing rate and pattern of discharge [8].

One function of low-voltage-gated (T-type) $Ca^{2+}$ currents is the generation of ►rebound bursting following hyperpolarization (e.g., after a prolonged inhibitory synaptic input), which removes its inactivation [8].

Many central neurons fire spontaneously (without overt excitatory inputs) and fairly regularly, and are called "►pacemakers". In some of these neurons, the "persistent" $Na^+$ current plays the major role to drive membrane potential to threshold, in others it is the $I_h$ current. In dopaminergic midbrain neurons, a sub-threshold $Ca^{2+}$ current appears to drive pacemaker activity [8].

### Fast-Spiking Neurons

Neurons capable of firing at high rates for prolonged periods, e.g., cerebellar ►Purkinje cells, often possess voltage-gated $K^+$ channels of the Kv3 family, whose fast and steeply voltage-dependent activation and inactivation kinetics allow them to produce narrow action potentials and short refractory periods suitable for fast repetitive firing. In some types of central neurons, this mechanism may be supported by a special "resurgent" $Na^+$ current, which activates transiently upon repolarization after inactivation due to strong depolarization and is sensitive to tetrodotoxin (TTX) [8].

## Synonyms

Action potential conduction

## Definition

Movement of the action potential along the cell surface.

## Characteristics

The evolutionary pressure to develop the ►action potential resulted from the inability of graded local membrane potential changes to electronically spread across the cell surface over wide distances (►Electrotonic Spread). Self-evidently, the action potential holds its promise to do exactly that, otherwise it would not have evolved. The mechanisms underlying the propagation along muscle fibers and axons are surprisingly simple: amplification of ►graded potential changes into much larger, all-or-none action potentials and electrotonic spread. Action potential propagation along a nerve or muscle fiber occurs automatically as a consequence of the axonal cable structure (►Cable Theory).

### Continuous Action Potential Propagation along an Axon or Muscle Fiber

First consider a smooth muscle or nerve fiber. The mechanism, somewhat simplified, is as follows.

#### *Propagation Mechanism*

Since charging or discharging of a capacitor takes some time, expressed in the time constant, the substantial depolarization-induced ionic ($Na^+$) currents are delayed. The amount of current needed to unload the membrane capacitor by a certain amount depends on the capacitor's surface, which increases linearly with fiber radius, and so the capacitative current required for depolarization should increase by a given amount. But note that the amount of source current also increases linearly with the fiber radius because the number of opening $Na^+$ channels does.

#### *Conduction Velocity*

In axons like the squid axon, the conduction velocity v is related to the ►space constant (►Cable Theory) for electrotonic spread. The reason is simple: The farther the local currents reach out in front at any moment, the more advanced are the membrane regions that are depolarized to threshold for action potential generation the next moment. Thus:

$$v \propto \lambda = \sqrt{R_M/Ri} \qquad (1)$$

where $R_M$ is the membrane resistance and $R_i$ is the longitudinal resistance of the fiber interior.

Since, with r being the fiber radius,

$$R_M \propto 1/(2\pi r) \qquad R_i \propto 1/(\pi r^2)$$

$$v \propto \sqrt{r} \qquad (2)$$

One means of increasing the conduction velocity is therefore to increase the fiber diameter. This means is used especially by invertebrates. For example, the squid giant axon innervates the mantle musculature whose rapid contraction ejects water in the squid's flight reaction. Clearly, a high action potential conduction velocity has a high survival value, and therefore the axon has evolved to reach fiber diameters of 0.5–1 mm and maximal conduction velocities of up to ca. 20 m $s^{-1}$ (depending on ambient temperature).

In higher organisms, however, the evolutionary pressure on the complexity and speed of neural information transmission increases dramatically, requiring an ever-increasing number of fast parallel signal channels. For example, the human optic nerve contains about 1 million

nerve fibers, many of them conducting several times faster than the squid giant axon. These values cannot be achieved with the squid solution of producing "giant" axons. Just imagine how the human optic nerve would look like if made up of giant axons of appropriate conduction velocities. The problem for Nature therefore was to invent a more efficient method that would allow for an increase in velocity without a proportional increase in space as well as metabolic and other costs.

## Saltatory Action Potential Propagation along an Axon

Since the conduction velocity is related to cable properties of the axon, a possible solution to the above problem would be to change one or the other cable parameter appropriately. A possible mechanism would be to increase the ►length constant $\lambda = \sqrt{R_M/R_i}$ by increasing $R_M$, that is, by thickening the membrane somehow (►Cable Theory).

### *Myelination*

The solution Nature came up with is a ►myelinsheath. In the peripheral nervous system, myelin sheaths are built by ►Schwann cells, in the central nervous system they are built by ►oligodendrocytes, this different origin having implications for diseases and restoration of function after injury. A myelin sheath is built by repetitively wrapping the cell membranes of a Schwann cell or oligodendrocyte around an axon, in which process the cytoplasm is squeezed out. Thereby a stretch of axon of 0.5–2 mm length becomes covered by a multi-layered stack of membranes, adjacent stretches being separated by gaps of 1–2 μm. These gaps are called ►nodes of Ranvier and the stretches in between internodes. There may be as many as 100 myelin wrappings between two nodes of Ranvier, producing a sheath as thick as 2 μm [2].

The myelin sheath is a good insulator. With 100 double-membrane layers in the sheath, the Ohmic resistance of the sheath to perpendicular current flow is 200 times higher than that of the single cell membrane. By contrast, because the capacity of a capacitor is inversely proportional to the distance of the plates, the capacity of the myelin sheath and, hence, the amount of charge stored across it for a particular potential difference, is 200 times smaller than that of the single membrane layer. The amount of charge stored on an internodal region of 2 mm length is only about half that stored in a single 1–2 μm ►node of Ranvier [2]. The reduced charge capacity and the higher resistance to transmembrane current flow cause resting and action potentials to be generated only at the nodes.

### *Saltatory Conduction*

When a node is depolarized during an action potential, local circuit currents depolarize the next one ahead, without discharging the internodal region. The excitation thus hops from node to node rather than coursing continuously through all membrane regions, this mode of propagation being called ►saltatory conduction (saltare, Latin for to leap, dance). The conduction velocity v is determined by a number of factors [2], but largely by the length of the ►internode, which is approximately proportional to the fiber diameter. In myelinated nerve fibers, the conduction velocity is linearly correlated with outer fiber diameter, with the proportionality constant (Hursh factor) being about 6 m/s per μm in cats, where maximal conduction velocities are on the order of 120 m $s^{-1}$ for a fiber of 20 μm diameter. For comparison, according to the square-root rule (1), an unmyelinated squid axon of 20 μm diameter would have a conduction velocity of 4 m $s^{-1}$ [2]. It should be noted that conduction velocity in myelinated and unmyelinated fibers also depends directly on temperature, because the operation of channels does. $Na^+$ channels, for instance, open more slowly at lower temperatures [2]. This is an experimental means of slowing nerve conduction in human and animal experiments.

Saltatory conduction confers several advantages:

1. Economy of space: A myelinated frog nerve fiber of 10 μm diameter has the same conduction velocity as an unmyelinated squid axon of 500 μm diameter, but 2,500 10-μm fibers can be packed into the volume of a squid giant axon. A mammalian muscle nerve typically contains on the order of 2,000 large-diameter (10–20 μm) fibers and is about 1 mm thick. If the nerve were composed of the same number of unmyelinated fibers of the same conduction velocities, its diameter would lie between 3.5 and 4 cm [2].
2. Economy of energy expenditure: The ►$Na^+$-$K^+$pump that generates and maintains the resting potential is needed only at and close to the nodes of Ranvier, amounting to an immense saving of metabolic energy.
3. High safety factor for conduction: The current density discharging the capacitor at the narrow nodes of Ranvier is so high as to easily secure action potential generation.

In the central nervous system, the "white matter" is characterized by high concentrations of myelinated axons, while the "gray matter" contains lower concentrations of myelin.

### *Problems with Myelination*

The myelin sheath has been an extremely useful invention of Nature to dramatically enhance information transmission and processing capabilities in the nervous system. However, as all good inventions, it has its drawbacks. These are indicated by limits to regeneration after injury (►Regeneration) and various neurological diseases involving myelin.

### Axon Regeneration and Its Limits

Prerequisites for functional recovery following axonal interruption (axotomy) in the nervous system are [3]:

1. Survival of the injured neuron.
2. Axon regrowth of sufficient length to reach its target.
3. Axon guidance and path-finding such that the appropriate connections are reformed.
4. Formation and maintenance of functional synapses.

Functional recovery following injury differs dramatically in the peripheral and the central nervous system (►Regeneration). If a peripheral nerve is injured so that some or all of its axons are severed, it usually regenerates by sending out new processes. Thus there is a robust growth of injured axons within the peripheral nervous system of vertebrates and in some regions of the central nervous system of lower vertebrates [3]. This is facilitated by the nerve sheath being intact or re-sutured surgically. By contrast, axon regeneration is much less likely in the central nervous system. In the central nervous system of adult mammals and higher vertebrates, neurons that survive axotomy extend their axons only a short distance (approximately 1 mm). The reasons for this are multiple and complex, from physical or molecular barriers built by glial scarring at the lesion site, to the possibility that the normal myelinated environment contains potent growth inhibitors or lacks growth-promoting molecules. However, combined approaches raise the possibility of overcoming these problems [4].

### Demyelination Disorders

The importance of myelin for normal nervous system operation is attested to by a number of demyelination diseases, two of which are the ►Guillain-Barré syndrome and ►Multiple sclerosis.

### Ephaptic Transmission

Demyelination disorders may impair fast action potential propagation, but also lead to non-synaptic contacts between nerve fibers with pathological transfer of electrical impulses.

### Composition of Peripheral Nerves

Peripheral nerves are composed of nerve fibers of different degree of myelination, diameter and conduction velocity. Using both histological and electrophysiological techniques, nerve fibers have been classified as shown in Table 1.

## Back-Propagation of Action Potentials

In many neurons, action potentials originate close to the origin of the centrifugal axon and then not only travel down the efferent axon, but also 'back-propagate' retrogradely into the dendritic tree. These back-propagating action potentials are supported by active, ►tetrodotoxin-sensitive, ►voltage-dependent $Na^+$ channels and possibly ►$Ca^{2+}$ channels, and decrease in amplitude but increase in width, the further they travel into the tree. The extent of this decremental back-progagation varies widely between different types of central neurons, different specimens of the same sort, and possibly different dendritic branches of individual cells. Back-propagation depends on cell morphology and densities of dendritic ion channels, modulatory influences provided by excitatory and inhibitory inputs and ►neuromodulators [8].

Several functions have been proposed for back-propagating action potentials, among which are [8]:

1. Short-term changes in ►synaptic efficacy due to the back-propagating action potential's drastic effects on membrane potential and voltage- and

**Action Potential Propagation. Table 1** Properties of different peripheral nerve fiber groups (Data from [5–7])

| Group | | Function | Diameter (µm) | Conduction velocity (m $s^{-1}$) |
|---|---|---|---|---|
| I | Aα | Ia afferents from muscle spindle endings (stretch) | ca. 12–20 | ca. 70–120 |
| | | Ib afferents from Golgi tendon organs (force) | | |
| | | Motor efferents to skeletal muscles | | |
| II | Aβ | Afferents from cutaneous mechano-receptors (pressure, touch, vibration) | ca. 6–12 | ca. 30–70 |
| | | Afferents from secondary muscle spindle endings (stretch) | | |
| II | Aγ | Motor efferents to muscle spindle (intrafusal ca. 2–8 muscle fibers) | ca. 2–8 | ca. 15–30 |
| III | Aδ | Afferents for mechano-, chemo-, thermo- and nociception | ca. 1–5 | ca. 5–30 |
| | B | Preganglionic sympathetic efferents | <3 | ca. 3–15 |
| IV | C unyelinated | Afferents for mechano-, chemo-, thermo- and nociception | 0.1–1.3 | ca. 0.6–2 |
| | | Postganglionic sympathetic efferents (motor to glands and smooth muscle) | | |

time-dependent dendritic ion channels, whereby the properties of synaptic conductances are changed.
2. Long-term changes in synaptic efficacy. It has been proposed that back-propagating action potentials change synaptic efficacy on a long-term time base. Long-term increases in synaptic efficacy often depend on increased $Ca^{2+}$ influx, which may elicit a cascade of metabolic events. The rises in intra-dendritic $Ca^{2+}$ concentrations occur following (i) activation of ►voltage-dependent $Ca^{2+}$channels due to the back-propagating action potential, (ii) activation of postsynaptic ►N-methyl-D-aspartate (NMDA) channels during depolarization [8]. Thus, nearly coincident pre- and postsynaptic activity and consequent intra-dendritic $Ca^{2+}$ increases would be expected to strengthen excitatory synapses.

The extent of action potential back-propagation into the dendritic tree is not invariant, but depends on several variables, such as interactions between synaptic inputs and postsynaptic activity and modulatory factors. Appropriately timed excitatory inputs to distal dendrites may enhance action potential back-propagation, and inhibitory (e.g., GABAergic) inputs suppress it [8]. Locally operating inhibitory inputs may control the routes of action potential propagation through the dendritic tree and thereby the action of action potentials on other synaptic inputs. Depending on where in the soma-dendritic tree the inhibition operates, it may differentially influence the propagation of excitatory synaptic currents to the action potential-generating site. Inhibition at the soma would globally shunt excitation originating in vast spaces of the dendritic tree, while local inhibition in the dendrites would counteract excitation originating peripherally to the site of inhibition. The converse may now hold for back-propagating action potentials. Synaptic inhibition acting at the soma may prevent or attenuate back-propagating action potentials and, hence, quench their effects on synaptic inputs widely distributed in the dendritic tree, while local dendritic inhibition may have subtle and selective local effects.

►Recurrent inhibition in the spinal cord is among the types of inhibition influencing action potential back-propagation in ►motoneurons. It has been proposed that recurrent inhibition might provide a mechanism involved in regulating, calibrating and adapting the patterns and quantitative characteristics of excitatory reflex inputs to motoneurons during the stance phase. It could do so by influencing the degree of retrograde invasion of the motoneuron dendritic trees by back-propagating action potentials [9].

# Action Representation

Laura Bamert, Fred W. Mast
Department of Psychology, University of Lausanne, Lausanne, Switzerland

## Definition

The brain represents actions and this information is used to prepare and execute voluntary movements. Action representations are also drawn upon when we imagine a movement or when we observe and understand actions of others. As regards the underlying brain structures, action representations involve brain activity in the frontal and parietal lobes.

## Characteristics

### Different Pathways for Perception and Action

Action and perception mutually depend on one another (e.g. when we look for a pen on our desk we first need to detect it visually before picking it up) and it is not evident that the underlying mechanisms can in fact dissociate. Visual input from the retina first reaches occipital cortex and the visual information is then further processed in the ventral and dorsal streams of the brain. Ungerleider and Mishkin [1] postulate that the dorsal stream, from the occipital primary visual areas to the inferior parietal lobule, is involved in the perception

of where objects are in space, whereas the ventral stream, which ends in the inferior temporal cortex, is associated with the perception and recognition of objects. In line with this view, the dorsal and ventral streams are referred to as the "where-stream" and the "what-stream" respectively. It has been suggested that the two streams differ primarily in terms of the output they provide [2]. Indeed, the output provided by the dorsal stream plays an important role in action related processes. Patients with lesions to the posterior parietal cortex (dorsal stream) have an impaired capacity to execute spatially accurate movements to visual targets despite the preserved capacity to correctly estimate the size of the target (optic ataxia) [3]. Lesions to the ventral stream, however, leave intact the ability to act appropriately whereas perceptual judgments are impaired.

Indeed, appropriate actions need not necessarily rely on a perfect perception of a visual target. Studies on visual illusions provide further evidence, an example of which is the Ebbinghaus-illusion: two identical circles appear different in size when one of them is surrounded by set of larger circles (leading to a relative decrease in perceived size) and the other one is surrounded by a set of smaller circles (leading to a relative increase in perceived size). Interestingly, this visual illusion shows up much weaker when measuring the finger grip as participants prepare to pick up the central circle [4]. Thus, the grip aperture turns out to be more adequate to the real size of the circle and thus depends less on the confounding visual context. The representations guiding our movements are provided by a neural substrate that does not completely overlap with those representations involved in visual perception.

## Action Observation

One of the most remarkable findings in recent neurophysiological research is the discovery of a population of visuo-motor neurons in the ventral premotor cortex [5]. These neurons were discovered in the macaque monkey's frontal area F5 (corresponds to area 44 in humans) and have been called "►mirror neurons" as they fire when a goal-directed action is executed and during observation of the same action performed by another agent. These findings gave rise to a new view on how actions are represented. It has been suggested that the mere observation of a motor act causes the observer's motor system to resonate [5]. Motor representations are thus used to understand the meaning of an observed motor action. Moreover, the premotor areas containing mirror neurons are not driven by the visual input alone as they are still activated when the final part of the observed action is hidden. In this context, intended actions are yet another important factor, which was studied by Iacoboni et al. [6]. In that study participants viewed videos displaying grasping movements. The video clips showed the action of grasping a cup in the absence of any other object, and exactly the same action in the presence of two different situational contexts: (i) displaying filled cups and cookies as before having tea, and (ii) an after tea setting with empty cups and crumbs. It was the context conditions, which specified the intention of the grasping movement (either for drinking or cleaning up). The activity of premotor areas increased in the context conditions, thus indicating that these neurons do not only fire when we recognize an action but they also take into account the goal behind a specific movement. It has been proposed that these neurons specifically code the "why" of an action. Furthermore, the mirror neuron system is not only involved in the understanding of an action per se, but also in the understanding of body postures or faces expressing emotions. It has been suggested that we infer emotions of others on the basis of an internal simulation.

## Imagined Actions

Neuroimaging and behavioral studies on improvements of motor skills showed similar results when participants imagined actions as compared to when the movements were executed (for a review on this topic see [7]). For example, imagined and executed actions are both principally controlled by the contralateral hemisphere and mental practice can improve both the accuracy and the velocity of an action as well as muscular strength. Moreover, heart and respiration rates are also increased during mental rehearsal of an action and this provides further support for the involvement of at least partly the same underlying mechanisms. According to Jeannerod [7] imagined movements can be conceived as covert actions, which involve several action-related mechanisms (with the difference being the non-execution of the action itself). Cerebral lesions provide yet another approach to explore whether and to what extent motor execution and ►motor imagery share the same mechanisms. It has been shown that brain lesions leading to an impaired capacity to execute specific body part movements also affect the capacity to imagine a movement of the same body part. Moreover, the use of mental practice has been shown to improve motor performance after peripheral or cerebral lesions.

Motor representations can also be involved in other mental imagery abilities such as ►mental rotation. For example, when participants have to judge the laterality of pictures of hands shown in different orientations on a screen (is this is a left or right hand?), they mentally rotate a representation of their own hand to line it up with the stimulus hand. In this case, a motor strategy is used automatically to process visual stimuli (pictures of hands).

As regards the underlying neuronal representation it has to be pointed out that not only frontal brain areas

play a role in motor imagery tasks. The parietal cortex is involved in predicting through mental imagery the time necessary to perform an action. Sirigu and colleagues [8] investigated the involvement of the parietal cortex in patients with unilateral lesions. They imagined a thumb-finger sequence with either hand. The patients' ability to mentally represent the sequence was impaired when compared to the actual motor performance. The key role the parietal cortex plays in monitoring motor intentions is also supported by a more recent study comparing patients with parietal and cerebellar lesions [9]. Patients were asked to indicate both the onset of a finger movement, and the moment when they have decided to move. Parietal patients were unable to discriminate the onset of movement from the moment in which they felt the urge to move, whereas cerebellar patients behaved like healthy control subjects. Parietal patients also showed a much less pronounced progressive and negative rise in the cortical potentials originating in contralateral motor areas before motor onset. This is supposed to be the neuronal correlate of the decision to initiate a motor preparation. It has therefore been suggested that the parietal cortex might be involved in a conscious self-monitoring of the motor intentions originating within the prefrontal areas.

### The Self-Other Distinction

It has been claimed that the experience of oneself being the cause of an action and the representation of the ►bodily self are related. Gallagher [10] distinguished between a "sense of ownership" and a "►sense of agency." We refer to the former as the feeling of the body belonging to ourselves. The sense of ownership appears to rely strongly on the afferent sensory input. The sense of agency is based on the ability to recognize oneself as the source of one's own actions, thoughts, and intentions. Therefore, the ►efferent information stream of centrally generated commands plays an important role and constitutes the awareness of having initiated an action. Afferent and efferent information are simultaneously involved when people execute actions and it is therefore not easy to isolate their relative contributions to the representation of a coherent bodily self. Imagine, however, someone grasped your forearm and moved it up and down. There is no reason to doubt that you will still consider yourself being the owner of your forearm even though you are not executing its movement and thus are lacking any sense of agency. Interestingly, it has been shown that the contribution of efferent information helps to better recognize one's own movements when proprioceptive and visual information are not conclusive. Clinical cases suggest dissociations in the reverse direction such as the alien hand syndrome (patients attribute to others their own body parts despite preserved motor functions).

## Action Tremor

### Definition

Also called kinetic tremor is a tremor that occurs during voluntary movement.

►Essential Tremor

## Activation

►Ion Channels from Development to Disease

## Activation Gating

### Definition

Specialized molecular regions of the ion channel protein, which undergo sequential conformational changes leading to channel activation (open-conductive configuration). For a voltage-gated channel the activation gate is controlled by a number of charged amino acids (gating charges), which move under the action of the electric field acting across the membrane and opens the channel.

## Activation Studies

### Definition

Studies based on the fact that alteration in neuronal activity in a region correlates with alteration of local cerebral blood flow in the same region during a task performance. Alteration (activation) of a region indicates that it is involved in the maintenance of the task activity.

►Positron Emission Tomography

## Activational Hormonal Effects

### Definition

Acute changes in structure and/or function of particular anatomic systems; often resulting from natural hormonal fluctuations (e.g. menstrual cycle) or laboratory manipulation (e.g. gonadectomy) of adult organisms.

## Activators

►Stimulants

## Active Avoidance Learning

### Definition

Active avoidance is a term applied to a class of tasks in which animals are required to actively exhibit certain experimenter-defined responses in order to avoid punishment. Behaviors that are more compatible with natural defensive responses to aversive stimuli (see SSDR in glossary) are more easily learned.

►Aversive Learning
►Passive Avoidance Learning

## Active Electrolocation

### Definition

The process by which weakly electric fish can sense their surroundings by detecting distortions in their own electric field.

## Active Touch

Christine Elaine Chapman
Groupe de recherche sur le système nerveux central, Département de physiologie & École de réadaptation, Faculté de médecine, Université de Montréal, Montréal, QC, Canada

### Definition

Active touch refers to the act of touching, and implies voluntary, self-generated movements. With active touch, the environment is explored using specialized touch organs (the hand or forepaw, whiskers in rodents) in order to gather information about the properties of surfaces (texture, hardness, temperature) and/or objects (size, shape, weight, location) located in the nearby peripersonal space. In contrast, passive touch, or the act of being touched, implies that the sensory input is generated by an external agent; this type of touch is not generally exploratory in nature (although there can be exceptions in the laboratory situation). For both modes of touch, the

sensory input can be dynamic, implying movement between the skin and the object, or static (no movement). For example, a hand-held object can be identified using a combination of active exploratory movements, turning the object over to examine all of its surfaces (dynamic active touch), combined with periods of static holds (static active touch). A special type of dynamic passive touch, often used in experimental situations, is to displace surfaces, mounted on a drum or a moveable platform, over a single region of skin.

## Characteristics

### Quantitative Description

Active touch is a complex, goal-oriented behavior. A wide range of relatively stereotyped movements accompany tactile exploration, and these are optimized to seek specific sensory information.

### Description of the Process

In humans and other primates, the hand is generally used for active tactile exploration of the surround. Early in development, human infants preferentially use the mouth and perioral region for active tactile exploration; these regions continue to play an important role throughout the life span, but with more restricted roles (appetitive and sexual). Other species use different body parts for active tactile exploration, an important experimental model being the rodent vibrissa system, along with the associated whisking behavior. In all cases, the body regions used for active tactile exploration are characterized by having a high density of peripheral sensory receptors, a correspondingly large cortical representation (both sensory and motor), and high sensory acuity.

One important difference between primates and most other mammals is, however, the fact that the hand is not only a touch organ, but also has highly developed effector functions as witnessed by their ability to make independent finger movements. Indeed, humans are distinguished from other primates because the manipulative functions of the human hand are combined with our unique ability to build and use complex tools. This essay concentrates mainly, but not exclusively, on studies of active touch in humans and non human primates.

#### *Sources of Feedback During Active Touch*

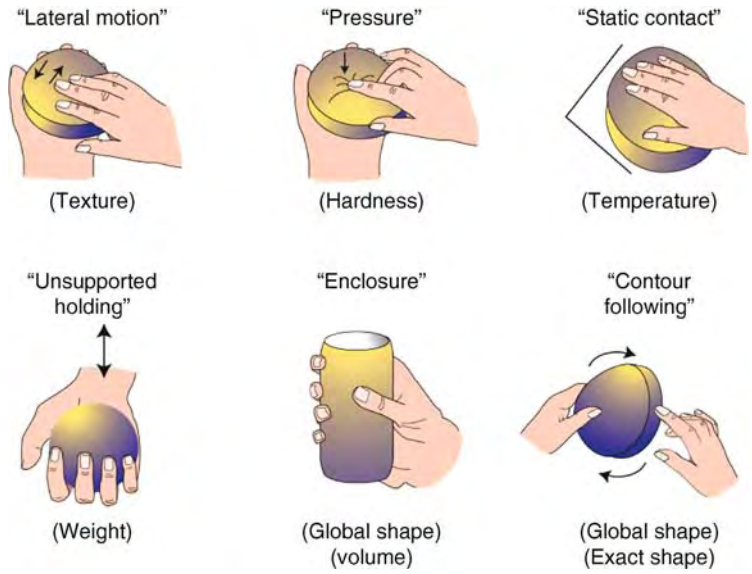
Depending on the exploratory strategy used (see below), active touch can generate both cutaneous and proprioceptive feedback. The specialized skin mechanoreceptors innervated by large fiber myelinated afferents are considered to play a key role in discriminative touch (texture, local shape and pattern recognition). Proprioceptive signals, related to joint movement (►kinaesthetic signals) and position, arise from muscle (muscle spindle, Golgi tendon organs), joint, and skin mechanoreceptors. Simultaneous cutaneous and proprioceptive feedback is often elicited when actively exploring the shape of an object, and this combined input is called haptic feedback [1]. The term haptic comes from the Greek term *haptesthai,* meaning "able to come into contact with" (OED online, http://www.oed.com/). In addition to the sensory feedback generated during active touch, subjects also have knowledge of the motor commands that guide the exploratory movements. Indeed, the ►primary somatosensory cortex (S1) is the only *primary* sensory receiving area to have direct, reciprocal connections with primary motor cortex, the region involved in the execution of active exploratory movements. Thus, S1 is well-placed to provide on-line sensory information critical for controlling the exploratory processes. Additional somatosensory inputs to motor cortex come from other parietal regions (area 5 and the ►secondary somatosensory cortex, S2), and also from the cerebellum via the motor thalamus (ventral lateral posterior nucleus).

#### *The Exploratory Process*

The movements used during active touch have the overriding goal of generating high quality sensory feedback. While tactile information can be gathered through a simple static contact, it is generally acknowledged that tactile perception is better with dynamic stimuli as compared to static stimuli. For example, roughness discrimination thresholds are approximately halved when using dynamic touch as compared to static touch [2]. The superiority of dynamic touch over static touch can be explained by several factors. Dynamic touch recruits rapidly adapting cutaneous mechanoreceptors [RA (►RA afferents) and ►PC afferents or Pacinian afferents] as well as slowly adapting cutaneous mechanoreceptors [SA types I and II (►SAI and SAII afferents)], while static touch only activates SA receptors. Also, the discharge rates for SA afferents are higher for dynamic stimuli than for static stimuli, increasing the signal-to-noise ratio. Finally, S1 neurones show a bias for dynamic as opposed to static stimuli, so that the population of neurones contributing to the processing of the tactile input is potentially larger for dynamic inputs.

During active tactile exploration, the types of movements made are critically dependent on the information sought. In fact, humans use a series of stereotyped movement patterns (also called exploratory procedures) in order to seek specific sensory information (Fig. 1) [3].

*Static contact* alone can provide information about the temperature, volume and global shape of an object, particularly for smaller or local geometric features (corresponding to what can be sensed with the fingertip) as well as providing some information about surface texture. The *pressure* exploratory procedure, essentially poking an object with the finger, gives information about its softness/hardness, along with other surface



**Active Touch. Figure 1** During active tactile exploration of objects and surfaces, different exploratory procedures are used depending on the property, or properties, sought (in parentheses). (After [3], with permission of the authors and Elsevier Ltd.).

properties (temperature, texture). *Lateral motion*, or rubbing the fingers back and forth over a surface, is important for texture appreciation. The other exploratory procedures are used for extracting information about global object properties. These include *unsupported holding* (object is held in the hand and often hefted; this movement is important for weight estimation), *enclosure* (provides a general appreciation of both the material properties and global shape of objects by enveloping the object closely in the hand; static hold alternates with movements to shift the position of the object in the hand), and *contour following* (trace out the exact shape of objects). The exploratory procedures that are specialized for seeking information about surface properties (texture, temperature, local geometric features) are characterized by the fact that exploration is performed using the most sensitive skin surface of the hand, the fingertips.

Active touch generally employs relatively slow movements. For example, when an otherwise smooth surface is explored to find a small raised square (0.28 mm in height), then average exploration speed is 85 mm/s (range 55–110 mm/s) [4]. To put this into context, fair to good Braille readers scan text at 60–125 mm/s, while excellent Braille readers use faster scans of up to about 190 mm/s. The optimal scanning speed may, however, vary as a function of the task. For example, when subjects evaluate surface texture within the context of a forced-choice texture discrimination task, then higher average speeds are used, 160 mm/s (sinusoidal movements corresponding to the lateral motion exploratory procedure) [2]. The importance of optimizing speed during tactile exploration is emphasized by observations that perceived roughness shows a modest decline when subjects are asked to adopt very rapid scanning speeds of ~200 mm/s; this latter falls outside the very wide range of speeds that subjects voluntarily choose when scaling roughness (~10–150 mm/s). With rapid movements, the stimulus likely becomes less effective, as there is less time for mechanical deformation of the skin as it passes over the textured surface. Finally, movements may slow considerably when the finger encounters a salient feature, presumably to optimize the quality of the sensory feedback elicited during the exploration. Thus, finger movement is very slow (3–4 mm/s) when subjects feel an object in order to estimate its softness or compliance.

The contact forces applied during active exploration with the fingertip are relatively light [4]. For example, average normal forces of ~0.5 N are used during tactile search for a small raised element. Most importantly, subjects adopt a strategy of keeping normal force relatively constant for a given tactile exploration task, but this is adapted depending on the goal. If subjects seek a small recessed, rather than an elevated, target, then normal force is slightly increased to ~0.65 N presumably to maximize the amount of skin penetrating the recessed square and so to improve detection.

## Lower Level Processes

The mechanisms involved in generating the active movements essential for active touch have been described in another essay. The sensory receptors found in the skin and various deep tissues (muscle, joints),

and that are activated during active touch, have also been described elsewhere.

## Higher Level Processes

### *Is Perception Equivalent With Active and Passive touch?*

Intuitively, it seems obvious that active touch, in which case the salient sensory inputs are self-generated, should show an advantage over passive touch because the exploration is controlled and optimized by the subject. Indeed, Gibson [1] argued strongly that passive touch, in which the parameters of stimulation are controlled by an external agent, is an unnatural experience. He argued that active touch should be considered an entirely different order of sensory experience since the sensory impressions are directly projected to the environment. For example, during manual exploration of an object like a pencil or a paper clip, it is the object that is perceived and not the areas of skin contacted or the finger movements.

A number of studies have compared perceptual performance using active and passive touch, but these have concentrated almost exclusively on tasks dependent on cutaneous feedback. Their results show that perceptual performance with active and passive touch is similar when exploratory conditions are suitably matched [5]. Equivalence for active and passive touch has been shown for a variety of cutaneous tasks, including the detection of minute surface irregularities, texture discrimination, scaling the roughness of various surfaces, and recognition of raised tactile patterns (letters, Braille characters). Occasionally, investigators have shown an advantage for active touch over passive touch, e.g. recognition of Braille characters, but the findings have not been confirmed in other studies using similar types of pattern recognition tasks.

Few studies have looked at abilities dependent on haptic feedback within the context of the active-passive debate. This is a difficult problem, one that cannot be easily addressed, because the presence of the motor command itself modifies the sensitivity of muscle and joint proprioceptors to limb movements. Coactivation of the gamma motoneurones along with the alpha motoneurones directly modifies muscle spindle sensitivity to stretch; activation of muscles inserting into the joint capsule also modifies joint receptor sensitivity to movement. Thus, the sensory feedback during passive movements is likely substantially different from that associated with active movement (see also below). Despite these reservations, there have been a few attempts to compare active and passive touch, e.g. comparing performance during active and passive tactual exploration of raised line drawings of the type used in reading aids for the blind [5]. This task combined tactile feedback from the exploring index finger along with kinaesthetic feedback from the arm as the image is explored. When exploration time was limited (5 s), then active touch was better than passive; this advantage disappeared when more time was allowed for passive touch (30 s). These observations suggest that active touch is more efficient than passive touch, but it is not clear whether the task used was truly haptic in nature, since performance depended most critically on the arm trajectory and so kinaesthetic feedback. With technological advances, it is now possible to use a robot arm with added force feedback to generate virtual shapes, and explore these by moving around a manipulandum (kinaesthetic feedback); force feedback is sensed both through the hand grip (cutaneous feedback), and the sense of effort required to perform the exploration. Although not directly tested yet, it appears that discrimination abilities may be similar for active and passive explorations of virtual shapes [6]. This is quite surprising given that the sensory feedback during passive movements is likely different from that during active movement (including no force feedback during the passive testing). If anything, the results argue in favour of considerable redundancy in encoding haptic shape.

To summarize, current evidence indicates that there is perceptual equivalence for active and passive touch in a range of tasks, mostly dependent only on cutaneous inputs. Active touch, on the other hand, likely enjoys an advantage over passive touch in being more efficient: the relevant sensory information is collected, and analyzed, more rapidly. More fundamentally, active, but not passive, touch is used for exploration.

### *Neuronal Mechanisms of Active and Passive Touch*

As much of the evidence points in favor of similar perceptual abilities with active and passive touch, there has been a tendency to consider that the underlying neuronal mechanisms must be the same. One school of thought believes that sensory inputs are processed in the same fashion, regardless of the mode of touch; another school of thought (above) believes that active touch is more than the sum of its parts (cutaneous and ►proprioceptive inputs), including as it does a voluntary, intentional component.

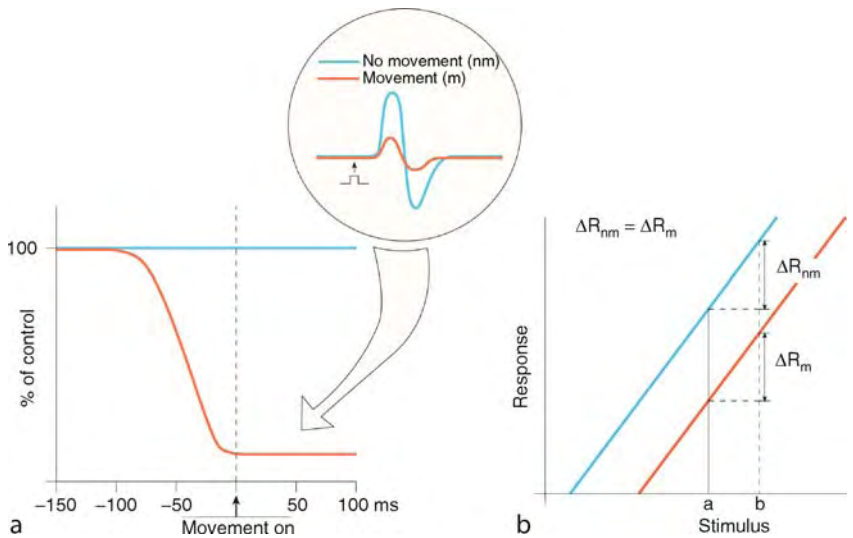
During active touch, recordings of neuronal activity in S1 cortex show that the pattern of discharge reflects the expected discharge of the various peripheral mechanoreceptors (cutaneous and proprioceptive) activated during tactile exploration [7], with active touch being inherently noisier than passive touch because of associated discharge related to joint movements. In addition, small numbers of cells are active well in advance of movement onset, possibly reflecting the motor command itself, given the existence of reciprocal connections between motor cortex and S1. A variety of discharge patterns are found during active touch: the discharge frequency of some cells varies with both the stimulus (e.g. surface texture) and the movement parameters (speed, contact force); others show invariant responses to tactile

features, independent of the motor kinematics or kinetics; yet others signal information about the movement parameters alone. In contrast, S1 neuronal responses during passive touch are more focused, reflecting the details of the applied stimulus. As with active touch, a proportion of S1 cells show invariant responses to tactile features during passive touch, independent of the parameters of stimulation, e.g. the speed at which textures are displaced under the finger tips.

The movements that accompany active touch bring an added complication to the central processing of somatic sensory signals since the act of movement modulates the transmission of tactile inputs to S1 cortex. This phenomenon is widely referred to as movement-related gating of sensory transmission [5]. Both the motor command (efference copy) and sensory feedback from the moving limb (movement reafference) contribute. Sensory inputs are most frequently diminished during movement, but there is also evidence that some inputs can be selectively enhanced during active exploration. Much of the evidence showing gating during active movement comes from studies in which externally generated test stimuli (e.g. air puff or electrical stimuli) are applied to the body surface, so corresponding to passive touch [5]. These studies have shown that sensory inputs from the moving limb are diminished prior to, and during, movement (Fig. 2a).

Parallel changes in tactile detection and magnitude estimates are seen. In contrast, the relative differences between suprathreshold stimuli are preserved (Fig. 2b). This latter observation is particularly important for the active-passive touch debate, because the majority of studies showing similar perceptual abilities for active and passive touch used tactile discrimination tasks, dependent on judgments of the relative differences between suprathreshold inputs, and not the absolute amplitude of the signals. Since relative differences are preserved during movement, performance is similar. This observation helps to explain the paradoxical observation of perceptual equivalence for active and passive touch, in the face of movement-related suppression in the transmission of tactile stimuli to S1 cortex.

Recordings from single S1 cortical neurons, in both monkeys and rats, indicate that even behaviorally relevant inputs during active touch show evidence for the existence of movement-related suppression of their responses: many neuronal evoked responses during active touch are smaller than those evoked during passive touch, consistent with a gating out of tactile inputs during movement [5,8]. Although it is difficult to ensure that stimulation is identical during both modes of touch, some S1 cells signal somatic stimuli equally well during active and passive touch, consistent with relative sparing from movement-related suppressive influences. In addition, the population of cells encoding behaviorally relevant inputs is actually smaller during active touch than passive touch, possibly reflecting some pruning of the inputs so that only cells directly involved



**Active Touch. Figure 2** (a) During movement, there is a decrease in the amplitude of somatosensory evoked potentials (SEPs) recorded from the dorsal column-medial lemniscal pathway that conveys cutaneous and proprioceptive feedback from the periphery to primary somatosensory cortex (S1) (inset). The time-course of gating is identical for both perception (detection of near-threshold tactile stimuli) and SEPs, with the decrease preceding the onset of movement. (b) Psychophysical results suggest that gating is associated with a downward shift of the stimulus-response curve: the perceived magnitude of suprathreshold stimuli is decreased during movement (red curve) while relative differences, ΔR, and so the discrimination threshold, are preserved.

in the behavioral task are activated. The functional role of this suppressive mechanism is most likely to reduce the flow of afferent information that can be predicted from the motor command so that the detection of unexpected or novel stimuli is enhanced. Finally, there is evidence that inputs can be selectively gated in during active touch: neurones in monkey area 2 (S1) that lack an obvious peripheral receptive field, discharge in relation to specific shapes actively grasped in the hand [9]. Similarly, no-receptive field neurones in S2 encode surface texture during active touch.

To summarize, there has been a long-standing debate about the perceptual equivalence of active touch and passive touch. The underlying neuronal mechanisms differ, in part, because only active touch involves active voluntary movements. Moreover, apart from laboratory studies, passive touch is not used for exploration. It thus seems unwise to generalize from results obtained using one form of touch to the other. For example, it is conceivable that the motor commands associated with active touch may trigger central mechanisms (e.g. attention) that contribute to enhance neuronal responses to salient inputs during active touch. Finally, active touch enjoys a number of advantages over passive touch: digits can be oriented so that the most sensitive skin areas contact the object and; movement speed can decline at critical times during exploration, so minimizing suppressive gating influences (themselves speed-dependent).

## Function

Active touch allows one to identify salient objects or surfaces in the immediate peri-personal space using the cutaneous and proprioceptive feedback generated during the exploration. One can then act on this information, either to control or interact with the surrounding environment. A typical example might be to search for a key in one's pocket; the key can then be used to unlock a door. This example highlights the use of the hand both as a touch organ and an effector (wielding a tool).

## Pathology

Lesions of the anterior part of the parietal lobe (S1) produce profound deficits in somaesthesia, including both simple (light touch, two-point discrimination, position sense, vibration sense) and complex abilities (e.g. tactile object recognition, visuotactile matching). In contrast, patients with lesions of the posterior parietal cortex (posterior S1 and areas 5 and 7) are particularly impaired on complex tasks. Some of these patients also show difficulties in generating exploratory and manipulative finger movements within the context of active touch, although they can imitate the appropriate finger movements [10]. Such observations suggest that posterior parietal cortex plays an important role in generating and executing exploratory movements within the context of using sensory feedback to choose and execute the appropriate exploratory procedure. This dissociation has been most clearly described in a case report of a patient with a deficit in tactile object recognition using active touch, but not passive touch. The patient had a large infarct that spared S1 but encompassed regions of the infero-posterior part of the parietal lobe (possibly including S2), as well as the temporal lobe and the frontal operculum. Thus, deficits in active touch do not necessarily follow directly from the problems in processing somatosensory information.

Active touch is also critically dependent on the integrity of the somatomotor system, and so lesions of, for example, the hand representation within the primary motor cortex (area 4 of the frontal lobe) result in profound deficits in active hand/digit movements, and so active touch. Even lesions restricted to more proximal parts of the arm representation (elbow, shoulder) can cause difficulties in active tactile exploration because the whole arm is frequently employed (for example, as one searches for a light switch in the dark).

Thus, active touch is critically dependent on the integrity of both the somatosensory cortical regions in the parietal lobe, as well as the various precentral motor cortical regions involved in planning and executing exploratory movements.

# Active Vision

Michael F. Land
Department of Biology and Environmental Science, University of Sussex, Brighton, UK

## Definition

The eyes are not static recorders of the visual surroundings. They scan the scene for new information by making fast eye movements (►saccades) up to 4 times a second. Active vision is the study of the relations of these patterns of fixations to the control of ongoing behavior [1].

## Characteristics

### Why Move the Eyes?

The human ►fovea, the region of maximum acuity, has a maximum angular diameter of 2°, which means that it covers an area equivalent to a thumb nail at arm's length. Acquiring detailed information from different places thus requires the eyes to move. A second requirement of vision is that, having moved, gaze must remain still until the next eye movement. This is because the ►photoreceptors are slow to respond, and image motion results in blurring at speeds of more than a few degrees per second. As a result our usual method of viewing the world is with a saccade-and-fixate strategy in which we take in information during "snapshots" that typically last about 300 ms. Our eyes are then in rapid motion for about 30 ms, during which we are effectively blind. A major question in active vision is how the sequences of fixations that we make are adapted to the needs of the current task.

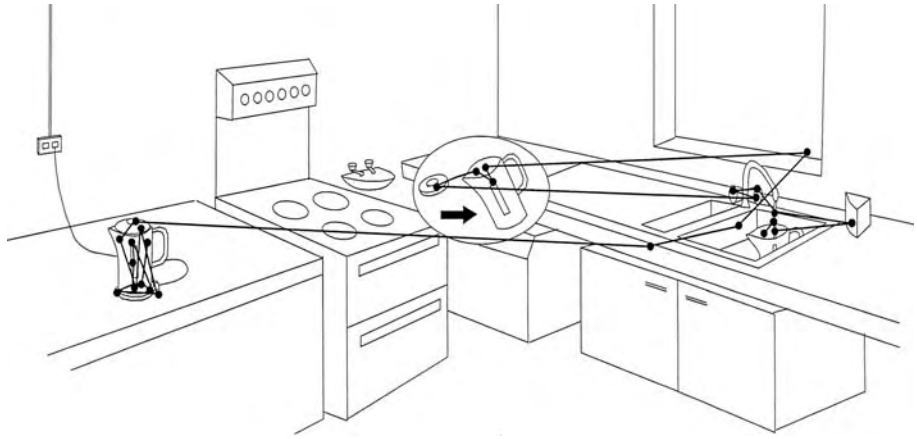
### Patterns of Gaze During Different Activities

The task we are engaged in determines the pattern of fixations that we make. In reading Western languages the eyes move saccadically from left to right taking in about seven characters per fixation [2]. Interestingly this number is almost independent of the size of the type, indicating that the brain can scale saccade size to fit the letter spacing. In sight-reading piano music gaze alternates between the upper and lower staves, reading approximately 3 notes per fixation. In both reading aloud and sight-reading the time between seeing a note or letter and speaking or playing it is about 1 s. Typing is similar. All three activities operate like conveyer belts. The content of each fixation passes through a processor to produce an appropriate motor act and leaves nothing behind, except meaning in the case of reading. Sight-reading is particularly interesting because the two staves are read serially, but combined in the processor to be emitted simultaneously by the fingers.

In ►locomotory activities such as walking vision is only used to guide the feet if the terrain is rough or there is a need to avoid obstacles. In those cases the point of gaze is about two steps ahead of the next footfall, though not usually exactly on the point of the footfall itself [3]. About twice as many saccades are made as there are footfalls, and the time interval between gaze position and footfall is again about 1 s. When driving the way gaze is deployed on the road varies with the type of road and traffic conditions. On winding country roads where continuous monitoring of curvature is essential many studies have found that drivers' gaze tracks the tangent point on the inside of the bend [4]. This is the moving point on the outward convexity of the road edge (or center line) where the line of sight is tangential to the lane marker. Provided the driver maintains a constant lateral position in the lane, the direction of this point relative to the driver's present direction of travel provides a direct measure of the curvature of the bend ahead, and hence can act as a direct feed-forward control signal for steering. In practice there is a very high correlation between observed tangent point direction and steering wheel angle, after a delay of about 0.8 s. The delay here is necessary because the vehicle has not yet reached the point where the curvature was measured. Town driving is very different. The main problem there is to find a route through parked vehicles, oncoming traffic and other obstacles. Gaze typically alternates between the various hazards, checking their moving locations at a rate of several fixations per second.

In ball games such as cricket gaze does not always follow the ball, but often anticipates its future position. Thus in cricket a batsman watches the bowler's delivery, and from the apparent speed of descent of the ball estimates the location of its bounce point. A gaze saccade is made to this point, reaching it about 100 ms before the ball [5]. In this way the location, time of arrival and behavior of the ball when it bounces can be observed, and from these the time and position of contact with the bat can be obtained. Much the same happens in table tennis, and no doubt lawn tennis as well, although that game is too fast to allow currently available head-mounted eye trackers to be used.

Some of the most interesting patterns of ►eye-hand coordination are seen in such ordinary domestic activities as food preparation [6]. These activities consist of a series of actions based around objects such as kettles, mugs, knives etc. (Fig. 1).



**Active Vision. Figure 1** Eye fixations during the first 10 s of a tea-making video in which the participant inspects the kettle, picks it up, moves it to the sink while removing the lid, positions it under the faucet and turns on the tap. The 26 fixations are almost entirely on the objects involved in the action (the sink tidy on the right is the sole exception). They supply the information required for the task at the time it is needed. From [6].

There are three motor components to these object-related actions. First, if needed, there is a movement of the whole trunk towards the next object; this is followed about half a second later by the first fixation of the eyes on the object, and about half a second after that the hands start to move to perform one or more manipulations on the object. Interestingly, gaze moves on to the next object in the sequence about half a second before manipulation of the present object is complete, implying the existence of a buffer holding whatever information is required to complete the last action. The functions of the different fixations that are made during such actions can be classified into four categories. "Locating" (or "look-ahead") fixations establish the locations or attributes of objects to be dealt with in the future, with no action occurring at the time. "Directing" fixations accompany actions where an object is fixated prior to a hand movement towards it or gaze moves to position where an object is to be set down. Typically only a single fixation is involved, and gaze usually leaves the object or set-down point before the hand reaches it, so that the act is completed without visual feedback. "Guiding" fixations are concerned with manipulations involving more than one object, for example a kettle and its lid, where both objects have to be guided relative to each other under visual feedback so that they dock in an appropriate way. Most tool use is of this kind (e.g. hammer and nail, spanner and nut). "Checking" fixations determine when some condition is met, for example the kettle is filled, the water boils, or the lid is off the bottle. Such fixations, which may be unusually long if there is a delay before the condition to be met, usually terminate actions and trigger the next one. Interestingly the hands themselves are rarely if ever fixated, nor are objects once they have been acquired by the hands. It seems that vision is a scarce resource and is only employed when ►proprioceptive and ►haptic information is unavailable.

## General Rules for the Use of Vision During Action

As the preceding paragraphs indicate, gaze is used to obtain the information needed by the action system, and each kind of action has a unique (though not exactly replicable) pattern of fixations associated with it. In other words the fixation sequences are highly task-specific. Early in the study of the subject Ballard [7] and his colleagues suggested two rules that seem to hold for most patterns of eye-hand coordination. The first is the "do it where I'm looking" strategy, which states that the point of fixation is usually very close to the point where action is taking place. Actions are not performed in peripheral vision, nor are they performed from memory when vision is available. The second is the "just in time" rule: actions are usually initiated within a second of the fixation that provides the information for that action. Both rules imply that memory is used frugally. Apart from look-ahead saccades, which do contribute to future action planning, there is little evidence that actions are set up in detail in advance of their execution.

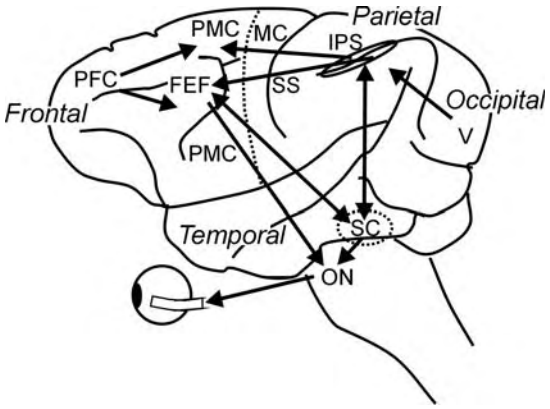
## What Drives Fixation Sequences?

A key question in the study of eye movements is: "What determines where the next saccade will land?" A popular model for the specification of saccade targets involves "►salience" [8]. Certain image features – contrast, color, high spatial frequency content, motion – are said to be salient, and it is argued that saccades are directed to those parts of the visual field where the appropriately weighted sum of such features is greatest. Whilst this may hold when vision is otherwise uncommitted, it certainly

does not hold during active vision. Yarbus [9] demonstrated over 40 years ago that when subjects are asked to look at a picture the pattern of eye movements they make depends crucially on what the experimenter has asked them to look for. Thus there is a very strong "►top down" control over fixation sequences, as opposed to "bottom up" control by image features. The same is true during visually guided actions. In food preparation, for example, it is very rare to see fixations directed to objects that are not relevant to the action sequence, even though there are distracting objects around which, on a salience basis, should attract gaze more strongly.

What then does determine fixation sequences during active vision? Electrode recordings from monkeys and ►fMRI scans in humans have provided some information about their neural basis. For complex routines such as tea making it is necessary to assume that it is the overall plan, or script, of the activity which determines what is targeted, and in approximately what sequence. These plans originate in the ►prefrontal cortex (PFC) in primates and man. They specify to the eye movement system what is the next object to be fixated, and with that provide information about its likely location and appearance. Remarkably, objects are often fixated with a single saccade even when they are in the far periphery, indicating the efficiency of this process. The script must also inform the motor system what action to perform, and the eye movement system what to monitor as the action progresses. Many parts of the brain are involved (Fig. 2).

Output to the ►brainstem nuclei of the oculomotor system (oculomotor nuclei, ON) which move the eyes comes from the ►frontal eye fields (FEF) and ►superior colliculi (SC), with the ►parietal cortex involved in the coordination of reaching and grasping [10]. The limb motor system also has an input from the parietal lobe and from the ►somatosensory cortex (SS) and generates its output to the ►spinal cord via the ►premotor cortex (PMC) and ►primary motor cortex (MC). Visual input to both systems comes ultimately from the occipital lobe, and the temporal lobe is also likely to be involved in establishing the identity of objects. The coordination of apparently simple actions is a complex neural operation.



**Active Vision. Figure 2** Drawing of the left-hand side of a macaque brain showing some of the regions and pathways involved in the neural control of reach-and-grasp movements. Details in the text. The names of the four lobes of the cortex are shown. Abbreviations: *FEF* frontal eye fields; *IPS* intraparietal sulcus; *MC* primary motor cortex; *ON* oculomotor nuclei of the brain stem; *PFC* prefrontal cortex; *PMC* premotor cortex; *SS* somatosensory cortex; *SC* superior colliculus of the mid brain; *V* primary and secondary visual areas of the occipital lobe. The cortical output to the limbs originates in the motor cortex (MC) and runs to the spinal cord via the brainstem.

## Conclusions

Although we can direct our gaze direction by an act of will, this rarely happens; for most of the time fixation patterns are automatic and are not available to conscious scrutiny. We are even unaware that we look around the room in a series of discontinuous jerks, rather than a smooth scan. The principal function of the eye movement system in man is to direct gaze to locations where the eyes can provide the executive systems of the brain with the information they need for perception and action. To do this the eye movement system has its own knowledge base – of where to look on a winding road, for example, or how to read a double stave of music – which we cannot access by introspection. Objective eye-movement recording is the only way to study this hidden information.

# Active Zone

Eckart D. Gundelfinger, Wilko Altrock, Anna Fejtová
Leibniz Institute for Neurobiology, Department of Neurochemistry and Molecular Biology, Magdeburg, Germany

## Synonyms

Site of regulated neurotransmitter release

## Definition

Physiologically, the active zone is defined as the restricted area of the presynaptic plasma membrane, at which ►synaptic vesicles can fuse and regulated neurotransmitter release can occur. The active zone, as defined here, consists of two major parts, the active zone plasma membrane and the associated cytoskeletal matrix, which is called presynaptic dense projection, presynaptic grid, presynaptic particle web or ►CAZ (cytomatrix assembled at the active zone) [1,2].

The general description given here refers to conventional chemical synapses of the central nervous system. It should be noted that different types of chemical synapses display differential adaptations of their active zones and the associated cytomatrices to their specific function. Of these specializations, we will briefly consider here the active zone of vertebrate ►neuromuscular junctions and of so-called ►ribbon synapses, i.e. specialized excitatory high-throughput synapses occurring, for example, in ►photoreceptor cells or bipolar cells in the retina or in ►inner ear hair cells.

## Characteristics

### Quantitative Description

Typically, the active zone has a diameter of several hundred nanometers. For representative conventional synapses in mouse hippocampus and piriform cortex, average surface areas of ~0.04 μm$^2$ (square microns) and ~0,095 μm$^2$ have been determined, respectively [3]. Active zones rarely exceed an area of 0.4 μm$^2$, and large synaptic boutons would rather form multiple active zones than exceed this upper "limit." On average, these active zones accommodate one docking site for synaptic vesicles per 3800–6200 nm$^2$ [3].

Specialized synapses have active zones of different sizes and shapes adapted to their particular function. At the vertebrate neuromuscular synapse, for example the frog's ►neuromuscular junction, the active zone is frequently 1–2 μm (microns) long and ~75 nm wide [4].

## Higher Level Structures

The active zone is a component of the neurotransmission apparatus of chemical synapses. It is part of the plasma membrane of presynaptic boutons [1]. The active zone faces the synaptic cleft and is surrounded by (and tightly linked to) an endocytic zone, where synaptic vesicles that have fused with the active zone membrane are retrieved by clathrin-mediated endocytosis [5,6]. The active zone is precisely aligned with the region of postsynaptic membrane that harbors the neurotransmitter reception apparatus, and is defined by the ►postsynaptic density (PSD). The PSD is particularly prominent in excitatory brain synapses.

## Lower Level Components

### *Ultra-Structure of the Active Zone*

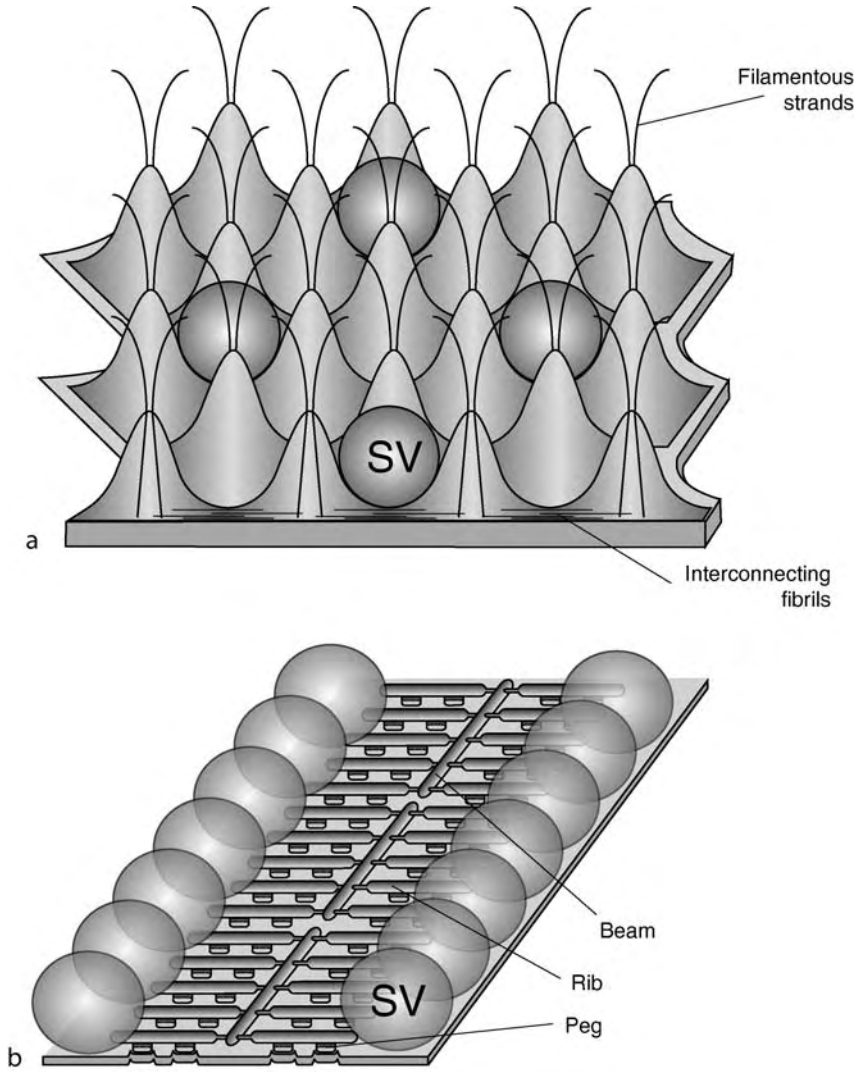
In the electron microscope, the CAZ or presynaptic grid appears as a more or less regular array of electron-dense cone-shaped particles, which extend ~50 nm into the cytoplasm. A meshwork of cytoskeletal filaments connects the 50 nm particles [2]. Additionally, filamentous strands extend 100 nm and more from the active zone plasma membrane into the presynaptic bouton (Fig. 1a).

At the frog neuromuscular junction, active zone material extents 50–75 nm into the cytoplasm of the terminal and has a regularly arranged ultra-structure consisting of "pegs," "ribs" and "beams" as revealed by electron microscope tomography [4]. The molecular composition of these structures is currently unknown (Fig. 1b).

►Synaptic ribbons in nerve terminals of ►retinal photoreceptors are horseshoe-shaped specializations of the CAZ, which extend 300–500 nm into the presynaptic cytoplasm and tether ►synaptic vesicles. They are connected to the active zone plasma membrane via a specialized structure called arciform density [7].

### *Proteins of the Active Zone Plasma Membrane*

Plasma membrane proteins present in the active zone primarily include ion channels and receptor proteins that are required for synaptic function, and cell adhesion molecules (CAMs) involved in adhesion and alignment of pre- and postsynaptic membranes as well as in trans-synaptic regulation of plasticity [8]. Most importantly, voltage-gated $Ca^{2+}$ channels (N-type [$Ca_v2.2$], P/Q-type [$Ca_v2.1$]) mediate the influx of $Ca^{2+}$ upon arrival of a depolarizing ►action potential, the trigger for synaptic vesicle exocytosis. Basically, all super-families of CAMs, including immunoglobulin superfamily members, integrins and cadherins, are represented at synaptic junctions and are involved in synaptic function and plasticity. Alpha- and beta-neurexins seem to be specific CAMs of the active zone membrane. Beta-neurexins make asymmetric contacts with postsynaptic neuroligins, while alpha-neurexins couple $Ca^{2+}$ channels to synaptic vesicle exocytosis in a manner that is not yet understood. Active zone and opposite PSD are surrounded by a belt

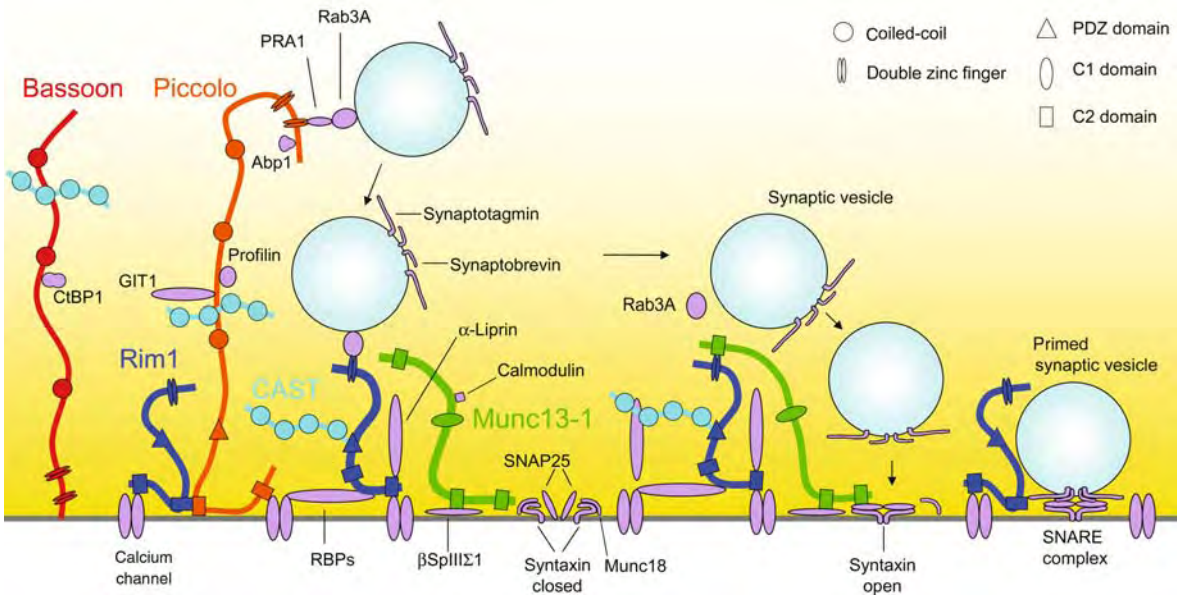


**Active Zone. Figure 1** Ultra-structure of the cytomatrix assembled at the active zone. (a) Schematic depiction of the presynaptic grid at conventional brain synapses. A more or less regular array of 50-nm cone-shaped particles is thought to define docking sites for synaptic vesicles (SV). Cones appear to be interconnected by fibrils. In addition, filamentous strands extend 100 nm and more from the active zone plasma membrane into the presynaptic bouton [3]. (b) Cartoon of the active zone at the frog neuromuscular junction as revealed by electron microscope tomography [5].

of cadherin/beta-catenin complexes. Additional cell membrane proteins thought to reside within the active zone include ephrin ligand-receptor systems and receptor tyrosine phosphatases, as well as a variety of metabotropic receptors.

### *Molecular Organization of the CAZ*

Only few CAZ-specific proteins have been identified to date [9]. These include the Munc13 synaptic vesicle priming factors; the ►RIM (Rab3-interacting molecules), multi-domain proteins that can interact with multiple other active zone proteins; ►Bassoon and Piccolo (►Piccolo/Aczonin), two very large CAZ scaffolding proteins; as well as ►CAST/ERC (CAZ-Associated Structural Protein Or Elks/Rab6-Interacting Protein/CAST), another family of CAZ-specific structural proteins. In addition, SH3 domain-bearing RIM-binding proteins (RIM-BPs) and alpha-liprins, which also bind RIMs and the receptor tyrosine phosphatase LAR, have been described as bona fide or potential CAZ components. These molecules are thought to form the scaffold of the CAZ, which links proteins of the active zone plasma membrane to the actin/spectrin-based cortical cytoskeleton and components of the synaptic vesicle cycle. Scaffolding molecules of the CAZ can physically integrate additional effector proteins that are involved in the organization and regulation of the synaptic vesicle cycle as listed in 1 and illustrated in (Fig. 2).



**Active Zone. Figure 2** Molecular organization of the CAZ. The CAZ-specific multi-domain proteins RIMs, Bassoon and Piccolo and the CAST/ERC proteins are thought to act as major scaffolding proteins of the presynaptic cytomatrix. They can recruit a variety of effector proteins to the CAZ and thereby organize presynaptic processes functionally and topologically. The CAZ-specific protein Munc13 serves as a priming factor for synaptic vesicles (for further details and the definition of abbreviations see Table 1). The figure was adapted from Dresbach, Altrock and Gundelfinger (2003), Neuroforum 3.03, pp 79–86.

Moreover structural components of the CAZ, such as Piccolo, may serve as a physical link between the exocytic and endocytic machineries that have to cooperate precisely in presynaptic boutons [5]. In addition, a trimeric complex consisting of the membrane-associated guanylate kinase homolog CASK and the adaptor proteins Veli/Lin7 and Mint (Munc18/Sec1-interactor), which interacts with active zone membrane proteins such as beta-neurexins and voltage-gated $Ca^{2+}$ channels, has been reported to occur at the active zone [9].

### *Specialization of the CAZ – Synaptic Ribbons*

The photoreceptor ribbon synapse is a unique type of chemical synapse, structurally and functionally specialized for the tonic release of neurotransmitter in the dark. Basically, all scaffolding proteins present in the CAZ of conventional synapses can be found in synaptic ribbons. In addition, a ribbon-specific protein, RIBEYE, has been identified as a major component of synaptic ribbons [7]. Interestingly, CAZ proteins fall into two groups: those that are associated with the actual ribbon (RIBEYE, Piccolo, RIM1 and the Kinesin KIF3A), and those that associate with the active zone membrane and/or the arciform density (Munc13–1, RIM2, CAST1/ERC2). Bassoon seems to be involved in anchoring the ribbon to the arciform density [7]. Major constituents of photoreceptor ribbons including RIBEYE, Piccolo and Bassoon are also present at inner hair cell ribbons.

## Higher Level Processes

The active zone is integrated into the process of synaptic transmission. In this context, it serves an essential function in regulated neurotransmitter release and the organization of the underlying membrane trafficking cycle (synaptic vesicle cycle).

## Lower Level Processes

At the active zone, processes of regulated exocytosis of neurotransmitter from synaptic vesicles, as well as refilling of synaptic vesicles (“kiss-and stay”) or their local recycling (“kiss-and-run” mode), takes place [5,6]. Components of the active zone plasma membrane and the associated CAZ are involved in the performance and regulation of these processes. Processes localized at the active zone include docking and priming of synaptic vesicles, entry and sensing of $Ca^{2+}$ ions, control of membrane fusion and retrieval as well as regulation of efficiency and fidelity of stimulus-secretion coupling.

## Process Regulation

### *Presynaptic Plasticity*

At the active zone, arriving action potentials trigger exocytosis. Incoming signals can be modulated as

**Active Zone. Table 1** Proposed protein–protein Interactions of CAZ proteins

| Protein (Synonyms) | Domains/Motifs | Interaction partners (*Literature*) | Proposed function for the interaction |
|---|---|---|---|
| Rab3 interacting molecules (RIMs: primarily RIM1α; RIM2α) | Zn finger | Rab3[1] | SV tethering?, Regulation of SV exocytosis? |
| | PDZ | Munc13–1[2] | SV priming |
| | C2A | ubMunc13–2[2] | SV priming |
| | Proline-rich sequence (PRS) | CAST1/ERC2[3,4] | Scaffolding |
| | C2B | Piccolo[5] | Scaffolding |
| | | N-type voltage-dependent $Ca^{2+}$ channel[6] | Channel anchoring |

[24]Wyszynski M et al. (2002) Neuron 34:39.

a function of the history of previous presynaptic activation (presynaptic plasticity). The major signal mediator, both for neurotransmitter release and its modulation is the bivalent $Ca^{2+}$ ion. Two parameters are thought to determine presynaptic plasticity, i.e. the conversion of an action potential to a $Ca^{2+}$ current and the conversion of a $Ca^{2+}$ signal to exocytosis [6]. Components of the active zone essentially govern processes of presynaptic plasticity. Recently, two CAZ proteins, RIM and Munc13, have been implicated in the regulation of presynaptic plasticity [6,10]. Regulation of the synaptic vesicle priming factor Munc13 by the ubiquitous calcium sensor calmodulin may be a long-searched for molecular mechanism for $Ca^{2+}$-dependent presynaptic plasticity. In addition, Munc13's function is regulated by the second messenger diacylglycerol [10]. RIM1alpha knock-out mice display deficits both in short-term plasticity of conventional synapses and in long-term potentiation of mossy fiber boutons of the hippocampal CA3 region [6,9]. As RIM1a and Munc13s can physically interact, it is conceivable that they fulfill their modulatory effect on presynaptic function in a concerted manner.

### *Developmental Assembly of the Active Zone*

During brain development, the active zone is assembled from distinct pre-formed packages in a quantal manner [8]. Assembly of the major components of the active zone including membrane proteins, such as N-type $Ca^{2+}$ channels, cadherins and the target SNARE protein syntaxin, as well as bona fide CAZ components, like Bassoon, Piccolo, RIMs and Munc13, occurs inside the neurons, probably at the trans-Golgi complex. According to the "active zone transport vesicle" hypothesis these pre-assembled complexes bud off the Golgi membrane, are transported into the axon along microtubules, and fuse with the presynaptic membrane in response to a yet unknown signal. Dense-core active

zone transport vesicles have a diameter of ~80 nm, and are found in axonal growth cones and along axons before synaptogenesis. This mode of assembly may explain the speed and efficiency with which new synapses can be formed during development.

### Function

The active zone, including the associated cytoskeletal matrix, is a specialized region of the presynaptic plasma membrane that serves the regulated release of neurotransmitter. Here, incoming action potentials are translated into chemical signals, which can then be detected by the postsynaptic cell. As both basic mechanisms of regulated exocytosis and processes of synaptic plasticity are triggered by calcium [6] (see above), the appropriate placement of voltage-dependent $Ca^{2+}$ channels and of $Ca^{2+}$-sensing and -modulating systems is of key importance. Various active zone proteins including Munc13s, RIMs and Piccolo as well as Synaptotagmins, which are thought to act as principal $Ca^{2+}$ sensors on synaptic vesicles, harbor multiple C2 domains as phospholipid-dependent $Ca^{2+}$-binding sites.

Proteins assembled at the active zone serve the local restriction as well as the structural and functional organization of the synaptic vesicle cycle [6,9]. They are involved in

- anchoring and clustering active zone membrane proteins, e.g. $Ca^{2+}$ channels and CAMs,
- recruiting effector molecules to the active zone,
- docking, priming, fusion and retrieval of synaptic vesicles,
- the local integration and regulation of the actin/spectrin-based cortical cytoskeleton
- linkage to the endocytic apparatus.

Proposed functions for individual CAZ components and their interaction partners are summarized in Table 1.

### Pathology

Mutations in CAZ genes may result in altered presynaptic plasticity, epilepsy and impaired vision and hearing. For example, RIM1alpha knock-out mice display a decreased probability of neurotransmitter release and impaired short-term and long-term synaptic plasticity [9]. Mice mutant for Bassoon suffer from rapidly generalizing epileptic seizures [9]. Moreover, in these mice, anchoring of synaptic ribbons to the active zone is impaired in retinal photoreceptors and cochlear inner hair cells [7] resulting in dramatic deficiencies in vision and hearing. To date, no corresponding genetic defects have been reported for humans. On the other hand, mutations in presynaptic calcium channels can result in episodic or spinocerebellar ataxia, familial hemiplegic migraine or idiopathic generalized epilepsy.

## Activity Phase

### Definition

Portion of the behavioral circadian cycle where the organism is active. In diurnal organism, the activity phase occurs during the daytime, in nocturnal organisms, during the nighttime.

►Arrhythmicity/Rhythmicity
►Circadian Cycle

## Activity-dependent Synaptic Competition

### Definition

A refinement process of neural circuitry to select stronger synaptic inputs among multiple inputs converging on the same target while the other weaker inputs are eliminated. This process is referred to as

"competition" because the relative strength of each synaptic input is evaluated.

►Activity-dependent Synaptic Plasticity
►Synaptic Elimination

## Activity-dependent Synaptic Modification

### Definition

Synaptic depression or facilitation induced by special patterns of activation of the synapse. Higher-frequency activation often causes synaptic facilitation, and lower-frequency activation gives rise to synaptic depression.

►Associative Long-Term Potentiation (LTP)
►Memory, Molecular Mechanisms

## Acquired Immunodeficiency Syndrome (AIDS)

### Definition

Illness and associated conditions caused by infection with the ►human immunodeficiency virus (HIV), a retrovirus. The syndrome may include neurological symptoms resulting from the combined degeneration (vacuolar ►myelopathy) of the ►corticospinal tract and the ►dorsal columns.

►Human Immunodeficiency Virus (HIV)

## Activity-Dependent Synaptic Plasticity

Michael A. Colicos
Department of Physiology and Biophysics, Faculty of Medicine, University of Calgary, Calgary, AB, Canada

### Synonyms

Neuronal plasticity

### Definition

The ability of the connections between neurons (the synapses) to change in strength in response to activity.

### Characteristics

#### Introduction

Central to the function of the nervous system is its ability to change dynamically in response to sensory input. The process of learning and the formation of memories allow the individual to adapt to and function in its environment. In order to accomplish this, the connectivity between the neurons must be able to change. Rather than occurring randomly, these changes must be guided by the information that flows through the neuronal network. Thus, activity dependent synaptic plasticity is an essential mechanism by which the cognitive function of the central nervous system is achieved. There are two tiers to the alteration of synaptic connectivity: changes that take place very rapidly, which allow immediate response to dynamic input; and more long-term changes that can consolidate memories for up to the life of the organism. As one would expect a mechanistic commonality between these two tiers exists, and short-term changes, if emphasized and repeated, will eventually become permanent.

#### Foundations

At the end of the nineteenth century the Spanish neuroanatomist Santiago Ramón y Cajal suggested that since no new neurons are created in the brain during the life of an individual, memories might be formed by improving the strength of the connections between them [1]. In the middle of the twentieth century Donald Hebb suggested a mechanism by which this strengthening could occur, postulating that through repeated and persistent stimulation of a neuron there is an increase in its efficacy of communication, arising from either a metabolic change in the cell or the activation of the growth process [2]. It is now generally accepted that the connectivity between neurons determines how information will be processed by the brain, and the ability to modify these connections in response to activity underlies learning and memory. The brain can change its information processing pathways in response to input by two basic mechanisms: by forming new connections or by strengthening the existing ones. Memory can be generally classified as being either short-term or long-term. While some forms of altered synaptic strength can last for extended periods of time (up to days or weeks), it is generally thought that short-term memory is associated with changes in synaptic efficacy, whereas long-term memory involves a structural change in the connectivity between neurons. These long-term changes can be expected to last for years. Of key importance to the function of the nervous system is that these changes in the strength of neuronal

connections arise in response to activity. This reflects an important aspect of how the brain functions, in that there is selective strengthening of circuits that are being used. In addition to activity-driven synaptic plasticity, subsequent regulatory plasticity can also occur. This is a slower process which modulates the changes in connectivity themselves, necessary to avoid a loss of stability in the neuronal network.

### Mechanism of Altered Synaptic Efficacy: Long-Term Potentiation (LTP)

Long-term potentiation is an experimentally-induced phenomenon by which high frequency activity at a synapse results in an enhancement, or potentiation, of subsequent synaptic transmission. Although demonstration of an identical phenomenon occurring in the intact brain is limited, it is widely accepted as a basic mechanism for learning and memory. LTP was first described by Terje Lømo in 1966, when he observed that stimulation of the perforant pathway into the rabbit hippocampus caused an enhancement of the excitatory postsynaptic potentials induced in the cells of the dentate gyrus [3]. Many types and stages of LTP exist. Two of the most studied are often defined by their dependence on either the NMDA or on the AMPA glutamate receptors. Moreover, multiple durations and phases of LTP rely on different biochemical mechanisms, all of which have been extensively investigated [4]. It is generally believed that LTP is a fundamental mechanism by which short-term changes in synaptic efficacy can be achieved.

### Long-Term Depression (LTD)

The counterpart to LTP, long-term depression, is a weakening of synaptic strength which results (in the hippocampus) from either persistent low-frequency stimulation or from an extremely strong synaptic stimulation such as occurs in the cerebellum. From a functional point of view, the presence of long-term depression of synaptic strength is essential. To develop a neural processing system based solely on enhancement of synaptic strengths would result in a general increase in activity in the brain during the life of the individual. The ability to reduce synaptic strength or prune out unwanted synapses is essential for the overall balance. Mechanistically LTD has not been as rigorously studied as LTP, however it is clear that many of the mechanisms are in common between the two, especially calcium influx [5].

### Spike Timing Dependent Plasticity (STDP)

Spike timing dependent plasticity illustrates the fine balance between LTP and LTD. A single dendrite of a neuron receives many inputs from multiple axons. The synapses at these junctions most often fire independently, each following its own rules and dynamics. Consequently, as excitatory postsynaptic potentials are induced and are traveling down a dendrite it is likely that other synaptic input will also be depolarizing the dendrites, causing the two signals to either summate or interfere with each other. Additionally, when a neuron fires there is a back propagating depolarization that arises from the action potential. This back propagating action potential can affect new incoming EPSPs. If neurotransmitter release occurs after a back propagating action potential arrives at the postsynaptic site, LTD can be induced and synaptic strength decreased. Conversely if the back propagating action potential arrives at the synapse after the EPSP, the potential is reinforced, and, LTP can be induced. Thus, the timing of the arrival of depolarizing potentials at the synapse can either strengthen or weaken it. The dependence of such changes in synaptic efficacy on the coincident timing of activity illustrate the ability of the nervous system to respond with a high degree of temporal specificity, and react in a finely tuned manner by changing the strength of the individual synaptic connections [6].

### Mechanism of Structural Plasticity: Synapse Number

Perhaps the most direct mechanism of synaptic plasticity is structural change. The strength of the connections between two neurons can be directly altered by either adding or removing synapses. In the 1980s Bailey and Chen demonstrated that the process of habituation in an invertebrate system can alter the number of connections between neurons [7]. This has also been demonstrated in mammalian systems, and researchers hypothesize that by making physical changes such as these in connectivity, permanent changes in the functioning of a neuronal system that last the lifetime of an individual can be achieved. The mechanism of such changes is often assumed to be related to the initial process of synaptogenesis that occurs during embryonic development, which is subsequently reinitiated by activity. If one views the changes in synaptic efficacy as a precursor to more permanent structural change, one would expect common signaling pathways between the two processes. The most studied candidate for this signal is the calcium influx that occurs during synaptic transmission. It can not only play a determinate role in altering synaptic efficacy through mechanisms such as LTP and LTD, but can also induce cytoskeletal changes through mobilization of actin, a requisite for morphological change. Additionally, the nature of the direct change in synaptic connectivity can be related to the information carried by the activity, for example high frequency stimulation will cause an increase in the number of connections, where as low frequencies result in a loss of connectivity. This change in synapse density has been eloquently demonstrated *in vivo*, using high-resolution imaging of neurons from

trained versus untrained animals [8]. Synaptic remodeling has also been observed under more controlled conditions using dissociated hippocampal neuronal cultures [9]. Thus, during learning and memory formation, the brain can encode new information in its structure by directly altering the number of connections between neurons.

### Spine Morphology

In addition to changing the number of presynaptic contacts, the shape and size of the postsynaptic structure can also be altered to modulate synaptic transmission. This can occur by both changing the size of the active zone, as well as by altering the diameter of the spine shaft. Changing the morphology of the postsynaptic spine will modulate the way an incoming depolarization propagates before actually entering the dendrite and proceeding to the cell body. Spine dynamics are also integral to the process of new synapse formation, acting as targets for synaptogenesis [10].

### Summary

Activity-dependent synaptic plasticity describes the change in neuronal connectivity that occurs as a direct result of synaptic transmission. This plasticity can be manifested as either altered synaptic efficacy or as direct physical synaptic change. The process is assumed to provide a mechanism of altering information flow through the neuronal system in a manner which reflects the incoming activity patterns that initiated the change, providing a system for learning and memory.

## Activity-dependent Synaptic Rearrangement

### Definition

A refinement process of neural circuitry regulated by the strength of neural activity in the pre- and postsynaptic cells.

►Synaptic Elimination

## Actogram

### Definition

An actogram depicts activity patterns of organisms.

Usually, activity on a time base of 24 h is plotted on horizontal lines below each other for consecutive days.

However, also other time bases can be chosen (modulo plots). Activity can be depicted quantitatively or as a state variable. Aligning the same actogram twice so that two consecutive time episodes are plotted one after the other and the second episode is repeated just below the first episode on the successive line is called a double plotted actogram, facilitating the identification of rhythms which cross the time base.

►Circadian Rhythm
►Circannual Rhythms

## Actualism

### Definition

The view that everything which exists actually exists; this implies that possible worlds, if they exist at all, have to exist as part of the actual world.

►Possible World

## Actuator

### Definition

An actuator is a device with the capability of transforming one type of energy into another. Actuator differs from sensor in the way it is used. The actuator is used to transform commands of a control algorithm into actions applied to the physical system to affect its behaviour (state).

►Control

## Acutance

►Contrast Enhancement

## Acute and Chronic Ataxic Neuropathy

►Large-Fiber Sensory Neuropathy

## Acute Brain Slice

►Slice Preparation

## Acute Disseminated Encephalomyelitis

### Definition

ADEM belongs to the group of ►idiopathic inflammatory demyelinating diseases (IIDDs) and is an autoimmune disease with multifocal lesions throughout the brain and spinal cord, usually following a febrile viral infection or vaccination, with the highest incidence during childhood. ADEM is characterized by ►encephalopathy and ►pyramidal, ►cerebellar, and ►brainstem signs, bilateral ►optic neuritis, transverse ►myelitis, and altered consciousness. ►Seizures are rare. The pathogenesis is unknown and may be triggered by a T-cell mediated autoimmune response to ►myelin basic protein. Treatment includes methylprednisolone, immunoglobulins, plasmapheresis, or cytotoxic drugs.

►Idiopathic Inflammatory Demyelinating Diseases (IIDDs)

## Acute Pain

►Incisional/Postoperative Pain

## Acute Sensory Neuronopathy Syndrome

### Definition

Acute loss of large myelinated sensory nerves subserving touch and proprioception (see Section on Large-Fiber Sensory neuropathy).

►Proprioception: Effect of Neurological Disease

## Adaptation of Saccadic Eye Movement

### Definition

The saccadic eye movement or saccade is a rapid eye movement to capture an object in the visual field. When the target is displaced during the saccadic eye movement, it changes so that the target can be captured.

The forward or backward target displacement causes a gradual increase or decrease in the saccade amplitude, respectively. Such a phenomenon is called adaptation of saccade.

►Saccade, Saccadic Eye Movement
►Sensory Motor Learning/Memory and Cerebellum

## Adaptation of Sensory Receptors

### Definition

Adaptation is the decline of the electric responses of a receptor neuron over time in spite of the continued presence of an appropriated stimulus of constant strength. This change is apparent as a gradual decrease in the frequency of spikes generated within the receptor neuron. Phasic receptors adapt rapidly and inform, therefore, about the rate of change of a stimulus. Tonic receptors adapt slowly and inform about the presence and strength of a stimulus. Many sensory neurons may unify both response properties and are called phasic-tonic receptors. They usually show a phasic response at stimulus onset, followed by a long-lasting, but lower tonic response.

►Sensory Systems

## Adaptation of Vestibulo-Ocular Reflex

### Definition

The vestibulo-ocular reflex is the eye movement driven by the head motion detected by inner ears. The eyeball turns in the opposite direction of head turn so that the image motion on the retina (retinal slip) is suppressed.

The amplitude of this reflex changes when there is a mismatch between the head and the eye movements.

The change works to reduce the retinal slip, thus it is regarded as adaptive.

►Retinal Slip
►Sensory Motor Learning/Memory and Cerebellum
► Vestibulo-ocular Reflexes

## Adaptation of Visual Perception

### Definition

Adaptation refers to the tendency of a sensory system to change its operating characteristics as a result of prolonged or repeated exposure to a specific type of stimulus. For example, a striped surface (a grating) that appears vertical when presented in isolation (test stimulus) can be made to look tilted if the observer first stares at (adapts to) a tilted grating for some time (say 60 s) and then looks at the isolated test grating again.

►Visual Illusions

## Adaptive Behavior

### Definition

The ability to adjust behavior to changes in the environment.

►Cognitive Elements in Animal Behavior

## Adaptive Control

### Definition

An "adaptive controller" is a special form of control law (see separate article on "control"). Adaptive controllers have the distinguishing feature that they incorporate some form of inbuilt mechanism for adjusting their characteristics, based on perceived changes in the characteristics of the system or the environment in which the system operates.

One helpful way of thinking about adaptive control is via the concept of internal models (see separate articles on "internal model" and "control"). It can be argued (see article on "control") that all controllers explicitly or implicitly contain internal models for both the system and the environment in which the system operates. A non-adaptive controller will typically utilize fixed internal models, whereas an adaptive controller will have some mechanism for changing the internal model, based on observations made regarding how the system responds to stimuli provided to the system through the actuators (see separate article on "control").

There is a helpful example given in the article on internal models regarding lifting a box. Quoting from that article:

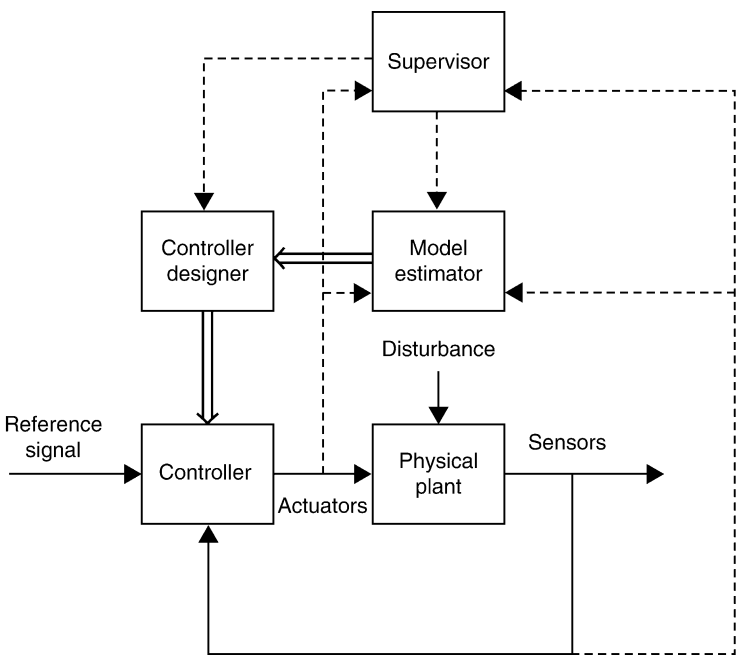
> When you get ready to pick up a box that you believe to be heavy, you prepare your posture for

generating a large lift force long before you begin lifting. If the box turns out to be empty, it will move unexpectedly fast. One may say that your internal estimate of the dynamics of the object was inaccurate, or that you had the wrong internal model of its properties. Because you used an incorrect internal model of the box to guide your actions, you generated unnecessarily large forces in trying to pick it up.

Continuing this example, if you are asked to pick up the same box a second time, then you will almost certainly use a different posture and apply forces that are more appropriate. In other words, you will have adjusted (or adapted) the internal model for the true system and this will, in turn, have changed (or adapted) your control law.

Based on the above heuristic description, we can see that adaptive control is an interesting and potentially very useful concept. Clearly, there seems to be substantial merit in having control algorithms that are capable of initially designing themselves based on only partial knowledge of the process to be controlled.

Of even greater interest would be control algorithms that were capable of redesigning themselves in the face of significant process variations. The study of adaptive controllers takes on different forms in different areas. In the life sciences, researches have postulated and studied the presence of adaptive mechanisms in biological control systems. In engineering, researchers have endeavored to capture the essence of adaptive control to design control laws for use in man-made systems. In both cases, the question arises as to what form of adaptive mechanism results in the overall system behaving in the required fashion. Indeed, it is a non-trivial exercise to specify the adaptive rules so that the resulting controller has desirable properties. Understanding the general rules that lead to stable (or convergent) adaptive behavior has proven to be surprisingly difficult. Indeed, this question has captured the interest of engineers and mathematicians for the past five decades. Many insights have been obtained but the general question remains largely open. In the sequel, we will attempt to give some insights into adaptive controllers from an engineering perspective. We will not attempt to give a precise definition of adaptive control. However, in Fig. 1 we provide a possible conceptual view of an adaptive control system. At the heart of it is a typical feedback control (solid lines in Fig. 1 indicate signal flow in this part of the system), which consists of the controlled physical plant and a controller with a feedback loop. The typical starting point for traditional feedback control design is the availability of a ►mathematical model for the physical plant to be controlled (see companion article on "control"). The model typically consists of structure and parameters and similarly, the design process is aimed at determining the controller structure and parameters. There are many control design methodologies [1]. However,



**Adaptive Control. Figure 1** A general adaptive control system.

irrespective of how the control law is designed, in a traditional setting, once the controller has been designed and implemented it stays "fixed." On the other hand, an adaptive controller has the capacity of changing the control law by adjusting its internal models.

Specifically, an adaptive controller is aimed at providing:

- Capability to estimate the model of the process applicable at the current time – the ►Model Estimator in Fig. 1
- Capability to redesign the controller (using some underlying design methodology) – the Controller Designer in Fig. 1
- Capability to make decisions as to when to re-initiate the processes of model estimation and controller redesign – the Supervisor in Fig. 1

Over the past 50 years, the idea of adaptive control has sparked the imagination of many researchers as well as control engineers. This resulted in thousands of papers and tens of books on the subject (see, e.g., [2,3,4,5] and many more). The adaptive controllers reported in the engineering literature (both in theory and in practice) differ in the way each capability is implemented. This will be further discussed below. Ideally, one would like to have an algorithm that was capable of changing the model and controller structure as well as their parameters. The reality, however, is that most adaptive controls in common engineering use, are limited to parameter adaptation only, while the structures of both model and controller are predetermined. As a result, the model estimation used in most contemporary adaptive controllers consists of parameter estimation and the redesign is limited to determination of controller parameters. Hence, a close connection has emerged between the area of system identification [6,7] (which studies how one can estimate model parameters from observations of input–output data) and adaptive control. Basically, one could attempt to combine any identification algorithm with any control design methodology to get an adaptive control scheme.

## Description of the Theory

### Direct and Indirect Adaptive Control

As shown in Fig. 1, estimated parameters are fed to the controller design block, which typically treats them as if they were true system parameters when designing the controller. This idea is called "►Certainty Equivalence" [5]. More sophisticated procedures may also try to give a measure of local accuracy of the current model and this can also be used in the control system design procedure.

There are also several ways that one can utilize the updated model information. For example, one could use the current model until one has a high level of confidence that on-line parameter estimation has led to a better model. In other schemes, every time new estimates reach the design block, the controller is redesigned. Unfortunately, the resulting systems typically turn out to be highly nonlinear and time varying, hence, very difficult to analyze. A stumbling block is often the Controller Design block, which introduces much of the nonlinear relationships. In very special types of simple control law design, it is possible to avoid the need for a control design block. In those cases, the system model is manipulated into a form where it is expressed directly in terms of the control law parameters. Namely, the system parameters and the controller parameters are identical. In this case, the control law design phase becomes trivial. These cases have been referred to in the literature as direct adaptive control while the other cases where one needs to translate system parameters into control law parameters have been called indirect adaptive control. ►Model reference adaptive control [5] and the self-tuning regulator [2] are prime examples of direct adaptive controllers.

### Analysis of behavior

An adaptive controller can thus be seen as a special form of nonlinear control law, which incorporates on-line adjustments to a feedback law. Not surprisingly, it is very difficult to analyze the behavior of these algorithms. Initial attempts focused on proving closed loop stability under idealized assumptions.

For the direct adaptive controllers, proof exists of stability in the literature (see, e.g., [3,4]) under idealized assumptions. It is also possible to extend these ideas to indirect adaptive control at the expense of additional simplifying assumptions [5].

Following these initial results, stability proofs were generated when the system was affected by disturbances and noise. Again, very idealized assumptions were made, e.g., time invariant, linear dynamics, stationary stochastic disturbances, etc.

Ideally, it would be good to have a theory that allowed one to understand the behavior of adaptive controllers in practical scenarios, e.g., when there is noise, non-stationary behavior, non-linearities and unmodeled dynamics. While some preliminary ideas are available in the literature (see for example, [8]), a comprehensive theory of adaptive control has proven to be illusive.

### Two Time Scale Adaptive Controllers

It is well known in the system identification literature, for the parameter estimators to work properly one needs to "shake up" the system to excite all its parts and exhibit its different behavioral patterns [6,7]. On the other hand, a controller typically tries to "calm" the system down. These two contradicting processes are at the core of the problem of adaptive control performance. One idea that has been shown to lead to

interesting properties is the use of two time scales (or, block invariance). The idea is to use different time scales, a fast one for the control law action and data collection for the purposes of identifying the model parameters, and a slow one for the controller redesign. Specifically, a ►sufficiently exciting signal [6,7] is inserted into the system while the controller parameters are kept constant. During this period the identifier improves its estimated parameters. At the end of this predetermined period, the redesign block is triggered, generating a new, improved, controller design. This process is repeated at predetermined fixed intervals. It has been argued (see [9]) that this idea can be applied to many combinations of identification algorithm and control design method leading to convergent behavior.

### Supervised Adaptive Controllers: Switched Control

While, in two time scale adaptive controllers, the controller redesign is "switched on" at predetermined instances, one could readily imagine the incorporation of additional logic that gets all the available information from the system and, based on some mechanism, decides when to switch on the redesign. Currently available configurations for this type of idea in the engineering literature are relatively simple. One idea is to utilize a finite set of fixed, distinct controllers with a supervisor which switches on the "most appropriate" controller at different times (see, e.g., [10]). So far the results in the literature have been limited to establishing stability of the resulting control system with no performance claims.

### Adaptive Controllers in Practice

A comprehensive theory of adaptive control is not yet available. This is perhaps not surprising, given the fact that these controllers are inherently nonlinear and exhibit complex behavior. Nonetheless, the idea of adaptive control is both persuasive and interesting.

Adaptive controllers have frequently been used in practical engineering applications [2]. Indeed, the authors of the current article have used a form of adaptive control in thickness control in rolling mills, where it has proven to be an effective design tool – allowing expensive sensors to be replaced by less expensive "virtual" sensors.

Physiological systems also frequently contain instances of control loops that appear to exhibit adaptive behavior. Indeed, it could be argued that the use of adaptive controllers by engineers is nothing more than a somewhat naïve attempt to mimic behavior which is intrinsic to all biological systems. In summary, adaptive control remains an exciting concept that will undoubtedly continue to attract interest from many fields including engineering and the life sciences.

## Adaptive Controller

### Definition

An Adaptive Controller consists of a controller with changeable parameters combined with an adaptive scheme that changes control parameters based on plant measurements.

►Adaptive Control

## Adaptive Immune Responses

### Definition

Also known as acquired immunity that has four characteristic attributes: (i) antigen specificity; (ii) diversity; (iii) immunological memory; and (iv) self/nonself recognition. Adaptive immunity is capable of specifically recognizing and selectively eliminating

foreign micro-organisms and molecules via activated T and B lymphocytes and the factors they release.

Activation of adaptive immunity is directed by the cellular responses in the innate immune response and can be activated faster and more effectively upon re-encounter with the same antigen, known as a memory response. In the central nervous system (CNS), immunity conferred by T and B cells as a result of their specific recognition of certain antigens assists in the recruitment, activation, and regulation of innate immune cells for the purpose of tissue maintenance, repair, renewal, and recovery.

►Autologous Macrophages for Central Nervous System Repair
►Immune System and Pain

## Adaptive Multi-Layer Systems

### Definition

An architecture of neural networks composed of multiple layers of adaptive neurons. A network normally has one input layer and one output layer.

Other layers are called hidden layers. There may be both inter-layer connections and intra-layer connections between neurons. The networks which have only feed-forward inter-layer connections from input to output are called feed-forward networks. Signals on the input layer are transferred through inter-layer connections to the output layer. By modifying the weight of connections according to an adequate learning rule, desired input-output relations can be acquired.

►Competitive Learning Theory

## Adaptor Protein

### Definition

An accessory protein having a number of different protein-binding modules that facilitate specific protein-protein (or other molecular) interactions. It thus promotes the formation of protein complexes, and plays a role in regulating signal transduction pathways.

►Synaptic Proteins and Regulated Exocytosis

## Addiction

### Definition

Addiction is a neuropsychiatric disorder characterized by compulsive thoughts and actions directed toward obtaining and consumption of pharmacological and natural reward stimuli, with no regard for the potential injury to health, family or society. Casual use of substances such as heroin, cocaine, or methamphetamine does not constitute addictive behavior. Addiction is also characterized as a "chronic-relapsing disorder" which may be triggered by drug-associated cues and environments, or stress, even after long periods of abstinence from drug-seeking behavior. Addictive behaviors often entail "risk-taking" and harmful activity which may constitute a danger to public health.

Repeated exposure to drugs of abuse, excessive sexual activity, or gambling has been show to activated specific brain systems, most notably dopaminergic and glutamateric pathways converging on the nucleus accumbens and prefrontal cortex. Long-term changes in synaptic plasticity, in the form of long-term potentiation and long-term depression in these pathways are hypothesized to be the neural correlate of addictive behavior, hence the claim that addiction is a brain disease.

►Learning and Motivation
►Long-term Depression
►Long-term Potentiation

## ADEM (Acute Demyelinating Encephalomyelitis)

### Definition

ADEM has a monophasic course, occurs more often in children and may follow immunization or infection.

Onset is usually abrupt with rapid progression.

Pathologically, perivenous inflammation with macrophage infiltration and associated demyelination in a sleeve like distribution along the perivenous zones is seen. Magnetic resonance imaging (MRI) shows perivenular inflammation, extensive demyelination and gadolinium enhancement of white matter in the brain and spinal cord and often involve deeper layers of cortical or subcortical structures.

Treatment may be attempted with high-dose corticosteroids or plasma exchange.

## Adenohypophysis

### Definition

►Diencephalon

►Anterior Lobe of the Hypophysis

## Adenosine

### Definition

Adenosine is a purine nucleoside that forms adenosine triphosphate (ATP), adenosine diphosphate (ADP) and cylic adenosine monophosphate (cAMP), which are all important in cell metabolism throughout tissues of the body.

During cellular activity (and formation of ATP from two ADP molecules), free adenosine is released and transported out of cells, including neurons. Extracellular adenosine levels increase with increasing activity or under pathological conditions. Adenosine acts upon different receptors, which are associated with inhibitory (A1 and A3) or excitatory (A2a and A2b) effects on target cells. In the heart, adenosine acts upon A1 receptors to inhibit pacemaker cells and slow heart rate in a manner that is thought to be protective, particularly under conditions of ischemia or hypoxia. In the brain, concentrations of extracellular adenosine increase during prolonged periods of waking and associated neural activity. Acting upon A1 receptors, adenosine can inhibit neurons of the arousal system to promote sleep. Caffeine, well known as one of the major stimulants, acts by blocking A1 receptors.

## Adenylate Cyclase

### Definition

Enzyme that generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphase (ATP).

Adenylate cyclase activity is either inhibited or stimulated by signaling through G-protein coupled receptors. There are nine mammalian adenylate cyclases.

## Adequate Stimulus

### Definition

Adequate stimulus denotes that physico-chemical stimulus, for whose reception a sensory receptor is specialized and responds to at the lowest possible intensity (energy). For example, under optimal conditions, rods in the mammalian retina respond very sensitively to low-intensity light, even single photons (adequate stimulus), while a strong blow to the eye may evoke flashes of light sensations (phosphemes), but at much higher intensity (inadequate stimulus).

►Sensory Systems

## Adjuvant Analgesics

### Definition

Adjuvant analgesics are drugs with analgesic properties that were initially developed to treat other health problems, such as anticonvulsants and antidepressants.

These drugs have become a cornerstone of pain control for children with chronic pain, especially when pain has a neuropathic component.

►Pain in Children

## Adolescent Pain

►Pain in Children

## Adrenal Insufficiency (Addison's Disease)

### Definition

Addison's disease is a condition in which patients excrete copious amounts of dilute urine and drink comparable volumes of water in compensation. The patient may suffer from adrenal tumor or atrophy.

## Adrenaline or Epinephrine

### Definition

Adrenaline is a catecholamine, which is released as a neurotransmitter from neurons in the central nervous system and as a hormone from chromaffine cells in the adrenal gland. Adrenaline is required for increased metabolic and cardiovascular demands during stress. Its cellular actions are mediated via plasma membrane bound G protein-coupled receptors.

## Adrenergic Fiber

### Definition

An adrenergic fiber is an axon of a postganglionic sympathetic neuron that synthesizes noradrenaline (or adrenaline in some amphibians and fish). These fibers are more commonly referred to as noradrenergic fibers when noradrenaline is the neurotransmitter. Adrenergic/noradrenergic fibers travel from sympathetic ganglia to target tissues within bundles, usually mixed with other autonomic and sensory nerve fibers, before they branch extensively and become varicose. Most adrenergic/noradrenergic fibers also contain co-transmitters like ATP or neuropeptide Y.

►Adrenaline
►Postganglionic Neurotransmitter
►Sympathetic Pathways

## Adrenoceptors

### Definition

Adrenoceptors are receptors of the sympathetic nervous system activated by the postganglionic transmitter noradrenaline or by adrenaline. They occur in the main subtypes of $\alpha_1$, $\alpha_2$, $\beta_1$, $\beta_2$ and $\beta_3$ and may occur as auto- or heteroreceptors modulating transmitter release.

## Adult Neurogenesis

Inmaculada Ortega-Pérez
Laboratory of Perception and Memory, Institute Pasteur, Paris, France

### Synonyms

Neuron production in the adult brain; Secondary neurogenesis; Ongoing neurogenesis

### Definition

Neurogenesis is the process by which new neurons are generated. It encompasses the entire series of events from ►precursor cell division to survival and functional integration of the neural progeny into the neural network.

### Characteristics

For many years, the idea that the brains of almost all mammals retained a constant structure throughout life and could not generate new neurons prevailed in the field of neuroscience. Reports contradicting this long-standing dogma first emerged in the early 1960s, but it was another 40 years before the notion of the adult brain as a static organ was finally overturned. With the advent of new methods for labeling dividing cells and improvements in imaging techniques, investigators have confirmed that neurogenesis takes place in discrete areas of the central nervous system (CNS) throughout life (reviewed in [1]). Ongoing neurogenesis is now thought to be an important mechanism underlying ►brain plasticity, enabling organisms to adapt to environmental changes and influencing learning and memory in adulthood.

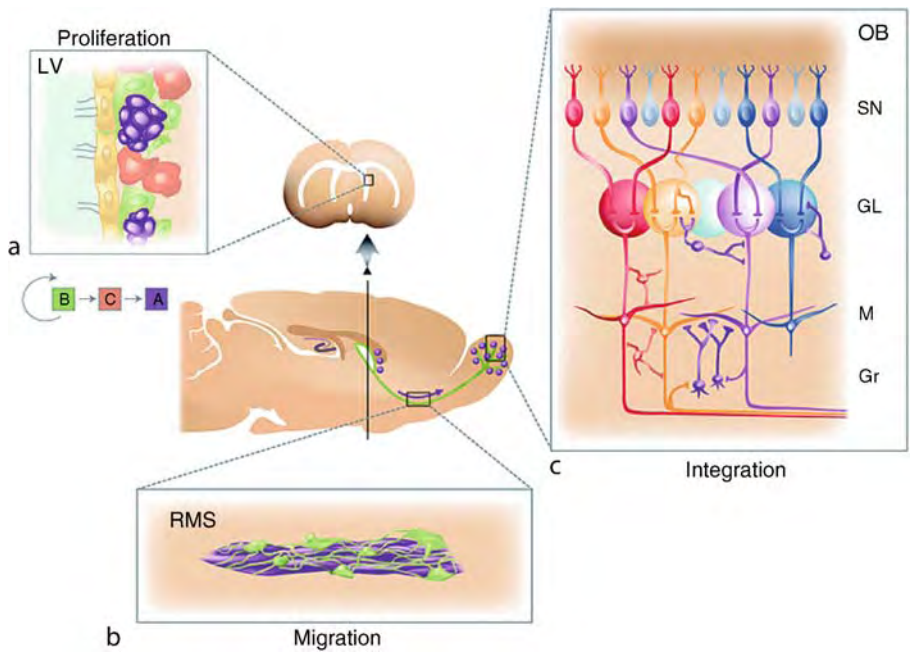
#### Adult Neurogenesis in Mammals

In mammals (including humans), new neurons are added to two main areas of the adult brain: the hippocampus [2] (which is involved in certain types of learning and memory) and the olfactory bulb (OB) [3] (which is involved in the sense of smell).

In the hippocampus, neurons are generated by neural precursor cells located in the dentate gyrus (DG), in a region known as the subgranular zone (SGZ). Neuroblasts generated in the SGZ migrate into the adjacent

granular layer, where they mature into granular neurons. In contrast, new olfactory neurons arise from neural precursors located outside of the olfactory system, in a region lining the border between the striatum and the lateral ventricle, the subventricular zone (SVZ). In this case, neuroblasts cover long distances as they migrate towards the OB along a path known as the rostral migratory stream (RMS). They migrate tangentially in chains, through tubular structures formed by astrocytes. After detaching from these chains and migrating radially from the RMS to the OB, the new neurons mature into olfactory inhibitory interneurons of two main types: granule cells and periglomerular cells. Both cell types make only local contacts in the bulb, directly or indirectly modulating the processing of sensory information by the OB's projection neurons: the mitral and tufted neurons (Fig. 1). Outside these two germinal regions, little or no neurogenesis seems to occur. In both the SGZ and the SVZ, precursor or ▶stem cells reside in specialized niches, providing a local microenvironment that influences the behavior of precursors and their ability to differentiate into neurons (reviewed in [4]). The transplantation of SVZ precursor cells into the hippocampus results in the generation of hippocampal neurons, whereas the transplantation of SGZ precursor cells into the RMS results in the generation of olfactory interneurons. Conversely, when implanted outside these neurogenic regions, these two types of precursor generate only glia. These observations indicate that neurogenesis depends on the presence of a permissive environment, rather than on regionally different properties of precursor cells [5].

The SVZ is the neurogenic region that generates by far the largest number of new neurons in the adult CNS. However, most of the cells generated in the SVZ die, with only a subset going on to achieve maturation and functional integration. OB neurogenesis appears to involve both neuronal turnover (neuronal replacement) and a net increase in the number of neurons (neuronal addition). The cell types and architecture of the SVZ have been characterized at the ultrastructural level, and four main cell types have been identified: astrocyte-like



**Adult Neurogenesis. Figure 1** *Neurogenesis in the adult olfactory bulb*: (a) Schematic representation of the SVZ showing the cell types present in this region and their organization. Multi-cilitated ependymal cells (*yellow*) line the wall between the lateral ventricle and the striatum. Neuroblasts (A, *purple*), appear forming clusters that are surrounded by astrocytes (B, *green*) and occasionally for rapidly dividing Type C cells (*red*). SVZ astrocytes can eventually extend a process to contact the lateral ventricle and exhibit a short single cilium. (b) New-born neuroblasts migrate tangentially along the rostral migratory stream to reach their final destination in the olfactory bulb. Migrating neuroblast group together in chains that are surrounded by tubular structures formed by the process of astrocytes. (c) After reaching the core of the olfactory bulb, neuroblasts detach from the chains and migrate radially to the overlaying layers, where they differentiate into two local interneuron subtypes: granule cells (located in the deeper layer of the olfactory bulb) and periglomerular neurons (located in the most superficial layer). LV: lateral ventricule; RMS: rostral migratory stream; OB: olfactory bulb; SN: sensory neurons; GL: Glomerular layer; M: Mitral layer; Gr: granular layer.

cells (GFAP-positive, with an astrocytic morphology, type B cells), intermediate amplifiers (type C cells), neuroblasts (type A cells), and ependymal cells lining the lateral ventricle (Fig. 1). B cells are thought to be multipotent neural precursors. They divide to generate the neuroblasts, via transit-amplifying C cells, which migrate though the RMS towards the OB. This region also contains a specialized basal lamina, which extends from blood vessels in the SVZ and terminates in small bulbs adjacent to the ependymal cells [4].

In contrast to neurons destined for the OB, which migrate over long distances, DG granule neurons are generated locally in the SGZ. Neurogenesis in the SGZ occurs in foci associated with blood vessels and containing primary precursors (astrocyte-like, type B cells), dividing immature (type D cells) cells that already express markers of neuronal differentiation, newly generated granule neurons and endothelial cells. D cells divide less frequently and are more differentiated than the type C cells of the SVZ [4].

Despite their astrocytic phenotype, not all the astrocytes in the germinal regions of the adult brain seem to act as stem cells. Only some of these cells proliferate slowly, giving rise to mature neurons in the OB or hippocampus. The other astrocytes may act as ►niche cells, possibly providing crucial signals to the diverse stem and progenitor cells in this lineage [6].

## Regulation of Adult Neurogenesis

The molecular mechanisms involved in regulating adult neurogenesis remain unclear. It is currently thought that the process is orchestrated by an intrincate, complex network of signals inducing or inhibiting the proliferation of ►precursors, influencing fate choice or favoring migration towards target areas. The transcription factors E2F or Notch 1, and molecules such as ephrins (Eph) and their tyrosine kinase receptors (EphB1–3 and EphA4) provide just a few examples of proteins involved in regulating the proliferative activity of stem cells [7]. The sonic hedgehog (SHH) pathway has also been implicated in ►progenitor cell maintenance during adulthood. A loss of hedgehog signaling results in abnormalities in the DG and OB, whereas stimulation of the pathway induces an increase in the rate of proliferation of adult progenitors. Finally, growth factors, such as brain-derived neurotrophic factor (BDNF), basic fibroblast growth factor (bFGF), insulin growth factor 1 (IGF1) and vascular endothelial growth factor (VEGF) also enhance the proliferation of progenitors in the DG or SVZ, or both [7].

Bone morphogenic protein (BMP) has been shown to induce the differentiation of neural stem cells into glial cells, whereas the local presence of BMP antagonists is associated with the generation of new neurons. Ependymal cells in the SVZ secrete Noggin and astrocytes in the SGZ secrete neurogesin-1, both of which are BMP antagonists. The Wnt signaling pathway may also guide cells toward a neuronal fate, and it has been shown that the WNT inhibitors sFRP2 and 3 (secreted frizzled-related proteins 2 and 3) partially block astroglial cell-induced neurogenesis in the DG [8]. The transcription factors paired box 6 (Pax6) and oligodendrocyte transcription factor 2 (Olig2) are involved in the mechanisms determining the fate of newborn cells and the timing of this specification along the SVZ-olfactory bulb pathway. Olig2 is produced in the SVZ, but only in transit-amplifying cells. The overproduction of this factor facilitates oligodendrocyte maturation, but represses neural development. By contrast, Pax6 is produced in only small amounts in the SVZ, but its repression is associated with a decrease in neuroblast formation. Pax6 is also produced in large amounts in the migrating neuroblasts along the RMS, providing further evidence of a role for Pax6 in promoting neuronal differentiation [8].

The process of migration is also highly regulated during neurogenesis. The tangential migration of neuroblasts from the SVZ to the OB is modulated by a cohort of factors, including PSA-NCAM, netrins and integrins. Reelin and tenascin-R play a role in radial migration, facilitating the detachment of neuroblasts from the chains. Neuroblasts also respond to ambient GABA levels by modulating their speed of migration [7].

## Adult Neurogenesis Under Pathological Conditions

Neurogenesis is also stimulated in the mammalian brain in response to injury and disease. Experiments in rodents have demonstrated that new cells are generated in response to ischemia or brain trauma. Remarkably, newly generated neurons can migrate to the site of the injury in the cerebral cortex or striatum (where neurogenesis does not normally occur) and differentiate into mature neurons forming connections with neighboring cells [9]. Enhanced neurogenesis has also been reported in degenerative diseases, such as Huntington's chorea and Alzheimer's disease. Although this injury-induced neurogenesis does not lead to recovery, many scientists believe it represents the brain's attempt at self-repair [8]. Neurogenesis also increases in response to seizure activity, but the production of new neurons is not beneficial because these neurons develop, migrate and integrate inappropriately, and actually seems to contribute to recurrent seizures [8]. The functional significance of abnormal neurogenesis in these and other medical conditions is not yet understood, but this area is the focus of intensive research, which may one day yield new treatments for these disorders.

## Functions of Adult Neurogenesis

The precise function of newly generated neurons in the adult brain remains unclear. It has been suggested that neurogenesis in the OB system may be a plastic response coupled to the high turnover of receptor neurons in the

olfactory epithelium. However, another potential role of bulbar granule neurons generated in adulthood has emerged in recent years. An odor-enriched environment enhances neurogenesis and improves olfactory memory, and the genetic disruption of olfactory neurogenesis has been shown to result in a loss of performance in odor discrimination tasks in mice. These observations indicate that newly generated neurons may contribute to perceptual and memory functions in the bulb [7,9]. The hippocampus has been shown to be involved in learning and memory, and it has been suggested that newly generated neurons within the hippocampus contribute to these processes. The conditions impairing adult neurogenesis, such as stress, have also been shown to impair learning. In contrast, conditions promoting the generation of new neurons, such as physical exercise, are often associated with improvements in memory and the learning of tasks dependent on the hippocampus [7,8]. Studies have also shown that learning promotes the survival of new neurons, and better learners seem to retain more new neurons, particularly when trained to perform difficult tasks [9]. Hippocampal neurogenesis may also play a role in various neurological disorders and diseases, including epilepsy and depression, as some of the treatments and drugs successfully used to treat individuals suffering from depression may increase the production of new hippocampal neurons [10]. Furthermore, the beneficial effects of some antidepressants are blocked by the inhibition of neurogenesis, suggesting that low levels of neurogenesis may be an underlying cause of depression.

## Advanced Sleep Phase Syndrome (ASPS)

### Definition

Advanced sleep phase syndrome (ASPS) is most common in the elderly. It is characterized by a difficulty in staying awake in the evening and by early morning awakening. Sleep maintenance insomnia is often related to ASPS. This disorder is treated by taking 0.5 mg of melatonin at each awakening during the night after 1 a.m. and a final dose of up to 0.5 mg at final awakening in the morning. Bright light (2,000–10,000 lux) scheduled between 7 and 9 p.m., ending no later than 1 h before desired bedtime is also helpful.

►Circadian Sleep Phase Syndromes

## Aerotaxis

### Definition

Motility in relation to a gradient of oxygen concentration such that the organism migrates to an optimal oxygen concentration in an oxygen gradient.

## Aetiology

### Definition

Causal explanation, the cause of a disease.

## A-Fibers of Dorsal Root of the Spinal Nerve

### Definition

C and A delta fibers innervate primarily nociceptors but also thermo- and some mechanoreceptors. Conversely,

A-beta and A-delta fibers innervate touch receptors of the skin. All these fiber types enter the spinal cord via the dorsal root.

►Medulla Spinalis

## Affect

►Emotion

## Affective Dimension

**Definition**

The way an individual feels or experiences emotion in response to a particular setting, process, characteristic, attitude, or sensation. A full description of a particular item would usually include the affective dimension of the item, along with its cognitive and behavioral dimensions (plus sometimes the sensory dimension).

## Afferent

**Definition**

The term afferent (from Latin "ad" = towards and "ferre" = carry) refers to nerves that carry information towards the central nervous system. Somatic afferent nerves innervate muscles, joints or skin. Visceral afferent nerves innervate body organs and blood vessels.

►Sensory Systems

## Afferent Innervation of the Heart

►Visceral Afferents

## Afferent Input to Rhythm Generating Networks

►Peripheral Feedback and Rhythm Generation

## Afferent Regulation of Locomotion

►Locomotor Reflexes

## AFP

**Definition**

Anterior forebrain pathway.

►Song Learning of Songbirds

## Afterdepolarization

**Definition**

Afterdepolarization (delayed depolarization) is the depolarization after the fast spike repolarization phase, either appearing as a slow phase of repolarization or as an intermittent depolarization between a fast afterhyperpolarization and a subsequent afterhyperpolarization.

►Action Potential

## Aftereffect in Circadian Rhythm

**Definition**

A long-term change in the endogenous circadian period as a result of entrainment to a light-dark cycle. For example, if a mouse with an endogenous period of 23 h

was entrained to a 24.5 h light dark cycle for a period of six months and released into constant darkness, it might show a new endogenous period of 24 h for several weeks to months before eventually returning to a period of approximately 23 h.

►Masking (Positive/Negative)

## Aftereffect Measurement

### Definition

Generally, an aftereffect is measured as follows: An observer judges a test stimulus in isolation (called a pretest trial or baseline measure) and then judges it in isolation again, but this time after prolonged adaptation to an inducing stimulus (called a posttest trial). There is no difference between the stimulus displays in the pretest and posttest because the inducing is removed prior to the posttest. The aftereffect, that is, the effect of the inducing stimulus on the test stimulus, is defined as the algebraic difference between the posttest and pretest judgments. Because the posttest stimulus is judged after the inducer is removed, an aftereffect is a successive effect.

►Visual Illusions

## Afterhyperpolarization (AHP)

### Definition

Afterhyperpolarization (AHP) – hyperpolarization following an (action potential). In the squid axon, the afterhyperpolarization is generated by the slowly inactivating voltage-dependent $K^+$ conductance activated during the action potential. In mammalian central neurons, AHPs may show different phases: fast, medium and slow, in some cases interrupted by afterdepolarizations. Second, the contributing $K^+$ channels include BK and SK channels and Kv7 channels mediating the M-current. BK-channel-mediated AHPs are usually brief, while SK-channel-mediated ones can last up to seconds.

►Action Potential

## Ageing

### Definition

Ageing refers to growing old, maturing or exhibiting the effects of the passing of time.

## Ageing of Autonomic/Enteric Function

Robert M. Santer
School of Biosciences, Cardiff University, Cardiff, United Kingdom

### Synonyms

Vegetative nervous function; Visceral nervous function; Gastrointestinal function

### Definition

The ►autonomic nervous system is part of the peripheral nervous system, which is instrumental in maintaining the internal environment of the body in a steady state and in returning the internal environment to a steady state following internal and external stimuli. In order to accomplish this, the autonomic nervous system maintains a controlling influence over the cardiovascular, digestive, thermoregulatory and urinogenital systems. This is achieved by both motor and sensory innervation of the major organ systems together with other structures such as sweat glands and intraocular muscles. Autonomic function is involuntary, and we are not usually conscious of ongoing autonomic activity except at times of increased emotions such as anger or fear, when autonomically induced increases in heart rate or in sweating occur.

The ►enteric nervous system is the intrinsic, local nervous system of the digestive system which controls the processes of digestion such as motility of the gut, secretion of chemicals for the breakdown of food and the absorption of the products of digestion. The enteric nervous system also regulates the flow of blood throughout the gastrointestinal tract. The enteric nervous system can also act autonomously but, like the autonomic nervous system, is under the control of the central nervous system. In old age, there is a tendency for the ability of autonomic and enteric function to be perturbed, such that it is not as capable of maintaining a homeostatic state as it is in the young adult. There is considerable variability in the extent to which different organ systems are affected by ►aging. As advanced health care in the developed world leads to increased longevity of the human population, the

incidence of ►autonomic and enteric dysfunction in the elderly will undoubtedly increase.

## Characteristics

### Quantitative Description

By virtue of the fact that autonomic nerves travel alongside the arteries of the body and within somatic peripheral nerves and their branches, the ►autonomic nervous system is present in all regions of the body. Likewise the ►enteric nervous system extends throughout the digestive system from the oral to the anal cavity.

### Higher Level Structures

The autonomic nervous system is divided into parasympathetic and ►sympathetic divisions, which usually both innervate the same organ but have opposing functions. In general, parasympathetic function is anabolic whilst sympathetic function is catabolic in nature.

The anatomical organization of both the parasympathetic and sympathetic divisions is essentially similar. The efferent (motor) limb is a two neuron chain originating in the central nervous system in which the two neurons synapse in an ►autonomic ganglion in the periphery. The first of these neurons is termed the ►preganglionic neuron, and it has its cell bodies located in the brainstem or spinal cord. The second neuron is termed the ►postganglionic neuron, having its cell body in a ganglion sending its axon to innervate the target organ. The position of the ganglion varies and in consequence so does the length of the axons of preganglionic and postganglionic neurons. In the ►parasympathetic system, the ganglia are located close to, or even within, the innervated organ, with the consequence that the preganglionic axon is relatively long and the postganglionic axon relatively short. Sympathetic ganglia are located closer to the central nervous system and in consequence the preganglionic axon is relatively short and the postganglionic axon relatively long. All preganglionic neurons are under the control of the central nervous system by descending supraspinal pathways or by local interneurons. The afferent (sensory) limb of the autonomic reflex consists of receptor endings in the walls of the viscera, a peripheral process running either in an autonomic or a somatic peripheral nerve trunk, a cell body in a spinal or cranial ganglion and a central process entering the dorsal horn of the spinal cord or grey matter of the brainstem.

The enteric nervous system consists of two networks, or plexuses, of neurons that are located in the wall of the digastric tract. The myenteric plexus (of Auerbach) is located between the outer longitudinal and inner circular layers of the muscularis externa, and is principally concerned with the control of gut motility such that the contents are propelled in an oral to anal direction. The submucous plexus (of Meissner) is located within the submucosa. Its role is to regulate gastrointestinal blood flow, control the functioning of the epithelial cell lining of the gut and in sensing the chemical composition of the contents of the gut lumen. The enteric nervous system has important connections with the sympathetic and parasympathetic divisions of the autonomic nervous system, and can therefore come under controlling influences of the central nervous system.

### Lower Level Components

The chemical neuroanatomy of the autonomic nervous system is relatively simple and can be summarized as follows:

1. Preganglionic neurons are multipolar and receive glutamergic, glycinergic, monoaminergic, cholinergic and peptidergic afferents.
2. All preganglionic neurons release acetylcholine at the ganglionic synapse.
3. All parasympathetic postganglionic neurons release acetylcholine at their targets but this is often accompanied by the release of vasoactive intestinal polypeptide (VIP), particularly at secretomotor terminals.
4. The majority of sympathetic postganglionic neurons release noradrenaline at their targets, often accompanied by the release of neuropeptide Y (NPY). The exception to this concerns sweat glands where acetylcholine acts as the neurotransmitter.
5. The occurrence of nitric oxide is widespread in both preganglionic and postganglionic autonomic neurons.

In addition to their extrinsic autonomic connections, ►enteric neurons secrete a wide range of neurotransmitters of which acetylcholine, nitric oxide, and many neuropeptides (principally substance P, VIP, NPY, galanin and somatostatin) which occur in different functional types of enteric neuron. The combinations of neurochemicals in enteric neurons have been used to code them and to define their functional characteristics [1,2]. In general terms, enteric neurons can be divided into the following categories:

1. Motor neurons controlling gastrointestinal motility by innervation of the muscularis and secretion from a variety of secretory cell types within the intestine.
2. Sensory neurons receiving information from terminals in the mucosa sensitive to chemical, osmotic thermal and mechanical changes and from terminals in the smooth muscle which are sensitive to stretch.
3. Interneurons responsible for the co-ordination of activity between individual ganglia of the plexuses and between the myenteric and submucous plexus. The co-ordination of descending (oral to anal) reflexes controlling peristaltic function is of special importance in promoting the passage of gut contents.

## Structural Regulation

Neurons of autonomic and enteric ganglia originate in the neural crest and migrate to their final locations. Their axons then grow into their target organs. These neural migrations are guided by a variety of factors such as neurotrophins and glial derived neurotrophic factor as well as constituents of the extracellular matrix. Failure of the ontogenetic process resulting in neurons not migrating into their correct locations results in serious malfunctions: for example, mice whose cardiac neurons have failed to reach the heart die at birth [2], and congenital dysfunctions of the gastrointestinal system such as motility disorders, megacolon and gastric outlet obstruction result from the failure of neuronal migration during development.

## Higher Level Processes

Cardiovascular System. Aging is associated with a reduced capability of the autonomic nervous system to maintain hemodynamic stability. A decline in the tonic influence of the parasympathetic system and an increase in sympathetic activity coupled with a change in the structure of the heart and major blood vessels from a supple nature to a more resistant, stiffer nature are characteristic of the elderly. This increased systemic vascular resistance leads to hypertension accompanied by increased systolic pressure and left ventricular hypertrophy. Decreases in cardiac output and stroke volume may be compensated for by reduced metabolic demand in the elderly. Changes with age occur in many cardiovascular reflexes including cardiopulmonary reflexes, respiratory sinus arrhythmia and in the baroreceptor reflex. Baroreceptors are stretch receptors in the carotid sinus and aortic arch, and the increased stiffening of the walls of these vessels with age results in a reduction in the ability of the receptors to respond to changes in blood pressure with a reduction in afferent input to autonomic regulatory centres in the brainstem. This is likely to be a factor in the increased occurrence of orthostatic hypotension in the elderly, a problem that is nowadays also associated with the administration of antihypertensive medication. Postprandial hypotension is also common in the elderly where there is inadequate cardiovascular compensation for the increased blood flow to the gastrointestinal system after a meal.

Urinogenital System. In old age, dysfunctions of urinary voiding are common and the frequency of micturition and the amount of urine voided are increased. Changes in the structure of the bladder wall and internal urethral sphincter, changes in the nerve supply of the bladder and changes in the central nervous system control of the micturition are implicated in the development of urinary incontinence. Normally, the smooth muscle of the bladder receives a dual innervation from the parasympathetic and sympathetic nervous systems. Sympathetic activity causes a relaxation of the bladder wall and a constriction of the base of the bladder, including the internal urethral sphincter allowing the bladder to fill whilst maintaining continence. The parasympathetic effects are directly opposite, thereby inducing a voiding of urine. The sensory innervation of the bladder is a crucial part of the voiding reflex. It is considered that the age-associated changes in micturition are more likely to be due to the neural control of the bladder than to changes in the responsiveness of bladder smooth muscle to adrenergic and cholinergic agonists. The pelvic neurons innervating the lower urinary tract are, in common with those innervating the internal genital organs, sensitive to circulating androgens such as testosterone which also has potent effects on reproductive behaviour. Testosterone affects the ability of these neurons to maintain their morphology, synthesize neurotransmitters and express receptors. The age-associated reduction of plasma testosterone is likely to have serious consequences for the maintenance of pelvic neurons resulting in dysfunction of urinogenital function.

Enteric Function. In elderly human beings there is an increased incidence of problems associated with gastrointestinal motility. Dysphagia due to reduced oesophageal peristalsis and relaxation of the oesophageogastric junction, increased transit time of gut contents with the danger of faecal stasis and also faecal incontinence are the most common ►enteric dysfunctions which may be attributed to the enteric innervation. Other age-associated dysfunctions include diminished ability to absorb certain constituents of the diet.

## Lower Level Processes

Cardiovascular System. Well documented changes occur in the sympathetic innervation of the cardiovascular system with age. There is a reduction in the density of sympathetic innervation of the heart and in many, but not all, arteries and veins, stimulus-induced noradrenaline release increases, beta-adrenoceptor vasoconstrictive responsiveness declines, the re-uptake of noradrenaline by sympathetic nerve terminals declines and there is an increase in the concentration of plasma noradrenaline.

Urinogenital System. Investigations of the effects of age on the innervation of the lower urinary tract [3] have revealed that the sympathetic innervation is much more susceptible than is the parasympathetic innervation. This differential susceptibility affects both the preganglionic and postganglionic neurons supplying the bladder but also the descending supraspinal afferents to the preganglionic sympathetic neurons. The supraspinal pathways so far investigated contain glutamate, GABA, substance P and monoamines. Age-associated changes in the sensory innervation of the bladder wall have not been detected. There is some evidence that the neurodegeneration of postganglionic sympathetic pelvic neurons in old age may be

attributable to decreases in calcium binding proteins, leading to raised intracellular calcium concentrations [4].

Enteric Function. Neurodegeneration in the enteric nervous system with increasing age is now a well established phenomenon and affects both the myenteric and submucous plexuses [5]. Moreover, thanks to the neurochemical coding of enteric neurons [6], it is now possible to determine which functional types of enteric neuron are susceptible to age-associated neurodegeneration. In summary, there is a significant loss of cholinergic neurons from the myenteric plexus, which is likely to impair the propulsion of gut contents [7] and also of sensory neurons of the submucous plexus, possibly also contributing to reduced gut motility [5]. The postganglionic sympathetic innervation which has an inhibitory effect on the myenteric neurons is also much reduced in old age [8]. The mechanism for age-associated neurodegeneration in the gut may well be the excessive production of reactive oxygen species, as this can be almost totally prevented by caloric restriction [9,10].

### Function

Autonomic and enteric functions are complex, vital processes in the maintenance of ►homeostasis of mammals. Perturbation of these processes during aging will be detrimental to the health of individuals and may eventually be life-threatening, thus influencing the longevity of an individual.

### Pathology

Some of the age-associated effects of the ►ageing autonomic nervous system are similar to those seen in multiple systems atrophy (Shy–Drager syndrome), a progressive disease of the autonomic nervous system, in which there is a ►selective vulnerability of certain brainstem nuclei that control the preganglionic autonomic outflow. This selective vulnerability is also a feature of ageing in autonomic ganglia, in which certain target-specific groups of neurons are affected in old age whereas others are not [9]. This observation is reinforced by neuropathological evidence of neuronal degeneration in sympathetic ganglia of both man and rodents.

### Therapy

Two factors which certain groups of autonomic and enteric neurons require for successful development and maintenance in adult life have been proposed as possible therapeutic agents in instances of autonomic and/or enteric change in old age: neurotrophic factors have possible wide-ranging application and androgens whose potential beneficial effects are restricted to the androgen-sensitive pelvic neurons.

## Agency

### Definition

The property of being an agent. That is, the property of being an entity that acts. Typically, the term “agency” is applied only to agents capable of acting intentionally or purposively.

►Freedom of Will

## Agent Causation

### Definition

Agent causation is a relation supposed to hold between a substance, the agent, and its actions. The agent is construed as a prime mover. Agent causation contrasts

with event causation, a relation between events (including a person's motivational and representational states), and is taken by some theorists to be the key for understanding how free will is possible.

►Freedom of Will
►Information

## Age-related Macular Degeneration

### Definition

An age-related degeneration of the central retina (macular region). It causes irreversible loss of central vision (see Inherited Retinal Degenerations).

►Inherited Retinal Degenerations

## Ageusia

### Definition

Ageusia corresponds to the inability to detect and discriminate taste qualities. Most complaints of 'loss of taste' correspond in fact to hyposmia or anosmia, the loss of olfactory capability, since olfaction is essential for flavor perception. True aguesia is rare and hypogeusia, which refers to a diminished, rather than lost, sense of taste, is more common.

Direct damage of the tongue is one of the causes for taste disturbances. It could result from head and neck radiation therapy, inflammation of the tongue (glossitis) or other conditions. Tobacco use and dry mouth (xerostomia), such as that resulting from Sjögren's syndrome, may also have the same effects.

The chorda tympani nerve, a branch of the facial (VIIth) cranial nerve, contains primary sensory neurons that transmit chemosensory information from the anterior two-thirds tongue. The glossopharyngeal (IXth) cranial nerve contains the peripheral taste fibres from the posterior third of the tongue. Damage to any of these nerves, for example due to trauma or surgery (e.g., iatrogenic chorda tympani lesion during otologic surgery) may cause hypogeusia. Ageusia from peripheral neural lesion is unlikely since multiple anatomically distinct nerves would have to be damaged. Central lesions (e.g., trauma, tumor or ischemia of the parietal lobe) may also cause loss of taste in discrete areas of the taste field. Non-traumatic peripheral or central neurological disorders, such as Bell's palsy or multiple sclerosis, may also affect taste function.

Systemic disturbances may also affect the sense of taste. Vitamin deficiency, endocrine disorders, cancer, renal or hepatic failure and multiple drugs, are known causes of ageusia. Aging is also typically accompanied by loss of taste sensitivity.

►Gustation

## Aggression

### Definition

Attack and threat; behavior directed to other organisms with the aim to intimidate, hurt or drive another animal away.

## Aging of Tactile Sense

Ronald T. Verrillo
Institute for Sensory Research, Syracuse University, Syracuse, New York, NY, USA

### Definition

### Characteristics

None of the sensory systems is immune from the deficits in function that occur as a consequence of the natural process of aging. It is a slow process that advances throughout the life span, but does not become noticeable until the mid-40 and 50 decades of life. Most people become aware of this decline when the visual system makes it necessary to wear "reading" glasses in order to bring a printed page into proper focus. The tactile sense (touch) is not exempt from the effects of advancing age. However these effects go largely unnoticed by most people because interaction with the environment is much more salient in vision and hearing and there is no dramatic "end product" such as blindness and deafness. For this reason there has been a paucity of research funding and effort in tactile research as compared to that of vision and hearing. Although these effects have been studied for about 80 years, for the most part the early studies used poorly controlled stimulators such as cotton swabs, hairs and primitive electronic devices. Hardly quantifiable, the

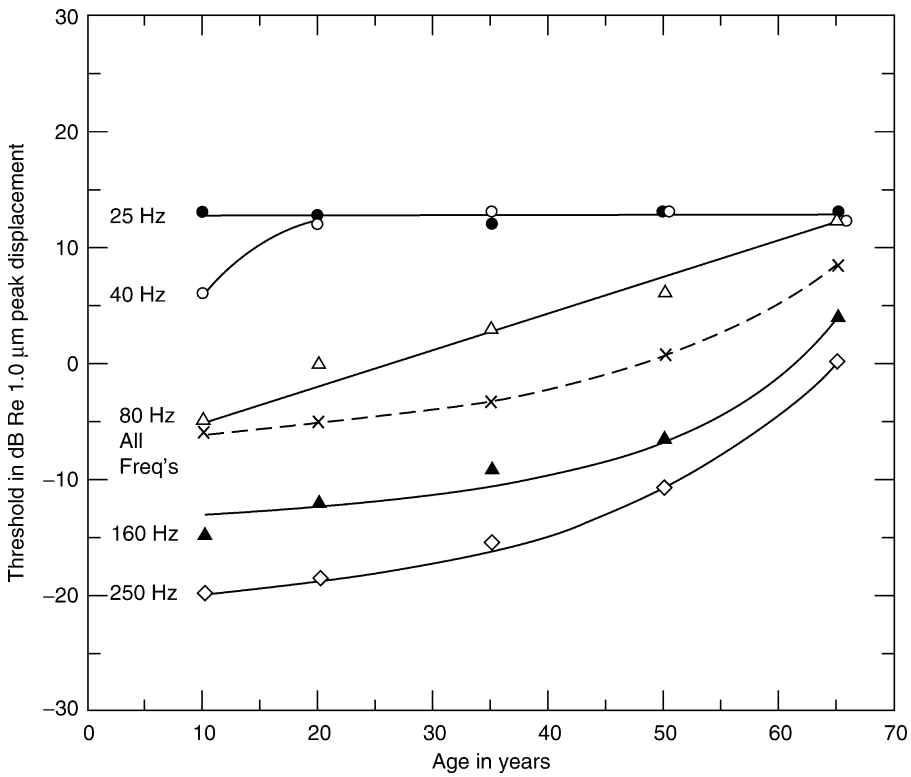
results of these experiments are difficult to interpret. Controlled laboratory experiments using modern technologies for measurement have been used routinely only in the past 35 years.

Studies of the tactile sense usually fall into two broad categories, namely measurements made at ▶threshold and at ▶suprathreshold levels of stimulation. Threshold experiments are performed to determine the minimal amount of energy that an observer is able to detect, in this case mechanical displacements (vibration). Suprathreshold experiments are performed in order to determine the observer's judgments and perceptions of energy levels well above the just-detectable level. Research on the effects of aging on the tactile sense has focused on measuring both threshold and suprathreshold responses.

## Threshold

The onset of a loss of sensitivity in the tactile system is measurable at a relatively early age. Between the ages of 10–20 years youngsters show a loss of sensitivity especially at frequencies above 80 Hz [1,2]. Later Verrillo [3] tested a different group of subjects at the age of 10 and the same subjects again at 23 years of age in a longitudinal study and found the same result. This confirmed that the results of the earlier study were not due to a bias in cross-sectional selection of subjects. All of the frequencies between 40 and 600 Hz were affected; only at 25 Hz was there no change in sensation. The span of ages was expanded further from 10 to 65 years in a series of experiments that determined that the loss of sensitivity was progressive throughout the life span, slow in the younger years but increasing more rapidly after about 55 years of age [4,5] which confirmed an earlier finding that covered approximately the same span of ages (20–70 years) [6]. Figure 1 shows the threshold values for vibrotaction in subjects ranging in age from 10 to 70 years. Increasing threshold values denote a loss of sensitivity.

The data also revealed an effect of gender; beyond 65 years of age in males suffered a greater loss of sensitivity than did females [5]. The loss of sensitivity in all of these studies occurred only at high frequencies from 80 to 250 Hz. At lower frequencies (25–40 Hz) the sensitivity to vibration remained constant through the life span. This suggests that in the ▶vibrotactile



**Aging of Tactile Sense. Figure 1** Detection thresholds of vibrotaction measured at five frequencies plotted as a function of age. The dashed line represents a composite of all frequencies combined. Decreasing sensitivity is indicated by increasing values along the vertical axis. From Verrillo [3].

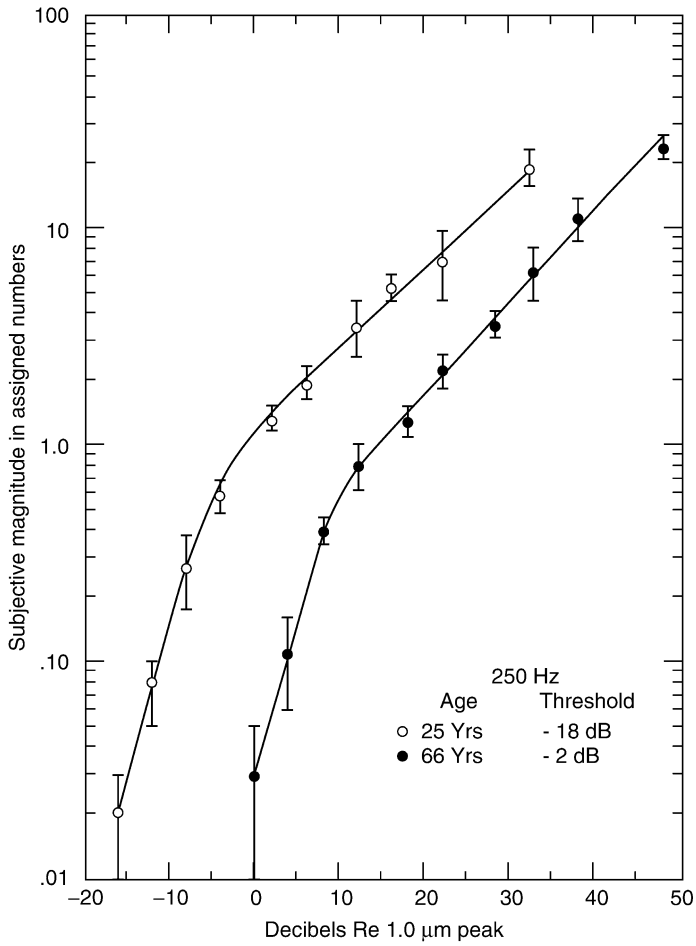
neural channel subserved by the ►Pacinian-corpuscle receptors, which are activated optimally by high-frequency vibration, there are anatomical and physiological changes in structure and/or biochemical composition that do not occur in non-Pacinian channels. Non-Pacinian receptors respond primarily to low-frequency vibrations. Many explanations have been offered to account for the loss of sensitivity with advancing age including changes in receptor morphology, loss of receptors, decrease of spinal-root fibers, decreased peripheral circulation and dietary deficiency. Throughout the life span, and especially in adulthood, there is a progressive loss of nerve fibers that is steady and continuous. A decrease in the number of receptor end organs accompanies the loss of nerve fibers. The large Pacinian corpuscles decrease in number, change in size and become more complex in structure with advancing years, becoming convoluted in shape, which can affect their ability to respond to mechanical deformations. Once fully developed in infancy, all of the cutaneous nerves and receptor end organs undergo a steady decrease in number and in morphological change that continues throughout the span of life. The rate of change is constant throughout the age span at 80 Hz, at about 3 dB per decade of age. At higher frequencies the loss accelerates at greater age levels. Throughout the span of years tested below the age of 65 there was no difference between men and women in the sensitivity to vibration, but beyond 65 years of age males suffered a greater loss of sensitivity than did females [5]. The loss of sensitivity in all of these studies occurred only at high frequencies from 80 to 250 Hz. At low frequencies (25–40 Hz) the sensitivity to vibration remained constant through the life span. It is likely that no single factor can explain the loss of sensitivity but that a combination of several or many of these is probably responsible.

## Suprathreshold

Because we live in an environment in which we are stimulated by and respond to stimuli that are, for the most part, above the threshold of detection, it is essential that the effects of these higher energy levels be considered. There are a number of psychophysical methods used to measure responses to suprathreshold stimulation, but the method of choice for measuring the relationship between the physical intensity of a stimulus and an observer's subjective impression of that intensity is a technique called Absolute Magnitude Estimation (AME). Subjects are asked to assign a number (greater or less than 1.0) whose magnitude is judged to be a match to that of the stimulation that is perceived. No standard, modulus or range of numbers is suggested by the investigator. The numbers assigned by the subjects are then plotted as a function of the physical intensities of the stimulus. The subject is free to use any number, large or small that seems an appropriate fit to the perceived intensity of the stimulus. The resultant curve is typically a power function. This method has been used in a number of sensory modalities and along many dimensions of the stimulus. The slope of the curve (exponent) is different for each sense modality, but it is consistent within each modality.

Figure 2 shows the results obtained when a group of 25 year olds was compared to an older group with a mean age of 66 years [7]. They were both tested using the AME method at a frequency of 250 Hz. The shift in the curve of the older group to higher intensities by 16 dB indicates that for the same perceived intensity in assigned numbers, the older group required at least a 16 dB increase in the physical intensity of the vibration. This means that at both threshold (Fig. 1) and at above threshold levels of stimulation there is a loss of vibrotactile sensitivity associated with the process of growing older. The 16 dB difference in threshold values would predict this outcome. However, the slopes of the two curves are identical; both slopes are about 1.0 in the mid-to upper-levels of physical intensity. This suggests that although there is a loss of sensation with age, there is no difference in the rate at which suprathreshold stimuli grow in perceived magnitude. This would imply that in the vibrotactile system the effects of aging are manifested more as a result of changes at central levels of the nervous system (cortical) rather than changes at the periphery.

Judgment of the subjective magnitude of vibration is not the only suprathreshold performance that suffers a deficit with advancing age. From a practical viewpoint the sense of touch has been used as a surrogate channel for both vision and hearing as an aid to communication for the blind and the deaf. The blind have used ►Braille for many years and more recently electromechanical devices to read the printed word with their fingertips. In a parallel effort, for many years researchers have made the effort to develop a method of substituting the tactile sense for hearing as an aid to the profoundly deaf. As the blind and the deaf grow older or develop pathologies such as adult-onset diabetes mellitus, which degrades the sense of touch, their ability to access the world becomes severely limited. The sensory input from the fingertips is a vital link with the world that has become reduced or disrupted. Human speech is the most sophisticated and complex form of communication throughout the animal kingdom. All animals communicate with one another in various ways, but none approaches the subtlety and richness of expression as that of human speech. To render this into a system of tactile stimuli has been a formidable task indeed.



**Aging of Tactile Sense. Figure 2** Absolute magnitude estimation of vibrotaction plotted as a function of the displacement intensity of the vibration. Comparison of a younger group (mean age 25 years) and an older group (mean age 66 years) is shown. From Verrillo [7].

In order to develop tactile sensory aids for the deaf (►tactile vocoders) investigators have studied a large number of speech parameters so that these elements might be incorporated into the design of a practical tactile device. One of the elements essential in understanding speech is the ability to distinguish rapidly changing temporal sequences of stimuli. In one study a group of subjects 22 years of age was compared to a group of 66 year olds in the ability to distinguish two short bursts of vibration separated by ►interstimulus intervals of various durations [7]. The younger group was able to detect two bursts separated by as little as 25 ms whereas the older group was unable to make that distinction when the separation of the double burst was less than 150 ms. Older subjects would be at a severe disadvantage in understanding the spoken word by the use of a tactile vocoder unless the design of the device would contain a feature to compensate for this serious limitation.

Another measurement used to assess the ability to understand speech (in the hard-of-hearing) is the test of gap-detection, that is, the ability to detect a silent interval between two long bursts of sound. Similar measurements have been made using the sense of touch [8]. Tests made using subjects between the ages of 8 and 75 years using both bursts of sinusoids and bursts of noise showed that the ability to detect a silent interval was significantly worse in older than in younger subjects. Again this limitation must be compensated for by design features of the tactile aid.

In summary, in every comparison of young and elderly persons tested at suprathreshold levels of stimulation, the performance of the elderly is poorer than that of the young. It is imperative that the designer of a tactile aid for the communication of speech takes these findings into consideration so that the aid can be used successfully by young and old alike. The reader is

referred to Verrillo [10] for a discussion in greater depth of the topics considered here.

## Agnosia of Form or Object

### Definition

Characterized by the difficulty a brain-damaged patient has in identifying an object without being blind. This affliction is also called “psychic or mind blindness”. There are two types of object agnosia. Apperceptive agnosia denotes the problem of putting together pieces of visual information into a coherent percept of objects etc.; the world looks fragmented and chaotic. This syndrome often follows ►carbon monoxide poisoning causing many small, disseminated brain lesions in the ►occipital lobe. Associative agnosia is the difficulty of associating visual perceptual input with stored information of similar objects. Patients with this disorder can tell whether two objects are the same, but cannot identify them because this would require reference to memory. This syndrome is not uniform and may result from lesions of the ►temporal lobes or temporo-occipital areas.

## Agonist (Pharmacological)

### Definition

A ligand that binds to a specific cellular receptors and triggers a response in the cell.

## Agouti-related Peptide

A

# Alertness Level

Hans P. A. Van Dongen, Gregory Belenky
Sleep and Performance Research Center, Washington State University, Spokane, WA, USA

## Synonyms

Arousal; Vigilance; Sleepiness (antonym)

## Definition

The ability to direct and sustain attention. It reflects cortical activation and is modulated by sleep/wake regulatory mechanisms.

## Characteristics

### Neurophysiologic Regulation of Alertness Level

The regulation of alertness is closely tied to sleep/wake regulation, as is obvious from its antonym ►sleepiness. As such, alertness level may be expressed on a scale ranging from wide awake to struggling not to fall asleep. There are two primary neurophysiologic processes of sleep/wake regulation driving dynamic changes in the waking level of alertness across hours and days: a homeostatic process producing a ►homeostatic sleep drive, and a circadian process (►circadian cycle) producing an opponent circadian wake drive [1]. These two processes have been instantiated in conceptual and mathematical models of sleep/wake regulation and alertness.

The homeostatic sleep drive increases progressively from the time of awakening until the beginning of the next sleep period, and decreases progressively during sleep. The dissipation rate during sleep is greater than the build-up rate during wakefulness, such that the homeostatic sleep drive pattern is stable from day to day for the average person given a typical schedule of 16 h of wakefulness and 8 h of sleep. If wakefulness is extended and/or sleep duration is reduced, the dissipation of the homeostatic sleep drive is incomplete.

In contrast to the homeostatic sleep drive, the circadian wake drive waxes and wanes with time of day regardless of sleep and wake duration, such that wake drive is highest in the early evening and lowest in the early morning. For a normal schedule of daytime wakefulness and nighttime sleep, the result is a sustained high level of alertness through most of the waking period [2]. The reason for this is that while the homeostatic sleep drive increases with time awake, it is also increasingly counteracted by the growing circadian wake drive. As such, the alertness level remains stable from morning to evening, with only a minor mid-afternoon dip observable in some individuals [3].

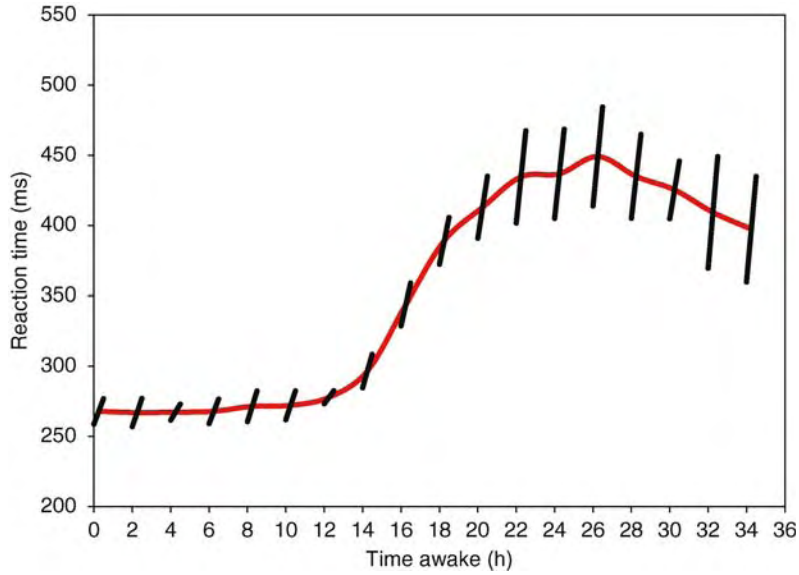
In the early evening hours, the circadian wake drive is high, such that it would be difficult to fall asleep if sleeping were attempted. This is known as the wake maintenance zone [2]. Later in the evening, however, the circadian wake drive falls and the homeostatic sleep drive becomes the dominant factor determining the alertness level. Thus, in late evening there is a rapid increase in sleepiness signaling that it is time to go to sleep. Assuming the sleep period is long enough to dissipate the homeostatic sleep drive, this pattern repeats itself the next day. Immediately after awakening there is a brief interval of residual sleepiness known as ►sleep inertia, but it quickly subsides to be followed by another daytime period of high, stable alertness.

If sleep is postponed and wakefulness continued into the night – as may occur in ►shift work settings – the further increasing of the homeostatic sleep drive and the further waning of the circadian wake drive produce a considerable deterioration of the alertness level. This continues until the next morning. At that time, the circadian wake drive begins to rise again, providing a partial rebound of alertness later in the afternoon and early evening. This is illustrated in Fig. 1.

Just as extending the waking period reduces the alertness level as modulated by the homeostatic process, so does altering the timing of the waking period reduce the alertness level through the action of the circadian process. This can be observed when traveling to another time zone, which results in a temporary misalignment of the circadian cycle with the new local day and night. This yields reduced daytime alertness and difficulty sleeping at night – a phenomenon known as ►jet lag. Depending on the number of time zones crossed, it may take several days for ►entrainment mechanisms to realign the circadian process with the local time.

In addition to the long-term action of the homeostatic and circadian processes, a variety of short-term neurobiological effects on the alertness level have been reported. For reasons not well understood, sustained attention to perform a task results in progressive declines of alertness while the task is ongoing [4]. This ►time-on-task effect is undone by a break from the task – see Fig. 1. The time-on-task effect is thought to be amplified by monotony or boredom, while it may be dampened in tasks that are inherently novel or interesting (although it is not clear what determines the latter). Reductions in alertness may be overcome by motivation (e.g., through incentives), but this effect is likely to be transient. Alertness is also affected by ►stress, where the nature of the stress determines whether alertness is increased or decreased. Posture plays a role as well, in that supine positions appear to enhance sleepiness while standing up enhances alertness.

The environment can influence the alertness level as well. Bright light (e.g., sunlight) is known to provide a short-lasting boost of alertness (in addition to its ►photoperiodic effect on the circadian cycle). Sound may enhance alertness, but chronic exposure to noise



**Alertness Level. Figure 1** Pattern of alertness across 36 h of total sleep deprivation beginning at 10:00 (10 A.M.), as measured by mean reaction time on a 10-min psychomotor vigilance task [5] administered every 2 h in a laboratory (averages shown for ten healthy young adults). The red curve displays the combined effect of the homeostatic sleep drive, which increases progressively across time awake, and the circadian wake drive, which waxes and wanes across the 24 h of the day. The black lines show deterioration of performance (assessed with linear regression) during each 10-min test bout, which is known as the time-on-task effect. The steeper the rise of the line, the greater the time-on-task effect. The time-on-task effect is greatest when the overall alertness level is lowest, revealing an interaction between this effect and the homeostatic and circadian processes. Note also that the breaks between the test bouts provide recuperation from the time-on-task effect.

may have the opposite effect. The effects of tactile and olfactory stimulation on alertness have not been well documented. When measuring the endogenous (neurophysiologically driven) alertness level, it is important to take these environmental factors into account (e.g., by standardization in a controlled laboratory environment).

## Neurobehavioral and Physiological Correlates

Changes in the alertness level can be observed in a variety of neurobehavioral and physiological variables. Individuals experiencing reduced alertness (e.g., due to sleep deprivation) report elevated feelings of sleepiness and fatigue, negative effects on mood, difficulty concentrating, and greater effort needed to stay awake. They show stereotypical behaviors such as yawning and muscle stretching. They exhibit ►cognitive impairment, ranging from increased ►reaction times and greater numbers of performance errors to ►executive control deficits and poor decision making. Indices of ►attention appear to be particularly affected, with tasks requiring sustained attention showing increased variability in responses. This latter effect has been hypothesized to reflect the episodic intrusion of sleep processes into wakefulness [5].

Indeed, reduced levels of alertness are associated with greater propensity to fall asleep, which translates into reduced sleep latencies – i.e., falling asleep faster – as determined through sleep physiological recording (►polysomnogram). This phenomenon, which is observed both when sleep is attempted and when it is to be resisted, provides a basis for physiological tests of sleepiness, including the ►multiple sleep latency test and the ►maintenance of wakefulness test. Physiological changes can also be seen before the occurrence of sleep, though. ►Visual evoked potentials and ►auditory evoked potentials show changes indicative of impaired signal processing under conditions of diminished waking alertness. The background waking ►electroencephalogram (EEG) also changes, reflecting enhanced synchronization [6] possibly associated with sleep initiation mechanisms in the brain (drowsiness).

Alertness changes are further reflected in ocular measures, including the appearance of slow-rolling eye movements, changes in blink rate, extended partial or complete eye closures, and variations in pupil diameter. Additionally, cardiovascular indices (heart rate, heart rate variability) have been reported to covary with alertness. These physiologic changes may be mediated by alterations in the tone of the ►autonomic nervous system.

There are considerable inter-individual differences in the effects of alertness-reducing interventions such as sleep deprivation on the various correlates of alertness described above [7]. The expression of these inter-individual differences is found to vary from one correlate of alertness to another. It might be concluded that there is not just a single overall level of alertness,

but that there are several alertness levels depending on which specific measure is considered. However, measures of alertness typically involve other neurophysiologic and neurocognitive systems as well, which contribute to the measurement outcomes in potentially non-trivial and/or person-specific ways. For instance, a cognitive performance measure of alertness is also affected by a person's aptitude for the performance task as well as any practice effects. Understanding such issues is important for the interpretation of alertness measurement data [3].

### Neuroanatomical Structures and Neurotransmitters

Although the neuroanatomical and neurochemical mechanisms underlying the regulation of alertness have only partially been delineated, it is known that there is a strong modulation of the alertness level by the ►ascending neuromodulatory projections. Briefly, this system involves ►arousal of the ►cortex by monoaminergic and cholinergic nuclei in the ►brainstem, ►hypothalamus and ►basal forebrain. These nuclei and their ►neurotransmitters include the ►locus coeruleus (noradrenalin), the ►tuberomammillary nucleus (histamine), the ►raphe (►serotonin), and nuclei in the ►tegmentum (►acetylcholine). The ascending neuromodulatory projections can be blocked by activation of the ►ventrolateral preoptic nucleus (►GABA, galanin), which initiates sleep [8]. It is possible that the activity of this system represents, in part, the homeostatic sleep drive, but definitive evidence is lacking and other pathways, neurotransmitters/►neuromodulators (►dopamine, ►adenosine) and mechanisms are likely involved as well [9]. The source of the circadian wake drive is much better understood. It is driven by the ►suprachiasmatic nuclei (►SCN) in the hypothalamus [1], the functioning of which has been elucidated in considerable detail.

The neurotransmitter systems involved in sleep/wake and alertness regulation are targets of a wide variety of pharmacological substances affecting alertness. These include hypnotics such as benzodiazepine receptor agonists, which reduce alertness and promote sleep; and ►stimulants such as caffeine and amphetamine, which enhance alertness. Hypnotics are particularly useful to improve sleep quality and increase sleep duration as part of the treatment repertoire for clinical sleep disorders. Stimulants are administered to treat excessive sleepiness associated with certain sleep disorders (e.g., narcolepsy), and to maintain optimal (baseline) alertness levels in operational settings [10] (caffeine being the most widely used). With specific stimulants (e.g., amphetamine), it is possible to temporarily raise alertness and enhance performance beyond the baseline level, although this does not necessarily translate into better cognitive/behavioral outcomes and often involves undesirable side effects. The mechanisms of actions of most hypnotics and stimulants have only partially been determined.

## Alginate

### Definition

Alginate is derived from brown seaweed. Alginate is a polysaccharide like glycosaminoglycan composed of two monosaccharides, β-D-mannuronic acid and α-Lguluronic acid.

## Allele

### Definition

Different forms or variants of a gene that occupy a given locus on a chromosome.

## Allocentric Cues

### Definition
Distal and local environmental cues used for navigation.

Distal cues are principally visual and provide information about the distance to landmarks and spatial arrangement among landmarks. Local cues, such as odors on the ground, are also allothetic. Typically contrasted with "idiothetic cues".

►Spatial Learning/Memory

## Allocentric Reference Frame

### Definition
Framework centered outside of the body of the subject such as mountain, or individual object.

►Spatial Memory

## Allocortex

### Definition
"Other" cerebral cortex, referenced against six-layered isocortex.

Allocortex includes cerebral cortical areas, such as the hippocampus and olfactory cortex, which comprise fewer than six-layers.

►Hippocampus
►Isocortex
►Olfactory Cortex

## Allodynia

### Definition
Pain due to a stimulus which does not normally provoke pain (e.g., gentle static pressure, non-painful thermal stimuli).

►Hyperalgesia and Allodynia

## Allodynia, Hyperalgesia

### Definition
*Hyperalgesia* denotes increased pain generated by a stimulus which is normally painful and excites nociceptors. It has a peripheral (sensitization of nociceptors) and/or a central component (sensitization of central neurons, e.g. in the dorsal horn of the spinal cord). *Allodynia* is pain generated by stimuli which activate low-threshold mechanoreceptors (mechanical allodynia) or cold receptors (cold allodynia). The mechanism of allodynia is central (central sensitization generated by persistent excitation of nociceptors). *Secondary allodynia* is pain elicited by stimulation of low-threshold mechanoreceptors in an area of skin which surrounds a territory with sensitized nociceptors (e.g. generated by inflammation) ***Causalgia.***

## Allometry

### Definition
Measurement and correlation of biological size of organs or organ-systems.

►Evolution and Brain-Body Allometry

## Allophone

### Definition
Phonetic variant of a phoneme; substituting one allophone for another does not change the meaning of a word (e.g., [bath] does not differ in meaning to [bat]; [th] is an aspirated /t/ and [t] is an unaspirated /t/).

►Phoneme

## Allosteric Enzyme

### Definition
An enzyme that alters its three-dimensional conformation as a result of the binding of a smaller molecule (at a site different to its active site), often leading to inhibition or activation of its activity.

## Allosteric Protein

### Definition
A protein that can adopt several conformations. These conformations can be stabilized by different molecules, that bind at the same, or different sites.

## Allothetic Information

### Definition
Stimuli providing information about the environment like visual, olfactory, sound, tactile inputs.

## Alpha (Activity Phase) in Circadian Cycle

### Definition
Alpha is the duration of the active portion of the daily rest-activity cycle.

►Circadian Cycle
►Rest-activity Cycle

## Alpha Rhythm

### Definition
A neocortical pattern of 8–13 Hz EEG activity characteristic of quiet wakefulness in humans.

►Brain Rhythms

## Definition

α-Synuclein is a small acidic protein of 140 amino acid residues and a member of a multi-gene synuclein family (Fig. 1a). The N-terminal part has seven imperfect repeats containing the consensus core sequence Lys-Thr-Lys-Glu-Gly-Val, whereas the C-terminal part (residues 96–140) has no recognized structural elements. The central portion of α-synuclein (residues 61–95) is known as the non-Aβ component of ►amyloid plaques in Alzheimer disease (Fig. 1b). It comprises the highly amyloidogenic part of the molecule that is necessary for a-synuclein (i) to undergo a conformational change from ►random coil to ►Beta Sheet structure, (ii) to form single cylindrical β-sheets, and (iii) to form protofibrils and fibrils. These features distinguish α-synuclein from its two close relatives β-synuclein and γ-synuclein that fail to form copolymers with α-synuclein [1]. α-Synuclein displays an extended unfolded structure and thus belongs to the group of natively unfolded proteins also comprising protein tau. α-Synuclein exists physiologically in both soluble and membrane-bound states, with an unstructured or alpha-helical conformation, respectively. The function of α-synuclein is poorly resolved, though it is attributed with wide-ranging roles such as molecular chaperone, axonal transport and turnover of synaptic vesicles [2].

## Characteristics

### Alpha-Synuclein and Neurological Disorders

Pathological accumulation of α-synuclein is associated with multiple neurodegenerative diseases that are collectively known as synucleinopathies (Fig. 2). The most prominent of these is Parkinson's disease (PD), a progressive disorder that impairs movement in nearly 2% of individuals over 65 years. Other disorders include Dementia with ►Lewy bodies (DLB), the second major cause of dementia in the elderly after Alzheimer's disease (AD), the Lewy body variant of Alzheimer's disease, multiple system atrophy, neurodegeneration with brain iron accumulation type 1, familial forms of AD and Down syndrome. α-Synuclein-containing inclusions are also found in several more disparate neurodegenerative diseases that are not commonly referred to as synucleinopathies [3].

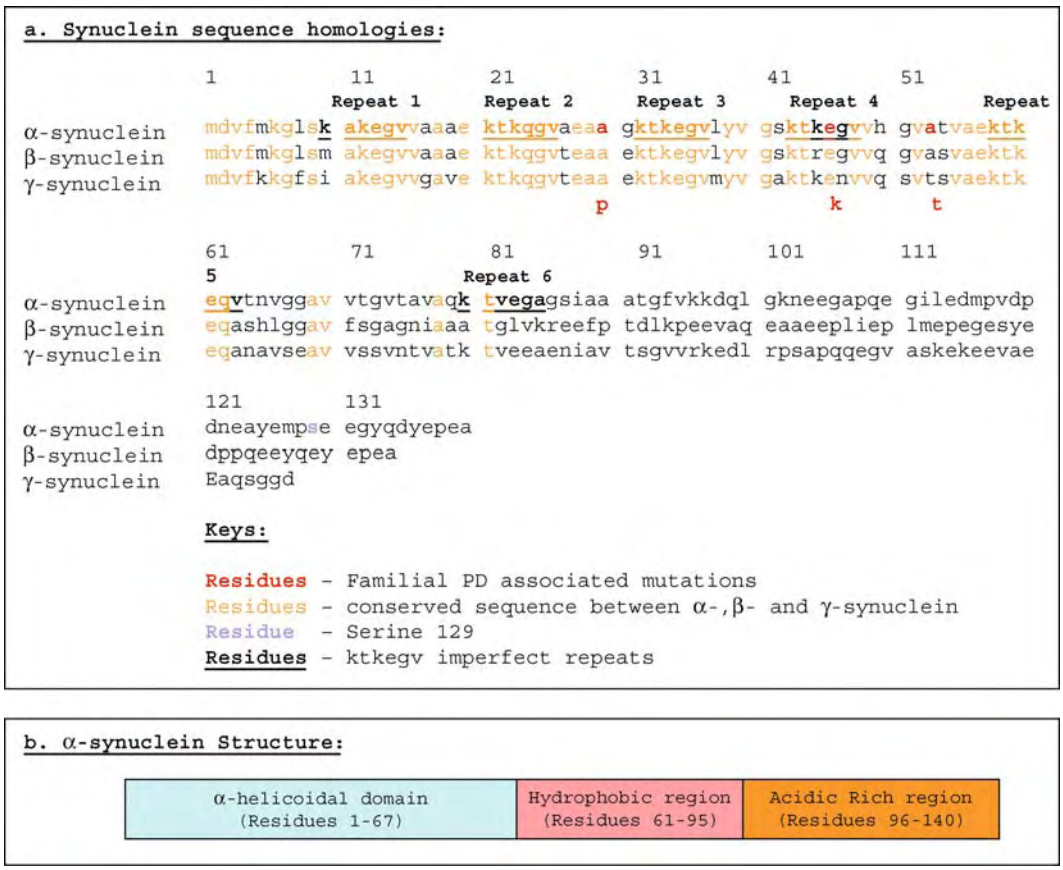
A causative role for α-synuclein in neurodegeneration was fortified by the identification of three mutations (A30P, A53T and E46K) in the α-synuclein gene, as well as multiplication of the normal gene that results in increased α-synuclein protein expression, in families with early-onset PD [4]. Affected family members present clinical and pathological features that are similar to sporadic PD that is clinically characterized by the three cardinal symptoms including muscle rigidity, bradykinesia and resting tremor [5]. These motor impairments are primarily due to degenerating dopaminergic neurons in the substantia nigra and the loss of their dopaminergic projections to the striatum and can be corrected by dopamine-replacement therapy. Moreover, histological analyses of PD brains reveal dense aggregations of insoluble material including α-synuclein in intracellular inclusions called Lewy bodies (LB).

Development of PD appears to be linked to processes that increase the rate at which α-synuclein forms aggregates. These processes include increased protein concentration (via either increased expression or reduced turnover), and altered forms of α-synuclein (such as truncations, missense mutations, or post-translational modifications [6]). Phosphorylated α-synuclein at Ser-129 has been observed in post-mortem analyses of patients with PD, multiple system atrophy, and neurodegeneration with brain iron accumulation type 1. Under normal physiological conditions, about 4% of α-synuclein is phosphorylated at Ser-129, but in LB, 89% of α-synuclein is phosphorylated at this residue. The effects of phosphorylation of Ser-129 on α-synuclein conformation are not known, but phosphorylation at Ser-129 caused a fourfold increase in insoluble α-synuclein and inhibited interaction of α-synuclein with phospholipids and phospholipase D2. Moreover, mutation of Ser-129 to alanine (to prevent phosphorylation) completely suppressed DA neuronal loss produced by expression of human α-synuclein, and substituting aspartate for Ser-129 (to mimic phosphorylation) significantly enhanced α-synuclein toxicity.

### Role of Alpha-Synuclein

α-Synuclein is widely expressed in mammalian CNS, and particularly concentrated in presynaptic terminals,

A



**Alpha-synuclein: From Neurological Disorders to Molecular Pathways. Figure 1** α-Synuclein homologies and structure. (a) The synuclein family consists of three members: α-synuclein, β-synuclein and γ-synuclein that range from 127 to 140 amino acids in length and are 55–62% identical in sequence, with a similar domain organization. (b) α-synuclein structure is divided in three regions: (i) N-terminal domain (residues 1–67) contains two α-helical regions separated by a short break; (ii) hydrophobic domain (residues 61–95) and (iii) C-terminal domain acidic rich region.

where it is associated with synaptic vesicles and freely-diffusible in the cytoplasm. While the exact functions of normal α-synuclein remain to be fully elucidated, several studies suggested it may play a role in synaptic plasticity; regulate dopamine (DA) neurotransmission via effects on vesicular DA storage and protecting neurons from neurodegeneration induced by the loss of ►cysteine string protein (Fig. 2; [7]). More recently, it has been suggested that α-synuclein may be involved in the trafficking of cargo within the endoplasmic reticulum/Golgi network since one of the most profound initial consequences of artificially expressing α-synuclein in yeast appears to be a disruption of ER-Golgi trafficking [8].

So far, the exact role of α-synuclein in healthy brain as well as in pathological conditions still remain unclear. However, several protein interactions with α-synuclein suggest a function in specific molecular pathways. Figure 3 summarizes potential functions associated with α-synuclein. However, it is unclear if the α-synuclein binding proteins compete for overlapping binding sites, interact differentially depending on α-synuclein conformation, or bind in a competitive/allosteric manner. It also remains to be determined if these interacting proteins bind to α-synuclein in distinct subcellular compartments. Conformational changes in α-synuclein due to temperature, pH and/or posttranslational modification could alter the protein and ligand binding properties of α-synuclein as well as its aggregation properties. In addition to lipids, various reports suggest that α-synuclein is capable of interacting with a variety of proteins including PLD2, UCH-L1, parkin, synphilin, 14-3-3, different PKC isozymes, BAD, Rab3A, Rab5A, Rabphillin, the ELK-1/ERK-2 complex, ERK-1/2, p38MAPK, and SAPK/JNK mitogen activated kinases, Aβ, MAP1B, heterodimeric but not microtubule Tubulin, tau, TBP-1, the DAT, the mitochondrial complex IV enzyme cytochrome oxidase, and TH, and calmodulin [1] (Reviewed by Dalfo et al.,

## Definition

Alternative splicing refers to the post-transcriptional modification process in which coding regions (exons) of a primary transcript are joined in different combinations through the removal or retention of non-coding intervening sequences (introns) to produce distinct mature messenger RNA (mRNA) transcripts.

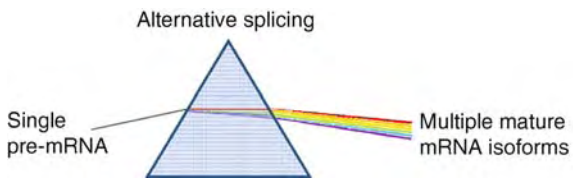
## Characteristics

### Mechanisms of Alternative Splicing

One surprising finding stemming from genome analyses is that proteomic diversity of an organism does not correlate with the number of protein-coding genes observed. It was later revealed that alternative splicing provides the major mechanism for increasing transcriptome and proteome complexity. An analogy to explain this idea would be to liken alternative splicing to a glass prism which can disperse white light into a spectrum of colors (Fig. 1).

Through alternative splicing, a single pre-mRNA can generate a diverse array of mRNA splice variants which will be translated into protein isoforms with varying structure and/or function.

Recent genome analyses have estimated that 60–80% of human genes are subjected to alternative splicing and this biological phenomenon is emerging to be of central importance in the nervous system [1,2]. Furthermore, sequence- and microarray-based analyses have suggested that transcripts from genes expressed in functionally complex tissues, such as that of the brain, undergo alternative splicing at a higher frequency [1].



**Alternative Splicing. Figure 1** Analogous to the dispersion of white light into the color spectrum by a glass prism, a single pre-mRNA can generate a diverse array of mature mRNA transcripts through alternative splicing.

There are several types of alternative splicing events leading to the generation of distinct transcripts: cassette exon, alternative 5′ splice site, alternative 3′ splice site, mutually exclusive exons, intron retention, alternative promoter, and alternative polyadenylation site (Fig. 2).

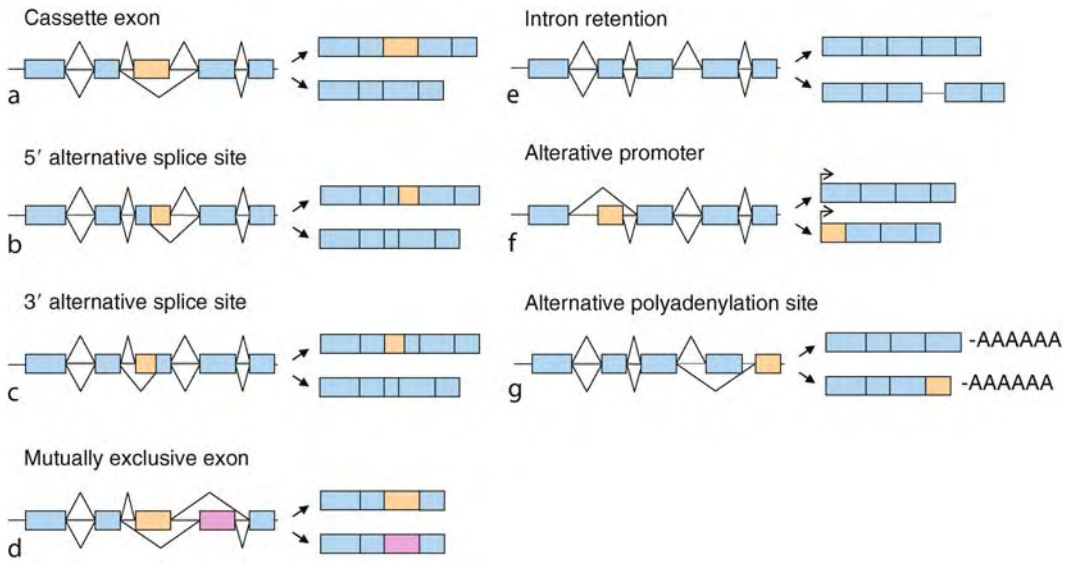
In general, these events occur in a combinatorial manner to produce multiple alternatively spliced isoforms or splice variants. The *Drosophila melanogaster* Down syndrome cell adhesion molecule (*Dscam*) gene is one of the best examples to illustrate this process. The *Dscam* gene, which contains four clusters of exons alternatively spliced in a mutually exclusive fashion (12, 48, 33, and 2 exons respectively), can theoretically give rise to as many as 38,016 different mRNAs by virtue of combinatorial alternative splicing [3]. Remarkably, this number is even greater than the predicted number of genes in the *Drosophila* genome.

Protein variations generated by alternative splicing can range from subtle to drastic [3]. While alternative splicing in the untranslated regions does not alter the protein sequence, it can affect mRNA stability and localization, which in turn influence the expression pattern and subcellular localization of the protein [3]. On the other hand, alternative splicing in the coding region can lead to the addition or removal of a functional motif or domain, or in some cases, bring about frameshifts that introduce premature termination codons that result in truncated, non-functional proteins [3].

### Regulation of Alternative Splicing

Pre-mRNA splicing reaction takes place on a cellular machinery known as the spliceosome, a large complex composed of five small nuclear ribonucleoproteins (snRNPs) (U1, U2, U4, U5, and U6) and many additional proteins. The spliceosome assembles onto the pre-mRNA in a stepwise fashion and catalyzes the removal of introns and ligation of exons. Four conserved sequence elements at both ends of the intron, namely the 5′ splice site, the branchpoint, the polypyrimidine tract, and the 3′ splice site, act as splicing signals that define the intron-exon boundary. However, additional *cis*-acting elements are required to ensure that the splicing process proceeds with high fidelity and accuracy.

Exonic and intronic splicing enhancers (ESEs and ISEs) and silencers (ESSs and ISSs) are splicing regulatory sequences in the pre-mRNA that facilitate correct splice site recognition [1]. ESEs and ISEs usually enhance the use of weak splice sites and thereby promote inclusion of an alternatively spliced exon; whereas ESSs and ISSs generally inhibit the use of splice sites and in doing so, promote skipping of an



**Alternative Splicing. Figure 2** Schematic illustrations of alternative splicing events. Exons are represented by boxes, while introns are depicted as thick grey lines. Alternative splicing can lead to (a) either the inclusion or exclusion of an exon, (b and c) the use of alternative splice sites, (d) the use of mutually exclusive exons, (e) the retention of an intron, (f) the use of an alternative site for translation initiation, or (g) the use of alternative site for translation termination.

alternatively spliced exon [1]. These sequences are bound by splicing factors, such as members of the serine/arginine-repeat (SR) and heterogeneous nuclear ribonucleoprotein (hnRNP) families of proteins which define the splicing pattern in many cases by either facilitating or blocking spliceosome assembly [1]. Expanding on the simplistic view that SR proteins mostly bind to ESEs and activate splicing, while hnRNP proteins mostly bind to ISSs and repress splicing, a recent global analysis of splicing regulators in *Drosophila* demonstrates that these two families can have both positive and negative effects on splice site choice [2].

Central to the regulation of alternative splicing is the combinatorial interplay of the *cis*-acting sequences with the *trans*-acting splicing factors [1]. A major mechanism used in the regulation of alternative splicing is the differential expression of splicing factors [2]. More specifically, unique alternative splicing patterns across different cell types can be achieved by the tissue-specific expression of splicing factors in one cell type but not others [2]. In addition, expression levels of splicing factors have also been found to vary across different developmental stages [2]. Further regulatory potential is derived from post-translational modifications of the splicing factors 2]. Such modifications can modulate functions of splicing factors by regulating their ability to bind to RNA or interact with other proteins [2]. For instance, phosphorylation is critical for the protein activity of SR proteins [2]. Recent studies have explored the regulation of alternative splicing events by cellular signaling pathways, and looked into alternative splicing events resulting from genetic polymorphisms and such events are characterized by the production of allele-specific transcript isoforms [2].

In the following sections, the role of alternative splicing in the nervous system will be illustrated with several examples. To truly understand the physiological significance of the utilization of an alternatively spliced exon in a specific excitable cell in the nervous system, however, will require multi-pronged studies. One approach is to determine the cellular or sub-cellular localization of an alternatively spliced exon to provide more defined clues as to its functional importance in the native cells. Another approach is to evaluate the functional diversifications via alternative splicing of cognate protein to provide important predictions of selective requirements for the splice variants in physiology or disease. A third approach is to examine the expression profiles of the alternatively spliced exons in response to physiological or pathophysiological signals to provide evidence for their dynamic roles in adaptation or response to changing cellular conditions or inputs. Finally, it will be of immense interest to genetically delete an alternatively spliced exon from the genome and to assess the physiological significance of its total

exclusion from the cognate protein in a transgenic mouse model.

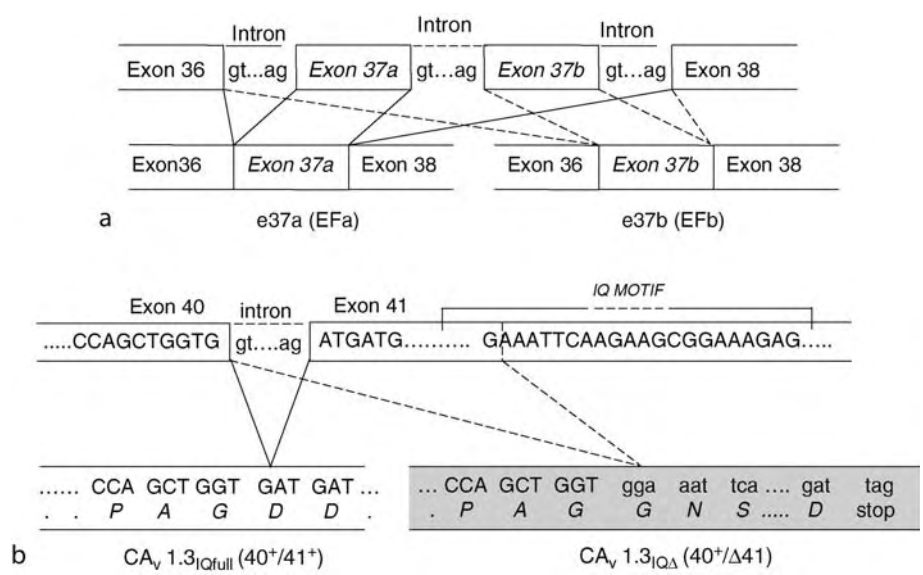
## Alternative Splicing as a Determinant of Subcellular Localization and Tissue Distribution

Alternative splicing of the calcitonin/calcitonin gene-related peptide (CT/CGRP) is one of the earliest examples of diversification of protein properties and localizations by alternative splicing. In the peptide-hormone system, the inclusion or exclusion of an exon in the final mRNA can alter the biological behavior of a molecule and change the peptide-ligand binding properties. In thyroidal C cells, the majority of the CT/CGRP pre-mRNA is processed to include exon 4 which leads to production of calcitonin peptide [4]. However, in neuronal cells, 99% of the CT/CGRP pre-mRNA is processed to exclude exon 4 and this leads to the production of CGRP peptide [4]. Clearly, through alternative RNA processing, two peptide hormones having completely different structures and functions are generated.

Recent studies indicate that alternative splicing is similarly important for controlling the function of voltage-gated calcium channels ($Ca_v$) in neurons. For instance, the mutually exclusive exons e37a and e37b in the $Ca_v2$ subfamily exhibit selective cellular or subcellular distribution in neurons (Fig. 3).

The $Ca_v2$ calcium channels are integrally involved in neurotransmission and pain processing. The N-type $Ca_v2.2$ calcium channels show specific expression of e37b in the neurons of the brain, while e37a is preferentially expressed in the nociceptive neurons of the dorsal root ganglia [5]. On the other hand, the pair of e37a/b exons of the P/Q-type $Ca_v2.1$ calcium channels show differences in subcellular localizations, where e37a is expressed preferentially in the soma, while e37b is found predominantly in the dendrites of the cerebellar Purkinje neurons [6]. Additionally, the e37a/b exons of the $Ca_v2.1$ calcium channels are developmentally regulated, with a switch in expression from e37b in the fetal brain towards more e37a in the adult brain. In the adult brain, the expression patterns also vary across different regions, where, for example, e37b is expressed at higher levels in the amygdala, and e37a in the thalamus.

Other proteins of the nervous system show similar selective expression patterns. Another example is the $K_v3$ subfamily of voltage-gated potassium ($K_v$) channels. The $K_v3$ subunits play an important role in driving fast repolarization of action potentials to enable neurons to fire repetitively at high frequencies. It has been proposed that alternative splicing of the $K_V3$ subunits mediates differential subcellular targeting and modulation. In neurons of the mouse brain, the $K_v3.1a$ isoform is localized exclusively on the axons and presynaptic terminals while $K_v3.1b$ channels are prominently expressed on somatic and proximal dendritic membrane [7]. Interestingly, $K_v3.1$ channels are co-expressed with $K_v3.4a$ channels that are found mainly in the globus pallidus neurons, CA1 hippocampal interneurons and subthalamic nucleus neurons that are all fast-spiking. $K_v3.4a$ channels are, however, absent in the regular-spiking hippocampal, striatal and basal forebrain neurons.



**Alternative Splicing. Figure 3** Postulated mechanism underlying splice variation of both $\alpha_1$ subunits of $Ca_v2.1$ and $Ca_v1.3$ calcium channels. The nucleotide sequences of the relevant exon-intron boundaries are displayed in the top, while the bottom shows the resultant transcript and encoded amino acids of each variant.

## Alternative Splicing as a Molecular Switch for Protein Function

Alternative splicing often results in isoforms with different functional properties. For instance, the e37a- but not the e37b-containing $Ca_v2.2$ channels allow large currents to flow and are regulated by G-proteins in a voltage-independent manner. Importantly, alternatively spliced exons located at other loci of the $Ca_v2.2$ channels modify other channel properties or control the trafficking of the channels.

Interestingly, the e37a/b exons of the $Ca_v2.1$ calcium channels act as an exquisite molecular switch to determine channel function. The e37a-containing $Ca_v2.1$ calcium channels respond to $Ca^{2+}$ -dependent regulation by promoting the opening of the channels in a process called $Ca^{2+}$ -dependent facilitation (CDF). This process may be important in short term plasticity as the increase in $Ca^{2+}$ influx will result in much greater neurotransmitter release at the CNS synapse [6]. This property is missing from the e37b-containing channels. Similar to $Ca_v2.2$ calcium channels, the other alternative splicing loci of the $Ca_v2.1$ calcium channels act to modify channel electrophysiological and pharmacological properties [5,6]. Interestingly, the paralogous pairs of e37a/b exons of the $Ca_v2.1$ and $Ca_v2.2$ channels instill dissimilar properties on the channels.

Clearly, alternative splicing can diversify protein functions providing a spectrum of protein isoforms customized to support the complex operations within the central nervous system where information has to be processed rapidly. In this regard, the discovery of the entire suite of alternative splicing loci in a gene, and their coordinated assembly, will provide a compendium essential for reference and for understanding of physiological relevance. Nonetheless, the identification of novel splice variation at single splice locus has been useful to explain discrepancies between observed activity of a protein and the cloned cDNA assayed in a heterologous system. One such example is the observed lack of $Ca^{2+}$ -dependent inactivation (CDI) of native hair cell $Ca^{2+}$ currents as compared to robust CDI exhibited by the cloned L-type $Ca_v1.3$ calcium channel. Recent work showed that a splice variant ($Ca_V1.3_{IQ\Delta}$) missing the IQ-motif that is important for CDI is expressed in the outer hair cells of the cochlea (Fig. 3b) [8]. The $Ca_V1.3_{IQ\Delta}$ channels expressed in HEK 293 cells showed total lack of CDI that in part explains the behavior of the native $Ca^{2+}$ currents in the cochlear hair cells.

## Alternative Splicing as a Molecular Switch for Physiological Responses

It is important to understand how cells alter their splicing patterns in response to extracellular stimuli and signaling pathways. Ion channels and neurotransmitter-receptor pre-mRNAs undergo extensive alternative splicing to generate multiple isoforms. An example is the vertebrate *Slo* (also known as *slowpoke* or *BK*) gene, which encodes a voltage-gated $Ca^{2+}$ and $K^+$ channel expressed widely in the nervous system. *Slo* splice variants containing the STREX exon exhibit slow deactivation and enhanced channel activation. Changes in the concentration of stress hormones can modulate STREX (stress axis-regulated exon) exon inclusion in the *Slo* pre-mRNA and evidence suggests that STREX splicing is repressed by depolarization of GH3 pituitary cells and signaling through $Ca^{2+}$/calmodulin-dependent protein kinase (CaMK) IV [9].

A good example of how alternative splicing regulates neuronal function is the pattern of expression of the *cSlo* (chicken *Slo* gene) splice variants that correlates well with the tonotopic frequency map along the cochlear basilar membrane [9]. In addition, alternative splicing could remodel synaptic proteins, ion channels or receptors to modify neuronal excitability, synaptic plasticity, and efficacy of synaptic transmission in order to adapt to the myriad of neuronal activities and inputs. For instance, with NDMA receptors neuronal activity influences the choice for the inclusion or exclusion of alternatively spliced exon C2 or C2' possibly to facilitate homeostatic regulation of synaptic plasticity [10].

## Alternative Splicing in Disease and Disorder

Alternative splicing generates phenotypic variations of proteins that impacts the diversity of their biological function. As such, it is not surprising that dysfunction or dysregulation of the splicing machinery can contribute to human diseases. Aberrant splicing of a gene can alter the abundance, spatial and/or temporal expression of a splice variant. Mutations in the tau gene can give rise to frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), by increasing the levels of proteins with the inclusion of exon 10 [9,10]. This tau isoform, which comprises four microtubule binding motifs, enhances the formation of filamentous tau aggregates in the brain [9,10]. In contrast, a translationally silent C to T nucleotide substitution in the survival of motor neuron protein 2 (*SMN2*) gene of spinal muscular atrophy (SMA) patients results in the skipping of exon 7 and the formation of a non-functional protein [10].

Alternative splicing can also play a role in modifying disease severity as evidenced in Timothy's syndrome, a disorder where patients suffer multi-organ dysfunction that includes lethal arrhythmias, cognitive abnormalities and autism. The severity of the cardiac arrhythmias depends on which mutually exclusive exon, e8 or e8a, carries the G406R mutation on the L-type $Ca_v1.2$ calcium channel, *CACNA1C*, gene. There is a correlation between the severity of cardiac arrhythmias and the level of expression of the cardiac-selective exon e8a in

the heart. Especially for genes critical for the survival of an organism, hereditary neurological disorders could arise because the genetic mutations were found on alternatively spliced exons or in regions that modulate splicing efficacy.

## Conclusions

Alternative splicing is an exquisite mechanism to customize and diversify protein function to cater and respond to the complexity and immense plasticity of the nervous system. The dynamic regulation of alternative splicing will allow the neurons to respond appropriately to changing conditions in physiology or disease. As such, it is important to evaluate the altered activities of a mutant protein, arising from single genetic mutations, in the backbone of the predominant combinatorial splicing code for that gene. However, answers to fundamental questions as to what directs the specific utilization of an alternatively spliced exon, what is the physiological role of a specific alternatively spliced exon, and how it behaves in the context of different combinatorial arrangements of other alternatively spliced exons will require a wide array of ideas and multidisciplinary approaches.

[2]Institut für Neurobiologie, Münster, Germany

## Definition

The number of protein-coding genes in an organism does not always correlate with its overall cellular complexity. Genes may be relatively simple, containing only a single or a small number of exons; some genes, however, may be incredibly complex and can give rise to literally thousands of different protein isoforms. One way to generate a huge variety of different protein variants from a gene with only moderately complex organization is ►alternative splicing. This mechanism amplifies the complexity of the 30,000 human genes to astronomic numbers. Furthermore, alternate splicing mechanisms may act on top of an already sophisticated transcriptional control system, and these combined mechanisms enable the development of complex organisms. Here we review how differential splicing regulates glial cell maturation in flies and mammals.

## Characteristics

Several known examples indicate that alternative splicing may result in distinct and even opposite functional consequences, either during embryonic development or in adult life. A prime example has been established for sex specification in *Drosophila*. In this system, the presence of the ►Sex lethal splice factor results in the differential ►3′ splice junction choice that routes an animal towards female (or in its absence, into a male) development [1]. Moreover, sexual dimorphisms in the nervous system are brought about by sex-specific alternative variants of the *fruitless* gene, $fruitless^{m}$ or $fruitless^{f}$, to induce either male or female behavior [2]. Another example is the alternative splicing of Apolipoprotein 2 (Apoer2), which induces an ►NMDA receptor isoform at postsynaptic sites that is sensitive to Reelin-dependent phosphorylation, thereby enhancing long term potentiation [3].

Terminal differentiation of cells is most often regulated by transcriptional activity and/or by cell/cell interactions. Interestingly, it was recently shown that differential splicing also plays an important and decisive role in cell differentiation. *Drosophila* glial cell differentiation depends on alternative splicing, which surprisingly, appears to be conserved during evolution. Two major components that control glial cell differentiation in *Drosophila*, Crooked Neck (Crn) and Held Out Wings (HOW) were identified. In mutants lacking either

of these genes, glial cells are correctly specified and initiate their normal migration towards their final destination. However, late glial cell differentiation, manifested by ►axonal wrapping, is impaired. Both Crn and HOW mediate alternative splicing of specific target genes essential for glial cell differentiation [4].

## Crn is a Conserved Splice Factor

The Crooked neck protein is conserved from yeast to humans. Yeast cells show little alternative splicing activity, though the molecular mechanisms underlying the splice reaction are conserved. The role of the yeast Crooked neck-like protein (Clfp1) is to promote assembly of a functional ►spliceosome. The yeast clfp1 mutant has been successfully complemented by the expression of the Drosophila Crn protein, demonstrating that the proteins not only share sequence conservation but also exhibit similar functional properties. In addition to its role in yeast, the function of Crn in the regulation of splicing was demonstrated in a number of examples in the *Drosophila* system. Crn proteins do not bind directly to RNA. Rather, through multiple TPR repeats that mediate protein-protein interactions, Crn proteins can function as assembly platforms.

## STAR Proteins Mediate Alternative Splicing in Specific Tissues

Proteins belonging to the ►STAR (►Signal Transduction and Activation of RNA) family of RNA-binding proteins have long been viewed as candidates for mediating alternative splicing decisions. These proteins share a single maxi ►KH domain, which binds to RNA and is highly conserved from *C. elegans* to humans [5]. Members of this family exhibit tissue-specific distribution. For example, *C. elegans* Gld-1 is expressed in the gonads of the nematodes, mammalian Quaking is expressed in ►oligodendrocytes, ►astrocytes and in ►Schwann cells, as well as in the heart, and *Drosophila* HOW is expressed in tendon, glial and muscle cells. Importantly, several members of this family were shown to regulate splicing of specific targets. For example, mammalian Quaking was shown to mediate the alternative splicing of the myelin-associated glycoprotein, MAG [6] in oligodendrocytes of the mouse brain. Thus, viable *quaking* mutants suffer from a severe ►demyelination phenotype.

## The *Drosophila* HOW and Crn Proteins Mediate Alternative Splicing Required for Glial Cell Differentiation

Recently, an association was demonstrated between the *Drosophila* STAR protein, Held Out Wing (HOW), and the splicing factor Crooked Neck (Crn) [4,7]. These two proteins appear to function together to regulate critical differentiation steps of both glia and tendon cells, suggesting that they form part of a general mechanism that mediates alternative splicing in a tissue specific manner. Similar to other STAR family members, the *how* gene itself produces at least two major protein ►isoforms by alternative splicing, HOW(L) and HOW(S). The nuclear HOW(L) isoform had been shown to mediate mRNA degradation, thereby reducing the levels of specific target mRNAs. In contrast, the HOW(S) isoform shuttles between the nucleus and the cytoplasm where it can interact specifically with the splicing factor, Crn, to induce alternative splicing of specific targets.

The functional link between the HOW-Crn-dependent alternative splicing events and tissue differentiation has been demonstrated recently in two distinct tissues, glia and tendon cells. In a genetic screen, *crooked neck* (*crn*) mutants were identified based on their glial differentiation phenotype. In *crn* mutant embryos, ►peripheral glial cells exhibit aberrant migration and fail to wrap the axons. While *crn* mutants exhibit additional phenotypes in other tissues, overall embryonic development proceeds relatively normally, possibly due to the contribution of maternal *crn* transcript (►maternal transcript). The glial-specific nature of the *crn* phenotype indicates that the process of glial cell maturation and its ability to wrap the axons is hypersensitive to the reduction of Crn levels. Since the general splicing machinery is still intact in the mutant, it is likely that Crn is involved in specific splicing events required for glial cell maturation. Analysis of *how* mutants revealed a glial phenotype similar to that of *crn,* in which the peripheral glia also fails to wrap the axons. Moreover, a genetic interaction between the two gene products was demonstrated. Crn was shown to enhance a gain of function phenotype in the wing following ectopic expression of HOW(S); reducing Crn levels partially rescues the HOW(S)-gain of function phenotype. These and additional experiments strongly suggested that both Crn and HOW form a protein complex in the cytoplasm that functions together to mediate glial cell maturation.

To reveal the basis for the alternative splicing-dependence of glial cell differentiation it was essential to identify glial-specific targets that are spliced in response to Crn-HOW complex formation. The ►HOW-response element (HRE) was recently characterized as a penta-nucleotide sequence (ACUAA), which is unfortunately too short to be used for bioinformatic screening as a tool for target gene identification [8]. Therefore, to find such genes that are differentially expressed in wild type versus *crn* mutants, we followed a ►GFP-exon trap approach. This procedure identified two proteins, NrxIV (Casper homolog) and Nervana2 (beta subunit of the $Na^+/K^+$ ATPase), whose expression was greatly reduced in the nervous system of *crn* mutants.

Both NrxIV and Nervana 2 are required for the formation of ►autocellular septate junctions formed by the glial cells that wrap the peripheral axons. Additional experiments strongly support a mechanism by which

*nrxIV* pre mRNA is associated with HOW, and undergoes specific splicing in the presence of both HOW and Crn. Glial specific splicing of *nrxIV* may help to establish tight temporal control of the formation of the autocellular junctions. Transcriptional regulation may provide a pool of pre-mRNAs that, upon an as yet unidentified signal, are processed to form autocellular junctions required to insulate axons at a very specific developmental stage.

### The Mechanisms that may Regulate Glial Specific Crn-HOW-Dependent Alternative Splicing

Taken together, our data suggest a model in which the HOW-Crn protein complex is shuttled from the cytoplasm into the nucleus to regulate the splicing and/or RNA stability of specific mRNAs required for the induction of glial cell differentiation. This process would contribute to the specific gene expression profile characteristic of the mature differentiation state of glial cells.

The mammalian STAR protein, Sam 68, undergoes phosphorylation by the protein tyrosine kinases Src and Fyn, as well as by ERK kinases. These phosphorylation events could affect different aspects of Sam 68 activity as they alter the subcellular distribution of Sam 68 (nuclear versus cytoplasmic) as well as its affinity to RNA. For example, the Sam 68-dependent inclusion of exon5 into the CD44 mRNA is induced upon ERK phosphorylation of Sam 68 [9]. Similarly, HOW-dependent splicing activity could be regulated by ERK-dependent signaling. Recently, it was shown that Fyn, a kinase of the Src family, phosphorylates the STAR protein, Quaking, which is essential for oligodendrocyte maturation [10]. The absence of Fyn activity in oligodendrocytes leads to specific alternative splicing of the Myelin Basic Protein, resulting in ►hypomyelination in the brain, a phenotype that is shared with viable *quaking* mutants in mice. It remains to be shown that the loss of Fyn-dependent phosphorylation of Quaking is the primary cause for the hypomyelination phenotype. Similarly, HOW phosphorylation may regulate its promotion of splicing in glial cells. These results are consistent with a model in which an external regulatory signal that leads to ERK, or Src-dependent phosphorylation of HOW, promotes the Crn-HOW interaction leading to alternative splicing only when glial cells undergo terminal differentiation.

Control of cellular differentiation needs to be carefully regulated. It makes sense that glial differentiation must not be initiated before all the cells are correctly localized; however, once they are, the signal for differentiation needs to be fast and efficiently executed. We speculate that this is one of the advantages provided by differential splicing. ►Pre-mRNA molecules can be generated and ready for use, but are rapidly spliced into the correct isoform only upon cells receiving a, still-elusive, signal.

In summary, the identification of the HOW-Crn complex, and its involvement in glial cell differentiation may represent a paradigm for a tissue-specific mechanism of alternative RNA splicing. Future elucidation of the mechanisms involved in the regulation of the HOW-Crn complex formation, and/or the promotion of developmentally-regulated alternative splicing, as well as the identification of glial-specific target mRNAs are essential for understanding how alternative splicing of specific targets is linked to glial cell differentiation.

# Altricial

## Definition

Altricial refers to animals that are born rather immature.

►Neural Correlates of Imprinting

## Altruistic Behavior

### Definition

Unselfish behavior; thus, the opposite of selfish behavior. In a strict sense a behavior that decreases the fitness of an animal. If individuals sacrifice their own reproduction for the reproduction of relatives, this is not, in a strict sense altruistic, because it will increase their fitness through kin selection.

## Alveus of Hippocampus

### Synonyms

►Alveus hippocampi

### Definition

The efferent fibers of the large pyramidal cells of the hippocampus course on the ventricular surface of the hippocampus. This lamella is called the alveus of hippocampus. It bundles to form the fimbria of the hippocampus and later enters the crus of fornix via which the fibers pass as part of the fornix into the direction of the diencephalon (hypothalamus).

►Telencephalon

## Alzheimer's Disease (AD)

### Definition

AD is a disabling neurological disorder that afflicts about 11% of the population over age 65. It involves widespread intellectual impairment, personality changes, sometimes delirium, and culminates in ►dementia, the loss of reason and ability to care for oneself. A person with Alzheimer's disease usually dies of some complication that affects bedridden patients, such as pneumonia. Brains of Alzheimer individuals show three distinct structural abnormalities: great loss of neurons in specific regions (e.g., ►hippocampus and ►cerebral cortex), plaques of abnormal proteins deposited outside neurons (amyloid plaques), tangled protein filaments within neurons (neurofibrillary ►tangles). Its causes are unknown, and it has no cure at the present time, although drugs that inhibit acetylchinesterase (AchE) mitigate the symptoms in 5% of patients.

► Memory and Dementia

## Alzheimer's Disease – Oxidative Injury and Cytokines

William K. Summers[1], Helen A. Korneva[2]
[1]Alzheimer's Corporation, Albuquerque, NM, USA
[2]Institute for Experimental Medicine, St. Petersburg, Russia

### Synonyms

Alzheimer's disease; Senile dementia of the Alzheimer's type; Senile dementia

### Definition

Alzheimer's disease is a progressive dementing illness, typically fatal within eight to ten years due to intercurrent infections such as pneumonia. At autopsy there is generalized shrinking of the brain. Microscopically the hallmarks are β-amyloid laden plaques and tau protein laden tangles. Current belief is that the disease is caused by toxicity from β-amyloid or tau protein.

### Characteristics

#### Alzheimer's Disease is not Caused by β-Amyloid

Tomb stones do not kill, unless they fall upon the living. Tomb stones mark where the dead reside. To discover the cause of death, the body needs to be exhumed and analyzed. Even then, the cause of death may not be discovered.

For three decades, scientists pursued plaques (β amyloid) and tangles (tau protein) as causal Alzheimer's disease (AD) [1]. It is not the first time science went in a wrong direction. Plaques and tangles are tombstones. But, evidence has been show that β amyloid and tau protein are toxic to neurons [1,2]. Yes. But this is similar to dropping tomb stones on the living.

What, then, causes AD? When does it start?

A logical hypothesis with substantial support is that various CNS insults initiate oxidative injury with a pathologic immune response resulting in smoldering CNS microlocalized inflammation (mLI) [2]. The mLIs create plaques and tangles. Over two or more decades these pockets of inflammation metastasizes to other areas of the brain. Ultimately this preclinical state is called mild cognitive impairment (MCI). As time

passes, this becomes Alzheimer's which leads down the familiar path to death.

What are the initiating brain insults? The general classes would be mechanical trauma (sports, auto accidents); infections (herpes simplex viruses, cytomegalovirus, HIV, chlamydia pneumoniae, syphilis); anoxia (stroke, cardiac arrest, hemodynamic shock, pulmonary emboli, sleep apnea syndrome); metabolic (diabetes, B12 deficiency, hypothyroidism, obesity, hypertension, homocysteinemia); and toxic (iron, mercury, bismuth) [2,3]. The list of CNS insults that are related to AD is growing.

## The Role of Excitotoxin Neurotransmitters and the Release of Free Radicals

The CNS insult must result in focal neuron death by either necrosis or secondary apoptotic damage. This results in massive release of the excitatory amino acid, glutamate into the extraneuronal space [3]. L-glutamate, the most abundant excitatory neurotransmitter, binds to AMPA and NMDA receptors to precipitate localized neuronal apoptosis. This is accomplished by Na+ ion influx with acute osmotic damage followed by apoptosis. Or it is accomplished by $Ca^{2+}$ influx and delayed apoptosis. Both necrosis and apoptosis release free radicals (ROS/RNS) into the intracellular space. Indeed L-glutamate is a neurotransmitter free radical. However, release of mitochondrial contents injects metals (copper, zinc, iron, etc) into the intracellular space. Homeostasis is threatened. This is where nitric oxide (NO), antioxidants, Beta amyloid and cytokines come into play.

NO is a free radical, but is part of homeostasis [3]. Rapidly formed, it interacts with superoxide radicals ($O_2^-$ to form more innocuous products which antioxidant mechanisms can manage.

## Oxidative Injury

Metabolism produces reactive oxygen species (ROS) and reactive nitrogen species (RNS) which is approximately balance by antioxidant defense systems of the body. Anoxia, blunt trauma, infections, and any cause of inflammations create an excess of ROS/RNS. Serious imbalance between production of ROS/RNS and the antioxidant defense results in oxidative injury or disruption of DNA, proteins (enzymes), and lipids.

The brain is uniquely vulnerable to oxidative injury [2]. In the milieu of local necrosis/apoptosis, the free radicals test the ability of the brain to protect lipid membranes. 50–80% of neurons by weight are lipids. The brain has antioxidant methods to protect the neuronal membrane [2,4]. As these local defenses fail, markers of oxidative damage should be evident. Indeed activated NFκB, 8-OHdG, protein carbonyls, nitrotyrosine, 4-HNE, and other markers of oxidative injury are elevated in AD. Further these markers are associated with senile plaques and paired helical filaments [4].

## Cytokines

Concomitant with and as the mLI persists, cytokines come into play. Cytokines are low molecular weight regulatory proteins secreted by cells to orchestrate host immune processes [2,5]. They regulate proliferation, maturation, enhanced inflammation or dampened inflammation. Important properties of cytokines are: (i) pleiotropy (one cytokine has multiple targets and multiple actions) (ii) redundancy (several different cytokines have similar actions) (iii) countervailing actions (one cytokine may stimulate or inhibit production of others) (iv) cytokines precipitate or truncate cascades of other cytokines (v) cytokines increase or decrease receptor sensitivity for other cytokines or even themselves (vi) CNS cytokines stimulate or inhibit both local cytokine response and distant (non-CNS) cytokine response.

Only recently has it been recognized that cytokines are produced by all four major CNS cell groups. These are neurons, oligodendrocytes, astrocytes, and microglia. Over two hundred distinct cytokines identified to date are divided into three groups and 12 sub groups (families) [2,5] Chemokines are a subgroup of 50 small cytokines that are central to mediation of inflammatory responses. Most of these are produced by CNS cells [6]. Some cytokines tend to be proinflammatory and promote apoptosis. Example are TNF-α, IFN-γ, IL1β, IL-6, IL-8, IL-18, MCP-1, MIP-1α, MIP-1β, IP-10, and RANTES. Some CNS cytokines tend to down regulate inflammation and promote growth/ repair. These would include BDNF, β-NGF, GDNF, G-CSF IL-1β, IL-4, IL-10, IL-13, and NT-3, 4/6, 6. This list changes near daily. Further one cytokine may be found to be proinflammatory in one region or circumstance, and have an opposite effect under other circumstances. CNS cytokines may stimulate distant response. For example, blood levels of IL-2 correlate with severity of Alzheimer's disease. External application of cytokines can induce CNS patterned responses. For example, administration of IL-2 will induce depressive symptoms.

Sustained elevations of cytokine productions are associated with pathologies. In the case of AD, the key cytokines are IL-1 which induces iNOS expression by astrocytes and then potentiates NMDA – glutamate neurotoxicity [7]. IL-1 may also be neuroprotective. Interleukin-6, produced by neurons, astrocytes and microglia co-localizes with Aβ plaques. Peripherally, IL-6 is a marker of chronic inflammation. Elevated IL-6 is seen in chronic simple anemia, rheumatoid arthritis, Crohn's disease and others [5]. IL-6 is involved in protecting neurons from methylmercury [7]. It is probably involved with Aβ neuroprotection by neutralizing metalloproteins ROS/RNS produced by apoptosis [2,8]. TNF-alpha typically is a harbinger that calls forth other inflammatory cytokines. In AD there is mixed evidence at the present time. Macrophage Colony Stimulating

Factor (MCSF, CSF-1) appears to be involved with upregulated cytokine/iNOS response to Aβ [7]. A growing list of chemokines is involved with AD. Transforming growth factor (TGF-β) cytokine family, which includes the neurotrophin subfamily, are expressed by neurons, astrocytes, and microglia. The neurotrophin subfamily include nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), insulin like growth factor (ILGF), glial derived neurotrophic factor (GDNF), and erythropoietin (EPO) [2,5,9] These stimulate repair, growth, and neurogenesis [2,10].

### The Role of Aβ in Alzheimer's Disease

Perry, Smith, et al offer a logical explanation [2,8] Aβ is actually part of the brain's efforts to maintain homeostasis. Apoptosis and necrosis resulting from mLI cause release of mitochondrial metalloproteins and metals (iron, zinc, copper, etc) into an acidic extracellular matrix. Aβ is induced by cytokines. Aβ binds copper, zinc, iron and others. Aβ absorbs these ROS/RNS as part of homeostasis. Adequate circulation should allow clearance of the Aβ-metal complexes. When the microglia are activated, and when the ROS/RNS are overwhelming, myeloid-specific enzyme myeloperoxidases (MPO) consume them to produce MPO-$H_2O_2$. This MPO-$H_2O_2$ creates cross linkage with Aβ protein to precipitate it into insoluble plaques [2].

With plaque formation, activated microglia, highly reactive ROS (including glutamate) the table is set for distant penumbra effect. The mLI can trigger distant microinflammations by transaxonalBtranssynaptic flow, intracellular flow, and vascular dispersion of ROS/RNS. So plaques and tangles develop elsewhere in the CNS, and after decades the victim dies of AD.

### Possible Interventions in Alzheimer's Disease

Use of cytokines, anti-cytokines, cytokine receptor modulators is not a current therapeutic intervention. The pleiotropy, redundancy, and unexplored effects of cytokine cascades would result in unanticipated adverse side effects [2,5] Down modulating the effects of glutamate is both practical and available. NMDA antagonists memantine and amantadine are available, and by personal experience of the authors effective early in the course of AD [7]. Third, are anti-inflammatory medications. These have been disappointing to date, possibly due to the drawbacks noted for cytokines [1]. Vaccinations against Aβ are fraught with problems, as one is developing immunity against a homeostatic mechanism. Finally there are antioxidants. Inexpensive vitaminers and herbals are available and have increasing scientific support [2,4,11]. Traditional medicine discounts these, while pursing patentable pharmaceuticals. Further research on synergistic combinations of antioxidants may prove effective.

Because the authors were limited to eleven references, the choice was made to cite recent books with a larger number of specific references.

Yerkes National Primate Research Center, Emory University, Atlanta, GA, USA

### Synonyms
Memory loss; Memory impairment; Memory dysfunction

### Definition
►Amnesia refers to an impaired ability to learn new information or recall details from the past.

### Characteristics
The definitive characteristic of amnesia is profound forgetfulness. It can be caused by brain injury, neurological disease, a cardiovascular event (e.g., stroke), as well as by neurodegenerative and psychological disorders. Amnesia can occur simultaneously with impairment in other cognitive domains (e.g., visuospatial, language, attention disorders), or in the absence of additional cognitive deficits. For this reason, patients with amnesia can perform in the average to above average range on intelligence tests (e.g., Wechsler Adult Intelligence Scale – Third Edition), while simultaneously performing in the severely impaired range on tests of memory (e.g., the Wechsler Memory Scale – Third Edition). This impairment in memory can be observed regardless of the sensory modality (e.g., auditory, visual) in which the information is presented. Interestingly, amnestic individuals can retain intact language and social skills, as well as intact memories for the remote past. Immediate memory remains intact as well. This is illustrated by their ability to retain information up to several minutes provided there is no distraction; the presented material does not exceed immediate memory capacity (e.g., eight or more items); and they are able to rehearse the material. These preserved characteristics explain why individuals with amnesia can appear quite normal in casual conversation. It is only when information must be recalled after an extended delay or distraction-filled interval that a memory impairment becomes apparent.

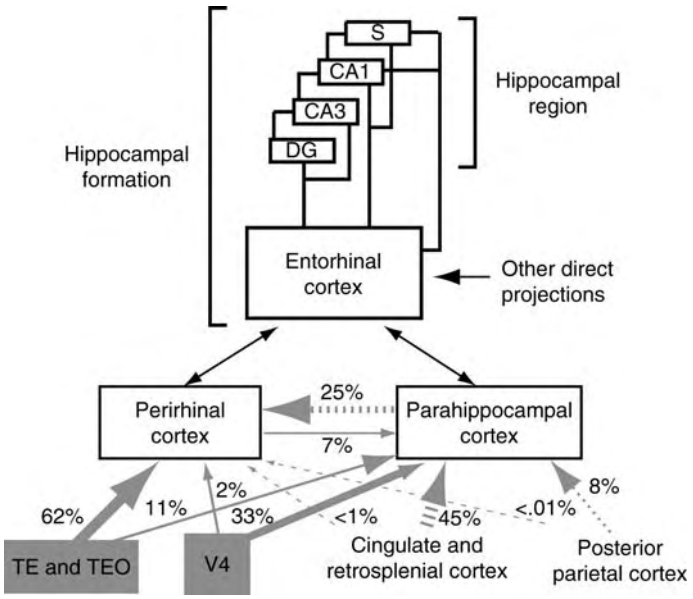
In 1957, Scoville and Milner detailed the discovery of the critical involvement of the medial temporal

lobe in amnesia in a report on famed patient, H.M., who underwent bilateral medial temporal lobe resection, and subsequently suffered severe memory impairment as a result [1]. A great deal has been learned about amnesia from well-studied amnesic patients such as H.M., as well as from the development of the animal models of human amnesia. Methodical work with the non human primate model subsequently revealed the system of medial temporal lobe structures recognized to be crucial for memory. This system consists of the hippocampal region (CA fields, dentate gyrus and subicular complex) and the adjacent perirhinal, entorhinal, and parahippocampal cortices [1,2]. There are continued efforts to try to further elucidate the types of memory properties (e.g., object versus spatial memory) processed by these regions within the medial temporal lobe (Fig. 1) [3].

Regions outside the medial temporal lobe, such as the diencephalon and basal forebrain, are also known to impair memory when injured. The essential structures within each of these areas for memory is still in need of further investigation. Suspected regions include the mediodorsal thalamic nucleus, the anterior nucleus, the internal medullary lamina, the mammillothalamic tract, and the mammillary nuclei. Amnesia resulting from lesions in medial diencephalic structures (e.g., medio-dorsal thalamic nucleus, mammillary nuclei) is referred to as "►medial diencephalic disorder" or "diencephalic amnesia." The behavioral presentation of diencephalic amnesia and ►medial temporal lobe amnesia can be similar. Therefore, it is thought that these two regions together perhaps form an anatomically linked, functional system.

## Multiple Memory Systems

Decades of research on amnesia have highlighted the fact that memory is not a single faculty but instead is composed of multiple separate systems (Fig. 2), only one of which is generally impaired in amnesia [5]. Human amnesia impairs the ability to acquire information about facts and events (►declarative memory or ►explicit memory), while typically sparing the capacity for skill learning, probabilistic classification learning, certain kinds of conditioning and habit learning, as well as the phenomenon of priming (collectively referred to as ►nondeclarative memory or ►implicit memory) [2]. Declarative memory is largely dependent upon the integrity of the medial temporal lobe and diencephalon, whereas nondeclarative memory largely relies on



**Amnesia. Figure 1** Schematic view of the medial temporal lobe memory system (adapted from references [3] and [2]) showing the percentage of cortical input from unimodal and polymodal association areas to the perirhinal and parahippocampal cortices in the medial temporal lobe (*black boxes*). The percentages of cortical input shown on this schematic are from Suzuki and Amaral [4]. The thickness of the lines approximate the relative percentages of cortical input. Buffalo et al. [3] suggest that the perirhinal cortex might be more important for object memory (*grey solid lines and boxes*) while the parahippocampal cortex might be more important for spatial memory (*grey dashed lines and boxes*). Additionally, they hypothesize the possibility that the perirhinal cortex is involved in both spatial and object memory due to the large amount of spatial information it receives via the parahippocampal cortex. See also ►Spatial Learning and ►Object recognition, visual. different brain systems than those damaged in amnesia (Fig. 2) [2].

The label "amnesia" is a broad term that describes the presence of some type of memory impairment. However, there are a variety of amnesic presentations. The following text explains more specifically what particular type of memory difficulties a person with a certain type of amnesia might experience. Additionally, given the majority of research that suggests that nondeclarative memory typically remains preserved in amnesic patients [5], the kinds of amnesia described below concentrate on what could be observed as a result of an impaired declarative memory system.

## Types of Amnesia

►Anterograde amnesia refers to an impaired ability to learn new information. An individual who experiences anterograde amnesia can have significant difficulty remembering new people, recent conversations, and new surroundings subsequent to the onset of amnesia. For example, Scoville and Milner [1] described patient H.M. as having severe anterograde amnesia. They detailed an incident where H.M. could not remember meeting a particular physician despite his having had a conversation with the physician only minutes earlier. It is important to note that the degree of severity of anterograde amnesia produced by medial temporal lobe damage is variable. However, research has demonstrated that damage limited to the hippocampus alone is sufficient to produce memory impairment. Additionally, work performed with both amnestic patients and animal models of amnesia suggest that memory impairment is exacerbated when damage includes cortical regions adjacent to the hippocampus. In other words, the severity of anterograde amnesia can increase as more regions of the medial temporal lobe memory system are involved in the injury.

►Retrograde amnesia is characterized by an impaired ability to remember facts or events that occurred prior to the onset of amnesia. It may or may not occur in conjunction with anterograde amnesia. Similar to anterograde amnesia though, the severity of retrograde amnesia can vary as a function of the extent of damage to cortical regions adjacent to and including the hippocampus. Furthermore, although memory for events close in time to the amnesic episode can be significantly impaired (e.g., details of an accident that resulted in head injury), memories for very remote events are typically preserved (e.g., childhood memories). This phenomenon is referred to as ►temporally graded retrograde amnesia. Scoville and Milner's report on H.M. [1] supplies a fine illustration of temporally graded retrograde amnesia. They described H.M. as having very poor memory for events occurring several before and up to his surgery, while retaining relatively intact memories from his youth. This sparing of remote memories is generally attributed to the process of ►memory consolidation. This term refers to the cortical processing and reorganization of neural substrates involved when forming memories. Memory formation is initially thought to be dependent on the medial temporal lobe system, but its role appears to diminish as more permanent memory is established elsewhere, presumably in neocortex [6]. Research suggests that memory consolidation processes for remote memories have had a sufficient amount of

time to be completed. Recently acquired memories have not had the same amount of time to undergo reorganization, and are thus more vulnerable to medial temporal lobe injury, whose structures are presumed to be involved in the early stages of memory consolidation [6].

►Source amnesia or ►contextual amnesia is a phenomenon that occurs when an individual can recall a fact or an idea, but cannot recall when or where the information was learned. In other words, the individual has access to and can recall information previously presented to them, but cannot recall the context in which the information was acquired. Source memory and source amnesia have been associated with frontal lobe function (or dysfunction in the case of source amnesia) due to its suspected processing of spatial-temporal (i.e., where-when) information [7,8]. Source amnesia can be commonly seen in young children as well as in the elderly. This observation has been attributed to the slow maturation of the frontal lobes relative to other brain regions during development, as well as the relatively increased vulnerability of the frontal lobes to the effects of normal aging. Additionally, source amnesia can be observed in normal adults when newly learned information is assessed after long periods of delay. An increase in the duration of the delay before testing corresponds to an increase in frequency of source memory errors [8]. Patients with frontal lobe lesions can often exhibit source memory difficulties. The pattern of deficits on memory tests suggest they fail to employ efficient memory strategies (e.g., semantic clustering) to enhance encoding and retrieval of previously learned information [7]. It is important to note that a person with anterograde amnesia does not necessarily have to also have source amnesia. Its appearance is variable in amnestic patients and seems to be a separate deficit that can occur in addition to impaired declarative memory. The variability of its co-occurrence with anterograde amnesia lends support to the idea that source amnesia is associated with regions outside the medial temporal lobe, such as the frontal lobes [7].

►Transient global amnesia is characterized by a sudden onset of both ►anterograde and retrograde amnesia, with no other obvious cognitive disturbances present. It can last for a few to several hours, but usually resolves within a day. It is most commonly observed in middle age to elderly individuals. The person experiencing transient global amnesia typically complains of memory impairment, but remains fully conscious and self-aware. Complete recovery is usually expected. However, research has demonstrated persistent mild cognitive deficits after transient global amnesia has resolved [9]. Its etiology is still unknown, although hypothesized causes include focal ischemic lesions, brain tumors, and migraine headaches. The medial temporal lobe is known to be particularly susceptible to the effects of stress, which could suggest its possible role. A recent study involving diffusion-weighted imaging has demonstrated the involvement of the hippocampus in the pathophysiology of transient global amnesia, providing structural evidence indicative of ischemic dysfunction in this particular brain region [10]. Given the pattern of advance in structural and functional brain imaging procedures, improved methods show promise in providing more substantial evidence of the neuroanatomical substrates involved in transient global amnesia.

►Mnestic block syndrome is sometimes referred to as "functional retrograde amnesia," or "psychogenic amnesia," and it is the type of memory disorder with which the average layperson is probably most familiar. It is also this kind of amnesia that has been most popularized by television and film. Mnestic block syndrome is characterized by a sudden onset of severe retrograde amnesia, in the absence of significant anterograde amnesia. This is reflected by the individual's memory loss for personal identity and autobiographical detail (e.g., cannot recall name or date of birth), as well as a period of wandering. It can also include impaired ►semantic memory and ►episodic memory. This collection of symptoms is often referred to as a "fugue state" [5]. Additionally, when a person recovers, he or she may have no recollection of what took place during their amnestic state. The extent of retrograde amnesia experienced by the individual can range from an inability to recall past memories for a limited time period, to complete lack of recollection for most memories prior to amnestic onset. Incidents of mnestic block syndrome are usually precipitated by premorbid periods of severe psychological stress (e.g., death of loved one, financial collapse, marital discord), hence the term "psychogenic amnesia." A recently proposed model tries to explain the psychogenic nature of mnestic block syndrome by hypothesizing an interaction between psychosocial stress factors and brain regions pertinent to autobiographical memory retrieval and personal identity. The model suggests that severe stress can directly inhibit the frontal control/executive brain system, which in turn negatively affects retrieval of memories [5]. Episodes of mnestic block syndrome generally resolve over a short period of time, but can last anywhere from a few hours to a few months. However, prolonged "fugue states" can raise the suspicion of simulation [5].

## Amnesic Aphasia

### Definition

A type of aphasia in which word-finding difficulty in spontaneous speech and in picture or object naming is the predominant symptom, with other language abilities being relatively spared. Despite the name, patients with "amnesic" aphasia do not exhibit amnesia or episodic memory deficits. Synonymous with anomic aphasia.

►Verbal Memory

## Amnesic Shellfish Poison

►Domoic Acid Neurotoxicity

## Amniote Egg

### Definition

An egg that contains everything needed for the development of an organism on land – protective shell and membranes (amnion, chorion, allantois), respiratory surfaces, and food and water reserves.

►The Phylogeny and Evolution of Amniotes

## Amniotes

### Definition

A group of vertebrates whose embryos develop inside extensive membranes that allow the offspring to be laid as eggs or carried by the female and born live. Early amniotes were known as reptiles, but they are now called early amniotes to distinguish them from the separate lines that led to present-day reptiles and mammals.

## AMPA

### Definition

α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid is an amino acid derivative that binds to the AMPA-type glutamate receptor.

►AMPA Receptors

## AMPA Receptors

### Definition

Ionotropic receptors for the excitatory neurotransmitter glutamate. AMPA receptors consist of GluR1

(GluRα1), GluR2 (GluRα2), GluR3 (GluRα3) and GluR4 (GluRα4) subunits and are localized at the postsynaptic site on the dendritic spine. The composition of the subunits determines the properties of AMPA receptor channels. When glutamate binds to the receptor channel, the channel opens and monovalent cations permeate through the receptor channel. Mainly, sodium ions permeate into the neuron at the resting membrane potential, resulting in the depolarization of the neuron.

## Amperometry

### Definition

A sensitive electro-chemical method to detect the release of transmitters or hormones (e.g. dopamine or adrenaline) that can be catalyzed to undergo a redox reaction by a voltage applied to the tip of an electrode (typically made of a carbon fiber). This method can monitor the rate of release of certain transmitters and hormones from individual vesicles in millisecond timescale.

## Synonyms

Amygdaloid body; Amygdalar nuclear complex

## Definition

The amygdala (Latin, almond) is a subcortical cluster of brain nuclei located in the temporal lobe of the cerebral hemispheres. It is involved in a wide range of functions, including emotion, biologically based behaviors, attention, memory and learning. It exhibits pathological and pathophysiological changes in several important neurological and psychiatric diseases including temporal lobe epilepsy, Alzheimer's disease, schizophrenia, anxiety disorders and depression.

## Characteristics

### Anatomical Organization

The amygdala is a part of the ►limbic system located in the temporal lobe of the cerebral hemispheres [1,2] (Figs. 1 and 2).

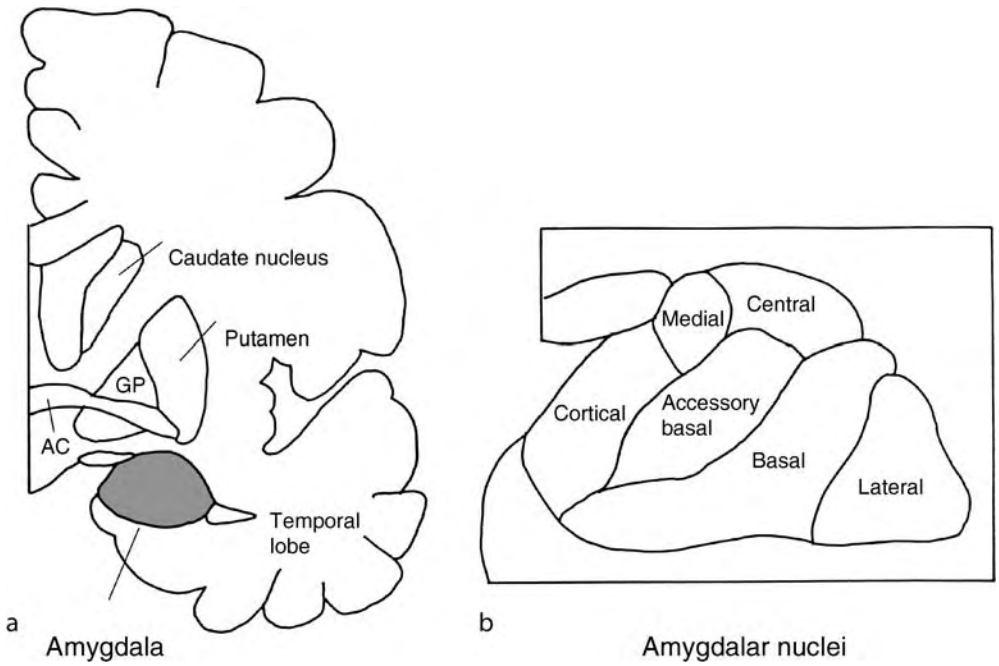
It is customary to categorize the amygdalar nuclei into groups that exhibit distinctive anatomical or functional characteristics. Traditionally, two major amygdalar nuclear groups were recognized, a superficial "corticomedial" group (including the cortical, medial and central nuclei) and a deeper "basolateral" group (including the lateral, basal and accessory basal nuclei) (Fig. 1). Recent studies however, indicate that the central and medial nuclei exhibit anatomical and histochemical characteristics that are distinct from those of the cortical nucleus. Therefore, it has been suggested that the amygdalar nuclei should be divided into a corticobasolateral nuclear group and a centromedial nuclear group [3]. In addition, attenuated portions of the centromedial nuclear group extend forward to become continuous with a brain region called the bed nucleus of the ►stria terminalis, which is located in the septal region adjacent to the anterior commissure. The term "►extended amygdala" has been used to collectively designate the centromedial amygdala and bed nucleus of the stria terminalis [4].

Cell types in the basolateral and cortical nuclei are very similar to each other. Most of the neurons in both groups are termed pyramidal cells because they resemble the pyramidal neurons in the cerebral cortex. The pyramidal cells are the main "projection neurons" of the cortical and basolateral nuclei (i.e. their axons project out of the amygdala and allow the amygdala to activate other brain regions). Pyramidal cells utilize the amino acid ►glutamate as an excitatory ►neurotransmitter. The remaining cell types in the basolateral and cortical nuclei are nonpyramidal neurons. The axons of these cells establish synaptic contacts with neighboring amygdalar neurons but do not extend beyond the amygdala (i.e. they are ►interneurons). They utilize $\gamma$-aminobutyric acid (►GABA) as an inhibitory neurotransmitter.

In contrast to the basolateral and cortical nuclei, neurons of the centromedial nuclei and the bed nucleus of the stria terminalis resemble neurons of the adjacent striatum (part of the ►basal ganglia) rather than the cerebral cortex. Most of these neurons utilize GABA as an inhibitory neurotransmitter, and many also contain ►neuropeptides that function as neurotransmitter-like substances.

### Functional Anatomy

In their classic study performed in 1937, Klüver and Bucy [5] found that lesions of the amygdalar region produced a profound loss of fear in monkeys ("►Klüver-Bucy syndrome"). These animals also exhibited



**Amygdala. Figure 1** (a) Coronal section through the human brain at the level of the amygdala (only the right half of the brain is shown; the amygdala is actually found on both sides of the brain). Note that the amygdala (*shaded area*) is located in the anteromedial part of the temporal lobe. **Amygdala. Figure 2** Lateral view of the human brain illustrating the anatomy of the main cortical pathways conveying sensory information to the amygdala. Note that somatosensory, auditory and visual information is transmitted to the amygdala over polysynaptic cortical pathways; only higher order cortical areas involved in processing the most complex sensory information in these modalities have projections to the amygdala. Reprinted from Encyclopedia of the Neurological Sciences with permission from Academic Press.

inappropriate sexual and feeding behavior. In general, it appeared that these amygdalectomized monkeys were unable to recognize the emotional or behavioral significance of visual stimuli. Subsequent studies revealed that animals with amygdalar lesions also did not respond appropriately to auditory, somatosensory and olfactory cues. Thus, it appears that the amygdala is critical for producing appropriate behavioral responses to biologically relevant sensory stimuli and events in the external world. In fact, the amygdala is thought to constitute an essential link between brain regions that process sensory information (e.g. the ►cerebral cortex and ►thalamus) and brain regions responsible for eliciting emotional and motivational responses (i.e. the ►hypothalamus, ►brainstem and ►striatum). For this reason, the amygdala has been called the "sensory gateway to the emotions."

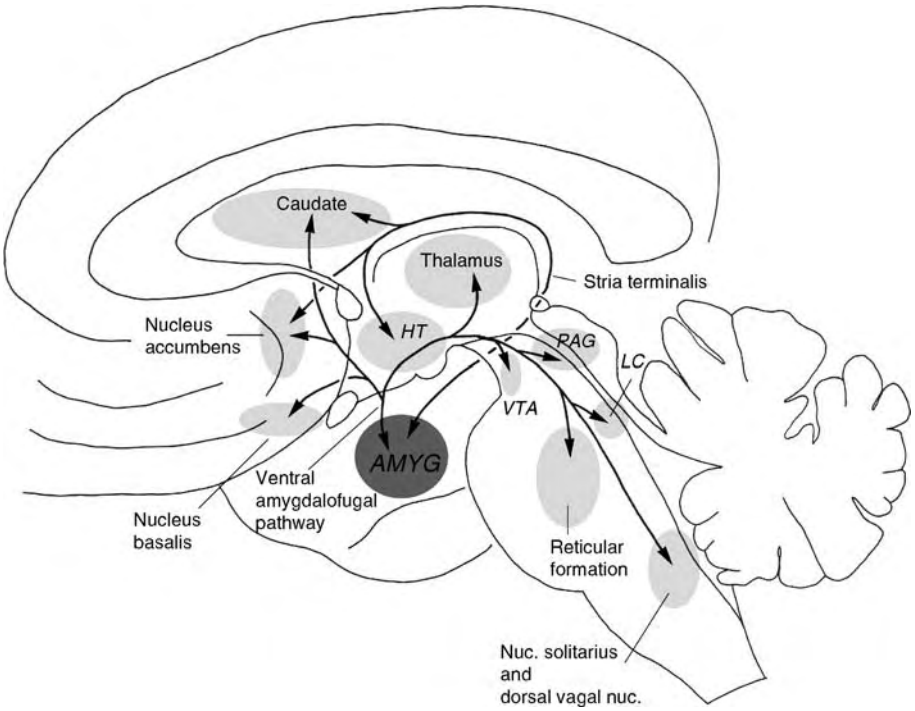
The amygdala receives sensory information through its connections with the olfactory bulb and sensory association areas in the cerebral ►cortex (Fig. 2). The cortical and medial nuclei receive olfactory information from the olfactory cortex and from the main and accessory olfactory bulbs. The latter structure is part of the vomeronasal system, which is involved in detecting special odors (pheromones) that are produced by individuals of the same species. Pheromones elicit hormonal and behavioral responses involved in species-specific reproductive and social activities. The amygdala receives visual and auditory information from the temporal lobe, ►somatosensory and viscerosensory (including gustatory) information from the insular lobe and polysensory information from the ►prefrontal cortex and ►hippocampus. These nonolfactory inputs primarily target the basolateral nuclei. The basolateral nuclei also have reciprocal projections back to these same cortical regions. It has been suggested that these amygdalocortical projections may be important for attention to emotionally and behaviorally significant stimuli and for the storage of emotional memories.

Projections from the ►thalamus to the amygdala arise mainly from the midline thalamic nuclei and from the medial part of medial geniculate nucleus and adjacent posterior thalamic nuclei. These projections, which terminate primarily in the basolateral and central amygdalar nuclei, convey auditory, somatosensory, viscerosensory and visual information to the amygdala. Amygdalothalamic projections are more limited and consist of projections from the central nucleus to the midline thalamic nuclei and from the basolateral amygdala to the mediodorsal thalamic nucleus. Since the latter nucleus has extensive reciprocal connections with the prefrontal cortex, it provides an indirect link by which the amygdala can influence the activity of the prefrontal region.

The amygdala produces emotional responses by way of its connections with several subcortical regions, including the ►hypothalamus, brainstem, striatum and ►basal forebrain. Some of these fibers course in the ►ventral amygdalofugal pathway, which runs (Fig. 3) near the inferior surface of the brain. Others course in a thin fiber bundle termed the ►stria terminalis, which takes a more circuitous route above the thalamus (Fig. 3). There are extensive reciprocal connections between the medial portions of the hypothalamic region and the amygdala, particularly the medial amygdalar nucleus, cortical nuclei and medial portions of the basolateral amygdala. Consistent with these connections, stimulation and lesion studies in experimental animals have shown that the amygdala is involved in behavior related to biological drives and motivation, including arousal, orienting and sleep, fight or flight, feeding and drinking and social, reproductive and maternal behavior. In humans, these behaviors are typically associated with emotional feelings (e.g. fear with flight and anger and rage with fighting and defensive behavior). In each of these affective states, the amygdala appears to elicit a coordinated response consisting of autonomic, endocrine and behavioral components by way of its projections to various subcortical regions, especially the hypothalamus. The endocrine responses produced by amygdalar stimulation are due to its indirect activation of the pituitary via the hypothalamus. Interestingly, many of the hormones secreted by the glands targeted by pituitary hormones can affect the activity of the amygdala via receptors expressed by amygdalar neurons. Thus, there is a very high density of estrogen and androgen receptors in the medial and cortical nuclei. Glucocorticoid receptors, activated during stress, are located in all portions of the amygdala, but particularly high levels are found in the centromedial nuclear group.

Another important subcortical target of the amygdala that is important for producing behavioral responses is the striatum (caudate, putamen and nucleus accumbens) (Fig. 3). This projection mainly originates in the basolateral nuclei and terminates primarily in the ventral and medial portions of the striatum, including the nucleus accumbens. Lesion studies indicate that the projections of the basolateral amygdala to the striatum are important for controlling behavior related to the reinforcing properties of sensory stimuli.

The central nucleus is the main amygdalar region exhibiting connections with the brainstem and basal forebrain. Among these targets are several brainstem areas involved in visceral function, including the parabrachial nucleus, ►dorsal vagal nucleus and ►nucleus solitarius. It also has projections to the ►periaqueductal gray and ►reticular formation, which are important for pain modulation and behavioral responses to stress. In addition, the central nucleus innervates several brain regions that give rise to neurotransmitter specific fiber systems that target the



**Amygdala. Figure 3** Medial view of the human brain illustrating the connections of the amygdala (*AMYG*) with subcortical brain regions. All connections are reciprocal except those to the caudate and nucleus accumbens, which do not have projections back to the amygdala. *HT*, hypothalamus; *LC*, locus ceruleus; *PAG*, periaqueductal gray; *VTA*, ventral tegmental area. amygdala and other forebrain areas. These regions include the locus ceruleus (noradrenergic), the substantia nigra and ventral tegmental area (dopaminergic), the raphe nuclei (serotonergic) and the nucleus basalis (►cholinergic). These transmitter specific systems, also known as ►ascending modulatory projections, are activated in certain behavioral states, particularly during stress and can modulate amygdalar activities related to emotion, attention and memory.

## Involvement in Neurological and Psychiatric Diseases

In agreement with the results of animal experiments, recent investigations of the human amygdala have shown that it is critical for the recognition of the emotional significance of auditory, visual and olfactory stimuli, including facial expressions, vocal intonation and expressive body movements. It has also been demonstrated that electrical stimulation of the human amygdala elicits fear, rage or other emotions. In addition, the human amygdala plays an important role in emotional learning, consistent with animal studies showing that the amygdala is essential for classical ►Pavlovian fear conditioning to simple sensory cues, as well as to complex sensory representations such as the context in which an emotional event has occurred [6,7]. Studies in both humans and animals have demonstrated that the release of noradrenaline in the amygdala is essential for the formation and recall of memories involving emotional events [8] and that there is over-activation of the amygdala in patients with post-traumatic stress disorder (PTSD).

The amygdala exhibits pathological and pathophysiological changes in several additional neurological and psychiatric diseases including ►temporal lobe epilepsy, ►Alzheimer's disease, schizophrenia, ►anxiety disorders and ►depression. Temporal lobe epilepsy (TLE) is the most common type of epilepsy and is often characterized by psychiatric disturbances. The amygdala exhibits cell loss in TLE and altered activity has been noted in recording studies. Studies in the rat have shown that the amygdala has the lowest threshold for "►kindling," a phenomenon that has attracted a considerable amount of interest as a model of TLE. The amygdala is also a major target of the classic neuropathological changes seen in Alzheimer's disease and it has been suggested that degeneration of the amygdala may be responsible for the emotional liability seen in this disease.

There is also amygdalar degeneration in schizophrenia and recording studies have detected abnormal activity in the amygdala in this condition. ►Dopamine

levels are increased in the amygdala in schizophrenia and this brain region may be one of the main sites of action of atypical ►antipsychotic drugs such as clozapine. Consistent with numerous rodent studies implicating the amygdala in fear and anxiety, there is evidence that anxiety disorders in humans are associated with excessive activity in the amygdala. Moreover, studies in animals and humans have shown that the amygdala has very high levels of benzodiazepine receptors and is a critical site of action for the anxiolytic effects of these drugs. Recent functional imaging investigations have demonstrated that there is increased activity in the human amygdala in major depression and that administration of ►antidepressants, which modulate levels of serotonin and noradrenaline in the amygdala, cause a decrease in amygdalar activity that is associated with amelioration of depressive symptoms [9].

## Amygdalar Nuclear Complex

►Amygdala

## Amygdaloid Body

### Synonyms

►Corpus amygdaloideum

### Definition

The amygdala is a large nuclear complex in the dorsomedial portion of the temporal lobe, at the inferior horn of the lateral ventricle. Reciprocal connections with the rhinencephalon, hypothalamus, thalamus, brainstem and some cortical areas. The amygdaloid body receives highly preprocessed sensory impressions and is responsible for initiation and integration of somatic and autonomic responses, associated with affective behavior.

►Telencephalon
►Amygdala

## Amygdalospinal Fibers

### Definition

Fibers, predominantly from the central amygdaloid nucleus which pass further through the brainstem into the spinal cord, where they may be involved in the regulation of autonomic processes.

►Pathways

## Amyloid Plaques

### Definition

These aggregates of primarily amyloid proteins and other carbohydrates are found in the brains of patients suffering from amyloidopathies, typically in Alzheimer's disease, and rarely in brain disorders of viral origin such as Acquired Immune Deficiency Syndrome (AIDS). The amyloid plaques can either be well defined or can occur as diffuse plaques, and play an important role in the pathogenesis of neurodegenerative disorders.

### Synonyms

Antinociception

### Definition

The word analgesia comes from the Greek words of An (negative) and Algesis (►pain) hence not sensing pain. We can think of analgesia as the process in which the sensation of pain is attenuated or inhibited. This is most often accomplished by the use of pharmaceuticals such as opioids that inhibit the activation of the neuronal pathways that relay pain sensations from the periphery to the central nervous system.

### Characteristics

#### Description of Pain and Analgesia

Pain is described as an unpleasant sensation associated with a specific part of the body [1] (►Nociception). It is produced by processes that either damage, or are capable of damaging, the tissues. Such damaging stimuli are called ►noxious and are detected by specific sensory nerve fibers called ►nociceptors [2]. These nociceptors are free nerve endings with cell bodies in the dorsal root ganglia and terminate in the superficial layers of the dorsal horn of the spinal cord. Here they relay messages of noxious stimulation by releasing neurotransmitters such as glutamate [3], substance P and calcitonin gene related peptide (CGRP) [4,5]. These "pain" neurotransmitters will result in the activation of the second order neurons *via* their corresponding receptors. The second order neurons cross the spinal cord to the contralateral side and travel up the spinothalamic tract until they reach the thalamus. From there the third order neurons are activated, traveling from the thalamus to the somatosensory cortex, hence allowing for the perception of pain. In addition to the activation of second order neurons that ascend *via* the spinothalamic tract, there are second order neurons that activate lower motor neurons in the ventral horn of the spinal cord provoking a reflex withdrawal from the ►noxious stimulus. Likewise, there are enkephalin and endorphin containing interneurons at the level of the spinal cord and brainstem that will modulate the neurotransmission of pain.

#### Analgesic Actions Along the Pain Pathways

Several sites for analgesic actions can be identified in the neural processing of noxious signals. Nociceptive afferent fibers are typically pseudounipolar neurons, with a peripheral terminal and a central terminal. Neurotransmitters that are produced within the cell body (i.e. in the dorsal root ganglia) are the same at both the central and peripheral ends of the nerve fiber. The neurotransmitters are released at both ends, participating in the pain signal peripherally and centrally. The release of neurotransmitters from the peripheral terminals of the afferent fibers is actually an "efferent" function of these afferent neurons. Peripheral release of neurotransmitter substances leads to the classic "axon reflex". This reflex leads to peripheral changes which are recognized as indicators of pain – redness, swelling, tenderness [6]. The peripheral terminals have ►opioid receptors on which compounds such as morphine, codeine, fentanyl, etc. or endogenous opioids such as enkephalin and endorphins can act to inhibit the release of such pain neurotransmitters that contribute to the activation of the nociceptors themselves. Opioid receptor activation (G-protein coupled receptors) results in the indirect opening of potassium channels. Potassium with its positive charge flows out of the ►nociceptor leaving the inside of the neuron more negative. The enhanced intracellular negative charge hyperpolarizes the nociceptor, resulting in a decrease in nociceptor activity (i.e. ►analgesia).

The periphery is the site of other analgesics including steroids (i.e. corticosteroids) and the family of

non-steroidal anti-inflammatory drugs (►NSAIDs) (i.e. ibuprofen, indomethacin, aspirin). Steroids and NSAIDs result in ►analgesia by inhibiting the pro-inflammatory and pro-nociceptive family of prostaglandins.

Opioids can act on the presynaptic terminal of the primary afferent nociceptor at the level of the spinal cord *via* the opioid receptor (G-protein coupled receptors) by indirectly blocking voltage gated calcium channels, as well as opening potassium channels. The inhibition of calcium entry into the presynaptic terminal as well as the efflux of potassium (hyperpolarization) results in the inhibition of pain neurotransmitter release from the primary afferent fibers, hence ►analgesia. Opioids have a second site of action at the level of the spinal cord. Opioid receptors on the postsynaptic nerve (the second order neuron), when activated by an opioid, indirectly open potassium channels resulting in hyperpolarization of the second order neuron, producing further ►analgesia.

The inhibition of pain, analgesia, also occurs by the activation of the cortical descending neural system. Activation of the cortical/bulbar/spinal descending pain inhibitory system to further promote ►analgesia is induced by the release of endorphins and, enkephalin, as well as by exogenously administered opioids acting again via opioid receptors. Thus far we know that these systems are activated in and around the periaqueductal gray (PAG) region of the midbrain. Such neurons then project to sites in the medullary reticular formation and the locus ceruleus (the major source of norepinephrine cells in the brain). These neurons that are opioid sensitive are activated through disinhibition - that is, inhibition of a tonically active inhibitory interneuron. Opioids are known to hyperpolarize neurons as detailed above, yet when given into these CNS regions activate neurons by simply attenuating the inhibitory GABAergic neurons (i.e. opioids act to remove the "GABA brake"). These descending fibers then project to the dorsal horn of the spinal cord along a tract called the dorsolateral funiculus (located in the dorsolateral portion of the spinal cord) to synapse with either the incoming primary afferent neuron, the second order pain transmission neuron, or interneurons. These descending pain modulatory neurons either (i) release neurotransmitters in the spinal cord, especially serotonin (5HT) and norepinephrine (NE) or (ii) activate small opioid containing interneurons in the spinal dorsal horn to release endogenous opioid peptides. The released NE and 5HT in the end (i) inhibit the release of pain transmitters from the incoming nociceptive afferent signal, and (ii) inhibit the second order pain transmission cell, hence producing ►analgesia. Activation of the descending pain modulatory system is a good example of why subjects report not feeling pain at all under conditions of stress, or perhaps other situations, where even though the pain is felt, the degree appears to be greatly modulated [7].

## Summary of Analgesic Sites

We can identify several analgesic sites. (i) activating opioid receptors in the periphery to inhibit the activation of the nociceptors, as well as use NSAIDs or steroids to inhibit the release of inflammatory mediators, (ii) activating opioid receptors at the central terminals of nociceptors to stop the release of pain neurotransmitters in the spinal cord, (iii) activating opioid receptors on the second order pain transmission cells to prevent the ascending transmission of the pain signal, and (iv) activating the opioid receptors in the midbrain and "turning on" the descending pain inhibitory systems (through disinhibition).

## Intracellular Mechanisms of Opioid Analgesia

Recent cloning has identified three distinct genes for the μ, κ and δ opioid receptors (this needs to be corrected by the author) [8–11]. All three receptors belong to the G-protein coupled receptor (GPCR) family. Agonist binding to opioid receptors leads to a conformational change in the opioid receptor resulting in the activation of an intracellular protein called a G-protein. The G-protein is made up of three separate protein subunits termed alpha, beta and gamma. The alpha portion of the G-protein associates with guanosine diphosphate (GDP). The alpha portion with its GDP will associate with the beta and gamma subunits and exist as an intracellular trimeric protein. An opioid bound to an opioid receptor undergoes a conformational change in the receptor resulting in the exchange of the GDP for a GTP on the Gα subunit. It is this exchange of GDP for GTP that activates the G-protein complex. Opioid receptors typically couple to a Gαi subunit and once the exchange of GDP for GTP has occurred, the αi subunit will dissociate from the βγ subunit and inhibit the activity of adenylate cyclase, a nearby membrane bound enzyme. Under resting conditions, adenylate cyclase converts ATP into cAMP at some basal rate. cAMP acts as a second messenger within the cell resulting in several events including the activation of protein kinases and gene transcription proteins. Opioid receptor activation by an opioid will result in the activation of the Gαi subunit and inhibit adenylate cyclase enzyme, hence significantly decreasing intracellular basal levels of cAMP. This opioid via opioid receptor-induced decrease in cAMP indirectly results in the inhibition of voltage dependent calcium channels on presynaptic neurons. These voltage dependent calcium channels are important in the release of neurotransmitter and transduction of neuronal communication, in this case pain transmission. Opioid receptors located on the presynaptic terminals of the nociceptive fibers, when

activated by an opioid agonist, will indirectly inhibit voltage dependent calcium channels via decreasing cAMP levels hence blocking the release of pain neurotransmitters such as glutamate, substance P and calcitonin gene related peptide (CGRP) from the nociceptive fibers resulting in ►analgesia.

In addition to the indirect inhibition of voltage gated calcium channels by opioid receptors, the βγ subunit of the G-protein will open inward rectifying potassium (GIRK) channels allowing $K^+$ to flow down its concentration gradient and out of the cell carrying its (+) charge. This results in a more negatively charged environment within the cell termed hyperpolarization. This opioid-induced hyperpolarization results in a decrease in cell excitability hence attenuating neuronal transmission [12] and ►analgesia.

## Definition

A formulation of the laws of ►mechanics based on the geometric concept of ►configuration space. In this approach, forces (or, more precisely, generalized forces) are considered as linear operators on vectors tangent to the configuration space (virtual displacements, or virtual velocities).

## Description of the Theory

The concept of *configuration space* is briefly discussed in the article on classical mechanics (q.v.), and the use of *generalized coordinates* has been introduced in the article on the ►principle of virtual work (q.v.). To effect the transition to ►analytical mechanics the so-called ►*principle of D'Alembert*, briefly discussed in the article on statics (q.v.), may be invoked. According to this principle the equations of motion of a system can be regarded as equilibrium equations that include fictitious inertia forces. Applying this idea to the principle of virtual work, the virtual work of the forces of inertia associated with the free motion of a single particle in space may be calculated. Working in an inertial frame, the force of inertia, as defined in the article on statics (q.v.), is equal to $-\dot{\mathbf{p}}$. Since the particle is free, any arbitrary virtual displacement $\delta\mathbf{x}$ is admissible. The virtual work of the force of inertia is, therefore, given by:

$$-\dot{\mathbf{p}}\,.\,\delta\mathbf{x} = -m\dot{\mathbf{v}}\,.\,\delta\mathbf{x}. \tag{1}$$

According to D'Alembert's principle, the incorporation of this extra term to the virtual work of the applied forces will deliver (by means of the principle of virtual work) the equations of motion of the particle. In fact, in many practical applications, including the derivation of approximate numerical algorithms for finding the motion of a system, this is all that is needed. But analytical mechanics does not stop at this point, since its inspiration came from a philosophical point of view (initially advocated in France during the eighteenth century by, among others, Maupertuis) according to which the laws of Nature must represent in some sense the most efficient possible way for phenomena to take place. This principle has its historical origins in the *principle of least time* of optics (already known for reflected rays to Heron of Alexandria and extended to refraction problems by Fermat), according to which light rays travel in a trajectory that minimizes the time of travel (or, at least, renders it stationary with respect to neighboring trajectories). Maupertuis advocated the existence of a similar principle in mechanics, except that the quantity to be optimized was not necessarily time, but some vaguely defined quantity called *action*. This general idea was further developed and made mathematically precise by Euler, Lagrange and Hamilton. To understand these developments, it is useful to realize that, even in the case of the rays of light, the quantity to be minimized is not an ordinary function of several variables, but rather a *functional*, namely, a function whose independent variables are themselves entire functions. Consider, for example, the trajectory of a ray of light in a refractive medium whose index of refraction varies smoothly from point to point. The time-minimizing trajectory is, therefore, expected to be a smooth curve (rather than a zigzag of straight pieces). In principle, all smooth trajectories starting at the source and ending at the receptor must be considered in an equal footing. The time of travel is thus a function of the whole trajectory, a function to be evaluated for each candidate curve, namely, a functional given by an integration over a curve of a certain function of the index of refraction and the element of length of the curve. Returning to Eq. 1 for the virtual work of the force of inertia for a single particle and integrating it between an initial time $t_0$ and a final time $t_1$:

$$\begin{aligned}\int_{t_0}^{t_1} -m\dot{\mathbf{v}}\,.\,\delta\mathbf{x}\,dt &= \int_{t_0}^{t_1} -\frac{d}{dt}(m\mathbf{v}\,.\,\delta\mathbf{x})\,dt + \int_{t_0}^{t_1} m\mathbf{v}\,.\,\delta\dot{\mathbf{x}}\,dt \\ &= -m\mathbf{v}\,.\,\delta\mathbf{x}\big|_{t_0}^{t_1} + \int_{t_0}^{t_1} m\mathbf{v}\,.\,\delta\mathbf{v}\,dt \\ &= -m\mathbf{v}\,.\,\delta\mathbf{x}\big|_{t_0}^{t_1} + \delta\int_{t_0}^{t_1} K\,dt,\end{aligned} \tag{2}$$

where $K$ is the ►kinetic energy of the particle:

$$K = \frac{1}{2}m\mathbf{v}\,.\,\mathbf{v}. \tag{3}$$

There are several subtleties involved in the derivation of Eq. 2. One is that the variations $\delta\mathbf{x}$ are vector-valued *functions of time*. In other words, they consist of entire variations (or perturbations) of a motion between the initial and the final times. So far, these variations have been permitted to be arbitrary, but now they must vanish at the end points. This is tantamount to saying that, although the actual trajectory of the particle is unknown, its positions for the initial and the final times are assumed to be known and that is why a non-zero variation is no longer being allowed at these times. Under these restricted conditions, the integrated virtual work of the force of inertia is exactly equal to the integral of the kinetic energy of the particle between the initial and the final times. Naturally, the kinetic energy depends on the trajectory chosen and thus its integral is not an ordinary function but a functional of the trajectory; for each candidate trajectory (always starting and finishing at specified points) a different value of the integral of the kinetic energy is obtained.

Having calculated the integrated virtual work of the force of inertia, the integrated virtual work of the actual forces impressed on the particle may be calculated. Assume that this force is conservative, namely, it is equal to minus the derivative of a ►potential energy function $V$ (see the article on the ►principle of virtual

work). In that case, the integrated virtual work of the impressed forces is:

$$\int_{t_0}^{t_1} \mathbf{f}^{ext} \,.\, \delta\mathbf{x}\, dt = -\int_{t_0}^{t_1} \delta V\, dt = -\,\delta \int_{t_0}^{t_1} V\, dt. \qquad (4)$$

Since, according to D'Alembert's principle, along the actual trajectory of the particle, the total virtual work must vanish at each instant of time, it follows that the integrated virtual work will also vanish identically. Collecting the results of Eqs. 2 and 4, and defining the ►*Lagrangian density L* as the difference between the kinetic and the potential energies, namely,

$$L = K - V, \qquad (5)$$

along the actual trajectory of the particle the variation of the integral of the Lagrangian density must vanish, viz.:

$$\delta \int_{t_0}^{t_1} L\, dt = 0. \qquad (6)$$

This result can be interpreted as follows. Among all the possible trajectories starting and ending at specified points and at specified times, the particle will choose a trajectory that, when compared with any of its neighboring trajectories starting and ending in the same way, renders the integral of the Lagrangian density stationary (for example, minimum).

An in-depth treatment of this important topic is beyond the scope of this article. Nevertheless, the validity of this principle extends to all conservative mechanical systems of a finite number of degrees of freedom with purely geometrical constraints. Systems with so-called ►*non-holonomic constraints* (constraints on the velocities rather than the positions of the system) require a special treatment.

The kinetic energy of a rigid body can be calculated on the basis of Eq. 9 of ►Newtonian mechanics (q.v.) as:

$$K = \frac{1}{2} M\, \dot{\mathbf{x}} \,.\, \dot{\mathbf{x}} + \frac{1}{2}\, \Omega \,.\, \mathbf{J}\Omega. \qquad (7)$$

The Lagrangian density $L$ will in general be a function of the generalized coordinates $q^i$ and of their time-derivatives $\dot{q}^i$ (or, *generalized velocities*). According to the principles of the *calculus of variations* (the mathematical discipline dealing with the determination of stationary values of functionals), a functional of the type shown in Eq. 6 is stationary if the functions $q^i(t)$ satisfy the so-called *Euler-Lagrange differential equations*:

$$\frac{\partial L}{\partial q^i} - \frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}^i}\right) = 0 \qquad (8)$$

These equations are not partial but ordinary differential equations. The partial derivatives appearing therein are nothing but indications of the operations to be performed with the Lagrangian density (seen as a function of the $2n$ independent variables, the generalized coordinates and the generalized velocities) to obtain the equations. The total time-derivative appearing in Eq. 8, on the other hand, needs to be calculated by the chain rule of differentiation, namely, taking into consideration that the generalized coordinates and velocities are ultimately functions of time. The Euler-Lagrange equations represent an alternative procedure for the derivation of the equations of motion of the system. Although they were derived by means of a time-wise global conceptual framework (the stationary value of an integral over time), they ultimately yield a time-wise local result (a system of differential equations). As compared with the derivation of the equations of motion by means of Newtonian mechanics (q.v.) the advantages are clear. In analytical mechanics only the expression of two scalar functions, the kinetic and the potential energy of the system, need be known. The rest is delivered automatically by the calculus of variations, thus avoiding the pitfalls of derivations based on free-body diagrams. These pitfalls are particularly severe in those cases in which extra geometric constraints are imposed whose associated forces are not easily represented in free-body diagrams (for example, a constraint of area preservation of a panel comprised between several bars). Even if these constraints are not easily factored out in the choice of generalized coordinates, the calculus of variations provides techniques for their straightforward incorporation in the formulation of analytical mechanics.

This is an elementary sketch of the so-called *Lagrangian mechanics*. There exists an equivalent formulation known as *Hamiltonian mechanics* in which the primary concept is the so-called *phase space*, rather than the configuration space. In phase space the generalized coordinates and the generalized momenta are given symmetric roles. In spite of the long-standing tradition of these two versions of analytical mechanics, there is still much research being carried out today. The discovery of a strong canonical geometric structure in phase space for example, has given rise to the *symplectic formalism*, which is specially suited to the definition of physically meaningful quantities in a global intrinsic way, rather than in terms of local coordinate expressions. These topics are beyond the scope of this article.

## Anandamide

### Definition

Anandamide also known as arachidonoylethanolamide or AEA, is an endogenous cannabinoid neurotransmitter. It was isolated and its structure was elucidated in the Laboratory of Raphael Mechoulam, at the Hebrew University in Jerusalem in 1992. The name is taken from the Sanskrit word ananda, which means "bliss". Its structure represents arachidonic acid linked to ethanolamine via an amide linkage.

## Anatomy and Function in the Respiratory Network

George F. Alheid, Donald R. McCrimmon
Department of Physiology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

### Synonyms

Anatomy of Breathing; Central Respiratory Mechanisms; Models of Respiration

### Definition

Breathing is an automatic somatomotor behavior serving homeostasis for $O_2$ and $CO_2$. The rhythm and pattern of breathing is shaped by an interconnected series of neural modules located mainly in the rhombencephalon (medulla and pons). Breathing is also voluntary in that it can be consciously started or stopped as well as it's depth and frequency altered.

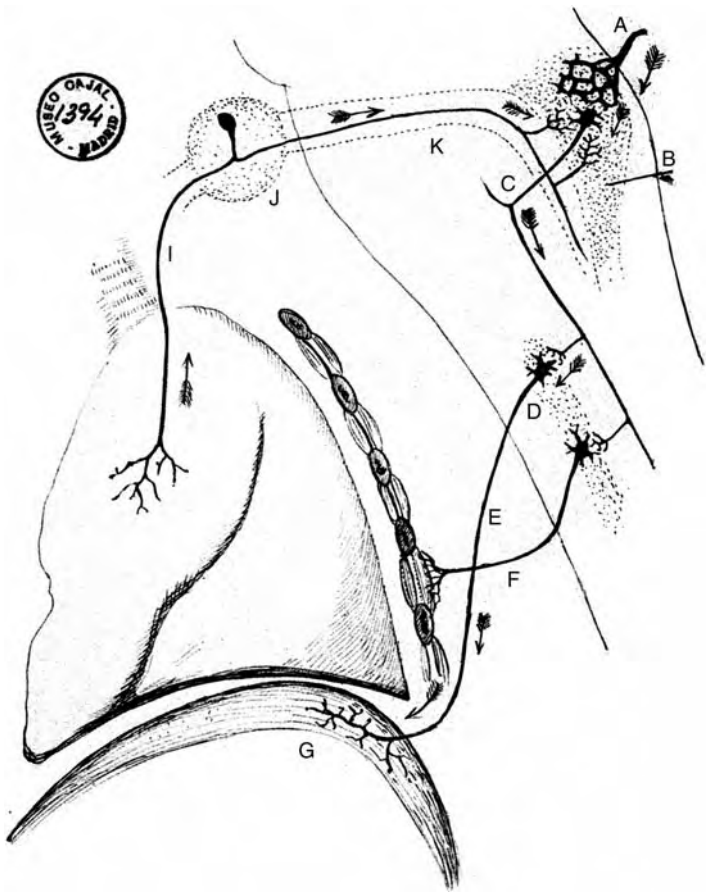
### Characteristics

Breathing is an essential homeostatic behavior persisting without significant interruption throughout life. Although it can be voluntarily controlled, respiration is served by highly automated central rhythmic oscillators located in the rhombencephalon. In general, the frequency (rhythm) and volume of respiration is unconsciously adjusted over a wide range. Brainstem reflexes respond to central and peripheral chemosensors monitoring the partial pressures of oxygen ($PO_2$) and carbon dioxide ($PCO_2$) in the arterial blood and in the brain parenchyma, as well as responding to receptors in the upper airways and lungs monitoring inflation or deflation (stretch receptors) or signaling the presence of toxins or irritants in the airways.

In addition to its vital role in homeostasis, breathing may be arbitrarily altered to serve other non-homeostatic behaviors ranging from walking and talking to postural adjustments. Breathing is also an (involuntary) component of emotional behaviors; it may be enhanced or inhibited relative to orienting and defensive responses, modulated within emotional state and in conditions such as panic disorder where hyperventilation may contribute to the dysphoria experienced by the affected individual. As a basic component of vocalization, the precise control of expiration and muscle contractions in the upper airways (including the larynx and tongue) underlies the motor output for one of the most complex cognitive activities of the brain.

## Functional Neuroanatomy

The importance of the brainstem in the control of breathing was appreciated relatively early on in the history of neuroscience, Cajal [3] for example, provided a relatively accurate overview of mammalian afferent and efferent pathways regulating breathing (Figs. 1 and 2). These include: (i) ascending sensory information from the airways that travel via the vagus to reach the nucleus of the solitary tract (NTS), (ii) integration by brainstem



**Anatomy and Function in the Respiratory Network. Figure 1** Diagram of respiratory circuits and the output to inspiratory muscles. This diagram provides an overview of the anatomical circuits controlling breathing, and, in particular, respiratory motor output via inspiratory pump muscles. Specifically, peripheral pulmonary stretch receptors (I,J,K), and peripheral chemoreceptors that monitor arterial $O_2$ and $CO_2$ (not shown – see text) provide afferents that terminate centrally in the nucleus of the solitary tract (B). Central chemoreceptors in this nucleus (A, and elsewhere in the brainstem – see Fig. 8) monitor $CO_2$ levels and brainstem respiratory rhythm generators in the ventrolateral medulla (see Fig. 3) integrate this information with feedback from pulmonary stretch receptors. Respiratory premotor neurons in the medulla (C, and see Fig. 5) give rise to descending axons that innervate inspiratory motoneurons in the cervical spinal cord (D – phrenic nucleus, E – phrenic nerve) and thoracic spinal cord (F) that innervate the inspiratory pump muscles. The latter include the diaphragm (G) and external intercostal muscles (F). From Cajal SR 1897–1899. **Anatomy and Function in the Respiratory Network. Figure 2** Diagram of respiratory circuits and their output to expiratory muscles. This diagram, initially intended to illustrate anatomical circuits involved in coughing and vomiting, also provides an overview of the respiratory motor output via expiratory pump muscles. Airway receptors (A – larynx) and pulmonary stretch receptors (see Fig. 1) provide afferents to the nucleus of the solitary tract (M) which relays this information to respiratory circuits in the medulla (D) and pons (see Fig. 3). The latter circuits provide afferents to spinal projecting expiratory premotor neurons in the medulla (D and Fig. 5) controlling the rhythm and pattern of activity on their axons which terminate on thoracic motoneurons innervating expiratory pump muscles, including abdominal (K) and internal intercostal muscles (E). From Cajal SR 1897–1899. "Textura del sistema nervioso del hombre y de los vertebrados," copyright Herederos de Santiago Ramón y Cajal. [English Transl Pasik P & Pasik T, 1999–2002 with the kind permission of Maria Angeles Ramón y Cajal.

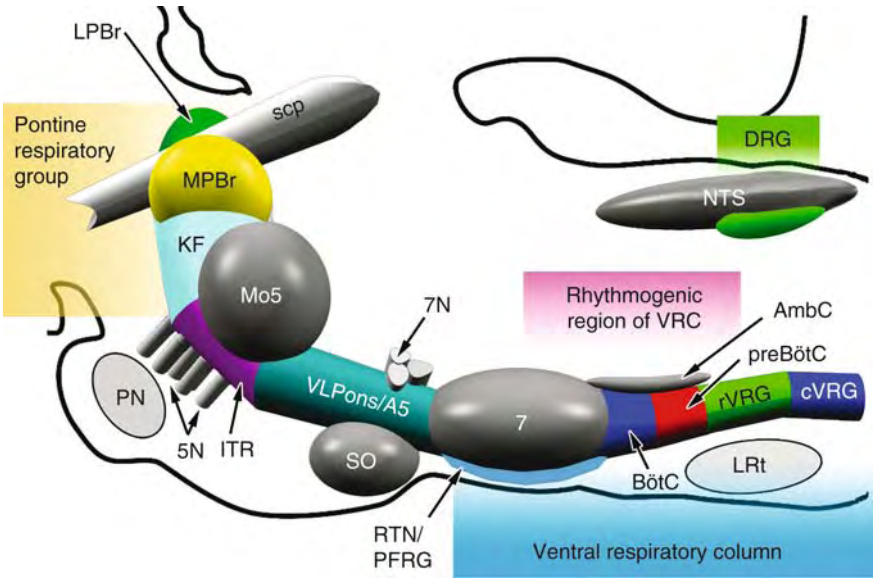
neurons of vagal respiratory afferent information with the central detection of $CO_2$ levels, and the control of brainstem premotor neurons. (iii) The latter innervate spinal motoneurons in the phrenic nucleus and thoracic spinal cord that activate the inspiratory pump muscles (i.e., the diaphragm and external intercostal muscles), and (iv) innervate motoneurons in the thoracic spinal cord that activate the expiratory pump muscles (i.e., internal intercostal and abdominal muscles). Over the past century physiological and anatomical research has resulted in considerable elaboration of this basic outline, including the identification of multiple compartments within the brainstem whose coordinated activity precisely controls breathing.

### Brainstem Respiratory Neurons

Neurons demonstrating bursts of action potentials phase-locked to the respiratory cycle, and dependant on a centrally generated respiratory rhythm are operationally defined as "respiratory neurons." These are distinguished from non-phasic firing respiratory related neurons, such as neurons in chemosensory pathways providing tonic inputs to respiratory neurons.

Not surprisingly, rhomencephalic respiratory neurons tend to fire in phase with either the inspiratory or expiratory phase of the respiratory cycle. Prominent brainstem collections of respiratory neurons are concentrated in three regions (Fig. 3). The first is located dorsally within the medulla in ventrolateral portions of the NTS and was accordingly designated the "dorsal respiratory group" (DRG). A second region, in the dorsolateral pons in and around the complex formed by the parabrachial and Kölliker-Fuse nuclei, was originally termed the "pontine pneumotaxic region," but more recently, the "pontine respiratory group" (PRG). The third consists of an elongated column of neurons in the ventrolateral medulla which is termed the "ventral respiratory column" (VRC).

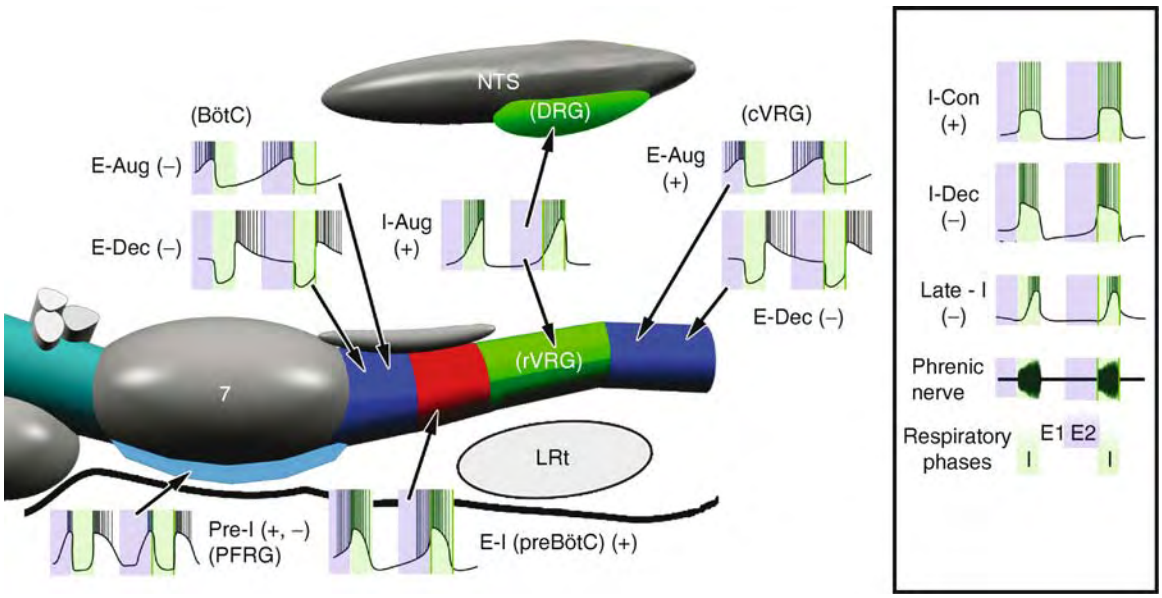
It is argued that three respiratory phases are necessary to characterize the breathing cycle, the inspiratory phase and early and late expiratory phases (Fig. 4). Specifically, activity on the phrenic nerve starts contraction of the diaphragm, expanding the lungs and beginning the inspiratory phase. Following lung inflation, action potentials on the phrenic nerve decline abruptly. At this point, the inherent elastic recoil of the lungs and thorax begin the expiratory phase of respiration. During normal relaxed breathing in humans, expiration generally depends on the passive recoil of the lungs and chest wall with little expiratory muscle contraction (e.g., abdominal and internal intercostal muscles). As the demand for gas exchange increases (for example during running) phasic activation of expiratory muscle activity is recruited. During the early part of expiration, adduction of the larynx slows expiratory airflow. There may also be residual activity on the phrenic nerve. This expiratory activity on a nerve innervating the major inspiratory muscle (the diaphragm) prompted the designation of early expiration as post-inspiration. If activity on expiratory muscles occurs (e.g., abdominal, internal



**Anatomy and Function in the Respiratory Network. Figure 3** Brainstem respiratory neurons and compartments. Respiratory related regions of the rhombencephalon (pons + medulla) are diagrammed by colored coded compartments against a parasagittal section of the rat brain (as viewed from the midline). Nearby landmark structures are shaded in gray. Brainstem respiratory neurons are concentrated in three regions: (i) The dorsal respiratory group (DRG) located in the region of the ventral and ventrolateral subnuclei of the solitary tract, (ii) the pontine respiratory group composed of several subdivisions of the parabrachial complex along with the Kölliker-Fuse nucleus, (iii) the ventral respiratory column (VRC) extending from the level of the facial nucleus caudally to the spinal-medullary junction. The VRC is composed of a serial succession of physiologically distinct compartments (see text) which are responsible for the automatic generation of the respiratory rhythm (particularly in the rostral portions of the VRC, see magenta shaded region) and integrating this rhythm with patterned activity on respiratory spinal-projecting premotor neurons (mainly in caudal portions of the VRC, see text and Fig. 5). The VRC is essentially continuous with the PRG, via respiratory-related neurons located along the boundaries of the facial nucleus that recollect in the ventrolateral pons and continue into the intertrigeminal region (ITR) before merging with the Kölliker-Fuse nucleus (KF). Abbreviations: 5N, trigeminal nerve; 7, facial nucleus; 7N, facial nerve; A5, A5 noradrenergic neurons; Ambc, nucleus ambiguus compact part; Botc, Bötzinger complex; cVRG, caudal part of ventral respiratory group; DRG, dorsal respiratory group; ITR, intertrigeminal region; KF, Kölliker-Fuse nucleus; LPBr, lateral parabrachial area; LRt, lateral reticular nucleus; Mo5, motor trigeminal nucleus; NTS, nucleus of the solitary tract; MPBr, medial parabrachial area; PFRG, parafacial respiratory group; preBötC, preBötzinger complex; pRG, pontine respiratory group; RTN, retrotrapezoid nucleus; VRG, rostral part of ventral respiratory group; PN, basilar pontine nuclei; Scp, superior cerebellar peduncle; SO, superior olive; VLPons, ventrolateral pons; VRC, ventral respiratory column.

intercostal muscles) it is usually most prominent during late expiration. It is notable that the extent to which the expiratory muscles participate in breathing varies considerably across the energy demands of the individual.

Individual respiratory neurons tend to fire with particular phase relationships to the respiratory cycle (Fig. 4), and the firing pattern as well as the synaptic interactions of individual respiratory neurons have been used to infer different functional roles. While a standardized nomenclature has not been agreed upon, the basic types include inspiratory (I) and expiratory (E) neurons as well as phase-spanning neurons whose activity spans the temporal limits between inspiration and expiration. Within the inspiratory or expiratory phase of the respiratory cycle, neurons have been further categorized by their augmenting (Aug), decrementing (Dec), or constant rate (Con) of firing within a specific respiratory phase, and whether the activity of a particular cell occurs in the early or late within the inspiratory or expiratory phase of respiration. Using these qualifications, types of respiratory neurons commonly identified include E-I phase spanning neurons, I-Con, I-Dec, I-Aug, and Late-I neurons, as well as E-Dec (or post-I) and E-Aug neurons. Additionally, a "pre-I" cell type has been described whose activity begins at the end of expiration, is actively inhibited during inspiration, and fires again at the beginning of expiration. The firing patterns of these various types of neurons are generally a result of their circuit interactions within the rhombencephalon



**Anatomy and Function in the Respiratory Network. Figure 4** Medullary respiratory neurons. This figure depicts the activity patterns for a representative sample of respiratory neurons on a parasagittal view of the rat medulla. These neurons are distinguished by the timing of their bursts of action potentials with respect to the inspiratory phase, or with respect to one of the two postulated expiratory phases of the respiratory cycle and the accompanying changes in their membrane potentials, and (when possible) by their axonal projections (see Fig. 5). Most of the respiratory compartments in the VRC are associated with "typical" (but not exclusive) concentrations of particular classes of inspiratory or expiratory neurons; the firing patterns of these neurons are depicted in relation to a sagittal diagram of the VRC and with respect to the DRG. Respiratory neuronal types commonly recorded in the VRC but not readily associated with a particular brainstem compartment are shown in the inset at the right side of the figure along with the "normal" pattern of firing for the phrenic nerve. For all of the respiratory neurons depicted, the inspiratory (I) part of the respiratory cycle is identified by the green shading. The first part of the expiratory phase (E1) is not shaded, while the second part of the expiratory phase (E2) is identified by purple shading. The characteristic excitatory or inhibitory nature of the particular neuronal types is indicated by plus or minus signs. Note that in some instances a single firing pattern may be associated with both inhibitory and excitatory neurons, as is the case for E-Aug neurons in the BötC or cVRG (respectively), or for pre-I neurons in the parafacial region. It should be further noted that the terminology used for respiratory neurons is not entirely uniform between different investigators in this field, and the depicted excitatory and inhibitory bursting patterns do not represent an exhaustive catalog of the possible respiratory neuronal types. Abbreviations: E1, early expiratory phase E2, late expiratory phase; E-Aug, expiratory neurons with an augmenting depolarization strting at the begin of E2; E-Dec, expiratory neurons with a decrementing depolarization pattern beginning in E1; E-I, phase-spanning neurons with a depolarization beginning at the end of E2 and continuing into the inspiratory phase; I, inspiratory phase of respiratory cycle; I-Aug, inspiratory neurons with augmenting depolarization and firing pattern; I-Con, inspiratory neurons with a constant deploarization; I-Dec, inspiratory neurons with decrementing depolarization; Late-I, inspiratory neurons depolarizing at later portion of inspiratory phase; Pre-I neurons, phase spanning neurons characterized by depolarization begining in E2, which are then actively inhibited during inspiration, and subsequently depolarized at the beginning of E1; (other abbreviations as in Figure 3).

and particularly within the medulla. Ultimately, the pattern of activity at motoneurons giving rise to nerves innervating the airways and pump muscles reflects premotor input to these motoneurons from various combinations of brainstem respiratory neurons.

### *The Nucleus of the Solitary Tract*

The NTS is compartmented and multifunctional, relaying visceral information from various peripheral organs relevant to physiological homeostasis and central reflexes. Afferents arising from the lung and airways as well as arterial chemoreceptors (carotid and aortic bodies) travel mainly in the vagus and glossopharyngeal nerves, and target neurons in caudal aspects of the NTS. Relative to breathing, pulmonary stretch receptors monitor the level of inflation of the lungs and via inhibitory second order NTS neurons increasingly inhibit inspiration as maximal lung volume is reached. Receptors in the airways additionally detect irritants, and their afferents to the NTS initiate protective reflexes

such as a cough or sneeze. Peripheral chemoreceptors for breathing are located mainly in the carotid body. They are activated by decreases in $PO_2$ or pH or an increase in $PCO_2$ of arterial blood and generally facilitate respiration during developing hypoxia or hypercapnia. Evidence suggests that a subset of neurons in the NTS also functions as central chemosensors for $CO_2$/pH. The targets of NTS second or higher order sensory relay neurons are predominantly within the VRC and the pontine respiratory group; a subset of these targets includes direct synapses on cranial motoneurons within the region of the VRC. Thus the respiratory related elements of the NTS function as sensory relays, as chemosensors, and as premotor neurons. The topography of respiratory related afferents to the NTS and the central reflexes they serve are discussed in greater detail elsewhere in this volume (*McCrimmon and Alheid, respiratory reflexes*).

## Populations of Respiratory Neurons

### *Dorsal Respiratory Group (DRG; Fig. 3)*

The dorsal respiratory group is comprised of "respiratory neurons" (predominantly inspiratory) located mainly in the ventral and ventrolateral NTS. These neurons receive a central respiratory drive that persists in the absence of peripheral afferent input. Interestingly, although they receive vagal and glossopharyngeal afferent input, they do not appear to be required for the production of peripheral reflexes which are relayed largely through neurons in other NTS subregions. Particularly in the cat, significant numbers of these DRG neurons are premotor with terminations in the phrenic nucleus, including monosynaptic input to phrenic motoneurons.

### *The Ventral Respiratory Column (VRC; Fig. 3)*

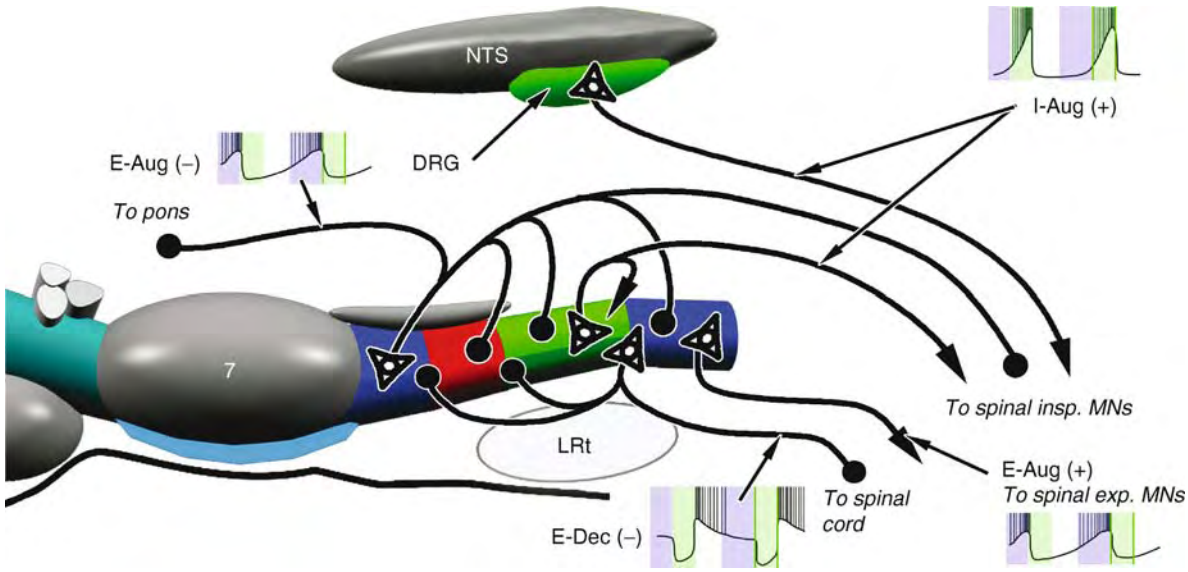
The VRC refers to a succession of six contiguous but physiologically distinctive collections of respiratory neurons in the ventrolateral medulla. This includes the principal neuronal circuits responsible for the intrinsic generation of respiratory rhythm, and for the pattern of respiratory activity on nerves innervating the muscles of the airways as well as on nerves innervating the pump muscles. In the caudal half of the VRC, premotor neurons for spinal respiratory motoneurons are concentrated within a region termed the "ventral respiratory group" (VRG). The VRG is divided into rostral (rVRG) and caudal (cVRG) components reflecting a predominance of inspiratory neurons rostrally and expiratory neurons caudally. The rVRG and cVRG represent the main foci of excitatory (glutamatergic) bulbospinal inspiratory (augmenting; I-Aug) and expiratory (Augmenting; E-Aug) neurons (respectively). They provide the alternating (phasic) central drive mainly responsible for determining the pattern of activity for spinal motoneurons of the respiratory pump muscles (Fig. 5). At least within the bulbospinal inspiratory neurons of the rVRG, enkephalin appears to be a co-transmitter with glutamate. Neurons in rVRG and cVRG appear to integrate afferents arising from second- or higher-order sensory relay neurons in the NTS as well as from respiratory-related neurons located throughout the ventrolateral medulla and pons (Figs. 6 and 7).

In the rostral half of the VRC, four additional concentrations of respiratory neurons have been identified, each with a distinctive physiological profile. From caudal to rostral, these include the pre-Bötzinger complex (preBötC), the Bötzinger complex (BötC), the retrotrapezoid nucleus (RTN) and the parafacial respiratory group (PFRG). At the most rostral end of the VRC, RTN neurons appear to be chemosensory, increasing their firing rate in proportion to central CO2 (or inversely proportional to pH) and activating respiratory neurons in the other VRC compartments. The remaining three anterior VRC compartments (PFRG, BötC, preBötC) appear to play a significant role in respiratory rhythm generation. In contrast, spinal premotor neurons in the posterior part of the VRC (rVRG, cVRG) provide the major source of rhythmic excitatory input to pump muscle motoneurons in the spinal cord but do not appear to contribute to the generation of respiratory rhythm. Chemical blockade in the cVRG, for example, blocks respiratory activity at abdominal muscles but does not change the respiratory rate measured on the phrenic nerve. It should be noted, however, that the transition between anterior rhythmogenic and posterior spinal premotor portions of the VRC is not abrupt. This may reflect the fact that the respiratory neuronal types (Fig. 4), characterizing a particular VRC region have distributions whose tails overlap with those of neuronal types typifying adjacent compartments.

### *The Retrotrapezoid Nucleus (and Central Chemosensitive Brainstem Regions)*

The RTN consists of a narrow layer of chemoresponsive neurons located near the surface of the brainstem ventral to the facial nucleus (Figs. 3 and 8). Specifically, hypercapnic solutions or acidification of these superficial regions, cause increased firing of glutamatergic neurons that project widely to medullary and pontine areas related to breathing, resulting in increased ventilation. RTN neurons also increase their firing in response to stimulation of peripheral chemoreceptors. This is consistent with the presence of excitatory projections from the commissural NTS, which is the primary target region of peripheral chemoreceptor afferent neurons. Consequently, it has been argued that the RTN integrates peripheral and central chemoreceptor information and provides a drive to respiratory circuits.

In addition to the RTN several other chemosensitive brainstem regions have been identified, including the preBötC, the caudal raphe nuclei (raphe magnus,



**Anatomy and Function in the Respiratory Network. Figure 5** Bulbospinal respiratory neurons. This parasagittal diagram of the rat medulla depicts various types of respiratory neurons in the VRC and DRG that provide the spinal premotor input that ultimately determines the activity of the respiratory pump muscles. Some of the neurons sending axons to the spinal cord also provide collaterals to the VRC; for I-Aug neurons in the rVRG (see Fig. 3), some of these collaterals appear to target other inspiratory bulbospinal neurons ipsilaterally or contralaterally, while other collaterals of I-Aug neurons appear to target cranial motoneurons (e.g., laryngeal, hypoglossal motoneurons). Also notable is the difference between E-Aug neurons that in the cVRG are excitatory (glutamatergic) and do not have medullary collaterals compared to E-Aug neurons in the BötC which are largely inhibitory and project extensively throughout the VRC and in some instances also send ascending axons to the pons. For the depicted E-Aug and E-Dec neurons the diagram is a summary of the axon collaterals since the individual neurons do not necessarily reach every potential target of these populations. Finally, many neurons in the NTS relay respiratory related afferents to the VRC and pons; these are not shown here but are depicted elsewhere in this volume (*McCrimmon & Alheid, Respiratory Reflexes*). For abbreviations see legends for Figures 3 and 4.

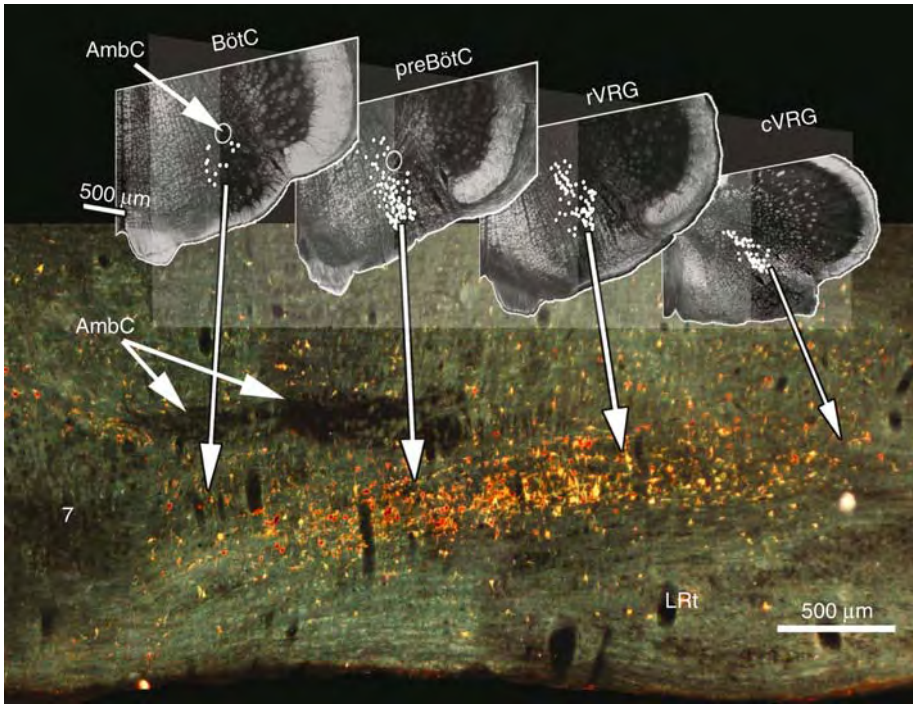
pallidus, and obscurus), the locus coeruleus, the fastigial nucleus of the cerebellum, as well as a subset of NTS neurons (Fig. 8). The occurrence of multiple chemosensitive brainstem sites related to brainstem respiratory circuits may reflect alternative redundant systems for this important function.

Attention has also been focused on the chemosensory role of neurons in the caudal raphe nuclei (raphe magnus, raphe pallidus, and raphe obscurus), by clinical pathology relating aberrations in serotonergic neurons and serotonergic receptors at the ventromedial surface of the brain (in the medullary arcuate nucleus of human brains), to sudden infant death syndrome (SIDS). The caudal raphe nuclei have a diffuse system of projections including the brainstem and spinal cord, and descending serotonergic projections appear to be important both for the tonic activation of motoneurons and for the modulation of sensory afferents. Serotonergic neurons appear to be chemosensitive and are activated by increasing $CO_2$/decreasing pH when tested using cultured neurons or brain slices. In addition to their role as potential central chemoreceptors, serotonergic projections to the phrenic nucleus are essential for the occurrence of long-term facilitation to intermittent hypoxia, a model of plasticity in central respiratory circuits.

### The Parafacial Respiratory Group and the RTN

Recently, it has been argued that "pre-I" neurons in the vicinity of the RTN function as an expiratory oscillator complementing an inspiratory oscillator located in the preBötC. *In vitro* imaging experiments of neonatal rat brainstems implicated neurons beneath lateral portions of the facial nucleus in the generation of rhythmic respiratory activity [9]. While not entirely separate topographically from the area normally associated with the RTN the term "parafacial respiratory group" (PFRG) has been used to designate this conceptually distinctive functional group.

The PFRG and preBötC are proposed to operate together as mutually inhibitory, coupled oscillators in the generation of the respiratory rhythm [5]. Data derived from *in vitro* and *in vivo* experiments (mainly on neonatal or juvenile rat brains) suggest that PFRG neurons are capable of generating rhythmic activity on

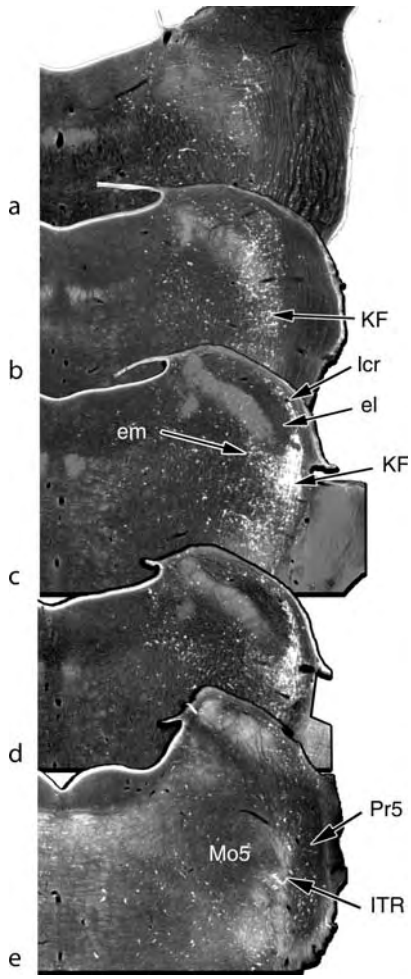


**Anatomy and Function in the Respiratory Network. Figure 6** Retrogradely labeled neurons in the ventral respiratory column of the rat brain. The anatomical location of respiratory neurons in the VRC is depicted after an injection of a retrograde tracer (FluoroGold) in the contralateral rVRG of two brains, one sectioned in the coronal plane (shown in perspective in the upper sections) and one in the parasagittal plane (lower section). Note that retrograde labeling is lighter in the RTN and in the BötC than in the more caudal portions of the VRC since the former regions have projections that preferentially target the ipsilateral side of the medulla. The parasagittal plane depicted is at the lateral level of the compact division of the nucleus ambiguus. This is indicated in the upper (coronal) sections by the parasagittal cutting plane indicated in light gray. In the coronal sections the location of the FluoroGold fluorescent labeling is identified by white dots mapped against darkfield images of the same sections in which the fluorescent cells were observed. In the lower parasagittal section, the Fluorogold labeling was enhanced by detection with an antibody to FluoroGold and a subsequent immunoperoxidase reaction to label the neurons with polymerized diaminobenzidine (DAB). (*Color version of monochrome figure published in Alheid et al., J Neurocytol 31:693–717, 2002, with kind permission from Springer Science and Business Media*). For abbreviations see legends for Figures 3 and 4.

the nerves innervating expiratory pump muscles, even following pharmacological blockade of neuronal activity in the preBötC. Based on *in vitro* experiments the PFRG appears to include both excitatory and inhibitory pre-I neurons. It is not at present clear whether some of the neurons comprising the PFRG are coincident with those cells serving chemosensory functions in the region of the RTN. The latter, however, appear to be exclusively excitatory (glutamatergic). It is also the case that for the adult brainstem, a clear physiological description of PFRG neurons functioning as an expiratory oscillator is still lacking. The concept of a brainstem expiratory oscillator has broad implications for the studies in the neurobiology of breathing. These have been addressed in the context of the evolution of vertebrate respiratory circuits and with respect to the pre- and post-natal developmental course of respiratory circuits [4]. Consequently, the topic of the PFRG and its persistence in the adult brainstem remains topics under intense scrutiny.

### *The Bötzinger Complex*

The BötC is located in the ventrolateral medulla immediately caudal to the facial nucleus (Fig. 3), and is identified physiologically by its content of expiratory, and mainly inhibitory (glycinergic) neurons (Fig. 4; augmenting or decrementing; E-Aug or E-Dec neurons). These projects widely to other respiratory related regions of the brainstem, and a subset of these neurons also provides descending projections to the spinal cord, including terminations in the phrenic nucleus (Figs. 1 and 5). BötC neurons (together with other inhibitory



**Anatomy and Function in the Respiratory Network. Figure 7** The anatomical distribution in the rat brain of pontine neurons projecting to the VRC shown in coronal sections. Neurons were retrogradely labeled after a tracer (FluoroGold) injected in the ipsilateral rVRG. A, the most rostral section in the series, is located at the mesencephalic-pontine border. The labeling of the neurons was enhanced by immunodetection and conversion to DAB. The darkfield images of the labeled sections were combined with inverted brightfield images of the densely DAB labeled neurons. (*From Jiang et al., Respir Physiol Neurobiol 143:215–233, 2004, with permission from Elsevier*). Abbreviations: DAB, diaminobenzidine; em, external medial subnucleus of the lateral parabrachial complex; el, external lateral subnucleus of the lateral parabrachial complex; Icr, lateral crescent subnucleus of the lateral parabrachial complex; PrS, principal (sensory) trigeminal nucleus; For other abbreviations see legends for Figures 4 and 5.

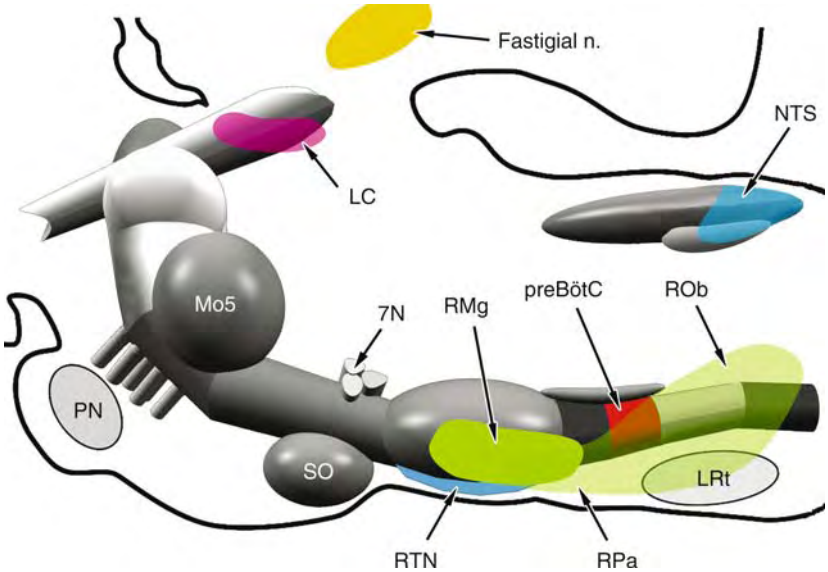
expiratory neurons scattered throughout the VRC) presumably account for the pronounced phasic inhibition of inspiratory neurons in the brainstem and spinal cord during the expiratory phase of breathing.

### The PreBötzinger Complex

Interposed between the BötC and the rVRG is the preBötC; this compact region contains excitatory phase-spanning neurons [10] essential for the generation of the respiratory rhythm, and particularly for the expression of rhythmic inspiratory activity. Even when isolated *in vitro* from the remainder of the medulla, neurons in the preBötC are capable of sustaining an inspiratory-like rhythmic bursting activity [5]. The latter derives mainly from excitatory local circuits within the preBötC since its oscillating activity persists after blockade of inhibitory transmitters. Compared to other portions of the VRC the preBötC appears to be distinguished by a particular set of neurons having an expiratory-inspiratory (E-I) pattern of activity, which use glutamate as a transmitter, and which express neurokinin-1 (substance P) and μ-opioid receptors. Recent observations in the rat indicate that somatostatin is also present in relatively high concentrations within preBötC neurons and is a likely co-transmitter with glutamate; somatostatin containing neurons are, however, not confined to the preBötC in this area of the medulla. The preBötC has widespread projections to other ipsilateral and contralateral brainstem respiratory regions, but at least in the rat characteristically lacks neurons with spinal projections.

### The Ventral Respiratory Column and Nucleus Ambiguous

Intermingled with or adjacent to VRC neurons are the cranial motoneurons in the dorsal portions of nucleus ambiguus (Fig. 9 and [2]). These include motoneurons of the larynx, pharynx, and esophagus. The activity of these motoneurons is not uniquely tied to respiration and serves a variety of additional behaviors including feeding, drinking, vomiting, and vocalizations. These types of homeostatic, protective, and social orofacial behaviors are served by neural networks in the forebrain and brainstem that are, to some extent, distinct from one another, and from the brainstem circuits underlying rhythmic respiratory activity. Nonetheless, these behaviors are often multiplexed with ongoing respiratory activity at the level of relevant cranial motoneurons. In fact, phasic respiratory activity is generally present on the cranial nerves innervating the airways, such as those supplied by pharyngeal and laryngeal motoneurons. Respiratory activity is also evident on subsets of motoneurons outside of nucleus ambiguus such as in the trigeminal, facial, and hypoglossal nuclei. Accordingly, axon collaterals from subsets of respiratory neurons in the VRC (including both propriobulbar and bulbospinal neurons) contribute premotor input to airway cranial motoneurons. Such connections have been shown for inspiratory bulbospinal neurons in the rVRG which also elaborate axon collaterals locally within the medulla. Similarly, expiratory neurons in the cVRG provide ascending axons that



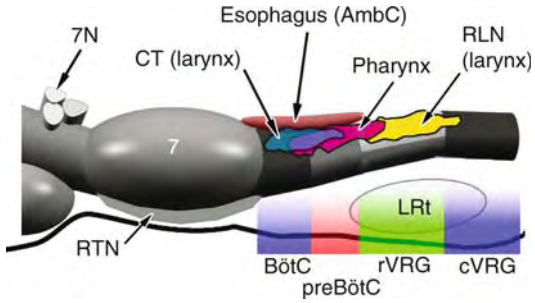
**Anatomy and Function in the Respiratory Network. Figure 8** Chemosensitive regions of the rhombencephalon. A parasagittal view of central chemosensitive regions depicted in color against brainstem regions (gray) related to breathing (see Fig. 3). Chemosensitive regions are identified by neurons with relatively early responses to hypercapnia (excess $CO_2$) or the accompanying low pH levels. Relative to breathing, a number of candidate regions have been identified in the rhombencephalon that both show chemosensitivity and are interconnected with brainstem or spinal areas involved in respiration. These are the fastigial nucleus (one of the efferent nuclei of the cerebellum), the locus coeruleus (LC; which projects widely throughout the forebrain, brainstem, and spinal cord, the retrotrapezoid nucleus (RTN), the preBötzinger complex (preBötC), the nucleus of the solitary tract (NTS, see text), and the caudal raphe nuclei (RMg, raphe magnus, RPa, raphe pallidus; ROb, raphe obscurus) For other abbreviations see legends for Figures 4 and 5.

innervate laryngeal and pharyngeal motoneurons; such projections may be of particular significance for vocalizations rather than for other laryngeal reflexes, since the latter appear to survive pharmacological inactivation of the cVRG while vocalizations (and the accompanying laryngeal activation) elicited by electrical stimulation of the midbrain periaqueductal gray do not.

In addition to its role in the expiratory phase of respiration, the cVRG, or as it is alternatively termed, "the retroambiguus nucleus," is identified as an important medullary focus for vocalizations, controlling a significant part of the activity of laryngeal muscles necessary for vocalizations, as well as providing for the activation of abdominal expiratory muscles. Abdominal muscles are involved in a variety of non-respiratory behaviors including vomiting, postural adjustments, and reproductive behaviors such as lordosis, all of which may access abdominal premotor neurons in the cVRG/retroambiguus region. The cVRG is consequently a particularly striking example of a respiratory compartment that is multiplexed with other behaviors. Whether individual cVRG neurons are recruited for multiple functions or whether distinct subgroups of these neurons are specialized for different behaviors is not entirely clear. Populations of "silent" neurons that are only activated under specific functional demands have been observed in cVRG, while some cVRG neurons with axons reaching the lower segments of the lumbar spinal cord demonstrate expiratory rhythmicity despite the absence of potential motoneuron targets serving respiration.

### *Pontine Respiratory-Related Circuits*

The brainstem column of neurons related to respiration does not end abruptly with the VRC at the facial nucleus. Neurons related to the control of breathing and connected with the VRC or with airway motoneurons in nucleus ambiguus are scattered around the margins of the facial nucleus, and continue rostral to it, forming an attenuated but essentially continuous and interconnected column in the lateral pons (Fig. 3 and [1]). At its rostral end this column expands into the larger aggregate of neurons in the region of the parabrachial and Kölliker-Fuse nuclei (Fig. 7). As with the VRC, respiratory-related neurons in the lateral pons do not appear to represent a functionally homogeneous column, but may be tentatively divided into distinct compartments. These include the ventrolateral pons/A5 region, the inter-trigeminal region, the Kölliker-Fuse nucleus, and medial and lateral nuclei of the parabrachial complex. As mentioned earlier, respiratory neurons in the parabrachial complex and Kölliker-Fuse nucleus together comprise the area designated as the pontine respiratory group.



**Anatomy and Function in the Respiratory Network.**
**Figure 9** Nucleus ambiguus cranial motoneurons and the ventral respiratory column. This figure depicts the topography of cranial motoneurons of the upper airways and esophagus (colored polygons; *based on Fig. 9 in* [2]) located in the dorsal portions of nucleus ambiguus and overlapping with the VRC (gray, also see Fig. 3). In addition to spinal motoneurons controlling the pump muscles (see Figs. 1, 2 and 5) the respiratory circuits of the VRC provide afferents to cranial motoneurons of the upper airways. These motoneurons, however, are also activated in a variety of other behaviors (see text) and are not exclusively controlled by the circuits controlling the rhythm and pattern of breathing. The subdivisions of the VRC are indicated by the labeled colored bands. Abbreviations: CT, motoneurons projecting to the crico-thyroid muscles of the larynx; RLN, motoneurons projecting to the larynx via the recurrent laryngeal nerve. For other abbreviations see legends for Figures 4 and 5.

### *Ventrolateral Pons/A5 Region*

At pontine levels just rostral to the facial nucleus is an area variously referred to as the A5 region and/or the ventrolateral pons (Fig. 3). The A5 noradrenergic cell group is located within the ventrolateral pons near the ventral surface of the brain. A5 neurons are reported to project to the adjacent facial nucleus and to ventrolateral medulla, but also send axons terminating throughout much of the spinal cord including terminations at sympathetic preganglionic neurons in the intermediolateral column of the spinal cord. It is important to note that the major proportion of neurons projecting to the VRC from the ventrolateral pons is not catecholaminergic. A specific role of the ventrolateral pons/A5 region in breathing has not been determined in any detail. Electrical or chemical (glutamatergic) stimulation in this region facilitates expiration (i.e., lengthens expiration time while reducing respiratory frequency). It has additionally been reported that the ventrolateral pons may be a necessary relay for a similar facilitation of expiration evoked by stimulation in the medial parabrachial region.

The ventrolateral pons has also been identified as an important area for vocalizations [7] and some of the interactions of the ventrolateral pons with the respiratory circuits in the VRC presumably reflect this function. It is argued that neurons in the ventrolateral pontine reticular formation are necessary for the organization of specific voluntary vocalizations (as opposed to emotional vocalizations), particularly including those sets of vocalizations requiring integration with auditory feedback. Consistent with this interpretation, some neurons in the ventrolateral pontine reticular formation both demonstrate a respiratory rhythm and receive auditory input.

### *The Intertrigeminal Area*

Rostrally and dorsally, the ventrolateral pons merges with the intertrigeminal region (ITR; Figs. 3 and 7). This region consists of neurons located between the pontine principal (sensory) trigeminal nucleus and the motor trigeminal nucleus. Apneas appear to be readily elicited from the ITR with low doses of glutamatergic stimulation. The relevance of this observation for normal breathing is not entirely clear, but are potentially related to upper airway protective reflexes.

### *The Pontine Respiratory Group*

Neurons in the parabrachial complex and Kölliker-Fuse nucleus are included within the pontine respiratory group (PRG). This region of the pons includes significant populations of respiratory neurons and is designated as the pontine respiratory group. Compared to the on–off firing pattern of most VRC neurons, the PRG has a larger percentage of neurons with tonic activity that is phasically modulated by the respiratory cycle.

### *The Kölliker-Fuse Nucleus*

The Kölliker-Fuse nucleus is an ill-defined but fairly large aggregate of neurons located at the rostral and lateral boundaries of the pons (Figs. 3 and 7). The Kölliker-Fuse nucleus has the largest aggregate of neurons extrinsic to the medulla that project to the VRC; it densely innervates every compartment of the VRC. Targets include bulbospinal neurons in the rVRG, cranial motoneurons in the ambiguus and hypoglossal nuclei, and phrenic motoneurons in the spinal cord. Despite the extensive knowledge about the circuitry of the Kölliker-Fuse nucleus, its specific functional role remains unclear. It has been suggested that the Kölliker-Fuse nucleus is part of the network coordinating orofacial and/or airway protective reflexes.

### The Parabrachial Complex

The parabrachial complex is composed of several functionally distinct subnuclei characterized by extensive and topographically specific reciprocal connections

with the NTS, as well as providing diverse (and to some extent reciprocated) efferents to the rhombencephalon and basal forebrain. The parabrachial complex surrounds the axons in the superior cerebellar peduncle (a.k.a. "brachium conjunctivum") as they exit the deep cerebellar nuclei. At its ventral limits the parabrachial complex merges with the dorsal portions of the Kölliker-Fuse nucleus. Only a subset of the multiple compartments that make up the parabrachial complex appear to be directly related to breathing. Based on retrograde labeling, these particularly include the lateral crescent subnucleus, the external medial subnucleus, and rostral portions of the external lateral subnucleus (Fig. 7). Only scattered neurons in the more dorsal parts of the medial parabrachial complex appear to directly target the VRC, and similarly there is only a dispersed field of VRC projecting neurons in the subcoeruleus region located just medial to the medial parabrachial complex and ventral to the locus coeruleus. Projections from the medial parabrachial region may also reach the VRC via relays in the ventrolateral pons.

The parabrachial complex plays a significant role in relaying viscerosensory information (a substantial portion of which originates in the NTS) via ascending axons, to the thalamus, hypothalamus, and basal forebrain. Nociceptive afferents also reach the parabrachial region directly from the spinal cord and from the sensory trigeminal nuclei. Via descending projections, the parabrachial complex in part reciprocates the projections it receives from the NTS but also targets neurons in the caudal pontine reticular formation (medially and laterally), and sends projections to the ventrolateral medulla. Via these descending projections, the parabrachial region appears to function as a relay integrating visceral reflexes with descending forebrain afferents. Together these forebrain afferents and the substantial parabrachial projections to the brainstem form part of the emotional motor system. The latter is responsible for evoking the involuntary motor and visceral responses that accompany strong emotions.

Differential effects on breathing follow stimulation in the medial vs. lateral parabrachial nuclei. When stimulated, the lateral part of the parabrachial complex appears to provide a facilitation of inspiration. In contrast, stimulation in the medial parabrachial region (and to some extent in the adjacent dorsal portions of the Kölliker-Fuse nucleus) leads to a facilitation of expiration. Facilitation of breathing during locomotion, or in response to painful stimuli, appears to involve relays in the lateral part of the parabrachial complex. One parabrachial region that appears to be involved in these responses is the lateral crescent, which receives direct projections relevant to painful stimuli from the dorsal horn of the spinal cord and which sends projections directly to the VRC.

### *Periaqueductal Gray*

Neurons surrounding the central canal in the mesencephalon play an important role as a relay to motor areas of the brainstem for a variety of behaviors originating in the forebrain. These include emotional vocalizations, reproductive reflexes, orienting responses, as well an antinociceptive role presumably related to facilitating adaptive responses in spite of bodily damage. Stimulation in lateral portions of the periaqueductal gray reliably evokes vocalizations that have been related to emotional behavior. Periaqueductal gray neurons directly and indirectly target the VRC and particularly, the cVRG. Respiratory changes occurring during other behaviors such as the orienting response appear to require an obligatory relay from the periaqueductal gray to the parabrachial complex.

### *Higher Order Neurons in the Hypothalamus, Basal Forebrain, and Cortex*

Higher order neurons in the hypothalamus, basal forebrain, and cortex also influence respiration, but with the exception of cortical regions related to vocalizations, most forebrain regions are not exclusively related to breathing. Nonetheless, in addition to vocalizations, the influence of neuroendocrine systems, thermoregulatory systems, locomotor regions, and emotional behaviors on breathing is an important and complex topic. This is, unfortunately, beyond the scope of the present survey of the functional circuitry of respiration.

## Anatomy of Breathing

►Anatomy and Function in the Respiratory Network

## Andersen Syndrome

### Definition

►Familial Periodic Paralyses

## Anencephaly

### Definition

Lack of encephalon resulting from failure of the ►neural tube to close.

►Neural Tube

## Angular Gyrus

### Synonyms

►Gyrus angularis

### Definition

The angular gyrus lies in the parietal lobe, and shaped like an angle, it surrounds the posterior end of the superior temporal sulcus Functionally, it is between the secondary auditory cortex and the area 18. And indeed the angular gyrus does play an important role in linking visual impulses with linguistic concepts. Damage to the angular gyrus causes alexia and agraphia. Those affected are often not able to assign objects they see to specified expressions. Instead of using the correct expression, they engage in circumlocutions in which the expression does not occur.

►Telencephalon

## Angular Momentum

### Definition

In classical (particle) mechanics, the angular momentum of a particle with respect to a point is defined as the cross product of the vector joining this point with the particle times the linear momentum of the particle. In continuum mechanics, the angular momentum density with respect to a point in space is obtained in a similar manner, using the linear momentum density. The total angular momentum is then obtained as the integral over the body of the angular momentum density.

►Mechanics

## Angular Vestibulo-Ocular Reflex (aVOR)

### Definition

The angular or rotational vestibulo ocular reflex (aVOR or rVOR) is the compensatory eye movement generated in response to an angular rotation of the head. The reflex is mediated by semicircular canals and the vestibular nuclei.

►Velocity Storage
►Vestibulo-Ocular Reflexes

## Animal Communication

### Definition

Interaction between two or more animals. A sender encodes and sends out a signal through a channel. A receiver decodes the signals and interprets it. For more information see essay on “Communication in electric fish.”

## Animal Model

### Definition

Species that have been used to study principles of neural and behavioral processing. Synonym: model system. Famous model systems are squids (for the investigation of the mechanisms underlying the action potential), caenorhabditis (genetics), drosophila (genetics), mouse (genetics), bats (biosonar), electric fish (acetylcholine receptor).

## Animat

### Definition

Artificial animal. Robot or computer simulation with sensors, actuators and nervous system that are directly inspired by actual living organisms.

►Computer-Neural Hybrids

## Anisocoria

### Definition

Pupils of unequal diameter. This is generally indicative of disruption of sensory, central, or lower motor neuronal components of the reflex circuitry.

►Neural Regulation of the Pupil

## Anisotropic

### Definition

Not invariant with respect to direction.

►Anisotropy

## Anisotropy

### Definition

Materials that have properties that change as the material is tested in different orientations are called "anisotropic materials." For example, if the uniaxial stress-strain behavior of a material is stiffer in one material direction than another (possibly because there is more collagen laid down in that direction), the material is anisotropic.

## Ankle Strategy

### Definition

A fixed support (feet in place) reaction to anteroposterior postural perturbation where the predominant stabilizing action involves active generation of ankle torque. Also commonly referred to as the "early automatic postural response" (APR).

►Postural Strategies

## Anomalous Monism

### Definition

Anomalous monism is the thesis in the philosophy of mind, formulated by D. Davidson, that every event with a mental description, i.e. a mental event, is also physical, i.e. has a physical description, but no strict, precise and exceptionless laws link the mental and the physical. If there are no psychophysical laws relating events under mental descriptions in terms of "believing/desiring/hoping that snow is white" with events under physical descriptions in terms of, say, oscillatory patterns in the brain, then there can be no conceptual reduction of the mental to the physical. Anomalous monism is a form of monism, because it claims that all events are physical, but it is "anomalous" ("a nomos" – not governed by law), because it denies the possibility of strict psychophysical laws, which would allow conceptual reduction of the mental to the physical. It offers a non-reductive conception of the relation of the mental and the physical, which accepts ontological monism, but preserves the autonomy of the mental with its concepts of belief, desire, reasons and actions.

►Theory Theory (Simulation Theory, Theory of Mind)

## Anomia

### Definition
Word-finding difficulty in naming a picture, object, or definition as well as in spontaneous speech. Anomia is found in various pathological cases resulting from brain damage, such as aphasia, Alzheimer's disease, semantic dementia and herpes simplex virus encephalitis (HSVE or HSE).

►Alzheimer's Disease
►Aphasia
►Verbal Memory

## Anorexia Nervosa

### Definition
Serious loss of appetite. The patient becomes greatly emaciated. Neurobiological risk factors are becoming apparent.

►Neuroendocrinology of Eating Disorders

## Anorgasm

### Definition
Anorgasm refers to difficulty achieving or lack of orgasm.

►Sexual Reflexes

## Anosmia

### Definition
A temporary or permanent lose of the sense of smell, which may be selective to a small number of odorants or affect detection of all odorants. Acute nasal infection can cause temporary loss of smell. Permanent loss often involves neural damage in the olfactory system, for example due to close head injury damaging the olfactory nerve or brain disease.

►Smell Disorders

## Anosognosia

### Definition
Denial or unawareness of one's handicap. After stroke or traumatic brain injury, usually with involvement of the non-dominant hemisphere (right side in 95% of people).

►Stroke

## Anoxic

### Definition
Conditions characterized by the absence of free oxygen.

## Ansa Lenticularis

### Definition
Fiber tract of the subthalamus. The lenticular fasciculus and ansa lenticularis together form the pallidothalamic projection, the biggest efferent of the globus pallidus. The fibers terminate in the ventral lateral thalamic nucleus, which in turn projects to parts of premotor cortex (area 6) and of the supplementary motor area. They arrive at the thalamic nuclei via the thalamic fasciculus.

## Ansa Peduncularis

### Definition
In the ansa peduncularis short tracts project from the amygdaloid body to the hypothalamus and to the medial thalamic nucleus.

## Antagonist Muscle

### Definition
Muscle acting to produce opposite motion or torque at a joint.

►Impedance Control

## Antagonistic Innervation

### Definition

Antagonistic innervation refers to the case in which an organ is controlled by two different kinds of nerves (double innervation), and the effects of nerves on the organ are antagonistic. An example would be the effect of sympathetic innervation of the heart which is facilitatory versus that of parasympathetic innervation is inhibitory.

## Antennal Lobe

### Definition

First central area of the insect olfactory system. This structure receives input from the olfactory nerve in the antennae and projects to the mushroom body. The architecture is very similar to the vertebrate olfactory bulb.

►Olfactory Information

## Anterior Cerebellar Lobe

### Synonyms

►Lobus cerebelli ant; ►Anterior lobe of cerebellum

### Definition

The anterior lobe is the part of the cerebellum rostral to the primary fissure, and is composed of vermis (lingula, central lobule and culmen) as well as hemispheres (quadrangular lobe, anterior part, and ala lobuli centralis). Functionally this subdivision has practically no significance, since the cerebellum evidences a functional arrangement in a vertical direction (vermis, intermediate part, lateral part).

►Cerebellum

## Anterior Cingulate Cortex

### Definition

The anterior cingulate cortex is the area of the cerebral cortex located in the medial wall of the cerebral hemispheres, just above the corpus callosum. The anterior cingulate has a major role in behavioral drive and regulation of affective behavior. It has extensive connections with the prefrontal cortex, amygdala, thalamus, and striatum; receives inputs from pain pathways, and contributes to the corticospinal tract.

## Anterior Column

### Synonyms

►Funiculus ant; ►Anterior funiculus

### Definition

The white mater between anterior median fissure and ventral root forms the anterior column, containing:

- Anterior pyramidal tract
- Medial longitudinal fasciculus

►Medulla Spinalis

## Anterior Commissure

### Synonyms

►Commissura ant.

### Definition

The anterior commissure is a bundle of nerve fibers connecting both hemispheres. It crosses the midline anterior to the third ventricle. The anterior commissure runs between parts of the temporal lobes (e.g. parahippocampal gyrus, amygdala) as well as between olfactory areas of the two hemispheres.

►Telencephalon

## Anterior Commissure, Anterior Limb

### Synonyms

►Commissura ant., pars ant; ►Anterior commissure, anterior part

**Definition**
Very narrow branch of the anterior commissure passing to the anterior perforated substance, where it joins the olfactory tract.

►Diencephalon

## Anterior Commissure, Posterior Limb

**Synonyms**
►Commissura ant., pars post; ►Anterior commissure, Posterior part

**Definition**
Main part of the anterior commissure passing to the frontal portion of the temporal lobe, hippocampus and amygdaloid body.

►Diencephalon

## Anterior Corticospinal Tract

**Synonyms**
►Tractus corticospinalis ant.

## Anterior Forceps

**Synonyms**
►Forceps minor; ►Minor forceps

**Definition**
The commissural fibers running in the splenium of the corpus callosum from the occipital lobe embark on a U-shaped course and are shaped like forceps. They are called the posterior forceps. The anterior forceps is formed from similar U-shaped fibers in the frontal lobe.

►Telencephalon

## Anterior Gray Commissure

**Synonyms**
►Commissura grisea ant.

**Definition**
In the gray commissure, the nuclear regions, more precisely the intermediate substance, of both halves of spinal cord meet each other. Whereas the anterior gray commissure runs ventrally to the central canal, the posterior gray commissure passes dorsally to the spinal canal.

►Medulla Spinalis

## Anterior Group Hox Genes

**Definition**
Hox genes expressed in the anterior region and located toward the 3 end of Hox clusters, this group includes Hoxa1.

►Hox Gene-Related Respiratory Control Disturbance

## Anterior Horn

**Synonyms**
►Cornu ant; ►Anterior horn of the spinal cord

**Definition**
In the anterior horn are situated the large alpha motoneurons which innervate the skeletal muscles. But the gamma motoneurons responsible for innervation of intrafusal fibers are also encountered here. They play an important role in the refinement of muscle-spindle sensitivity. The anterior horn evidences a somatotopic arrangement and has two zones:

- Medial motor cells
- Lateral motor cells

►Medulla Spinalis

## Anterior Hypothalamic Nucleus

### Synonyms

►Nucl. ant. hypothalami; ►Anterior nucleus of hypothalamus

### Definition

The anterior hypothalamic nucleus has myriad diverse afferents, e.g. from the limbic system, other hypothalamic nuclei and the Mesencephalon. Efferents go to the surrounding hypothalamic nuclei, but also to the rhomben-cephalic nuclear regions.

Functionally, the nucleus is involved in regulation of body temperature, respiration and cardiovascular tasks (context: affective defense behavior).

►Diencephalon

## Anterior Limb of Internal Capsule

### Synonyms

►Capsula interna, crus ant; ►Anterior limb of internal capsule

### Definition

The internal capsule features the following pathways: posterior limb of internal capsule:

- Pyramidal tract
- Superior thalamic peduncle
- Posterior thalamic peduncle
- Parietopontine tract
- Corticotegrnental fibers

Anterior limb of internal capsule:

- Frontopontine tract
- Anterior thalamic peduncle

►Telencephalon

## Anterior Lobe of Cerebellum

### Definition

Several classifications are used to subdivide the cerebellum based on anatomical, phylogenetic and functional (i.e. termination of cerebellar afferents and efferents) findings. Anatomically, both sagittal and horizontal subdivisions can be distinguished. The cerebellum consists of two large lateral parts called the hemispheres and a midline structure, the vermis.

The cerebellum is further subdivided into three major horizontal components, the flocculonodular, anterior and posterior lobes, the latter two forming the corpus cerebelli. The anterior lobe is separated from the posterior lobe by the primary fissure and the flocculonodular lobe is separated from the posterior lobe by the posterolateral fissure.

►Posture Role of Cerebellum

## Anterior Lobe of the Hypophysis

### Synonyms

►Adenohypophysis

### Definition

The glandular tissue of the anterior lobes produce gonadotropic hormones that regulate the secretion of peripheral hormone glands (ACTH → NNR hormones, TSH → thoroid gland hormones, inter alia) but also effector hormones that act directly (PRL → mammary gland, FSH → gonads inter alia). Regulation is effected via releasing and release-inhibiting factors secreted by neurons of the hypothalamus (infundibular nucleus) into the portal system of the gland.

►Diencephalon

## Anterior Median Fissure

### Synonyms

►Fissura mediana ant.

### Definition

Fissure in the ventral side of the spinal cord.

►Medulla Spinalis

# Anterior Occipital Sulcus

## Definition

Relatively constant continuation of the preoccipital notch.

The sulcus could be called a "three-lobe corner," since here the occipital lobe, parietal lobe and temporal lobe meet.

►Telencephalon

# Anterior Olfactory Cortex

►Anterior Olfactory Nucleus

# Anterior Olfactory Nucleus

Peter C. Brunjes, Kurt R. Illig
Department of Psychology, University of Virginia
Charlottesville, VA, USA

## Synonyms

Anterior olfactory cortex

## Definition

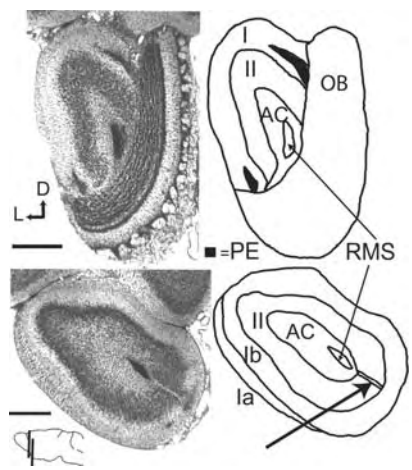
The primary component of the region of the telencephalon located between the olfactory bulb and the ►piriform cortex.

## Characteristics

The olfactory system is highly developed in vertebrates, particularly in "macrosmic" mammals (such as many rodents) where olfaction is the primary sensory system used to navigate in the world. As olfactory ability has evolved, there has been a concurrent increase in the size and complexity of cortical structures dedicated to encoding and deciphering olfactory information (►cortical circuitry). Below is an overview of one of these cortical regions, the ►anterior olfactory nucleus (AON), which plays a central, though largely uncharted role in olfactory information processing [1].

In vertebrates, odor information is transduced by olfactory receptor neurons that line the nasal cavity (or olfactory rosette in fishes). The information is sent via the olfactory nerve (Cranial Nerve I) to the olfactory bulb, an evagination of the ventral forebrain that is the rostral-most portion of the telencephalon and is commonly found just behind (or above) the nasal cavity. The general circuitry of the olfactory bulb is similar to that of the retina in that a) incoming sensory information is parsed into separate data streams, and b) it contains two layers of inhibitory interactions to reinforce the differences between these data channels. Axons of the two major output neurons, the mitral and tufted cells, travel caudally and ventrally in the bulb, coalescing to form the lateral olfactory tract (LOT) that courses along the ventrolateral surface of the forebrain.

The area directly behind the olfactory bulb is often referred to as the ►olfactory peduncle (or retrobulbar area, Fig. 1). The peduncle contains the anterior olfactory nucleus (AON) as well as two other much smaller regions, the *tenia tecta* (or dorsal hippocampal rudiment) and the dorsal penduncular cortex. The olfactory peduncle merges caudally with the ►olfactory tubercle on the medial side and with the piriform cortex laterally. The core of the peduncle is formed by a subependymal layer that is continuous with the rostral extension of the lateral ventricle, and comprises the



**Anterior Olfactory Nucleus. Figure 1** *Left panels*: Photomicrographs of coronal Nissl-stained sections at two levels of the rat olfactory peduncle (Small panel on bottom left shows the approximate location of these two sections). *Right panels*: diagrams of cytoarchitectural features in the left panels. The two top panels show an anterior section that includes *pars externa* (PE). The bottom panels depict a section approximately 600 µm more caudal, where *pars principalis* predominates. Abbreviations: *I* = Layer I of the AON; *Ia, Ib* = sublaminae within Layer I; *II* = Layer II of *pars principalis*; *LOT* = Lateral olfactory tract; *RMS* = Rostral migratory stream; *AC* = Anterior limb of the anterior commissure; *OB* = Olfactory bulb; *D*, *L* = dorsal and lateral. Scale bars = 150 µm.

"rostral migratory stream" that provides new interneurons to the olfactory bulb throughout life. Overlying the rostral migratory stream is the anterior or olfactory limb of the anterior commissure, the source of centrifugal fibers, including some from the medial forebrain bundle, to the region.

## The Anterior Olfactory Nucleus is Comprised of two Separate Structures

The first is a thin ring of cells encircling the rostral end of the olfactory peduncle known as "*pars externa*." *Pars externa* contains large cells with apical dendrites that have long and thin dendritic spines. Evidence gathered from injections of neuronal tracers suggests that there are topographical projections from the olfactory bulb to *pars externa*: cells in the lateral and medial portions of the bulb project to corresponding regions in *pars externa*. No evidence for patterning in the rostral-caudal dimension has been reported. Axons from *pars externa* travel via the anterior commissure to the contralateral olfactory bulb where they synapse in the internal plexiform layer.

The second and largest region, "*pars principalis,*" appears as a two-layered structure in coronal sections from rodents (Fig. 1). The deepest (Layer II) is a thick ring of cell bodies surrounding the anterior limb of the anterior commissure. Many of the resident neurons are similar to neocortical pyramidal cells with a thick apical dendrite, several basal dendrites, and dense dendritic spines. The outer layer has been subdivided into a superficial zone (Layer Ia, which contains the output axons from the olfactory bulb) and a deeper area (Layer Ib) where these axons synapse with the dendrites of Layer II neurons. The subdivisions of Layer I are easily discernable in Nissl-stained sections based on patterns of glial staining.

Since the only landmark in *pars principalis* is a small, cell-free gap in the ventromedial region of Layer II (Fig. 1), most studies divide the region on the basis of the "compass points," yielding *pars dorsalis*, *pars ventralis*, *pars medialis*, *pars lateralis*, and *pars posterioralis* (often combined with *pars ventralis* to form *"pars ventroposterioralis"*). However, since there are few obvious ways to make these subdivisions, the boundaries employed are often arbitrary and exhibit wide variations, leading to considerable confusion [2].

*Pars lateralis* is often defined as the area that lies directly under the major portion of the lateral olfactory tract. Caudally, *pars lateralis* merges with the piriform cortex. The transition occurs with the emergence of a deep polymorphic cell layer (Layer III, the "polymorphic cell zone" of the piriform cortex), and the emergence of the pre-endopiriform and endopiriform nuclei.

*Pars medialis* appears in anterior regions caudal to the remnant of the granule cell layer of the olfactory bulb. In posterior regions the structure is replaced by the ventral tenia tecta. The ventral border of the subregion is the cell-free notch in Layer II, while the dorsal border can be difficult to delineate and is often determined by examining variations in cell size and density.

*Pars dorsalis* is typically defined by exclusion: it is found between *pars lateralis* and *pars medialis* on the dorsal aspect of the AON. The superficial plexiform layer overlying both *pars dorsalis* and *pars medialis* has few myelinated fibers except in the area of transition with *pars lateralis*, reflecting a relatively small innervation by the olfactory bulb. The caudal border of *pars dorsalis* occurs with the emergence of the dorsal peduncular cortex and the transition zone between the AON and the frontal neocortex.

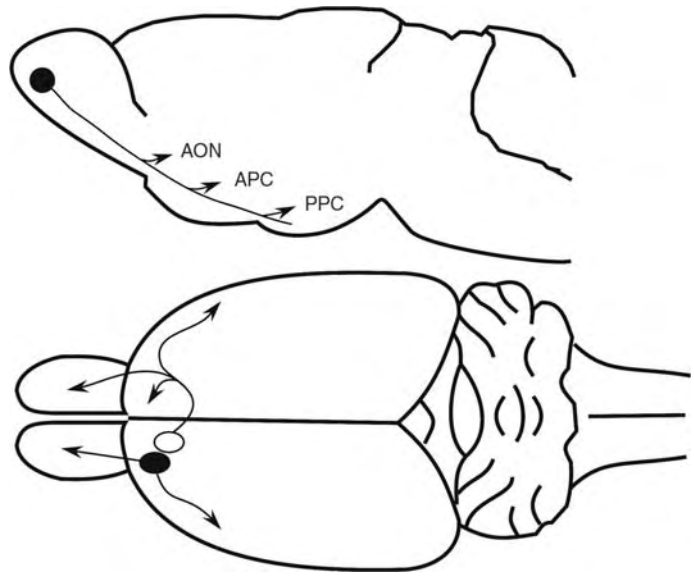
*Pars ventralis* can also be defined by exclusion as the area between *pars lateralis* and *pars medialis* on the ventral surface. It is relatively small, often only slightly larger than *pars medialis* in coronal sections. In caudal areas, *pars ventralis* merges with *pars posterioralis*. In posterior regions this area forms the caudomedial boundary of the AON with the olfactory tubercle.

## Role in the Olfactory Information Processing

The position of the AON in the olfactory circuit suggests that it plays a crucial role in olfactory information flow (Fig. 2). The fact that the region receives a substantial input from the olfactory bulb has been known for a century; indeed, Ramon y Cajal formed his "law of dynamic polarization" (information flows from the axon of one cell to the dendrites of the next) partly by observing the projection of mitral and tufted cell axons onto the dendrites of AON cells. There is a broadly topographical organization in the anterior olfactory peduncle and LOT, with fibers from the dorsal olfactory bulb contacting the dorsal AON, ventral bulb to ventral AON, etc. The LOT continues through the olfactory peduncle to innervate the piriform cortex. The projection appears to be organized in that deep relay cells in the bulb (e.g., mitral cells and the deep tufted cells) send axons all the way to the entorhinal cortex while more superficial tufted cells rarely project caudal to the AON and rostral piriform cortex. Evidence for more specific topographical patterns is difficult to find, indeed, it appears that individual projection neurons innervate broad regions in both the AON and PC.

The AON sends a substantial reciprocal input back to the olfactory bulb. The connections are so widespread that the AON is capable of interacting at nearly every synaptic step in bulb processing. Significant regional differences have been observed these projections. Converging evidence indicates that *pars medialis* fibers are heaviest in the deep granule cell layer of the ipsilateral bulb, while *pars externa* predominately innervates the contralateral internal plexiform layer. The remaining regions have bilateral projections to broader regions.

The AON projects predominantly to the ventromedial portion of anterior piriform cortex (APC), primarily to the region deep to the LOT and extending from the



**Anterior Olfactory Nucleus. Figure 2** Schematic view of a mouse or rat brain from the lateral (*top*) and dorsal (*bottom*) sides. Top panel depicts the trajectory of the lateral olfactory tract, leaving the olfactory bulb (*on left*) and distributing information to the anterior olfactory nucleus *AON*, anterior piriform cortex *APC* and posterior piriform cortex *PPC*. Bottom panel shows the ipsilateral (*bottom*) projections of the AON (to the olfactory bulb and anterior piriform cortex) and contralateral (*top*) projections (to opposite AON, olfactory bulb, and APC).

olfactory tubercle laterally to just beyond the border of the LOT. Axons run primarily in deep Layer Ib, adjacent to the compact cell body layer. A broad topography exists, with the heaviest projections from *pars dorsalis*, *pars lateralis* and *pars ventroposterioralis* going to the dorsolateral, central, and ventromedial APC respectively. There is an abrupt decrease in labeled fibers at the boundary with the posterior piriform cortex.

Back-projections from the piriform cortex to the AON are also complex. The APC projects primarily to *pars lateralis*, with a smaller projection to both *pars dorsalis* and *pars ventroposterioralis*, and maintains the broad medial-to-lateral topography displayed in the projections from AON. Interestingly, connections from PPC to the AON are apparently plentiful to all parts of the AON except for *pars externa*.

While much remains to be learned about the precise nature of the projections into and out of the AON, it is obvious that the region is involved in the feedforward regulation of information passing from the bulb to the anterior piriform cortex, and in the feedback regulation of the return circuit. Further, it regulates information flow between the left and right olfactory bulbs via the anterior commissure, and it serves a similar role in distributing information to the left and right piriform cortices.

## Development

AON neurons in the rat are generated during the last week of embryonic development in two distinct patterns. All divisions exhibit a caudal-to-rostral gradient of neurogenesis similar to that seen in the PC. A second superficial-to-deep gradient is also observed which contrasts with the "inside-out" sequence typical of cortical areas. Patterns of axonal ingrowth from the bulb follow the sequence of cell proliferation. Axonal projections from *pars externa* develop sooner than those from other, deeper AON regions. Similarly, the earliest contralateral projections of *pars lateralis* arise from its caudal- and superficial-most regions, while more rostral, deeper cells send projections 2–3 days later. Finally, three different patterns in the postnatal growth of the subregions of the AON have been reported: a) relatively little expansion (*pars lateralis*), b) moderate growth with overshooting of size and subsequent reduction (*pars medialis*), and c) exuberant growth with subsequent size reduction (*pars dorsalis* and *pars ventroposterior*). Such independent development of the various subregions is compelling evidence that they may serve different functions.

## Anterior Olfactory Nucleus or Anterior Olfactory Cortex?

Several have suggested that the AON would more properly be labeled the anterior ►olfactory cortex. Arguments include the fact that the area is rigidly laminated and populated by pyramidal-shaped cells characteristic of the cerebral cortex, and that it gradually merges with the three-layered piriform cortex. An argument based on functional attributes has been made by Haberly [3], who suggested that the AON shares features with the primary sensory cortices of other

sensory modalities. Haberly split the traditional AON into two functionally distinct areas (the "anterior" and "medial" olfactory cortices), opening the door for further research examining regional differences within the structure. In light of its substantial connections with both the olfactory bulb and the piriform cortex, the AON is likely to play a central role in olfactory information processing; understanding this role will lead to a more complete understanding of vertebrate olfaction.

## Anterior Parolfactory Sulcus

### Synonyms

►Sulcus parolfactorius ant.

### Definition

The subcallosal area is enclosed by the anterior parolfactory sulcus and posterior parolfactory sulcus.

►Telencephalon

## Anterior Peduncle of Thalamus

### Definition

Corticothalamic and thalamocortical fibers together form the thalamic peduncles:

- Anterior peduncle of thalamus: rostral parts of the cerebral cortex and of cingulum
- Inferior peduncle of thalamus: temporal striate cortex, retrosplenial region
- Posterior peduncle of thalamus: occipital lobe without area 17 (striate cortex)
- Superior peduncle of thalamus: precentral gyrus, postcentral gyrus, prefrontal area.

►Diencephalon

## Anterior Perforated Substance

### Synonyms

►Subst. perforata ant.

### Definition

The anterior perforated substance has a typical, perforated appearance and lies beneath the putamen and globus pallidus, at the site where the olfactory bulb divides into the medial stria and lateral stria (olfactory trigone). It passes laterally in the direction of the limen insula and contains various nuclei of the secondary, olfactory area and limbic system.

►Telencephalon

## Anterior Poliomyelitis

### Definition

►Polioencephalitis

## Anterior Pyramidal Tract

### Definition

In the pyramidal decussation 70–90% of the fibers cross to the contralateral side forming the lateral pyramidal tract.

The remaining 10–30% continue their ipsilateral course and descend in the anterior pyramidal tract crossing, however, on entering the gray mater of the spinal cord and innervating also the motoneurons. The tract extends only as far as the cervical cord.

►Nerves

## Anterior Spinocerebellar Tract

### Synonyms
►Tractus spinocerebellum ant

### Definition
This tract conducts proprio- and exteroceptive impulses (skin receptors, muscle spindles, tendon spindles) of the spinal cord (lumbar cord) to the cerebellum without synapsing in the lateral column. They are the only afferent fibers to enter the cerebellum via the superior cerebellar peduncle.

►Cerebellum

## Anterior Thalamic Nucleus

### Synonyms
►Nuclei ant. thalami; ►Anterior nuclei of thalamus

### Definition
This nucleus of the lateral nuclear group is divided into three parts: anteromedial nucleus, anterodorsal nucleus, anteroventral nucleus. Afferents come from the mammillary body, lateral nucleus and the mammillary body, medial nucleus.

In addition, the nucleus has reciprocal connections with the limbic cortex of the cingulate gyrus, the retrosplenial area and the pre- and parasubiculum.

Eunctions in this regions are emotion, motivation and short-term memory.

►Diencephalon

## Anterograde Amnesia

### Definition
New memories are not formed following the incident (e.g., trauma), but events prior to the incident can be remembered.

►Amnesia
►Memory Improvement

## Anterograde Degeneration

### Definition
Anterograde degeneration is the breakdown of fibers (axons) that occurs distal to the point of injury of an axon i.e., away from the cell body. In contrast, retrograde changes take place toward, and can include, the cell body.

## Anterograde Tracing Techniques

### Definition
Neuron tracing techniques take advantage of the fact that axoplasmic transport of materials goes in both directions within the axon. Anterograde transport is away from the cell body, and has fast (400 mm/day) and slow (1–5 mm/day) components that involve the microtubules. Early studies utilized reduced silver techniques or radio autographic methods using labeled amino acids, to outline axons and/or terminals. A variety of immunocytochemical methods are now used to trace and reveal transmitters and other neuron components.

## Anterolateral Column

### Synonyms
►Tractus anterolat; ►Anterolateral tract

### Definition
The white mater between the ventral root and dorsal root gives rise to the lateral column, containing:

1. anterolateral column with
   - anterolateral fasciculus
   - parts of the anterior spinocerebellar tract.
2. posterolateral column with
   - posterior spinocerebellar tract
   - parts of the anterior spinocerebellar tract
   - lateral pyramidal tract.

►Medulla Spinalis

## Anterolateral Fasciculus

### Synonyms

►Lemniscus spinalis; ►Spinal lemniscus

### Definition

Somatotopically organized column of the spinal cord containing somatosensory afferents in the direction of the brain. The following tracts course in this column:

- Spinotectal tract
- Spinothalamic tract
- Spino-anular tract
- Spino-olivary tract

►Medulla Spinalis

## Anterolateral Tract (Pain & Temp Pathway)

►Anterolateral column

►Tractus anterolat.

The fibers in this pathway originate from neuron cell bodies in the dorsal gray of the spinal cord, cross the midline in the anterior commissure at their level of origin, and ascend the spinal cord in its anterolateral quadrant. A portion of the tract, the spinothalamic fibers, ends in the thalamus. Many of the ascending anterolateral quadrant fibers end in the brainstem reticular formation.

## Anti-aliasing Filter

### Definition

A filter placed before a sampling element, designed to prevent frequency components higher than half the sampling frequency entering the sampler. Such frequency components would be incorrectly sampled according to the Nyquist sampling theorem.

►Nyquist Sampling Theorem
►Signals and Systems

## Anti-amnesic Agents

### Definition

Agents that reverse or ameliorate amnesia.

►Memory Improvement

## Anticipatory Motor Action

### Definition

Skilled action requires that we predict the sensory consequences of our actions, since the sensory signals conveying information about the world and our body are processed too slowly to allow fast, skilled movements.

For example in rapidly reaching for an object, we estimate the distance between our hand and the object and, in an anticipatory, feed-forward manner, compute the time at which we need to activate the appropriate muscles to brake the movement at the proper point in space.

## Anticipatory Postural Adjustment (APA)

### Definition

A predictive motor response that acts to counter, in a preemptive manner, the postural destabilization associated with a forthcoming movement. For forward and backward stepping movements, the APA acts to propel the center of mass of the body toward the stance limb prior to the lifting of the swing foot, so as to counter the tendency of the body to fall laterally toward the unsupported side during the swing phase.

►Anticipatory Postural Responses

# Anticipatory Postural Responses

Marjorie Woollacott
Department of Human Physiology, University of Oregon, Eugene, OR, USA

## Synonyms

Feedforward postural control; Preparatory postural adjustments

## Definition

►Anticipatory postural adjustments are defined as the activation of postural muscles in a feedforward manner before a voluntary movement begins, in anticipation of the destabilizing forces caused by the movement.

## Characteristics

Investigation of the characteristics of anticipatory postural adjustments was initiated in the 1960s, when researchers in Russia studied the way humans control posture to steady the execution of tasks. This original research showed that when a standing human is asked to raise one arm, postural (leg and trunk) muscles were activated both before and after the activation of the prime mover (arm) muscles. The first part of the postural activity was in preparation for the movement, to compensate in advance for the destabilizing effects of the movement. In this case, leg and trunk muscles were activated more than 50 ms in advance of the prime mover arm muscles. Thus, anticipatory postural adjustments are activated in a feedforward manner, in anticipation of any sensory feedback associated with potential postural instability related to the movement. In addition, the postural muscles were activated after the arm muscles in a feedback manner to stabilize the body further [1,2].

When specific muscle synergies were identified as basic units of reactive postural control, a study was performed to determine if the same muscle synergies used in feedback postural control were also used during anticipatory postural adjustments. Cordo and Nashner [3] asked subjects to perform a task that required anticipatory postural adjustments (pushing or pulling on a handle while standing in a reaction time task) and measured the muscle response organization of the postural muscles activated in advance of the arm muscles (biceps or triceps). Results showed that the very similar postural response synergies used to react to external perturbations to balance control were activated as anticipatory synergies, before the arm flexion or extension movements. Thus, when a participant pulled on the handle in front of him/her, first the gastrocnemius, hamstrings and trunk extensor muscles were activated, followed by the prime mover the biceps.

To determine the extent to which anticipatory postural synergies adapt to the initial support conditions, researchers compared anticipatory postural responses under two conditions. In the first condition, subjects were asked to stand without additional support, as described above. In the second condition, subjects leaned forward against a horizontal bar at chest height, thus eliminating the efficacy of postural muscle activation in the legs. The research showed that anticipatory postural muscle responses in the legs were reduced or disappeared when subjects were supported. In addition, the voluntary reaction time latencies in the arm were shorter when subjects did not need anticipatory postural muscles in the legs for stability.

These data suggest that there is a preselection of an anticipatory postural muscle synergy associated with each voluntary movement task, as a function of the synergy's contribution to postural stability. This preselection or tuning of sensorimotor systems in anticipation of tasks is often described as "central set." ►*Central set* is defined as a state of the nervous system readiness that is influenced or determined by the context of a task [4]. In the experiment described above, the subject's leaning against a horizontal bar changed the context under which balance would occur during the arm movement task. As a result of the change in context, there was an associated change in central set. A different set of anticipatory postural muscles was selected in advance of the movement, based on their ability to contribute to balance under the new task conditions [5,6].

Anticipatory adjustments are usually discussed in relation to tasks in which postural muscles are activated in advance of prime mover muscles; however, anticipatory control based on central set is also used when postural adjustments to balance threats are scaled in amplitude according to the expected perturbation velocity or size. Experiments designed to test the effect of expectation on postural response characteristics used three platform perturbation contexts: (i) serial versus random conditions, (ii) expected versus unexpected conditions and (iii) practiced versus unpracticed conditions. Results showed that expectation contributed to the modulation of the amplitude of postural responses, with participants giving hypermetric responses when they expected a larger perturbation than they received and hypometric responses when they expected a smaller one. There was also a practice effect, with a reduction in postural response magnitude and in the amplitude of antagonist muscle responses with repeated trials. However, central set did not affect EMG onset latencies. The authors noted that when different perturbations were presented in random order, all scaling disappeared. Results that suggest that scaling

of postural responses is based on prediction of what is needed in a specific context [7,8].

Anticipatory postural adjustments are also used in arm movements in which one arm serves a postural role (holding an object) and the second arm is the prime mover manipulating the object. In experiments examining anticipatory postural adjustments in this context, a 1 kg weight was lifted from the subject's forearm either by the subject or the experimenter. Results indicated that when the subject actively unloaded the arm, there was preparatory biceps muscle inhibition to keep the arm from moving upward during unloading. There was also a coupling between the anticipatory reduction in the biceps EMG of the arm holding the object and the onset of contraction of the biceps of the lifting arm. This inhibition of the biceps activity was not found in the condition in which the experimenter lifted the object (passive unloading) [9].

Animal experiments have been performed to examine the neural circuitry contributing to these anticipatory adjustments [10]. Cats were trained to perform a leg-lifting task that required them to activate postural muscles simultaneously in the other three legs when they lifted the initial leg. Researchers found direct stimulation of the motor cortex or the red nucleus in the area of the forelimb flexors could also produce the leg-lifting movement. When the cortex or red nucleus was stimulated, the leg-lifting movement was accompanied by a postural adjustment in the other limbs, initiated in an anticipatory or feedforward manner. This has led to the hypothesis that postural adjustments are organized at the bulbospinal level and that the pyramidal tract activates these postural response centers as it sends descending commands to the prime mover muscles. In addition to the basic control of postural adjustments occurring at this level, there is also modulation of these responses by other neural subsystems, including the cerebellum.

# Anticonvulsants

Tim A. Benke
Pediatrics, Neurology, Pharmacology and Neuroscience Program, University of Colorado Health Sciences Center, The Children's Hospital, Aurora, CO, USA

## Synonyms

Anti-seizure medicine; Anti-epileptic medicine

## Definition

Anticonvulsants are medicines used to stop seizures or prevent recurrent seizures in ►epilepsy. Currently, none of the anticonvulsants are known to actually be anti-epileptic in that they do not prevent or cure epilepsy.

## Characteristics

### Overview

Anticonvulsants are medicines used to stop seizures or prevent recurrent seizures in epilepsy. A single ►seizure may affect 2–4% of the entire population, while recurrent unprovoked seizures or epilepsy may affect 0.5% [1]. Seizures and epilepsy have many causes and are discussed in detail elsewhere, however particular anticonvulsants are often more suited to a particular type of epilepsy. According to the International League Against Epilepsy (http://www.ilae-epilepsy.org/), these types are broadly broken down into (i) localization related epilepsy (LRE), (ii) generalized epilepsy, which includes absence epilepsy (GE), (iii) undetermined focal or generalized epilepsy (UE) which includes some

forms of myoclonic epilepsy and (iv) situation-related syndromes. Seizures due to situation-related syndromes (fever, infection, etc) are treated in concert with their underlying cause. Approximately 25% of patients have medically refractory epilepsy that does not respond favorably to two or more medications. Treatment decisions, consequences of seizures, and specific management of seizures and epilepsy are addressed in numerous texts.

A variety of conditions have been treated by anticonvulsant drugs. These have included ►neuropathic pain, migraine, ►movement disorders, sleep disorders and ►mood and anxiety disorders.

## Causes of Seizures and the Basis of Drug Design

Seizures are caused by imbalances between excitation and inhibition in the normal pattern of communication between neurons in the central nervous system. The imbalances lead to abnormal, repetitive discharges that are often sustained by the underlying neuronal circuitry. Typically, the circuit re-excites itself leading to the sustained, repetitive discharges that are the hallmark of seizures. Due to their innate recurrent circuitry, certain regions of the central nervous system are more prone to seizures, such as the ►hippocampus. Abnormal formation of recurrent circuitry due to developmental or other causes can also underlie seizures and epilepsy.

Neuronal communication happens through a combination of electrical and chemical signaling. Communication along a neuron is electrical while communication between neurons is mostly chemical. Neurotransmitters mediate the chemical communication between neurons and ►gap junctions mediate electrical transmission between neurons. Proteins that mediate the various means of communication are the molecular targets of anticonvulsants. The mechanisms of neuronal communication and the networks that sub-serve them are under the control of developmental as well as environmental influences. Thus, the molecular targets of anticonvulsants vary according to developmental and environmental influences. Achieving the balance of preventing abnormal and preserving normal communication is the ultimate goal of anticonvulsant drug design.

Most anticonvulsants interfere with at least one form of neuronal communication [1–3]. Electrical and chemical communication is either depolarizing or excitatory or hyperpolarizing or inhibitory. ►Voltage-gated ion channels are proteins that mediate selective ionic fluxes across the neuronal membrane. These channels open in response to the potential, changing or static, of the neuronal membrane around them. ►Neurotransmitter receptor-channels open in response to the binding of a neurotransmitter. The relative concentration of ions on either side of the membrane, the membrane potential and the relative ion selectivity (e.g., sodium, potassium, calcium, chloride, etc.) of the channel direct the overall net flux of ions across the neuronal membrane according to the ►Goldman–Hodgkin–Katz equation. The net flux of ions through the ►ion channels can result in depolarizing or hyperpolarizing influences that in turn affect neuronal communication.

Neurotransmitter release involves many tightly linked processes. Only specialized structures and regions are involved in neurotransmitter release. Initiation involves either local voltage-gated changes or second messenger systems activated by neurotransmitters themselves. Vesicles, membranous spheres filled with neurotransmitter by pumps within the vesicular membrane, fuse with presynaptic membranes to release neurotransmitter into the ►synaptic cleft that separates the presynaptic neuron from the postsynaptic neuron. Alternatively, neurotransmitters may be directly pumped into the cleft. Neurotransmitters are either enzymatically ►degraded in the cleft or pumped back out of the cleft by ►transporters into the presynaptic terminal, postsynaptic neuron or surrounding ►glial support cells. From there it is either enzymatically broken down, recycled and shuttled across membranes, resynthesized or pumped backed into vesicles.

While each neuronal communication process (e.g., excitation, neurotransmitter release) can be thought of as "generic", these must all be differentiated when considering the effects of anticonvulsants and rational drug development and design. Since most anticonvulsants are unable to differentiate between "good" communication and "abnormal" communication (seizures), side effects are the result. In terms of understanding the different types of seizures, epilepsy and anticonvulsants, it must be kept in mind that specific types of neurons in unique anatomical locations use specific subtypes of channels for each individual process. The few characterized genetic epilepsies occur through single gene (often ion channel) defects and therefore rational drug design should seek to directly restore, enhance or limit function (depending on loss or gain of function) of the affected ion channel. In principle, this should be considered even in cases of epilepsies caused by multiple genetic defects.

The ideal anticonvulsant, therefore, should recognize and correct not only specific ion channel dysfunction in a particular brain region, but also recognize that defects are also likely limited to unique aspects of neuronal structure. Neurons are multipolar structures, that is, they have unique compartments designed for unique functions. As part of this, unique subtypes of ion channels are segregated to unique compartments. For example, a particular type of ►voltage-gated potassium channel (hyperpolarizing) may be segregated to dendrites, while another type (also hyperpolarizing but with different voltage-dependent properties and pharmacological sensitivity) may be segregated specifically to presynaptic terminals. Neurons themselves are also

segregated as inhibitory or excitatory, depending on the type of neurotransmitter(s) they may (predominantly) release. Each class of neuron may also express a unique complement of subtyped ion channels.

## Historical Perspectives of Drug Development

Up until recently, the anticonvulsant drugs in use were developed not only before the genetics of epilepsy were imagined but before the nature of neurotransmission itself was understood. As a result, most drugs were discovered through brute force trial and error in animal models. These animal models typically used injected pro-convulsants or direct electrical stimulation. As such, these often did not directly mimic human seizures or epilepsies, occasionally resulting in a mismatch between model and human efficacy. This has been somewhat improved by the use of different animal models of genetic epilepsies [1]. Effective parent compounds (e.g., carbamazepine) have been used as models for later drugs (oxcarbazine) with better side-effect profiles.

As techniques in neuroscience have advanced, for example the development of ►patch-clamp techniques for recording currents through single ion channels in the early 1980s, the mechanisms of anticonvulsant drugs have more recently become better understood. Despite advances in molecular neuroscience, many anticonvulsants are still classed according to the general types of ion channels that are affected. ►Voltage-gated sodium channels (VGSCs) are somewhat broadly categorized while ►voltage-gated calcium channels (VGCCs) are segregated according to their biophysical properties (T, P/Q, N, and L/HVA-type) due in part to the fact that most anticonvulsant drugs do not themselves segregate the different molecular entities of ion channels.

Similarly, as more detailed descriptions of neurotransmission are presented, it has been found that anticonvulsant drugs can affect chemical neurotransmission at all stages of the process from neurotransmitter synthesis, vesicular fusion, neurotransmitter reuptake as well as neurotransmitter receptors themselves. Inhibitory transmission, primarily mediated by ►GABA-A receptors (GABARs), is often enhanced by anticonvulsants while excitatory transmission, primarily mediated by glutamate receptors, is typically reduced. The effects of anticonvulsants on glutamate receptors are pharmacologically divided into ►AMPA-type (GluRs), ►kainate-type (KARs) and ►NMDA-type (NMDARs) primarily because it is still contentious how their molecular diversity equates to their functional and pharmacological diversity. NMDARs and perhaps KARs, due to their ability to flux the second messenger calcium, hold important distinction because of their role in triggering specific forms of synaptic plasticity and thus may play a role in epileptogenesis. Another class of glutamate receptors that is directly linked to second messenger systems, the ►metabotropic glutamate receptors (mGluRs), has not been demonstrated to be a target of currently used anticonvulsant drugs.

Valproic acid has the broadest pharmacological and clinical spectrum of all of the anticonvulsant drugs [2]. Most of its anticonvulsant effects can be attributed to enhancing GABA-mediated inhibitory transmission. Additional effects, which may play a role in its use as a mood altering drug, include inhibiting excitatory transmission. Valproic acid may have antiepileptogenic effects by its effect on DNA binding proteins with subsequent alteration of gene expression.

Adrenocorticotropin and prednisone are frequently used to treat infantile spasms, a form of myoclonic/UE. The mechanisms for these agents are not entirely understood. Vigabatrin is often used to treat infantile spasms caused by ►Tuberous sclerosis; however lack of FDA approval has prevented its use in the United States (Table 1).

## Rational Drug Development

At present, there are three major thrusts in anticonvulsant rational drug design [3,4]. First, the parent structures of anticonvulsants currently in use are being modified to find drugs with improved efficacy and tolerability. This rational has been used in developing many of the drugs in current use. Second, drugs with specific molecular targets that have been suggested either by discovery in the molecular genetics of epilepsy or advances in neuroscience research are being sought, developed and further modified for efficacy and tolerability. Finally, novel anticonvulsant compounds with possible antiepileptic properties are actively sought. Many potential compounds, especially those targeting NMDARs, have been pursued and subsequently abandoned due to lack of efficacy and poor tolerability. GluR antagonists, due to sedation issues, are likely to be more appropriate for ►status epilepticus. Serendipity continues to play a major role as our understanding of neuroscience, seizures, and epilepsy expands (Table 2).

## Future Directions in Drug Development

The fact that 25% of all epilepsies are drug resistant with only 50% of these potentially amenable to surgical treatment (itself with significant cost and morbidity) dictates that further drug development is necessary. Animal studies have suggested several important lines for future development. Group I mGluR agonists or Group II mGluR antagonists are thought to have both anticonvulsant and antiepileptogenic potential [5]. Since these modulatory receptors do not directly participate in fast excitatory synaptic transmission, it is felt that targeting these receptors would be effective with fewer side effects compared to agents that directly modulate GluRs and NMDARs. Similarly, targeting

KARs [6], which to some extent also modulate fast excitatory transmission, holds promise, as has been shown with topiramate that antagonizes KARs [2]. Other receptor systems (amines, peptides, acetylcholine, etc.) have also been suggested as targets [2].

Targeting potassium channels with anticonvulsive agents that augment their function may be helpful, as suggested by the progression of advanced clinical trials with retigabine. Many additional potassium channels other than the KCNQ-type have been proposed. For instance, $I_h$, a potassium channel that modulates dendritic excitability, has been implicated in epilepsy. Long-term alteration of $I_h$, resulting in reduced function of this potassium channel, has been induced by experimental models of seizures and epilepsy [7]. Thus, by attempting to reverse this process, it may be possible to obtain better seizure control as well as reverse epilepsy. It is thought that the primary anticonvulsant mechanism of lamotrigine is to augment $I_h$ function [2]. Recently it has been shown that the ketogenic diet, used to treat medically refractory epilepsy, may augment function of another type of potassium channel that is sensitive to ATP (K-ATP channels) [8].

Agents that do not target ion channels directly but rather accessory proteins that modulate their

| Rufinamide | Triazole | Unknown |

function are also on the horizon. For instance, it has been shown that the direction of chloride flux through GABARs is developmentally regulated by the expression of specific transporters. Targeting transporters with a diuretic to maintain the "correct" direction of chloride flux has been shown in an animal model to attenuate otherwise medically refractory seizures [9]. Furthermore, aberrant expression of transporters has been found in human epileptic tissue, potentially resulting in "wrong-way" chloride fluxes [10]. Thus targeting these transporters with diuretics that can cross the blood-brain barrier would present a novel therapeutic approach. In the end, targeting either the specific enzymes capable of altering ion channel properties (for instance by ►phosphorylation or de-phosphorylation) or the genetic expression of aberrant channels and transporters are likely to be the key to anticonvulsant and antiepileptogenic drugs of the future. For example, the phosphorylation state of $I_h$ is critical in regulating dendritic excitability and preventing this may alter the course of epilepsy. Also, targeting the selective activation of ►kinases and phosphatases that underlie the long-term alteration of excitatory synapses (►synaptic plasticity) in the early stages after a first seizure might prevent epilepsy before abnormal synaptic modifications induced by the seizure become "hard-wired". By targeting these processes early in the course of epilepsy or just after the first seizure, the long-term consequences (of medical refractory epilepsy or learning impairment) could potentially be averted.

# Antidepressants

Cynthia L. Darlington
Department of Pharmacology and Toxicology, School of Medical Sciences, University of Otago Medical School, Dunedin, New Zealand

## Definition

The symptoms of unipolar depression may vary widely between individuals and may include apathy, subdued mood, sadness or sorrow, loss of libido, sleep disturbances, weight loss or gain, and in children and adolescents, irritability. A defining symptom of depression is the loss of self-esteem, for which there may be no apparent explanation. Chronic depression is a debilitating disease that sometimes leads to suicide and is more prevalent in females than in males. In the USA it is the third leading cause of death among people aged 15–24 Years. It is an expensive disease in terms of lost working capacity, increased use of social services and impairment of family and social relationships. Antidepressants are drugs that are used in the treatment of unipolar depression, although they are often used in conjunction with some form of psychological therapy. In addition, some antidepressants are used for certain subtypes of anxiety disorders, such as obsessive compulsive disorder and phobias, as well as neuropathic pain.

## Characteristics

There is a genetic component to unipolar depression in many cases, with an increased incidence of the disease being reported in individuals with first degree relatives who also suffer from depression. In long-term depression, enlarged adrenal and pituitary glands have been observed, as have increased levels of cortisol in the blood, CSF and urine of patients. Elevated levels of corticotrophin releasing factor in the plasma of patients have also been observed. Taken together, these observations indicate constant elevated levels of stress and consistent with long term stress, in some patients, a reduced volume of the hippocampus has been observed.

Depression is attributed to a decreased availability of the biogenic amine neurotransmitters, noradrenaline, serotonin, and to a lesser extent, dopamine [1]. Current strategies in the treatment of depression aim to increase the available amount of these neurotransmitters. There are four main categories of antidepressant drugs: tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors and an "atypical" category that includes dopamine modulating drugs. Interestingly, the different categories of drugs all have a therapeutic lag of 2–3 weeks and a similar efficacy in treating depression. This therapeutic lag presents a problem in the initiation of antidepressant treatment, particularly in patients expressing suicidal ideations. The primary differences between the drugs are in the side effects and a patient's acceptance of a particular drug is often side effect dependent.

### Tricyclic Antidepressants

The first successful antidepressants were the tricyclic antidepressants that became widely available in the 1960s [2]. Tricyclics such as imipramine, clomipramine and amitriptyline, inhibit the reuptake of noradrenaline from the synaptic cleft with moderate selectivity. Most of the drugs in this category have a relative long plasma half-life, and some have active metabolites, that further prolong the drug's action. This prolonged action provides stable levels of the drug in the blood plasma and reduces the occurrence of fluctuating side effects that many patients find annoying. Although newer antidepressants are slowly replacing tricyclics in clinical practice, many prescribers prefer them because their long clinical use has provided evidence for their relative safety and efficacy.

The side effects associated with tricyclics include sedation, postural hypotension and anticholinergic effects including dry mouth, blurred vision and urinary retention. The occurence of postural hypotension is a particular problem for elderly patients and has led to the preferential prescription of SSRIs in this patient population. There are also effects on the cardiovascular system that require consideration. In addition, these drugs can be fatal in overdose and may be contraindicated in patients expressing suicidal ideations. Tricyclic antidepressants generally have interactions with a number of other drugs including alcohol and these drugs are therefore contraindicated in alcoholic patients. Tricyclic antidepressants are included in Category D of the FDA classification of potentially teratogenic drugs. This category includes drugs for which there is evidence of risk in humans, however the benefit of the drug may outweigh the potential risk.

### Selective Serotonin Reuptake Inhibitors (SSRIs)

SSRIs have now overtaken tricyclic antidepressants as the most prescribed drugs for the treatment of unipolar depression [3]. Although they have similar efficacy to tricyclics, SSRIs demonstrate less acute toxicity and less risk of overdose, making them an overall safer choice for the severely depressed patient. SSRIs inhibit the reuptake of serotonin from the synaptic cleft with greater selectivity for serotonin than for noradrenaline. For most SSRIs, the selectivity for

serotonin is a factor of 10 greater than the selectivity of tricyclics for noradrenaline.

The side effects of SSRIs include nausea, insomnia, agitation and sexual dysfunction. For some patients, the experience of sexual dysfunction ultimately leads to dissatisfaction with the drug and a change to a different antidepressant. Although generally safer than tricyclics, there are two drug interactions with SSRIs that raise concern. In an effort to achieve better control of their depression, a number of patients have resorted to self-medication with the herbal remedy, St. John's Wort. St. John's Wort contains significant levels of serotonin and a life threatening "5-HT reaction" has been observed that includes muscular rigidity, hyperthermia and in the most severe cases, cardiovascular collapse. The other interaction is with cannabis, which can cause severe anxiety, panic, hypertension and muscle spasms.

### Monoamine Oxidase Inhibitors (MAOIs)

Monoamine oxidase is the enzyme in the presynaptic terminal that breaks down the aminergic neurotransmitters to allow recycling to their constituents. Inhibition of this breakdown increases the amounts of transmitter available for release into the synaptic cleft. MAOIs were discovered in the late 1950s and originally studied as drugs known to produce mania. These drugs have a number of other effects, including lowering blood pressure, and at one time were used as antihypertensives. Although MAOIs are effective treatments for depression, particularly when it is associated with anxiety and phobias, they are now used primarily when a patient has failed to respond to tricyclics and SSRIs.

There are two subtypes of monoamine oxidase, type A, that breaks down noradrenaline and serotonin, and type B, that breaks down dopamine. The early monoamine oxidase inhibitors were not specific for monoamine oxidase subtypes and, as a result, severe side effects were associated with their use. One of the most dangerous side effects associated with MAOIs was the hypertensive crisis resulting from interactions with tyramine containing foods or with other drugs. Interactions with tyramine containing foods pose the greatest problem for many patients, with banned foods including cheeses, beer, wine, yeast, chocolate and cream. Other common side effects include postural hypotension and sedation or excitation. There is also a severe interaction with tricyclic antidepressants, so that if a patient is changed from a tricyclic to an MAOI, a drug free washout period is necessary.

Newer MAOIs have been synthesized that are specific for monoamine oxidase subtypes. Moclobemide, for example, is selective for type A monoamine oxidase. Moclobemide and similar drugs have side effects similar to tricyclics, although cautions for tyramine containing food still apply. In addition, seizures have been reported to be associated with acute overdose.

### Atypical Antidepressants

This is a mixed category of drugs that has been demonstrated to be effective for the treatment of depression in some cases, and includes trazodone, nefazodone and bupropion. The neuropharmacology of these drugs is less well understood, hence the name "atypicals." One of the major advantages of drugs in this category is that they tend to be safer and better tolerated by patients with fewer, if any, cardiovascular effects. It has been suggested that because of their relative safety, atypical antidepressants should be the first choice for the treatment of unipolar depression in geriatric patients.

Of particular interest in this category is bupropion, a reuptake inhibitor for noradrenaline, serotonin and dopamine. Bupropion is generally well tolerated and in addition to its antidepressant properties, it is also useful in withdrawal from nicotine [4]. Bupropion is not suitable for individuals with seizure disorders or a susceptibility to seizures. It has also been reported to produce mania in some depressed patients.

### Overview

While the immediate effect of antidepressants is to increase the availability of biogenic amines in the synaptic cleft, it is the longer term effects, developing over 2–3 weeks, that are thought to provide the antidepressant effects. The characteristic therapeutic lag associated with these drugs suggests that it is long term changes in receptors and transporters that provide the therapeutic effect. One consequence of this therapeutic lag is that antidepressants cannot be administered acutely "as required." Another consequence is that when the depression has been alleviated, the drug must be withdrawn slowly to allow the receptors or transporters to gradually adapt to a drug-free state.

In cases of severe recurrent depression, where antidepressants alone are not fully effective, administration of lithium has been reported to be an effective supplement to antidepressant treatment [5].

### Bipolar Disorder (Bipolar Depression)

Bipolar disorder is a mood disorder characterized by periods of depression followed by periods of mania or hypomania. Although depression is a significant part of the disorder, treatment with antidepressant drugs is not effective in the manic phase and may indeed exacerbate it. Instead, treatment is required that will stabilize the individual's mood, preventing both the episodes of depression and the episodes of mania [6].

In 1949 lithium was introduced for the treatment of mania but it was not until the 1970s that it became accepted world wide as an effective treatment for bipolar disorder. The effectiveness of lithium in bipolar disorder is interesting because a therapeutic dose has no discernable effect in a person without bipolar disorder. This distinguishes it from other drugs, such as tricyclics, that produce sleepiness when administered to non-depressed individuals. The actions of lithium are not well understood. It is speculated that it may produce its effect by acting upon sodium channels or possibly by inhibiting the release of dopamine and noradrenaline but not serotonin [6].

Although lithium is generally well absorbed after oral administration, absorption is somewhat erratic, with peak plasma levels exceeding the threshold for adverse events. Slow release lithium prevents the early erratic plasma peaks, but may result in later accumulation of the drug resulting in gastrointestinal side effects. Overall, lithium is a difficult drug to use. It has a very low therapeutic index, meaning that the therapeutic dose is in a very narrow margin between the ineffective dose and the toxic dose. Initiation of lithium treatment requires consistent monitoring until steady state plasma levels are achieved. Often the required dose, even for the slow release preparations, is given in divided doses throughout the day to minimize the fluctuating plasma levels. Acute toxic effects of lithium include gastrointestinal disturbances, tremor and sedation. More serious side effects include severe gastrointestinal side effects, coma and even death.

Because of the numerous problems associated with lithium administration, in recent Years there has been a move towards the use of antiepileptic drugs, particularly carbamazepine and valproic acid, for the treatment of bipolar disorder.

Autoimmune disease; Inflammatory response; Self-antigen; Systemic lupus erythematosus; Glutamate receptors

## Definition

Molecular ▶mimicry refers to the similar structures shared by molecules from different genes or different proteins. In autoimmune or infectious disease, molecular mimicry also refers to shared cross reactive epitopes for B- and T-cells with the host. The concept of molecular mimicry evolved from monoclonal antibodies in which mutation analysis led to cross reactive B-cells and T-cells and now to its participation in human diseases.

## Characteristics

### Activation of Cross-Reactive Lymphocytes

The innate immune system, which recognizes shared determinants on microbes, together with general tissue barriers function as an effective first line defense against the world of pathogens while an adaptive immune response with memory function develops. B- and T-cells form the central components of the adaptive immune response; each expresses one of an enormously diverse repertoire of antigen receptors and each is highly selective. The frequency of T- and B-cells expressing any given receptor can increase through clonal expansion or decrease through negative selection, the process of eliminating cells with specificity for self-antigens. B-cells or T-cells that cross-react with both foreign and self antigens may escape tolerance mechanisms because the self-antigen is present in too low a concentration to mediate negative selection, or because the affinity of the antigen for the antigen receptor is below the signaling threshold. If these B-cells and T-cells are initially activated by pathogens that resemble the self antigens, they may subsequently be able to respond to both foreign and self-antigens. In autoimmune-prone individuals, despite the disappearance of the foreign pathogen and the down regulation of the immune response, some degree of

immune activation may persist, sustained by the presence of cross-reacting antigen.

## Antibodies in Diseases without Antecedent Infection; Molecular Mimicry and SLE

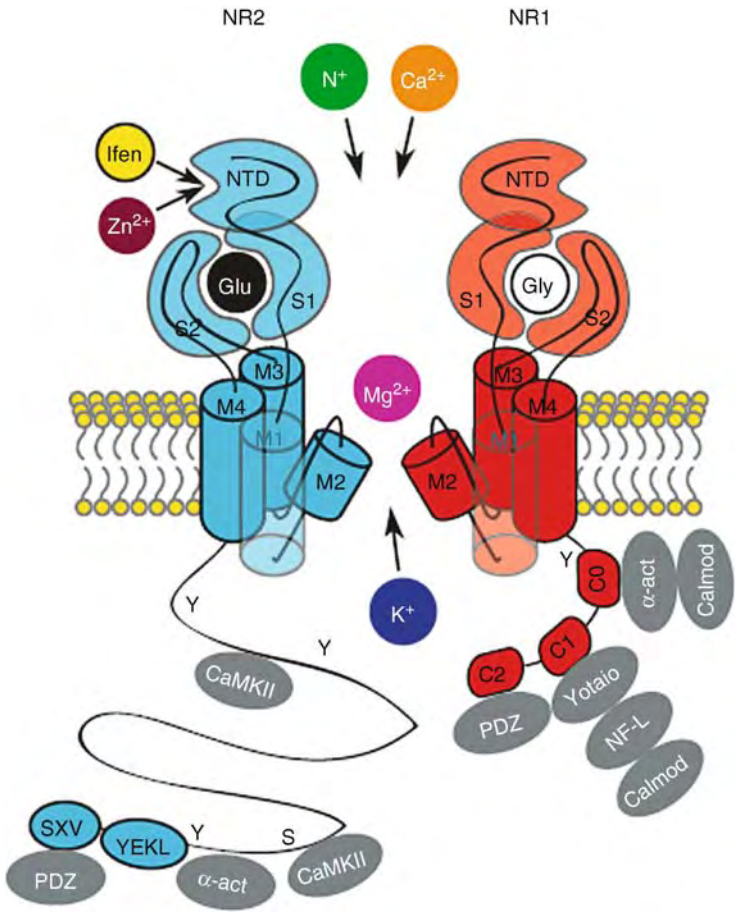
Understanding the antigens involved in molecular mimicry also called antigenic ►cross-reactivity is of some therapeutic importance because knowledge of either the eliciting antigen or a cross-reactive target antigen may suggest interventions that prevent immune activation or organ damage. In this brief discourse, we will discuss only the diseases of the central (CNS) and peripheral (PNS) nervous systems in which one or the other antigen is known, and refer briefly to diseases in which the antigen is suspect. Our focus on cross-reactivity of anti-DNA antibodies in ►systemic lupus erythematosus (SLE) is derived from the observation that an antibody to phosphorylcholine (PC), the dominant epitope in the cell wall polysaccharide of Streptococcus pneumonia (pneumococcus), could acquire a single amino acid substitution and gain reactivity to DNA [1]. This led to an analysis of antibodies produced by splenic B-cells from a patient with lupus who had just received a pneumococcal vaccination prior to splenectomy. Over half of the anti-pneumococcal antibodies cross-reacted with DNA. Similarly, over 40% of B-cells reactive with pneumococcus from mice immunized with PC coupled to a protein carrier cross-reacted with DNA. Normally these B-cells are regulated such that they do not secrete antibody and only B-cells specific for pneumococcus develop into antibody secreting plasma cells. Poor regulation of B-cells activated by microbial antigen may lead to autoantibody production. In fact, anti-DNA antibodies cross-react with many microbial and viral antigens [2]. In order to test whether protein antigens could elicit anti-DNA antibodies in SLE, we used a murine anti-DNA antibody to screen a phage peptide display library, and we found a consensus sequence, D/E W D/E Y S/G, that was bound by this antibody [3]. Immunization with a multimeric form of this consensus sequence induced an antibody response to both peptide and DNA. The peptide motif is present in pneumococcal choline kinase, and also on the extracellular ligand binding domain of the murine and human NR2A and NR2B subunits of the *N*-methyl D-aspartate receptor (NMDAR), a class of receptors activated by the amino acid glutamate.

## Glutamate Receptors

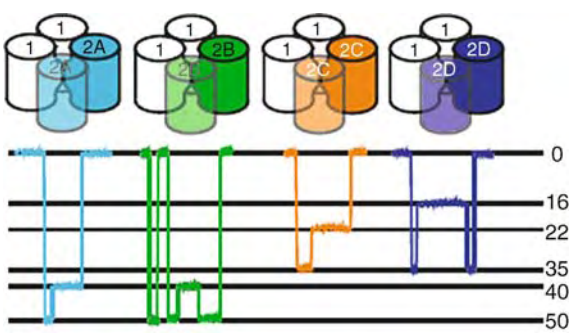
NMDARs are localized within the synapses of the forebrain (see Figs. 1 and 2) [4]. During excitatory synaptic transmission, glutamate is released from presynaptic terminals and binds to receptors on the postsynaptic membrane, resulting in rapid depolarization of the postsynaptic membrane. Growth- and survival-promoting signals derive from synaptic NMDARs enriched with NR2A subunits, especially related to the regulatory role of mitogen-activated protein kinases, and distinct gene expression programs. Conversely, pro-death signals emerge from hypoactivity of synaptic NMDARs or extreme activity of extrasynaptic NMDARs. Pro-death signals are responsible for shutting-down cAMP response element binding protein function and triggering mitochondrial depolarization. The mechanism of cell death is believed to depend on the severity of the insult. Slow apoptotic cell death occurs after a mild (although ultimately toxic) episode of NMDAR activation. Rapid cell death occurs after acutely excessive NMDAR activation, and it is usually referred to as excitotoxicity. This condition is known to occur in several acute diseases (ischemia, trauma, and epileptic seizures).

Because lupus patients in growing numbers suffer from symptoms due to brain dysfunction – disorders of thinking and memory and mood, we tested whether a possible mechanism might depend on antibody-mediated NMDAR dysfunction. In fact, sera and cerebrospinal fluid (CSF) from SLE patients harbor antibodies to DNA that are cross-reactive with NMDARs, and these antibodies can cause apoptosis of neurons [5]. ►Anti-NMDAR antibodies are present in 30–50% of patients with SLE, and may present more frequently in those with cognitive complaints [6]. Furthermore, cross-reactive antibodies are found in the CSF of lupus patients where their presence correlates with symptoms of neuropsychiatric SLE. In one study, the symptoms of brain dysfunction in patients with SLE were improved commensurate with a decrease in the NMDAR antibody in CSF [6]. In mice immunized with multimeric peptide so that there is a high titer of NMDAR antibody that is also DNA reactive, there is no neurological damage unless the blood-brain barrier is breached [7]. Once the antibodies have access to brain, they mediate neuronal death leading to a cognitive or behavioral disturbance depending on the agent used to breach the blood-brain barrier and the site of the neuronal damage [7,8]. The presence in serum and CSF of autoantibody to a defined cell surface antigen that is known to function in neurocognitive processes which are disturbed in clinical disease strongly suggests that NMDAR antibodies may play a role in neuropsychiatric SLE. The development of an animal model in which anti-NMDAR antibodies actually mediate disease increases the potential validity of this mechanism.

As much as animal models can ever mimic human disease, these murine studies demonstrate histopathological and behavioral outcomes consistent with the cognitive and behavioral disorders that occur in SLE. Recently in human post mortem specimen, we were able to identify IgG localized to NMDARs on neurons in the hippocampus. Furthermore, IgG eluted from the



**Anti-DNA Antibodies against Microbial and Non-Nucleic Acid Self-Antigens. Figure 1** (from [4]) The NMDA receptor has conserved domains (S1 and S2) to form the binding site for glutamate (NR2) and for glycine (NR1). The extracellular region can contain modulatory sites that bind $Zn^{++}$ or ifenprodil. The channel lining region, M2, enters the membrane from the intracellular membrane. The ion channel is permable to $Na^{+}$, $K^{+}$, $Ca^{++}$. Extracellular $Mg^{++}$ binds deep in the pore and causes voltage-sensitive block. The C-terminal tail of each subunitbinds to kinases and structural proteins.



**Anti-DNA Antibodies against Microbial and Non-Nucleic Acid Self-Antigens. Figure 2** The NMDA receptor is formed as a tetramer of pairs of NR1 with NR2A, NR2B, NR2C, or NR2D. Each sub-type produces distinct receptor-channel properties. NMDA receptor with NR2A and NR2B subunits produce high conductance states, and those with NR2C and NR2D produce low conductance.

brain of a lupus patient demonstrated neuronal toxicity [9]. Finally, the mechanism of the observed neuron death in peptide immunized mice exposed to blood-brain barrier breaching agents suggests direct antibody toxicity. Preliminary electrophysiological analysis demonstrates that the antibody can act at the NMDAR as a partial agonist. It is noteworthy that there is precedent for antibodies to affect the electrophysiology of neurons without cytotoxicity. Patients with human T-lymphotropic virus type 1 (HTLV-1)-associated myelopathy (also called tropical spastic paraparesis) develop antibodies to heterogeneous nuclear ribonuclear protein-A1 that cross-reacts with HTLV-1-tax (a viral regulatory protein). These antibodies functionally inhibit the firing and amplitude of dopamine and pyramidal neurons in a dose dependent manner [10]. Whether differential binding characteristics of anti-NMDAR antibodies will lead to alternate behavioral and cognitive outcomes, and whether some are more

likely to moderate neuronal function and less likely to mediate toxicity remains to be investigated; nevertheless, this class of NMDAR antibodies may mediate aspects of brain dysfunction in patients with SLE.

### Antibodies in Autoimmune Diseases Lacking Antecedent Infection; Molecular Mimicry and Neuromuscular Disease, Paraneoplastic Syndromes and Encephalitis

The isolation and measurement of antibodies to acetylcholine receptor (AchR) from the serum of patients with myasthenia gravis (MG), led to the detailed description of anti-AchR antibodies, and the identification of antigenic epitopes on each of the two alpha subunits of the receptor and distinct from the acetylcholine binding site. The pathogenic activity of these antibodies has been demonstrated in studies in which adoptive transfer leads to weakness in recipient animals, and studies in which animals immunized with peptide fragments of the human extracellular domain of the alpha-AchR become weak. In MG there is no apparent antecedent infection and the auto-antibodies are currently thought to arise directly in response to the epitopes on the AchR. It is possible that antigen from a possible microbial source activates cross-reactive antibodies. It is even possible that the cross-reactive antibodies are not pathogenic, but that a process called epitope spreading in which a response to one determinant of an antigen (in this case the AchR) spreads to multiple determinants, and stimulates the generation of antibodies that cause the disease.

Other neurological diseases in which there is no antecedent infection or, at best, obscure or controversial prior inflammations include multiple sclerosis and the paraneoplastic disorders. In the paraneoplastic syndrome characterized by cerebellar dysfunction and associated with breast or ovarian cancer, the tumor expresses a protein termed cdr2 antigen that is routinely expressed in Purkinje neurons. The immune response generated against the tumor can also target brain, once the antibody or antigen-specific T- or B-cells traverse the blood-brain barrier to contact brain.

Small cell lung tumors express voltage gated calcium channels; if the immune system makes antibodies that down-regulate these calcium channels and reduce acetylcholine release, the patient develops severe muscle weakness. In yet another paraneoplastic syndrome, small cell lung and breast tumors stimulate the production of antibodies to amphiphysin, a synaptic vesicle associated protein, which result in aching, stiff axial muscles associated with painful spasms. A related antibody-mediated disease that also induces severe muscle stiffness occurs with ►autoantibodies to glutamic acid decarboxylase (GAD), the rate limiting enzyme in the synthesis of the neurotransmitter gamma amino butyric acid. While paraneoplastic syndromes may improve when the tumor load is decreased, the anti-GAD antibody syndrome responds to immunomodulation.

Finally, Rasmussen's encephalitis that causes intractable epilepsy and is often preceded by febrile seizures, although a particular infection has not been identified, appears to be caused by auto-antibodies to the amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptors (AMPARs) which mediate fast excitation, through the influx of sodium into the postsynaptic cell, resulting in rapid depolarization of the postsynaptic membrane. Immunosuppression was shown to be an effective therapy to avoid neurosurgical approaches to epilepsy control, supporting the pathogenic function of the autoantibodies. There is controversy whether the anti-AMPAR antibodies are specific for this disease or are widely present in other forms of epilepsy.

### Antibodies in Autoimmune Diseases With Antecedent Infection; Campylobacter and Autoimmune Polyneuropathy

The Guillain-Barre syndrome is the prototypical post-infectious autoimmune inflammatory polyneuropathy, with or without axon sparing, caused by antibody and complement deposited on Schwann cells and myelin membranes. This disease depends on molecular mimicry between epitopes on bacteria and gangliosides on neurons. It is preceded by an often trivial infection, most commonly a Campylobacter infection, which can last for approximately a month and leaves variable neurological impairment that correlates with the location of antibody deposition and complement-mediated destruction. Prompted by earlier studies of specific T-and B-cell related responses to myelin (the so-called experimental allergic neuritis model), investigators have identified antigenic epitopes in axonal glycolipids specifically recognized by anti-ganglioside antibodies. Gangliosides are enriched in the synapses of neural tissues and bear structural similarities among these and the lipo-oligosaccharides of the Campylobacter jejuni and Hemophilus influenza. When antibody to ganglioside Q1b is abundant, the cranial nerves are involved in the demyelination process (the so-called Miller Fisher variant), thereby providing support for the hypothesis that toxic antibodies cross the blood brain barrier and produce destruction in the central nervous system, as well as the histopathologically verified damage to the peripheral nervous system.

### Antibodies in Autoimmune Diseases With Antecedent Infection; Group A Streptococcus and Movement Disorders

Another infectious agent that stimulates the immune system to generate cross-reactive antibodies is Group A Streptococcus-pyogenes. Antibodies to Streptococcus binding both the streptococcal M protein and cardiac myosin have been implicated in rheumatic heart disease. Cross-reactive antibodies now also appear responsible

for the neurological manifestations. The precipitating infection occurs a week to 6 months prior to the neurological sequela which include the classic movement disorder, chorea, but also include dystonias, tics, hemiballismus, and myoclonus. Recently, antibody derived from a human hybridoma generated from B-cells of a patient who developed chorea after a strep infection was demonstrated to cross-react with mammalian lysoganglioside and *N*-acetyl β D-glucosamine (GlcNAc), which is the dominant epitope of the group A streptococcal carbohydrate. The monoclonal hybridoma derived antibody, as well as acute sera from patients with chorea, induced Ca/calmodulin-dependent protein (CaM) kinase II activation in a human neuroblastoma cell line, and recognized cell surface antigen in a neuroblastoma line and caudate-putamen *in vivo*. On further analysis, the chorea associated antibodies from sera and CSF were demonstrated to cross-react with lysoganglioside GM1 and GLcNAc. Similar to the molecular mimicry that occurs in SLE; antibody-mediated neuron signaling may underlie the pathophysiology of the post-streptococcal neurological disorders.

Molecular mimicry between epitopes on the basal ganglia and Group A Streptococcus-pyogenes carbohydrate has fueled interest in the pediatric clinical disorders in which children have tics or dystonias associated with psychiatric maladies like obsessive compulsive disorder, the so called pediatric autoimmune neuropsychiatric disorders associated with Streptococcal infections. The possibility that there is a pathogenic autoantibody was supported by the felicitous effect of plasma exchange in early studies, but larger trials have been disappointing.

Recently it has been suggested that Parkinsonism, and possibly encephalitis lethargica as well as a wide spectrum of neuropsychiatric syndromes can also be provoked by a prior strep infection. It is not determined whether any of these disorders are caused by antibodies.

## Conclusion

Molecular mimicry is a phenomenon in which antibodies or T-cells cross-react with identical or highly homologous epitopes that are present on both foreign and self-molecules. A "two-hit" model for disease, autoantibody plus breach in blood-brain barrier integrity suggest that to consider a mechanistic role for antibodies in disease requires: a cell surface antigen relevant to disease symptoms; antibodies in serum, and spinal fluid, and target nervous system tissue; the transmission of the disease to animals by human serum; successful treatment of the disease through immunomodulation.

# Antidromic

## Definition

Propagation of action potentials in the direction opposite to the naturally occurring direction.

►Action Potential Propagation

# Antidromic Activation

## Definition

A method for identifying the axon projection target of a single neuron which can also be functionally studied.

An electrode passes a brief current directly activating an axon and resulting in an action potential that

travels "backward" to the cell body. There, it can be recorded using standard extracellular electrophysiological techniques.

The stimulating electrode can be moved to follow the path of the axon and a map of this pathway can be generated. Additional information about the response properties of the recorded neuron can be obtained by applying the appropriate stimuli to the receptive field.

►Extracellular Recording
►Receptive Field

## Anti-epileptic Medicine

►Anticonvulsants

## Antigen Presentation

### Definition

Antigen presentation is a process of antigen peptide fragments bound to MHC molecules on the surface of cells being specifically recognized by T cell surface receptors expressed by T lymphocytes. $CD8^+$ T lymphocytes recognize antigen peptides bound to MHC class I molecules on nucleated cells, while $CD4^+$ T lymphocytes recognize antigen peptides bound to MHC class II molecules on professional antigen presenting cells, such as dendritic cells, B lymphocytes, macrophages and microglia.

►Immune System and Pain

## Antigen-presenting Cell

### Definition

Antigen-presenting cells first take up antigen by pinocytosis or phagocytosis. The antigenic proteins are processed into antigenic peptides and presented on the major histocompatibility complex (MHC) to T cells. T helper cells recognize antigens presented on MHC II and cytotoxic T cells recognize antigens presented on MHC I respectively.

## Anti-GQ1b Antibody

### Definition

## Anti-Motion Sickness Drugs

Arata Horii
Department of Otolaryngology, Osaka University School of Medicine, Suita, Osaka, Japan

### Synonyms

Anti-sea sickness; Car sickness; Air sickness; Space motion sickness; Space adaptation syndrome drugs

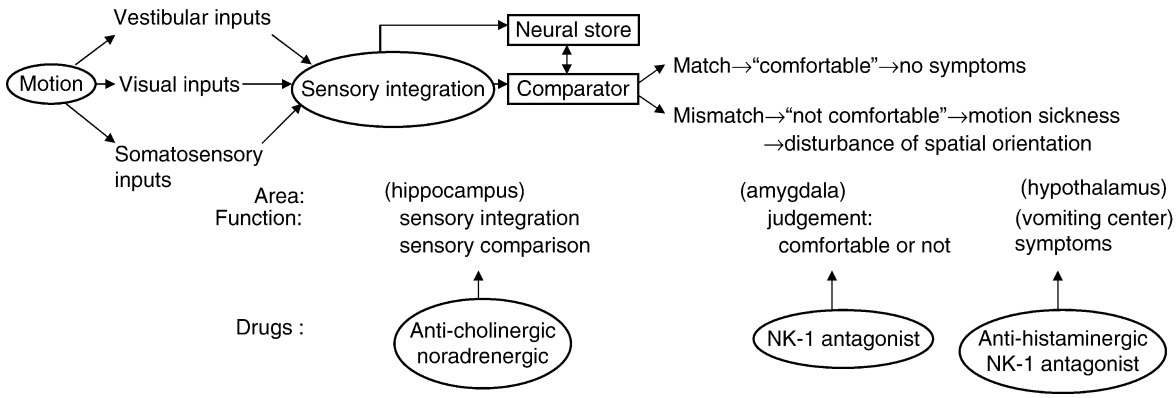
### Definition

Motion sickness is a disorder characterized by nausea, vomiting, pallor, cold sweating, and increased salivation, which occur when exposed to certain types of real or apparent motion. It usually occurs during passive motion stimuli by vehicles, ships, airplanes, however, apparent motion by a simulator or virtual reality can cause the similar symptoms. Anti-motion sickness drugs are used for prevention of motion sickness. There are three types of drugs used for motion sickness: Anti-histaminergic drugs, anti-cholinergic drugs, and adrenergic drugs. Recently, other types of drugs such as anti-neurokinin1 (NK-1) receptor blockers, anti-arginine vasopressin 1 (AVP1) receptor blockers and serotonin (5-HT1A) receptor agonists have been tested for their effectiveness on motion sickness in animals.

### Characteristics

#### Neural Mechanisms of Motion Sickness

Neural mismatch theories for motion sickness are widely accepted [1,2]. According to this theory, ►spatial orientation is disturbed by a conflict between sensory inputs during ongoing motion and the expected pattern of sensory signals established by earlier



**Anti-Motion Sickness Drugs. Figure 1** Neural mechanisms of motion sickness and possible effective sites of anti-motion sickness drugs.

experience. Disturbance of spatial orientation finally causes motion sickness symptoms as a warning signal to withdraw the body from unfamiliar stimulus situations. Main sensory information involving sensory integration and maintenance of spatial orientation are the inputs from vestibular, visual, and somatosensory systems. It should be noted that deafened (and perhaps with no normal vestibular function) patients do but rarely experience motion sickness, probably because there arises fewer mismatch signals from fewer sensory modalities. Fig.1 shows the scheme of neural mechanisms of motion sickness and possible effective sites of anti-motion sickness drugs.

## Classification of Anti-Motion Sickness Drugs by Neural Mismatch Theories

According to the neural mismatch theories of motion sickness, there are three steps from motion perception to motion sickness symptoms: (i) perception of sensory information during motion stimuli, (ii) integration of new sensory information and comparison with stored sensory patterns, and (iii) final development of motion sickness symptoms. Takeda et al. postulated that anti-motion sickness drugs could be also divided into three classes [2]: Class A drug, reduces neural mismatch signals by a blockade of sensory inputs; Class B drug, facilitates the acquisition of habituation to a new pattern of sensory inputs; Class C drug, blocks the development of symptoms. Although each of these drugs could be effective in preventing motion sickness, their effects on habituation to motion stimuli would differ as follows: Class A drugs would retard the acquisition of habituation, because there are no longer new sensory inputs; Class B drugs would accelerate the habituation to motion stimuli; Class C drugs would not affect the habituation. Based on precise studies using a rat animal model of motion sickness, Takeda et al. demonstrated that cholinergic muscarinic receptor blockers and histamine H1 receptor blockers are the Class B and Class C drugs, respectively [2]. Glutamate receptor blockers might be Class A drugs, however, it would be difficult to use Class A drugs in practice, because glutamate receptors are involved in most excitatory synaptic transmission in the brain.

## Central Activation and Inhibition by Peripheral Vestibular Stimulation and Its Relation to Motion Sickness

It has been reported that vestibular information is processed not only in the short brainstem and cerebellar circuits but also in higher center levels in the brain such as the hypothalamus, amygdala and hippocampus. Recent progress in this area could provide further information on neural substrates for motion sickness.

### *Histaminergic Neurons*

Histamine is well known as a chemical mediator of Type I allergy in the peripheral tissue, however, it also acts as a neurotransmitter in the central nervous system. Histaminergic neurons are known to have important roles in arousal, feeding, thermo regulations, circadian rhythms and other autonomic functions. In vivo release of hypothalamic histamine measured by a microdialysis technique was increased by electrical/caloric vestibular stimulation [3] or 2G-hyper gravity stimulation in rats. Histamine H1 blockers are clinically effective in the prevention of motion sickness and it is also demonstrated that H1 blockers prevented the final development of motion sickness symptoms without affecting the habituation process in the rat model of motion sickness (Class C drugs) [2]. The hypothalmus, which contains the histaminergic cell bodies, is the center of autonomic function and the histaminergic neurons project their nerve fibers to brainstem ►vomiting center. Therefore, it is postulated that the histaminergic neurons, which are activated by the vestibular inputs and provocative motion stimuli, would be involved in the final development of motion sickness symptoms.

### Cholinergic Neurons

Several lines of evidence suggest an important role of hippocampal cholinergic neurons in the central processing of vestibular information. For instance, spontaneous firings of neurons in the CA1 area of hippocampus are increased by the electrical stimulation of the vestibular nuclei and firing properties of place cells in the rat hippocampus, which fire only when an animal locates at a specific area in the space, was disturbed in rats that received bilateral vestibular deafferentation. The hipoccampus is an area with many converging sensory inputs and therefore it would suit the hypothesis that the hippocampus acts as a neural store and a comparator in the neural mismatch model of motion sickness. Moreover, acetylcholine release from the hippocampus was increased by vestibular stimulation in rats [4] and anti-muscarinic drugs facilitated the habituation to motion in the rat animal model of motion sickness (Class B drugs) [2]. All these findings suggest that the integrated sensory signals would be compared with the stored patterns of sensory signals in the hippocampus and muscarinic blockers would facilitates the adaptation to the new sensory signals.

### Noradrenaline Neurons

Catecholamine releasers such as amphetamine and ephedrine are effective in preventing motion sickness, although addiction is a big problem for their clinical use. It is well known that a high degree of emotional or physical stress, which activates the noradrenergic neuron system, can prevent motion sickness. Therefore, these drugs would increase an arousal state and thus prevent motion sickness. In turn, it is reported that caloric vestibular stimulation decreases the spontaneous firing of Locus Coeruleus (LC) neurons, which is the largest nucleus of noradrenergic neurons. This might account for the drowsiness seen in motion sickness.

### Serotonergic Neurons

Serotonin 5-HT1A agonists are used clinically for anxiety disorders and have also been shown to prevent motion sickness in animals [5,6], although their effects have not been tested on humans. 5-HT1A receptors are located on both the pre-synaptic and post-synaptic sites. Pre-synaptic 5-HT1A receptors are the autoreceptors, whose activation decreases the release of serotonin from nerve terminals. Although the precise mechanisms of 5-HT1A agonists in preventing motion sickness are not clear, depletion of serotonin by the serotonin synthesis inhibitor parachlorophenylalanine was not effective against motion sickness, suggesting that active sites for 5-HT1A agonists for motion sickness may not be the pre-synaptic autoreceptors. A 5-HT1A agonist would affect any post-synaptic receptors among the neural circuit responsible for motion sickness. For instance, the firing of vestibular nuclei neurons was negatively regulated by a 5-HT1A agonist [7]. Serotonin 5-HT3 receptor blockers are used for emesis induced by anti-cancer drugs, however, they are not effective for emesis associated with motion sickness.

### Substance P Neurons

Substance P and its receptor neurokinin-1 (NK-1) function not only in peripheral tissue but also in the central nervous system. NK-1 receptor blockers were developed as anti-depressants and as anti-emetic drugs. Animal studies demonstrated their efficacy in the prevention of motion sickness [8]. Because these drugs are effective on emesis induced by both motion stimuli and emetic chemical agents, their effective site would be the brainstem vomiting center, which is the final common structure responsible for the emetic reflex. We reported that substance P mRNA was increased by 2G hypergravity stimulation in the amygdala and NK-1 receptor blockers were effective in preventing motion sickness in rats [9]. The Amygdala substance P neuron system is important for the judgment of whether the situation is "comfortable" or not. We hypothesized that neural mismatch signals from hippocampus might be sent to the amygdala and are then judged as to whether they are comfortable or not. If the signals are not "comfortable" for the body, they are sent to areas relating to the expression of motion sickness symptoms, working as warming signals. NK-1 receptor blockers may affect both the brainstem vomiting center and the amygdala.

### Vasopressin Neurons

Vasopressin is a pituitary hormone which has an antidiuretic effect. Intra venous application of vasopressin induces emesis and arginine vasopressin 1 (AVP-1) blockers are effective in the prevention of motion sickness. Moreover, plasma vasopressin levels were increased by electrical/caloric vestibular stimulation in rats [10]. Therefore, AVP-1 blockers are expected to be effective on motion sickness and have been tested by several researchers. However, the effects of AVP-1 receptor blockers on motion sickness are different between species [6].

## Anti-NMDAR Antibodies

### Definition

NMDA (N-methyl D-aspartate) receptor (NMDAR) antibodies. Antibodies to a protein molecule on the neuronal surface that bind to glutamate, a neurotransmitter that participates in excitatory neurotransmission.

Activation of NMDARs is important for learning and memory; overactivation of NMDARs injures the cell.

►NMDA Receptors

## Antinociception

►Analgesia

## Antinodes

### Definition

A point, line, or surface of a standing wave in which some characteristic of the wave field is maximal.

►Acoustics

## Antipsychotic Drugs

Robert Miller, Honorary Fellow
Department of Anatomy and Structural Biology, University of Otago, Dunedin, New Zealand

### Synonyms

Neuroleptic drug; Major tranquilizer; Ataractic drug

### Definition

Antipsychotic drugs are medications use to treat the state of mental turmoil called "►psychosis".

### Characteristics

#### History

Antipsychotic drugs were discovered in 1952. A drug-development program by the French pharmaceutical company Rhône-Poulenc, primarily aimed at finding medications to alleviate post-operative shock, produced the agent chlorpromazine ("Largactil"). This was found to produce a remarkable calming effect on patients to whom it was given, and it was suggested that it be used to "tranquilize" disturbed patients in psychiatric hospitals. It was found to be effective in reducing symptoms of psychosis. However, right from its earliest use, it was found also to produce major motor side effects, reminiscent of symptoms of ►Parkinson's disease. Further pharmaceutical research soon produced a variety of other medications with similar effects. The combination of their two effects (antipsychotic main effects and motor side effects) led to this group of drugs being called "►neuroleptic drugs".

##### *Antipsychotic Drugs and the Dopamine Hypothesis of Psychosis*

Research in the early 1960s led to the proposal by Carlsson that the common property of antipsychotic drugs was that they are antagonists of the forebrain neurotransmitter dopamine, a deficit of which had also recently been found to underlie many of the symptoms of Parkinson's disease. This led to formulation of the so-called "►dopamine hypothesis of ►schizophrenia".

However, this was always a misnomer: The phrase "dopamine hypothesis of psychosis" would have been more accurate, since the neuroleptic drugs do not alleviate many of the non-psychotic symptoms of schizophrenia. Even some of the distinctive apparently-psychotic symptoms of schizophrenia (auditory verbal ►hallucinations, and the group of symptoms described by Kurt Schneider [see "►passivity experience"]) can often persist despite otherwise effective antipsychotic drug treatment.

The birth of the "dopamine hypothesis" has led to many attempts to reveal directly an overactivity of dopamine in the forebrain of persons in active psychotic states. One line of enquiry has sought an excess of dopamine receptors associated with schizophrenia. Although much evidence for such an excess has been obtained, it has been difficult to show that this is really a feature of the illness, rather than a by-product of antipsychotic drug treatment, and there is no precedent for any illness caused by a primary excess of any receptor type. The other possibility is that there is excess release of the transmitter itself in these states. Starting with Reith et al [1], using a method based on ►Positron Emission Tomography, several studies have now shown such an excess.

### Prediction of Antipsychotic Effects

Pharmaceutical research in the 1960s revealed a variety of behavioral effects of neuroleptic drugs in animal tests, which could be used to predict whether a new compound would have antipsychotic activity. Some of these tests were based on production of syndromes equivalent to the motor side effects seen in humans. However, the most reliable animal behavioral tests for determining the antipsychotic potency of new compounds were based on antagonism of simple ►instrumental conditioning tasks (such as avoidance responding).

### Receptors Targeted by Antipsychotic Drugs

In the mid-1970s radio-ligands became available specific for the pharmacological receptors by which dopamine produces its effects. This provided independent verification of the thesis that the common property of neuroleptic drugs was their ability to block dopamine receptors. It was found that the affinity of a variety of antipsychotic drugs for the relevant ►dopamine receptor varied in parallel with their clinical potency as antipsychotic agents. By the early 1980s, when ligands for different dopamine receptors became available, it was clear that the dopamine receptor type which showed this close relation to clinical effects was the so-called "►dopamine D2" receptor. From this evidence, it became widely believed that the D2 receptor was the essential target of antipsychotic drugs, and that this single receptor mediated both the therapeutic effects and the motor side effects of antipsychotic drugs.

More recently, several bodies of evidence have appeared which challenge this view. *First*, not all antipsychotic drugs are "neuroleptic", in the sense of also producing motor side effects. This was known in the 1970s, when some the clinical properties of the antipsychotic drug clozapine were defined. More recently a wider range of medications has been developed with antipsychotic potency, but with a low tendency to produce motor side effects, at doses which are effective against psychosis. These are the "second generation" or "►atypical" antipsychotic drugs. *Second*, the role of dopamine in instrumental conditioning depends on its actions as a psychological reinforcing signal in the brain, a role now generally believed to be independent of its role in motor performance [2]. Psychopharmacological experiments have generally shown the reinforcing role of dopamine to be based on its actions at the so-called "►D1" dopamine receptor, and recent studies of the processes of synaptic plasticity in the striatum, upon which instrumental conditioning depends, support this [3]. Part of the mechanism underlying such dopamine-dependent synaptic plasticity is the increased production of the intracellular messenger ►cyclic-Adenosine-Monophosphate (cAMP). As mentioned, blockade of instrumental conditioning is the best predictor of antipsychotic potency, and tests of this in animals recognize clozapine and similar drugs as antipsychotic agents when production of motor side effects in animals by these drugs does not [2]. This is paradoxical if it is assumed that the D2 dopamine receptor is the only essential target of antipsychotic drugs. *Thirdly*, in the 1990s methods became available to determine the percentage "occupancy" of dopamine receptors by antipsychotic drugs needed to produce therapeutic effects. For most antipsychotic drugs occupancy of 70–80% was needed. For clozapine, a substantially lower occupancy would suffice [4]. This suggests that receptors in addition to the dopamine D2 receptor are influential in antipsychotic drug therapy.

### Theory of Antipsychotic Drug Action

Starting in the mid-1970s, the author of this article has developed a theory to resolve these paradoxes [5]. A central fact in this work is that the full therapeutic effect of antipsychotic drugs is not achieved until long after the relevant receptors are blocked [2,6]. This applies particularly to ►delusions (Symptom of Psychosis), which are the symptom which responds most slowly during antipsychotic drug therapy. The extended time course of antipsychotic drug therapy is still debated by some, but was clearly revealed in clinical trials in the 1960s, is mentioned explicitly in some "first-person" accounts of psychosis, and was

referred to in a recent symposium on antipsychotic drug treatment [6]. For patients whose psychotic state has remained untreated for a long period, it may take many months of drug treatment before resolution of symptoms is complete. This central fact was explained as follows: Active psychosis occurs when dopamine release is excessive, and this leads to an exaggeration of a process of dopaminergic reinforcement. In humans, this reinforcement is directed mainly at distinctively human cognitive information, whose representation in cerebral processes then becomes exaggerated and distorted. Many of the details of psychotic psychology can be explained on this basis (for instance the production of delusions, "incorrigible" by any amount of reasoning or contrary empirical evidence) (see reference [5], chapter 9). Administration of antipsychotic drugs halts the production of such exaggerated and distorted material, but does not immediately abolish that which has already been laid down in memory. However, by reducing the overall "pressure" on cognitive processes it becomes possible for a patient to gradually "work through" the conflicts of belief set up during the period of psychosis, and thus to work out which beliefs were symptoms of an illness, and which are more trustworthy. This process inevitably takes time.

The paradox about the dopamine receptor type involved in antipsychotic therapy is then accounted for by the proposal that D2-blocking neuroleptic drugs act indirectly, the ultimate target being either a reduction of activation at the dopamine D1 receptor (which mediates psychological reinforcement), or an attenuation of intracellular processes "downstream" to, and usually controlled by, this receptor type. At present, the most likely mechanism for this indirect action [5] is as follows: In the striatum, which has the highest concentration of dopamine, one class of neuron (about 2% of the total neuron count there) are the cholinergic interneurons. Dopamine, acting at D2 receptors inhibits the firing of these interneurons [7]. It is then expected that D2-blocking neuroleptic drugs would release these neurons from inhibition, leading to a sustained increase in acetylcholine release in the striatum. The principal neurons in the striatum bear cholinergic receptors of various types. Of importance are the so-called M4 receptors which reduce production of cyclic-AMP when the receptors are activated by acetyl choline [8]. Thus, D2 blockade would indirectly reduce cAMP production, an effect similar to that produced more directly by D1 blockade, and which would attenuate the dopaminergic reinforcement process.

### Adverse Effects of Long-Term Treatment

Antipsychotic drugs have been controversial. In the past this has been because of the unpleasant nature of the motor side effects, a drawback which is less important with the advent of the atypical antipsychotic drugs. An additional hazard of the traditional neuroleptic drugs, recognized as early as the late-1950s, was that they were a contributory cause of a more persistent motor abnormality, referred to as ▶tardive dyskinesia. In this syndrome, abnormal involuntary movements occur, especially of tongue, mouth and face. The atypical antipsychotic drugs have a lesser tendency to cause this syndrome, but since tardive dyskinesia, once established, is often quite persistent and difficult to treat, there is still a legacy of disability due to past use of first-generation neuroleptic drugs, especially when they were used in large doses. The persistence of these abnormal movements suggests that they arise due to permanent cell loss in the brain. In 1993 [9] it was suggested that during neuroleptic treatment, the prolonged overactivity of the striatal cholinergic neurones might be so intense that it led to damage and destruction of these cells, this being the necessary cause of tardive dyskinesia. Animal experiments support the view that prolonged regimes of neuroleptic drugs can lead to loss of striatal cholinergic interneurons. Loss of such cells has also recently been documented in post-mortem brains of human schizophrenia patients treated with neuroleptic drugs (review in reference [5], chapter 10).

Psychotic states are not always alleviated by antipsychotic drugs. However, it is well established that clozapine is often an effective treatment when other antipsychotic medications have failed [10]. In addition, it has been suggested that prolonged treatment with traditional neuroleptic drugs, especially in high doses leads gradually to the re-emergence of psychotic symptoms despite drug treatment, and eventually to psychosis resistant to conventional treatment, though often still responsive to clozapine ("neuroleptic-induced supersensitivity psychosis"; review in reference [5], chapter 10). The parallel between this course of development, and the emergence of tardive dyskinesia during neuroleptic treatment, led to the suggestion that they are parallel pathologies, due in both cases to loss of striatal cholinergic interneurons, but in different parts of the striatum. The special effectiveness of clozapine then suggests that this drug acts more directly than typical neuroleptic drugs, by-passing the link through striatal cholinergic interneurons. Its direct action could be by either of two mechanisms, a direct blockade of D1 receptors (supported by the fact that clozapine has somewhat higher relative affinity for D1 versus D2 receptors than other antipsychotic drugs in clinical use), or by direct stimulation of M4 cholinergic receptors (for which clozapine may have an affinity, probably as an agonist). Either of these mechanisms would reduce cAMP formation, and attenuate the dopaminergic reinforcement process even when the normal mechanism for this, dependent on transmitter release from intact cholinergic interneurons, is no longer possible.

# Antiretrovirals (ARVs)

## Definition

These are the agents active against retroviruses, and act at one or more sites. These inhibit reverse transcriptase, protease or integrase of the retroviruses or inhibit fusion of the virus with the host cells. Highly Active Anti-Retroviral Therapy (HAART) is a combination of the highly active anti-retrovirals with different mechanisms of action, and is used to prolong the life of a patient suffering from Acquired Immune Deficiency Syndrome (AIDS).

# Anti-Saccade

## Definition

A saccade triggered by the appearance of an eccentric target but directed away from that target into the opposite, empty visual hemifield. Antisaccades are not a natural behavior but generally only obtained upon instruction. To generate an antisaccade, first the reflexive saccade toward the new target (often called prosaccade in this context) must be suppressed, a task requiring considerable attentional effort and imparting the antisaccade a long reaction time. The antisaccade task is of considerable practical interest as an elevated frequency of errors (inability to suppress prosaccades) is suggestive of frontal dysfunction.

►Oculomotor Control (Theory)
►Saccade, Saccadic Eye Movement

# Anti-Saccade Task

## Definition

At the beginning of a trial, a visual target is presented, and the subject (human or monkey) is required to fixate it. At the end of the fixation period, this target is extinguished at the same time that a second target comes on. The subject must then make a gaze shift to the location that is equal to the target in eccentricity, but opposite in direction.

## Antisense RNA

### Definition

Antisense RNA is a single-stranded RNA copy that is complementary to the sequence of nucleotides found in an mRNA. Antisense RNA can be introduced into a cell to block translation of mRNA.

## Anti-SSA (Anti-Ro)/Anti-SSB (Anti-La) Antibodies

### Definition

Antinuclear antibodies that typically occur in pSS.

Anti-SSB (Anti-La) antibodies are more specific to pSS, whereas anti-SSA (Anti-Ro) antibodies are also commonly associated with other autoimmune diseases, such as subtypes of systemic lupus erythematosus.

►Central Nervous System Disease in Primary Sjögren's Syndrome

## Anurans

### Definition

Anuran amphibians are one of three orders of living amphibians (order Anura). They are commonly referred to as frogs or toads. These are in many ways highly specialized vertebrates quite unlike ancestral amphibians.

Their visual systems are expanded and have specialized features related to visual prey capture. Their auditory systems are likewise enlarged with processing specializations reflecting the use of vocal signals in reproductive social communication. The characteristic body shape of frogs and toads reflects the specialized mode of salutatory, or jumping, locomotion seen in many anuran species. There are no doubt motor system functional specializations related to this and to the vocal production common in this amphibian group. Anurans have by far been the subject of most neuroanatomical and neurophysiological studies of the amphibians.

## Anxiolytic and Hypnotic Drugs Acting on Ionotropic GABA Receptors

Tina Hinton, Graham A. R. Johnston
Department of Pharmacology, The University of Sydney, NSW, Australia

### Definition

Anxiolytic and ►hypnotic drugs are used in the treatment of anxiety disorders and sleep disturbances

to reduce anxiety and promote sleep. These drugs encompass a number of different classes of compounds, including the ►benzodiazepines. Most of the currently used anxiolytic and hypnotic drugs act on ►ionotropic receptors for ►GABA, the major inhibitory neurotransmitter in the brain. This reflects the importance of GABAergic systems for anxiety and sleep related behaviours [1].

The focus of this essay is on compounds acting at ionotropic GABA receptors and the development of new anxiolytic and hypnotic drugs. There is great diversity in these receptors and of particular interest are compounds that show selectivity for specific subtypes of ionotropic GABA receptors.

## Characteristics

### Ionotropic GABA Receptors

Ionotropic GABA receptors comprise the $GABA_A$ and ►$GABA_C$ receptors, whereas $GABA_B$ receptors are metabotropic [2]. Ionotropic GABA receptors are ►ligand-gated ion channels that are formed from five protein subunits surrounding a chloride channel, thus controlling the flow of chloride ions into nerve cells. To date, fifteen $GABA_A$ receptor subunits (α1-6, β1-3, γ1-3, δ, ε, θ) and three $GABA_C$ receptor subunits (ρ1-3) have been cloned from the mammalian brain. ►$GABA_A$ receptors are heteromeric (►Heteromeric receptors), while $GABA_C$ receptors are known to be homomeric (►Homomeric receptors). The majority of $GABA_A$ receptors are assembled from two α, two β and one γ subunit with the arrangement αβαβγ. The most commonly occurring $GABA_A$ receptors are α1β2γ2 receptors, α2, β2/3, γ2 and α3, βn, γ2/3 heteromers. $GABA_A$ and $GABA_C$ receptors differ significantly in their molecular biology, pharmacology and physiology [2]. $GABA_A$ receptors are present on most, if not all, neurones in the brain, whereas $GABA_C$ receptors have a much more restricted distribution. $GABA_C$ receptors are considered to play an important role in vision, memory and sleep [3].

### Anxiolytic Drugs Acting on Ionotropic GABA Receptors

Benzodiazepines are the most well known class of ►anxiolytic drugs. Examples of widely used benzodiazepines include diazepam, oxazepam, nitrazepam, flunitrazepam and temazepam. Benzodiazepines act as allosteric ►modulators of many subtypes of $GABA_A$ receptors, enhancing the action of GABA at these receptors. In the presence of GABA, benzodiazepines increase the frequency of chloride channel opening without increasing the maximal response to GABA. Benzodiazepines are considered to be relatively safe and effective, however their main drawbacks are associated with dependence, ataxia and amnesia [4].

In addition to their anxiolytic effect, the classical benzodiazepines are also sedative (►sedative drugs), ►hypnotic (sleep inducers), anticonvulsant and myorelaxant. This is due to the fact that they act at all $GABA_A$ receptors containing α1, α2, α3 or α5 subunits, coupled with a γ2 subunit. Benzodiazepines bind to the interface between α and γ2 subunits. The γ2 subunit is essential for high affinity benzodiazepine binding, while the α subunit predicts benzodiazepine ►efficacy.

Studies using knock-in point mutations at the α1, α2, α3 and α5 benzodiazepine binding site that render the subunit insensitive to benzodiazepines, show that the different α subunits mediate different actions of benzodiazepines [5]. We now know that the α1 subunits mediate the sedative/hypnotic and anticonvulsant actions of benzodiazepines, the α2 subunits contribute to the anxiolytic action, and the α3 and α5 subunits partly mediate the myorelaxant effect. That α2 subunit-containing ►$GABA_A$ receptors contribute to the anxiolytic effects of benzodiazepines is consistent with localization of these subunits in the central nucleus of the amygdala, a key area in the brain for control of emotions and fear. There is also evidence that α3 subunit-containing $GABA_A$ receptors contribute to the anxiolytic effects of benzodiazepines.

### Anxiolytics Specific for Subtypes of $GABA_A$ Receptors

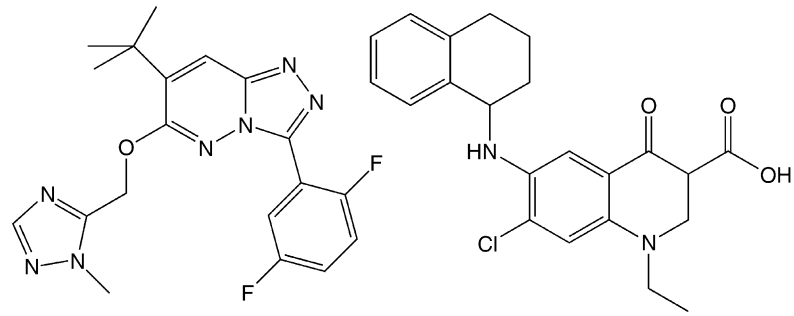
On the basis of this knowledge, subtype selective benzodiazepines have been developed. L-838,417 (Fig. 1) is one of a series of novel site ligands, selective for α2 and α3 subunits and which block α1 subunits, that have recently been described. Such agents produce anxiolysis and myorelaxation without associated sedation [4]. New benzodiazepine-site ligands with selectivity for α2 or α3 over α1 $GABA_A$ receptors are being developed but have yet to reach the clinic [2,4].

Patients taking fluoroquinolone antibiotics such as norfloxacin are known to show a low incidence of anxiety and convulsions. Chemical modification of norfloxacin has led to "compound 4" (Fig. 1) that shows α2 subunit selectivity as a $GABA_A$ receptor modulator. It is a non-sedating anxiolytic whose action is independent of classical benzodiazepine receptors [2].

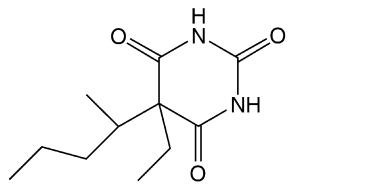
### Hypnotics and Ionotropic GABA Receptors

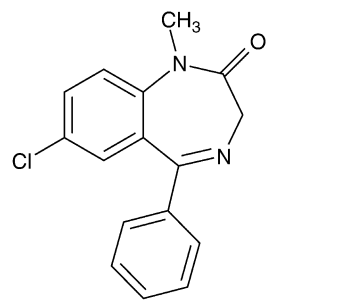
GABA mechanisms play an important role in the sleep-wake cycle and it is well established that activation of $GABA_A$ receptors favours sleep [6]. This is the mechanistic basis of the action of three generations of hypnotics (Fig. 2) with increasing $GABA_A$ receptor subtype selectivity leading to more selective actions.

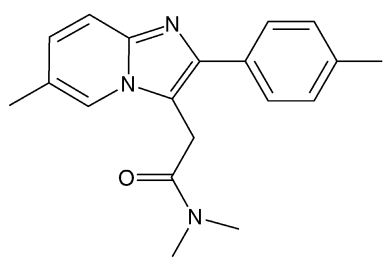
Barbiturates (such as pentobarbitone) enhance the activation of most, if not all, $GABA_A$ receptors by GABA. Benzodiazepines (such as diazepam) have a more specialised action, as noted above, acting only on subsets of $GABA_A$ receptors containing α1, α2, α3 or α5 subunits, coupled with a γ2 subunit. The third



**Anxiolytic and Hypnotic Drugs Acting on Ionotropic GABA Receptors. Figure 1** Agents acting selectively on subtypes of GABA receptors.







**Anxiolytic and Hypnotic Drugs Acting on Ionotropic GABA Receptors. Figure 2** Therapeutic agents acting on ionotropic GABA receptors.

generation of hypnotics (so-called "non-benzodiazepines" such as zolpidem, zolpiclone and indiplon) act on still more specialised subsets of $GABA_A$ receptors, acting preferentially on $GABA_A$ receptors that contain α1subunits [7].

The development of new hypnotics is necessary due to significant problems associated with currently available agents. Barbiturates, in addition to their induction of liver enzymes and potential for lethal overdose, are far from ideal hypnotics as they massively extend the "intermediate stage" of sleep between slow-wave sleep and paradoxical sleep at the expense of the latter [6]. In the 1970s barbiturates were largely replaced as hypnotics by benzodiazepines; these were far safer drugs that enhanced slow-wave sleep. However, their use as hypnotics was associated with residual daytime sleepiness, anterograde amnesia and significant potential for dependence [7]. The third generation hypnotics showed significant improvement over the classical benzodiazepine hypnotics producing sedation without ataxia, but significant adverse effects have been reported with some of these agents. Indeed, zolpidem has been linked to bizarre compulsive activity including sleep walking and binge eating.

The sedative action of diazepam is abolished in mice in which the α1 $GABA_A$ receptor subunit has been made insensitive to diazepam by a point mutation [1]. This appears to be consistent with the hypnotic action of α1-preferring ligands such as zolpidem. However, changes in sleep patterns induced by diazepam are strongly attenuated in mice lacking a diazepam-sensitive α2 $GABA_A$ receptor subunit. This indicates that the sedative and hypnotic effects of diazepam are not equivalent and that more than one α-subunit type contributes to the overall effects of diazepam on sleep. While the third generation hypnotics are classified as α1-preferring agents they do show some activity at α2 and α3-subunits. Thus th situation regarding the relative importance of specific α-subunits to the hypnotic actions

of these agents is nowhere near as clear cut as originally thought. We need agents with significantly increased subunit selectivity to sort this out.

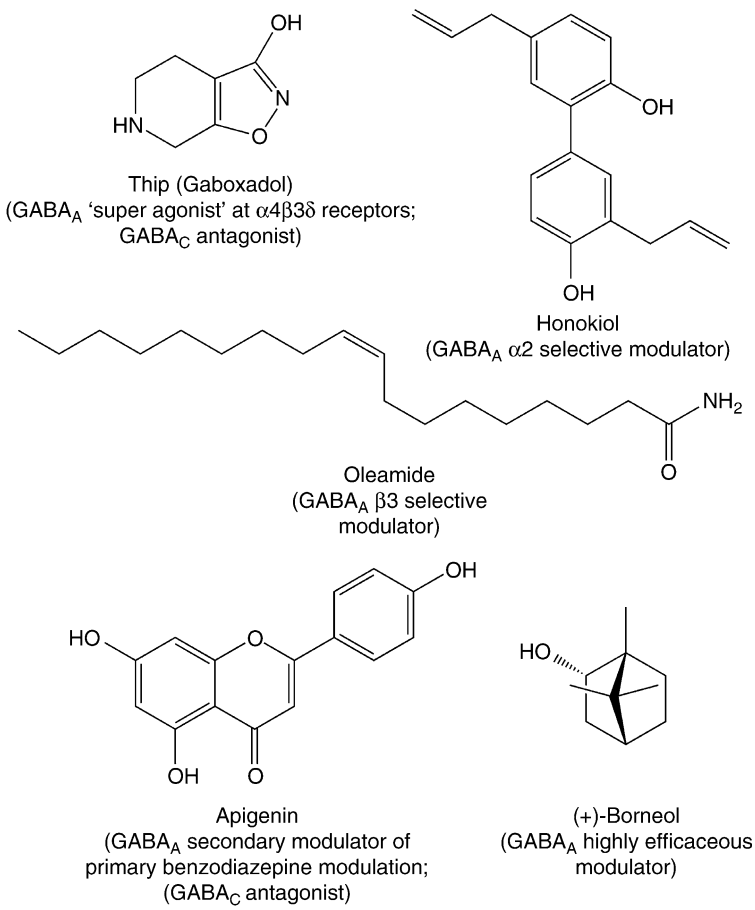
## Future Generations of Hypnotics Acting on Ionotropic GABA Receptors

It has been suggested that the development of newer GABAergic hypnotics might be targeted to producing changes in EEG patterns that correspond to those during physiological sleep [1]. A promising approach appears to be to move away from benzodiazepine-like modulation altogether and to target sites on ►ionotropic GABA receptors that are insensitive to the classical effects of benzodiazepines [3].

Oleamide (Fig. 3) is an endogenous cannabinoid that promotes sleep (see Chapter on Cannabinoids). It acts as a modulator at $GABA_A$ receptors that contain β3 subunits, being inactive in β3 knockout mice. Its action is flumazenil insensitive and thus independent of classical benzodiazepine sites. Interestingly, a patient with chronic insomnia is known to have a β3 $GABA_A$ receptor subunit mutation. Oleamide represents a lead for the development of new hypnotics based on modulation of β3 containing $GABA_A$ receptors [2].

There is considerable interest in extrasynaptic δ subunit-containing $GABA_A$ receptors on thalamocortical neurones as molecular targets for future generations of hypnotics [8]. Such receptors are more sensitive to GABA than most $GABA_A$ receptors and appear to be involved in tonic inhibition, regulating neuronal excitability. They are insensitive to benzodiazepines and are potently modulated by ethanol.

THIP (Gaboxadol, Fig. 3) is an important lead compound in the development of new types of hypnotics. THIP was originally developed as a novel GABA agonist of restricted conformation. It was found to be a potent analgesic, but unwanted sedative effects curtailed its clinical development. The sedative effects led to its investigation as a hypnotic [9]. THIP was found to produce high quality sleep characterised by increased non-rapid eye movement sleep and decreased awakenings. Studies with healthy elderly volunteers indicated that THIP reverses typical age-related changes in sleep by improving sleep efficiency and by boosting



**Anxiolytic and Hypnotic Drugs Acting on Ionotropic GABA Receptors. Figure 3** Chemically diverse natural and synthetic agents acting on ionotropic GABA receptors.

slow wave sleep, which declines with age [7,9]. Studies in animals indicated that the hypnotic effects of THIP were not potentiated by benzodiazepines or ethanol. THIP is known to act as a "super agonist" at α4β3δ $GABA_A$ receptors, i.e. it produces a greater activation of these receptors than does GABA. The activation by THIP of these receptors in the thalamus is thought to produce a firing pattern that promotes restful, slow-wave sleep. THIP went into clinical trials in 2004, but it was withdrawn during stage three trials early in 2007 because the overall clinical profile for THIP in insomnia did not support further development.

THIP is almost as potent at $GABA_C$ receptors, where it acts as an antagonist, as it is as an agonist at α4β3δ $GABA_A$ receptors [3]. It is possible that an action on $GABA_C$ receptors may confound the hypnotic properties of THIP as other studies have shown that $GABA_C$ receptors that are insensitive to benzodiazepines and barbiturates are targets for the development of novel hypnotics [3,6]. Studies using TPMPA, a specific $GABA_C$ receptor antagonist that decreases slow wave sleep, show that these receptors are involved in sleep-waking regulation. $GABA_C$ receptor agonists and modulators, as distinct from antagonists, may be suitable for development as novel hypnotics [6].

## Herbal Preparations for Anxiety and Sleep Disorders

Many herbal preparations that have long been used for their anxiolytic and sleep promoting properties are now known to contain compounds that modulate ionotropic GABA receptors [10]. These preparations include valerian, chamomile and green tea, and their active constituents (Fig. 3) include flavonoids (e.g. apigenin), terpenoids (e.g. (+)-borneol) and polyphenolic compounds (e.g. honokiol). The rich chemical diversity of these GABA receptor modulating compounds and their effects on brain function provide a rational basis for the anxiolytic and hypnotic properties of the herbal preparations from which they are derived and may lead to the development of new therapeutic agents.

Plant flavonoids have long been known to interact with benzodiazepine binding sites on $GABA_A$ receptors and have served as lead compounds for the development of synthetic flavonoids that have anxiolytic and sedative properties. Two flavonoids, apigenin (from chamomile, Fig. 3) and epigallocatechin gallate (from green tea), have shown to have unique additional effects at $GABA_A$ receptors, enhancing the modulatory effects of benzodiazepines [10], and thus being the first known secondary modulators of $GABA_A$ receptors. In concentrations at which they have no direct effects on $GABA_A$ receptors they act as secondary modulators of primary modulation by benzodiazepines. This action is restricted to enhancing the modulation by benzodiazepines and is not seen with barbiturate or neurosteroid modulation. These compounds are anxiolytic in animal models of anxiety suggesting that they are modulating an endogenous benzodiazepine-like modulation. Furthermore, the action of these flavonoids offers the opportunity of reducing the dose of benzodiazepine needed, possibly reducing side effects and dependence liability of benzodiazepines.

The terpenoid (+)-borneol (Fig. 3), an active constituent of valerian (*Valeriana officinalis*), acts with high efficacy at $GABA_A$ receptors, enhancing GABA action through a benzodiazepine-insensitive mechanism [10].

Honokiol, a polyphenolic compound from *Magnolia* species (Fig. 3), is an anxiolytic in animal models of anxiety without causing sedation, and this effect can be blocked by the benzodiazepine antagonist flumazenil [10]. It is thought that this compound acts preferentially at α2 subunit-containing $GABA_A$ receptors, consistent with its non-sedating anxiolytic properties.

## Conclusion

Site-directed mutagenesis and the availability of increasingly subtype selective compounds acting at $GABA_A$ receptors has led to a greater understanding of the molecular basis of anxiolytic and hypnotic drug effects. This understanding, coupled with the availability of a diverse range of compounds from herbal preparations and lead development will result in new and better agents to treat anxiety and sleep disorders.

## AP2α

### Definition

AP2α is a member of transcription factor AP-2 gene family that consists of three different genes. AP-2 is shown to have important functions in differentiation of neural crest-derived cell lineage. AP2α is thought to be required for a number of morphogenetic events including aspects of craniofacial development and midline fusion.

## Aperture Problem

### Definition

The aperture problem refers to the fact that the motion of a one-dimensional spatial structure, such as a bar or edge, cannot be determined unambiguously if it is viewed through a small aperture such that the ends of the stimulus are not visible. In the context of visual motion processing, the aperture problem is faced by individual neurons with receptive fields that sample only a spatially restricted region of the retinal image.

►Visual Motion Processing

## Aphasia

### Definition

Inability to produce and/or understand language that results from damage to portions of the brain that are responsible for language. Depending on which portion is affected, the language disability changes. Damage to the frontal lobe tends to cause a more expressive aphasia (the patient may understand what people say but cannot produce words), while damage to the temporal/parietal, i.e., auditory areas tends to cause more of a receptive aphasia: the patient speaks fluently but makes no sense nor understands other people talking. The damage is always on the dominant side of the brain which, in 95% of people, is the left.

## Apoptosis

### Definition
A type of programmed cell death in response to stress, oxidants and genetic aberrations. It may also be a controlled process during development and cell differentiation which it involves a cascade of complex biochemical events leading to characteristic changes in cell morphology prior to death. The main feature of apoptosis is that events, including chromatin condensation and DNA fragmentation, are accomplished in such a way to dispose of cellular debris without inducing an inflammatory response.

►Development and Regeneration

## Apparent Motion

### Definition
Apparent motion is an illusion of motion that can be produced by presentation of a sequence of discrete "snapshots" rather than a continuously changing image signal. For example, the motion in movies is apparent rather than real as it involves the rapid presentation of a series of static images.

►Visual Motion Processing

Explorative or goal-directed behavior.

## Appetitive Conditioning

### Definition
Conditioning with a rewarding unconditioned stimulus (US).

►Operant Conditioning

## Appetitive Response

### Definition

A class of conditioned Pavlovian responses that occurs to a stimulus predictive of the subsequent delivery of a reward (usually food or water). Increased salivation, licking, increased pupil dilation, and approach behavior can all be elicited in such appetitive situations.

►Value-based Learning

## APP/Secretase

### Definition

APP/secretase – an enzyme which cleaves inside the β/A4 portion of the amyloid precursor protein (APP); abnormal processing of APP occurs in AD brains.

►GAL4/UAS

## Apraxia

### Definition

Non-paralytic disorder of learned movements in the absence of sensory loss, weakness, incoordination, or the inability to understand commands. There are different forms of apraxia, related to different body parts and functions: buccofacial apraxia, truncal apraxia, limb apraxia, apraxia of eyelid opening, apraxia of speech. For example, in limb apraxia, patients may make simple movements but not perform complex motor acts with sequences of movements, such as combing their hair, shaving, toothbrushing. Ideomotor apraxia is characterized by disturbances of performing communicative gestures, e.g., waving the hand for goodbye, or imitative or requested tool-use gestures, such as using a hammer or other tool.

## Aprosodias

### Definition

Disturbances in recognizing or producing prosody (musical intonation) of language, which is an expression of affective components of speech. Aprosodia is associated with lesions of the right hemisphere. Damage to anterior regions produces aprosodic, emotionless, flat tone of voice; damage to posterior regions entails incomprehension of affective components in other people's speech.

## Aquaporins

### Definition

A family of 7 members of molecules that form the water pores in the cell membrane.

►Drinking Disorders and Osmoregulation

## Aqueduct of Sylvius

### Definition

This is the cerebral aqueduct. It is a channel located in the midbrain that connects the third and fourth ventricles. It is filled with cerebrospinal fluid, and if constricted can cause hydrocephalus.

## 2-Arachidinoyl Glycerol (2-AG)

### Definition

2-Arachidonoyl glycerol (2-AG) is an endogenous cannabinoid neurotransmitter first isolated from canine gut. It is an ester formed from arachidonic acid and glycerol. Compared to anandamide, 2-AG is present at relatively high levels in the central nervous system.

►Cannabinoids

## Arcuate Nucleus (Hypothalamus)

### Definition
This nucleus (also called the infundibular nucleus) is located in the floor of the hypothalamus adjacent to the ventralmost part of the third ventricle. Its axons project to the pituitary portal vessels at the median eminence of the hypothalamus. Its neuroendocrine cells contain various neuropeptides involved in the control of the anterior pituitary gland.

## Arcuate Nucleus (Medulla)

### Definition
The arcuate nucleus in the medulla is ventral to the pyramid that is continuous with the pontine gray. It projects to the contralateral cerebellum as mossy fibers via ventral external arcuate fibers.

## Are Humans Sensitive to Pheromones?

### Definition
Anatomically, there is clear evidence that the vomeronasal organ of human adult exists. However, there are serious doubts about its functionality. In the human genome, only five orthologs of the V1R genes are still functional, all the others are pseudogenes and, to date, no intact human V2R gene has been reported, suggesting that humans have a very limited number of functional vomeronsal receptors. In addition, the other members of the signal transduction cascade (PLCβ2, TRPC2 channel) existing in vomeronasal cells of rodents, are pseudogenes. No ligand is known for any of the human vomeronasal receptors. There are various behavioral studies that implicate putative pheromones in regulating endocrine dependent behavior such as menstruation, but the detailed mechanisms of actions are unknown so far.

## Area Centralis

**Definition**
The area centralis or central area is a small region, typically located in temporal retina, where neuron density peaks and neurons are smallest. It is the region of highest visual acuity and is used for the fixation of objects. Some animals (e.g. rabbit) have a horizontally elongated area centralis, which is termed a visual streak. The extent of the area centralis is somewhat arbitrarily defined by a ganglion cell density threshold or in some species by the presence of more than one tier of ganglion cell somata in the ganglion cell layer.

## Area Postrema (AP)

### Definition

Belongs to circumventricular organs and is located dorsal to the nucleus tractus solitarii (NTS) on the dorsal surface of the medulla oblongata at the caudal end of the fourth ventricle, where it forms an about 1 mm long, but rather narrow elevation. The postremal area is strongly vascularized, during the second half of one's life degenerated, and rich in cells and fibra with different transmitters. Since blood vessels do not have a blood-brain-barrier here, substances with compulsory barriers reach the nervous tissue as well, which are analyzed here. The AP is the "vomiting center" of the brain, though is also plays an important part in vegetative processes, such as food intake, drinking and cardiovascular regulation. AP projects heavily to the adjacent NTS and dorsal motor nucleus of the vagus (DMV) using acethylcholine as the main neurotransmitter.

If intracranial pressure increases, the ensuing concomitant stimulation of the area postrema can elicit emesis.

To curtail elicitation of emesis, dopamine antagonists, inter alia, are used, to act upon the dopamine receptors of the AP, thus suppressing their activating effect.

Loss of tendon reflexes and may be genetic or due to a number of neurological diseases.

## Arginine Vasopressin

### Definition

A peptide hormone synthesized by neurons in the hypothalamus and released from the posterior pituitary.

►Motion Sickness

# Argument

Ralf Busse
Institut für Philosophie, Universität Regensburg, Regensburg, Germany

## Synonyms

Reasoning; Inference

## Definition

An ►argument is a piece of text or speech that can be put forward in order to support a thesis. An argument in standard form is a finite sequence of meaningful sentences

$P_1$
…
$P_n$
$\therefore C.$

$P_1$, …, $P_n$ are the ►premises, $C$ is the ►conclusion, which is typically the thesis to be supported. Putting forward an argument normally involves three claims: firstly, that all premises are in fact ►true; secondly, that all premises are ►justified or warranted independently of justification or warrant for $C$; thirdly, that the conclusion ►follows from the premises, or at least that the premises together strongly ►support the conclusion. An argument is ►valid just in case this third claim is true. An invalid argument is called a ►fallacy. An argument may also be presented with the third claim only, just to see where certain assumptions would lead. Or it may be presented together with the claim that the conclusion is already established as false so that it provides reason to give up at least one of the premises (►reductio ad absurdum).

## Characteristics

### Good, Valid and Sound Arguments

A large part of what may be called the theory of human rationality is concerned with criteria for distinguishing ►good arguments from bad ones. An argument as it is normally put forward is good just in case all three claims indicated above are true. The standard distinction is between valid and sound arguments: an argument is valid just in case the conclusion does indeed follow from or is strongly supported by the conclusion. It is ►sound just in case in addition to being valid it has only true premises. Consequently, there are two steps in checking an argument. The first step is to find out whether it is valid or not. If it is valid, the second step is to find out whether all premises are true or not. Establishing the truth of the premises is a matter of particular empirical or formal research. Critical reflection on arguments as such primarily concerns their validity.

An argument in standard form is valid if and only if acceptance of all premises makes it rational also to accept the conclusion, or at least to attribute a high probability to the conclusion's being true. A special case of extraordinary importance is ►deductive validity. In a deductively valid argument the conclusion is a ►consequence of the set of premises, i.e. it follows from this set. So acceptance of the premises of a deductively valid argument makes it rational to accept the conclusion, because the truth of the premises ►excludes the falsity of the conclusion and so ►guarantees its truth: it is ►impossible that the conclusion is false while all premises are true.

This suggests an intuitive test for deductive validity: try to describe a consistent scenario that would render all premises true but the conclusion false. The scenario can be far-fetched and highly improbable. It can, for instance, involve science fiction elements such as beaming. The consistency of the scenario suffices to show that the argument is deductively invalid.

### Deductive Logical Validity: Conditional Premises

The kind of deductive validity that has by far been studied best is validity according to deductive logic [1]. An argument is ►logically valid (in the sense of deductive logic) just in case the truth of its premises excludes the falsity of the conclusion for *logical* reasons rather than for reasons that concern the descriptive content of the sentences involved. This can be explained by means of an important kind of arguments that are subject to deductive logic, namely arguments with ►conditional premises. Suppose that prior medical examination has established the conditional premise "If test T is positive, the patient has illness I." Now the positive test result is submitted. The premise "Test T is positive" is added and the conclusion "The patient has illness I" is inferred. The whole argument is an instance of a certain logical schema:

| Argument | Logical schema |
|---|---|
| If test T is positive, the patient has illness I | If *A* then *B* |
| Test T is positive | *A* |

In the schema, only the connective "if – then" is retained, which may plausibly be dubbed a ►logical expression. The connected sentences are replaced by the place-holders "*A*" and "*B*." It is impossible to find an argument of the same logical schema all premises of which are true, while the conclusion is false (i.e. not true). The meaning of the logical expression "if – then"

excludes the falsity of the conclusion given that all premises are true. It is hence by logical reasons alone that it is excluded that all premises are true while the conclusion is false. The argument is logically valid.

This can be generalized. A ►logical schema only contains logical expressions and place-holders for descriptive expressions. Descriptive expressions can be sentences, but also sub-sentential expressions such as names like "Peter" or predicates like "is happy." A particular argument is an ►instance of a logical schema just in case it can be obtained from the schema by replacing all occurrences of a certain place-holder by the same descriptive expression. An argument is a ►counter-instance to a logical schema just in case it is an instance of the schema and its conclusion is false, while all its premises are true. A ►logical schema is logically valid if and only if there is no possible counter-instance to it. A particular ►argument is logically valid if it is an instance of a logically valid schema. The general idea is that if an argument is an instance of a schema that has no counter-instance, the meanings of the logical expressions in the argument and the way they are connected to descriptive expressions alone guarantee the truth of the conclusion if all premises are true. It is by logical reasons alone that it is excluded that all premises are true but the conclusion is false. The argument is logically valid.

It is hard and perhaps impossible to systematically capture the exact logical behavior of ordinary conditional sentences. But in many cases asserting an indicative conditional can be understood as excluding the possibility (for whatever reason) that the antecedent *A* of the conditional is true but its consequent *B* false. Thus, when a person argues from a premise "If *A* then *B*" in the indicative we may often understand her as arguing from the premise "It is not the case that it is true that *A*, but false that *B*." Let us abbreviate this latter sentence schema as "$A \rightarrow B$," which we will read for convenience as "If A, then B." Its instances are called ►material or ►truth-functional conditionals.

The two most important logically valid logical schemata with conditional premises are (1) and (2). They can be contrasted with the two invalid schemata (1*) and (2*):

| (1) Modus ponens | (2) Modus tollens | (1*) Invalid | (2*) Invalid |
|---|---|---|---|
| $A \rightarrow B$ | $A \rightarrow B$ | $A \rightarrow B$ | $A \rightarrow B$ |
| $A$ | non-$B$ | $B$ | non-$A$ |

Here "non-…" is short for "It is not the case that …." In both (1*) and (2*), substituting a false sentence for *A* and a true sentence for *B* yields the counter-instance.

Further important valid schemata are (3) and (4):

| (3) Contraposition | (4) Conditional transitivity |
|---|---|
| $A \rightarrow B$ | $A \rightarrow B$ |
| $\therefore$non-$B \rightarrow$ non-$A$ | $B \rightarrow C$ |

A good part of the logical behavior of ordinary conditional sentences can be retained by standard translations by means of the material conditional "→":

| Ordinary sentence schema | Translation |
|---|---|
| If *A*, then *B* | $A \rightarrow B$ |
| *A* is sufficient for *B* | $A \rightarrow B$ |
| Only if *A*, *B* | $B \rightarrow A$ |
| *A* is necessary for *B* | $B \rightarrow A$ |

## Deductive Logical Validity: General Premises

So far we have been concerned with argument schemata with place-holders for complete sentences only. But there are important logically valid schemata with premises and conclusions of one of the so-called categorical forms:

| | Affirmative | Negative |
|---|---|---|
| General | All *F*s are *G*s | No *F* is (a) *G* |

"*F*," "*G*" and "*H*" are place-holders for English predicates such as "is an animal" rather than for sentences. Here is an instance of a famous valid schema called ►modus Barbara:

| Argument | Schema (modus Barbara) |
|---|---|
| All men are animals | All *F*s are *G*s |
| All animals are mortal | All *G*s are *H*s |

A convenient way of looking for counter-instances to such schemata makes use of naïve set-theoretical predicates such as "is a member of the set {1, 2}." A perspicuous counter-instance to an invalid schema can be formulated as follows:

| Invalid schema | Counter-instance |
|---|---|
| All *F*s are *G*s | All members of {1, 2} are members of {1, 2, 3, 4} |
| Some *G*s are *H*s | Some members of {1, 2, 3, 4} are members of {3, 4} |

Notice that if an argument is an instance of an invalid logical schema, it can still be valid because it is an instance of a more subtle schema that is valid.

Deductive arguments in scientific practice often involve sentences that contain relational predicates such as "is greater than" and iterations of means of quantification such as "all" and "some" or "there is." An example from arithmetics is "For every natural number there is a greater number." This should be construed as an instance of the schema "For every individual $x$ there is an individual $y$ such that $y$ stands in relation $R$ to $x$." The inference from this to "There is an individual $y$ such that every individual $x$ is such that $y$ stands in $R$ to $x$" is invalid. For every number there is a greater one, but there is no number that is greater than all numbers. If one fails to see through the fallacy from "For every – there is" to "There is – for every," one can "prove" the existence of a necessary being:

| | |
|---|---|
| $P_1$ | Ex nihilo nihil fit |
| $P_2$ | There exists something now |
| $C_1$ | ∴ There was no time at which nothing existed. (from P1 and P2) |
| $C_2$ | ∴ But then there is something that has existed at all times. (from C1) |
| $P_3$ | But no contingent being exists at all times |

The invalid step is from ($C_1$) to ($C_2$).

## Non-logical Deductive Validity and Implicit Premises

The following argument appears to be valid, though the corresponding schema is invalid:

| Argument | Schema |
|---|---|
| Peter is a bachelor | *a* is *F* |

The argument's validity rests on the meanings of the descriptive expressions. Consequently we cannot apply the testing method of trying to find counter-instances to a logical argument schema. Often the intuitive test suffices: if a consistent scenario can be depicted that would render all premises true but the conclusion false the argument is deductively invalid. But in order to make one's arguments perspicuous one should turn non-logically valid deductive arguments into logically valid inferences. In the example, just add as a premise the analytic truth "All bachelors are unmarried." The relation between the meanings of the descriptive terms "bachelor" and "unmarried" on which the validity rests is thereby made explicit.

Arguments in science and philosophy are seldom in standard form, and very often they are incomplete [2,3]. Even when spelled out in an explicit sequence of sentences they rely on hidden premises that are not just uncontested explications of meanings. For example, nothing of scientific interest does directly follow from an experimental result formulated in a premise of the form "Activity in brain area $B$ occurs whenever a subject performs cognitive task $T$." A huge amount of substantial background assumptions is required for correctly deducing a conclusion to the effect that there is a typical process in area $B$ that *is* or *realizes* the achievement of $T$. In many cases the background assumptions are scientific common ground. But the more general and substantial the conclusions become the more they draw on profound theoretical or even metaphysical assumptions that can reasonably be contested. A researcher is seldom explicitly aware of the way her scientific convictions or prejudices enter into her reasoning. So although scientists rarely spell out their scientific inferences in detail, knowledge of what a full-fledged deductively valid argument would look like can help them to keep a check on themselves and to deal reasonably with their disagreement.

## Reductio ad absurdum and Paradox

"From your hypothesis it follows that $C$ is the case, which is absurd; so your hypothesis is false." This popular mode of critique of another person's hypothesis or theory is called reductio ad absurdum. However, usually the alleged absurdity $C$ follows from a hypothesis $H$ only if certain background assumptions $P_1 \ldots P_n$ are made. Moreover, the alleged refutation of $H$ requires the assumption that $C$ is false. A complete reductio ad absurdum is of the following form:

| | |
|---|---|
| $P_1$ | The critic's background assumptions |
| … | |
| $P_n$ | |
| $H$ | Assumption of the hypothesis for the sake of argument |
| ∴ $C$ | Conclusion inferred from $P1 \ldots Pn$ and $H$ |
| non-C | Assumption of the negation of C as the main premise |

From $P_1 \ldots P_n$ and $H$ the critic infers $C$, which contradicts her main premise non-$C$. She thereby shows that at least one of the premises $P_1 \ldots P_n$, non-$C$ and $H$ must be false. Insisting on her own claims $P_1 \ldots P_n$ and non-$C$ she infers non-$H$. In order to evade this rebuttal all the proponent of $H$ has to do is to reject ►one among the critic's premises $P_1 \ldots P_n$ and non-$C$. Often this is easy to do, as the background assumptions tend to involve

fundamental but contested convictions of the critic's which the proponent need not share. Given the proponent's background theory even conclusion *C* may be acceptable.

There is a famous case in the history of science in which an attempted ►reductio backfired [4]: Poisson showed that the wave theory of light implied that a bright spot had to occur at the center of the shadow of a disk (conclusion *C*). Making the common sense assumption that this is false (his main premise non-*C*) he took the wave theory to be refuted. But in careful experiments the spot was in fact observed. Unwillingly Poisson had contributed to an impressive confirmation of the wave theory.

►Paradoxes are particularly fascinating philosophical arguments [5]. A paradox is a seemingly valid deduction of a seemingly unacceptable conclusion from seemingly inevitable premises. Skeptical arguments with conclusions such as "We do not know anything about the external world (or: the past, other minds, the laws of nature)" are paradoxes. Different reactions are possible: that the conclusion is in fact true and only *appears* to be false; that one of the premises is in fact false; or that the deduction rests on a logical or meaning explicating principle that should be rejected.

# Arm Trajectory Formation

Tamar Flash[1], Uri Maoz[2], Felix Polyakov[1]
[1]Department of Computer Science and Applied Mathematics, Weizmann Institute of Science, Rehovot, Israel
[2]Interdisciplinary Center for Neural Computation, Hebrew University of Jerusalem, Jerusalem, Israel

## Definition

Arm ►trajectory formation refers to the principles and laws that invariantly govern the selection, planning and generation processes of multi-joint movements, as well as to the factors that dictate their kinematics, namely geometrical and temporal features.

## Characteristics

The repertoire of human and animal goal-directed actions is broad and diverse, ranging from relatively simple single-joint movements to complex interactions among several limb segments or even among different limbs. These movements may follow various motion ►paths with numerous ►speed profiles along each ►path, resulting in countless possible trajectories. Nonetheless, focusing here specifically on arm movements, there seem to be some stereotypical trajectories that the central nervous system (CNS) chooses for the arm to perform. Although many questions still remain open, some underlying principles behind the selection, planning and execution of these trajectories have emerged from the combination of behavioral and computational studies of trajectory formation.

### Computational Problems Associated with Trajectory Formation

The motor system transforms neural signals into contractile forces in muscles, which produce motion and enable us to act upon our environment. Some prominent research questions that have received great attention in recent years are as follows:

1. What are the geometric and temporal characteristics of simple and complex movements?
2. What coordinates or reference frames are used in movement representation and generation?
3. What are the interactions between CNS-based planning, body mechanics and physical laws and constraints in dictating the emerging movements? How do these aspects influence trajectory planning?
4. How does the nervous system resolve kinematic redundancies, especially those associated with the planning and execution of multi-joint arm movements?

5. To what extent are the produced behaviors constructed from a limited set of motion primitives, i.e., basic building blocks? What syntactic rules are used in constructing complex and/or sequential movements from such simpler elements?
6. Is the motor system hierarchically organized? Does trajectory formation and generation occur at different levels of representation?

Some attempts at answering these questions are presented below.

In robotics, the problem of trajectory formation is usually composed of two separate problems: trajectory planning and trajectory tracking. The first deals with the selection and planning phase. The second refers to the execution of the planned trajectory and to feedback control, guaranteeing minimal deviation from the desired trajectory. When investigating how disjoint these two problems might be in human movement generation, some analogy can be made with the question of whether there is a clear separation in the motor hierarchy between kinematics and dynamics in biological trajectory formation. Some recent load adaptation studies provided evidence that human arm trajectories tend to obey the same kinematic plan independently of the external force conditions [1]. These, among others, support the notion that the desired behavior is independent of movement dynamics. However, although there is some evidence that the kinematic and dynamic aspects of motion constitute two distinct levels of the motor hierarchy, this is neither sufficient nor conclusive enough to unequivocally decide the matter (this matter is also discussed in the "Internal models" article).

## Coordinate Frames for Trajectory Formation

When reaching for a cup of coffee, the hand can theoretically follow a wide variety of paths, each with numerous speed profiles. These hand trajectories could further result from different sets of joint rotations. Understanding how the motor system plans and executes motion under redundancy, or in the presence of an excess number of degrees of freedom (DOF), beyond those required to carry out a motor task, is paramount (the redundancy problem, or Bernstein problem, is also discussed in the articles "Equilibrium point control" and "Coordination").

Numerous studies have demonstrated that during point-to-point movements in the horizontal plane the hand tends to follow rather straight hand paths (see Fig. 1a). This has prompted the suggestion that arm trajectories are planned in hand rather than in joint coordinates. By contrast, during unconstrained three-dimensional movements, or during movements in the vertical plane, the hand paths are likely to become considerably more curved [3] (see Fig. 2). This may be due to the presence of gravity or the lack of a continuous visual tracking of the movements.

## Optimality and Trajectory Formation

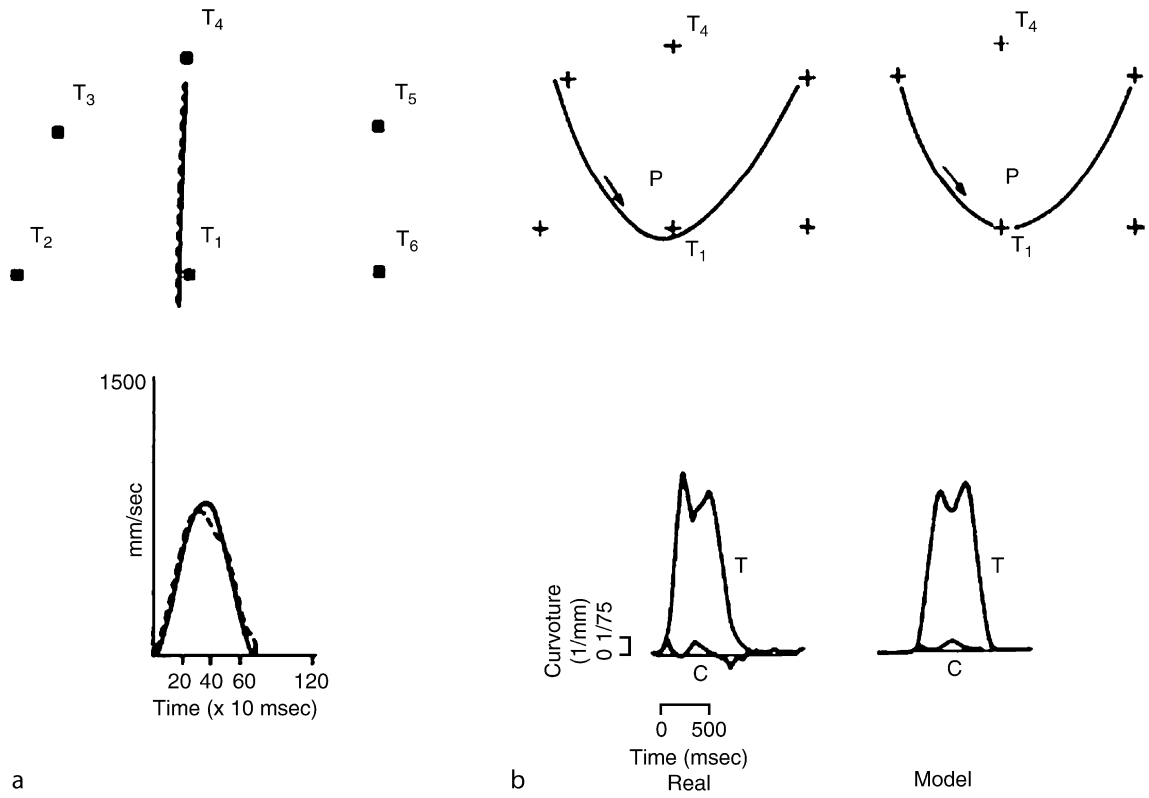
Many studies have attempted to account for the observed characteristics of arm movements based on optimization theory [2]. Optimization theory is an important venue for discovering what organizing principles govern the generation of goal-directed motor behavior. It provides a convenient way to formulate a coarse-grained model of the underlying neural computation, without requiring specific details of the way those computations are carried out. Generally speaking, this approach consists of defining a quantitative objective function that defines the optimum (i.e., best) performance. Optimization tools are then applied in order to identify the specific behavior that achieves that optimum. Quantitative hypotheses regarding the goals of motor actions and their relation to observable behavior must therefore be explicitly stated.

Not all motor behaviors are necessarily optimal. Nevertheless, attempts to identify optimization principles can be useful for developing a taxonomy of motor behavior and for gaining insight into the neural processes that produce motor behavior. In particular, several different optimization principles were hypothesized in the context of reaching movements. These included smoothness maximization, expressed through the minimization of hand ►jerk [2], the rate of change of joint torques [4], the minimization of movement variance [5] and optimal feedback control [6].

While in the minimum-jerk model the ►cost function is kinematic in nature, some of the other models' ►cost functions depend on dynamic variables such as torque change, muscle-tension or motor-command. A critical difference between the kinematics- and dynamics-based models is the separability of planning and execution. Kinematic models, which specify the hand trajectory in external or in joint coordinates, require separate movement execution processes to delineate the joint torques or muscle forces and eventually the motor commands that are needed in order to realize the desired trajectory. In contrast, the solutions to dynamic models are the joint torques, muscle forces and possibly also the motor commands (depending on the definition of the cost function) required to achieve the movement; and therefore planning and execution are no longer separated.

## Laws of Motion and Motor Invariants

A basic notion in current thinking about trajectory formation is that the motor memory does not store a huge collection of "motor tapes," each encoding the neural commands specifying the generation of an individual movement. Rather, based on evidence from



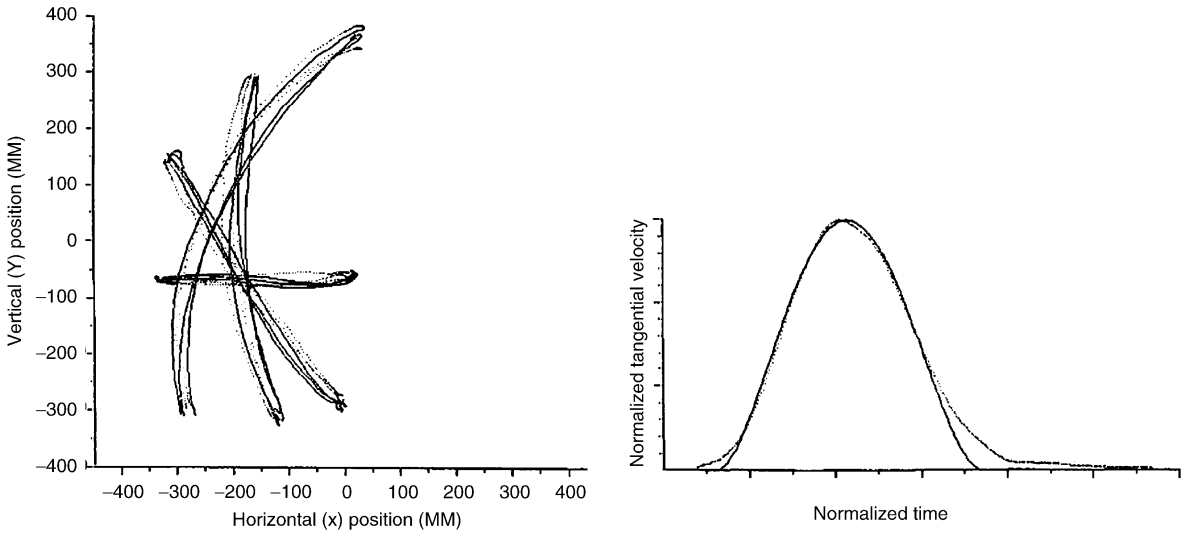
**Arm Trajectory Formation. Figure 1** An example of hand trajectories in the horizontal plane. (a) The experimental data are depicted by a *dashed line*, and the minimum-jerk model prediction is portrayed by a *solid line*. A point-to-point reaching movement is characterized by a *straight line* path (*top panel*), with a bell-shaped speed profile (*bottom panel*). (b) Reaching from one point to another through an intermediate via-point. The experimental data are given on the *top left* and the minimum-jerk prediction is on the *top right*. This time the path is curved and the speed profile shows a slowdown in the movement around the region of maximal curvature (*bottom panel*; T is movement speed and C movement curvature). As is apparent, there is good correspondence between the experimental data and the model predictions in both cases. Adapted from [2].

both behavioral observations and accurate kinematic analysis of movements, it is argued that motor memory stores more general plans, or programs. These dictate all the movements belonging to a particular class, which share similar geometric, kinematic and temporal characteristics.

A central problem in motor control research is therefore one of taxonomy, namely classifying and grouping all possible movements into different classes. This critically depends on our ability to define metrics that can be used to evaluate the similarity between different movements and motor behaviors. Another possibly more scrupulous method of classifying movements is by searching for differences among the principles that underlie the planning of different movements. Both schemes are based on the identification of ►motor invariants.

Several kinematic and temporal invariants have been observed in human arm movements. For example, point-to-point reaching movements in the horizontal plane tend to follow straight paths with single-peaked bell-shaped speed profiles (see Fig. 1a). For more curved motions, as when reaching through a via-point, the movements slow down around the point of highest ►curvature (see Fig. 1b). Both behaviors are predicted by the minimum-jerk model [2], but also by the minimum torque-change and minimum variance models. In three-dimensional movements and movements in the vertical plane, the hand paths are more curved, though they still vary in a consistent manner across the workspace, while the speed remains more or less bell-shaped [3] (see Fig. 2). Studies that examined the symmetry of the speed profiles, found them to range from highly symmetrical profiles to ones which are more skewed or contain additional speed peaks. This may possibly indicate multiple corrections, as observed when subjects are instructed to be highly accurate.

One persistent temporal invariant is that of isochrony [7]. Global isochrony refers to the observation that



**Arm Trajectory Formation. Figure 2** Point-to-point reaching movements in the vertical plane. The left panel shows the superimposed paths of four different typical reaching movements. Upward movements (and leftwards movements, for the horizontal movement) are *dotted lines*, where downward (and rightwards movements, for the horizontal case) movements are *solid lines*. While the horizontal movement is rather straight, the other hand paths tend to be much more curved for both upward and downward movements. The right panel shows a typical experimental speed profile as the *dotted line*, with the minimum-jerk model prediction as the *solid line*. Adapted from [3].

the average speed of movements increases with the path length, thereby maintaining movement duration nearly constant. Local isochrony is the tendency to carry out motion subunits of unequal lengths in roughly equal times. For example, if subjects trace out a figure eight in which the two lobes are of unequal size, they are traversed with approximately equal durations. This second type of isochrony becomes an emergent property of the maximization of movement smoothness, i.e., the minimization of jerk [7] as well as other costs [4–6].

In addition to characterizing the path and ►speed profile separately, many studies have examined the dependency of the speed on the path geometry. Although there is no a priori reason for it, coupling between the geometrical form of the path and the hand speed have been repeatedly observed. When drawing simple forms like ellipses, this relationship takes the form of

$$V = K\, C^{-\beta}, \qquad (1)$$

where $V$ is the tangential speed, $K$ is constant and $C$ is the curvature. Expressing the same law in terms of angular speed, we get

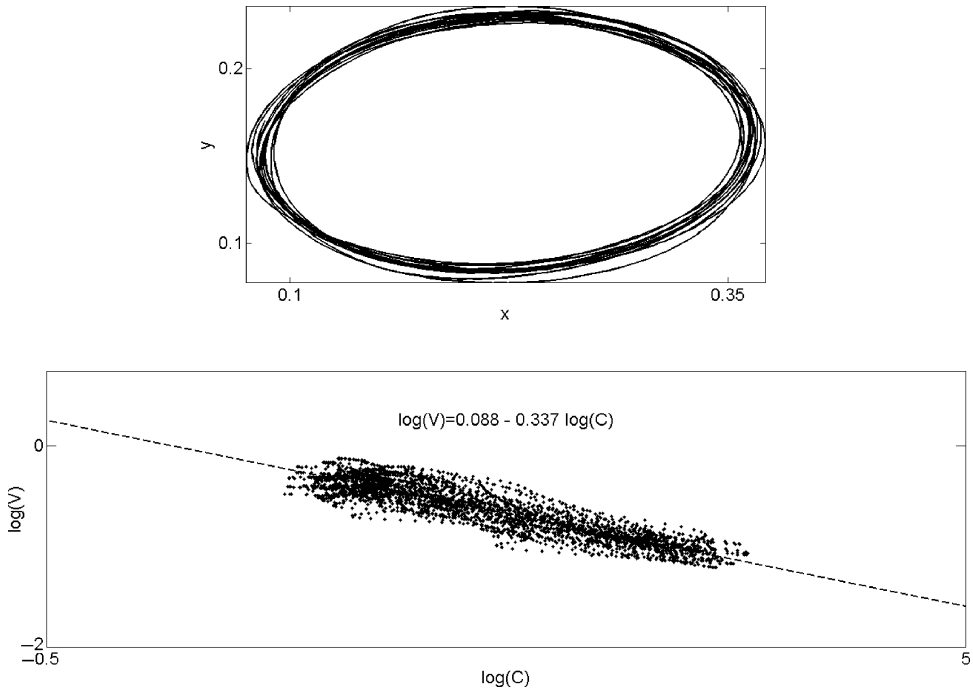
$$A = K\, C^{1-\beta} \qquad (2)$$

where $A$ is now the angular speed. Originally the power $\beta$ was found to be close to 1/3, and the second formulation lent it the name "the two-thirds power law" [8] (see Fig. 3). Nonetheless, in other non-elliptic paths the exponent was found to range between 0.2 and 0.4.

## The Notion of Motor Primitives

There is evidence that suggests that the brain may store a limited set of motor templates, and that it possesses mechanisms that generate our rich motor repertoire by applying some basic operations or transformations onto those elementary primitives, joining simple movements into more complicated behavior. This organization provides a parsimonious representation of our huge motor repertoire and eases learning of new behavior.

Some recent studies of the characteristics of hand trajectories that emerge following a period of extensive practice, suggest the emergence of purely geometric sub-movements from which the learned goal-directed movements are composed. Yet these sub-movements may not encompass the most elementary level in the plausible hierarchy of movement construction based on motor primitives. If we associate this hierarchy to that of an alphabet from which words are composed, which in turn are combined to yield complete sentences, the geometric primitives might correspond to words, not to letters. It remains to be seen, however, whether it is possible to identify a limited set of universal building blocks from which a wide variety of diverse movements are constructed. Nevertheless, the notion of the compositionality of complex movements via



**Arm Trajectory Formation. Figure 3** A demonstration of the two-thirds power law. Top panel: an ellipse traced continuously and repetitively in the horizontal plane. Bottom panel: taking the logarithm of both sides of the power-law formulation, we get: *log(V) = log(K) – β log (C)*. Therefore, plotting *log(V)* versus *log (C)* results in a roughly straight curve with a slope of about –1/3, in good agreement with the power law (1).

sequencing and superposition of sensory-motor primitives proved useful in robotic applications, such as robot humanoids learning from imitation.

## Three-Dimensional Trajectory Planning

The realm of three-dimensional (3D) arm movement was significantly less studied than that of planar arm movements. Movements that are restricted to the horizontal plane were, in turn, extensively studied. Moreover, the invariants of horizontal planar motion do not all scale up to 3D movement. The bell-shaped speed profiles of point-to-point reaching movements seem to be conserved. Yet the paths in 3D are much more curved, possibly suggesting motion planning in terms of joint coordinates. The two-thirds power-law describes 3D arm motion considerably less well than for horizontal planar movements. However, non-trivial mathematical considerations have led to a new power-law of 3D motion, which captures 3D drawing data quite well, namely:

$$V = K\, C^{-\beta} T^{-\gamma}, \qquad (3)$$

where $T$ designates the path's ►torsion (all other symbols are as above). Here $\beta$ is about 1/3 and $\gamma$ about 1/6, although their exact values depend on path geometry, both global and local. We name this the "curvature-torsion power-law" [9].

The redundancy problem, mentioned above, is especially problematic for 3D arm movements. For horizontal plane motion, humans tend to utilize only two of their four DOF at the shoulder and elbow to produce the two DOF of the hand motion within the horizontal plane. Yet, in unconstrained 3D motion, all four DOF are utilized, while only three DOF are needed to specify hand position and movement in 3D space, resulting in the excess of one DOF. Transforming hand into joint coordinates, termed the inverse kinematics problem, does not have a unique solution and therefore it is ill-posed, making its solution far from being trivial.

Another reason for this complexity is that rotations are not commutative, meaning that an object's orientation after rotations along two non-co-linear axes depends on their order. This has severe implications for joints with three DOF (e.g. the shoulder). It implies that, if no constraints are imposed, a limb's orientation would depend on previous joint rotations. Some recent studies investigated the idea of intrinsic constraints, which restrict the number of DOF at the wrist, elbow and shoulder joints during hand-motion, thus resolving the kinematic redundancies [10]. These intrinsic constraints include kinematic ones such as Donders' and Listing's laws, which were originally developed in order to account for the observed 3D end-point eye orientation (Donder's law), and angular rotations

(Listing's law) during human saccadic eye movements. Examining whether these laws are also pertinent to 3D human arm movements, it was shown that while these constraints do account for certain aspects of the observed behavior, they cannot fully account for the entire spectrum of kinematic features of 3D arm reaching and pointing movements [10].

As is apparent from the material reviewed above, studies carried out in the last 20–30 years have made considerable contributions to our understanding of the principles underlying human arm trajectory formation. New models were conceived and old ones were refined and improved or discarded in view of new empirical observations. Yet there is still much work ahead, before we can claim to fully understand the complicated processes of arm trajectory formation during goal-directed motor behavior.

# Aroma

## Definition

"Aroma", like "odor" refers to a mixture of chemical molecules that are perceived by the sense of smell.

While the term "odor" by itself is neutral in judgment, "aroma" refers frequently to odors of pleasant nature and is associated with the smell of consumables like food and coffee. Commercial interest in chemical aroma compounds derives from the food industry. Only 5% of the □8,000 odor molecules identified in food are present above detection thresholds that result in odor perception.

These so called key-food odorants determine the aroma of consumables. The aroma of roasted coffee for example is encoded by 27 key-food odorants out of 400 different compounds identified. Methyl-pyrazines are typical examples for key-food odorants that are formed during roasting of coffee, cocoa beans, and fried food.

►Odor

# Arousal

## Definition

Central nervous system stimulation driven by the ascending neuromodulatory projections, nervous system, and/or neuroendocrine systems resulting in heightened sensory sensitivity and readiness to respond. Arousal is involved in wakefulness, alertness, attention, cognition, awareness, motivation, sexual activity, emotion, and stress. The Yerkes-Dodson Law states that there is a U-shaped relationship between arousal and cognitive performance – either too little arousal (e.g., due to sleepiness from sleep deprivation) or too much arousal (e.g., from excessive caffeine consumption) has an adverse effect on performance.

Arousal can also be observed during sleep, where it may cause a transition to a lighter sleep stage or result in awakening.

►Alertness Level

# Arousal Threshold

## Definition

A measure of central nervous system response to external stimuli.

►Sleep States

# Arrhythmicity/Rhythmicity

Christian Beaulé
Department of Biology, Washington University, St. Louis, MO, USA

## Synonyms

Aperiodicity/periodicity; Arrhythmic/rhythmic; Irregularity/regularity

## Definition

Refers to characteristics of cellular, physiological or behavioral variables that fail to display a rhythm or regularity (arrhythmicity) or that show such rhythm or regularity (rhythmicity).

### Types of Rhythms

Most biological variables display cyclic changes in their basal levels. These cyclical changes are called biological rhythms. Rhythmicity is expressed at the level of the whole organism (i.e., rhythms in behavior) all the way down to the molecular and genetic levels (i.e., rhythms in gene expression). The length of these cycles is extremely varied and can be classified based on the intrinsic period of the biological oscillation. Rhythms can be grossly classified into three non-overlapping categories.

### Circadian Rhythms

From the Latin *circa*: "around" and *dies*: "day." Biological rhythms occurring with a frequency of one cycle per day (period of approximately 24 h in length). Examples of circadian rhythms include the ►rest-activity cycle, daily oscillations in core body temperature or blood pressure.

### Ultradian Rhythms

Biological rhythms occurring with a frequency of more than one cycle per day (period significantly shorter than circadian rhythms). Examples of ultradian rhythms include the 90 min Rapid-Eye Movement (REM) cycle during sleep, heart rate (72 beat/min, in humans), or the rhythm of human growth hormone secretion (3 h).

### Infradian Rhythms

Biological rhythms occurring with a frequency of less than one cycle per day (period significantly longer than circadian rhythms). Examples of infradian rhythms include the menstrual cycle (28–30 days in humans), seasonal migration cycles, and reproduction cycles. Infradian rhythms can be further sub-classified based on their period length. For example, ►circannual (about 1 year), circatidal (about 12 h, associated with ocean's tides), and circalunar (about 30 days, associated with cycles of the moon) can be used to further characterize ►infradian rhythms.

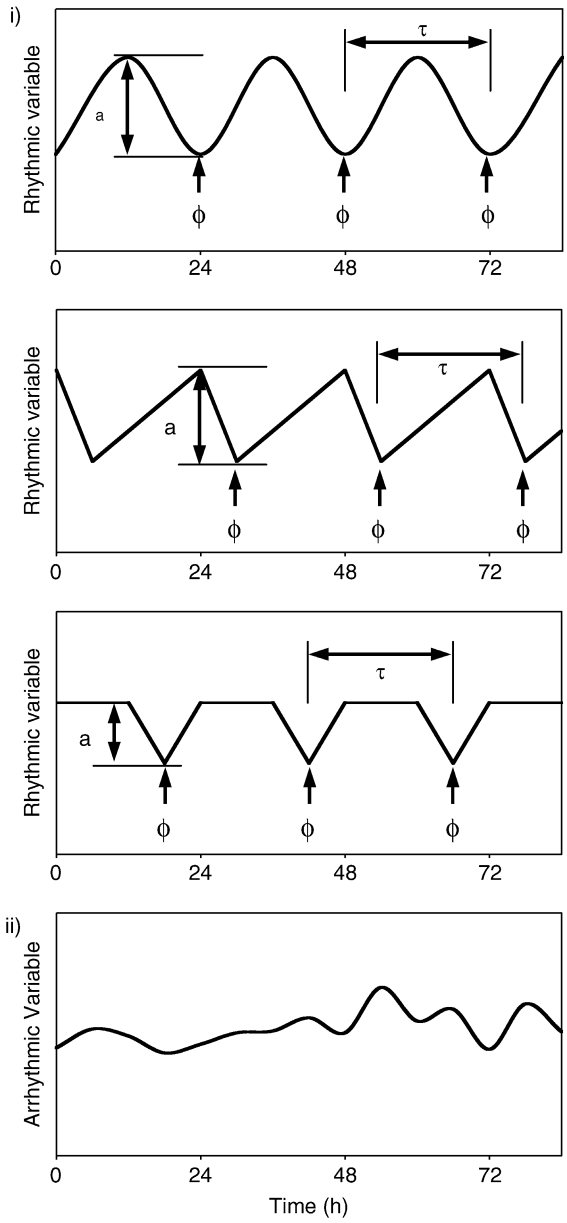
The present encyclopedic entry will focus on circadian rhythms.

## Characteristics

Circadian rhythms evolved as a need to adapt to the daily transitions between days and nights. This imposed day/night cycle shaped behavioral and physiological processes and led to the emergence of circadian clocks that generate biological oscillations with a period of approximately 24 h. This ensures that each organism is optimally tuned to its environmental niche (►nocturnal vs. diurnal), and capable of anticipating the transitions between days and nights. The ability to display circadian rhythms is endogenous and widely expressed across a very wide range of living organisms [1]. Naturally occurring, complete absence of rhythms in physiology and behavior (arrhythmicity), is uncommon.

The circadian fluctuations in a physiological variable can be plotted, in a simplistic manner, as a function with a period of approximately 24 h (Fig. 1 i). Note that the shape of circadian oscillations may vary greatly and will be determined by the physiological variable being measured. From this function, several measurements can be made. The phase of the circadian rhythm, (represented by the Greek letter p*hi*, φ) is a point of the function that can be reliably be measured over successive cycles. This phase marker is useful in determining other parameters of the circadian oscillation (or, in fact, any oscillation). The frequency of the circadian oscillation, or ►period of the rhythm (represented by the Greek letter *tau*, τ), can be measured between two or more consecutive stable phase markers on the curve. The amplitude (represented by the letter a), is defined as the difference between the maximum (acrophase or peak) and minimum (bathyphase or trough) values of the physiological variable measured. Of special interest to circadian ►oscillators is the fact that these parameters (phase, period, and amplitude) are endogenous, self sustaining, and relatively constant through time when the organism is kept in ►constant conditions. In contrast, during circadian arrhythmicity, none of the above parameters are constant (Fig. 1 ii). No reliable period can be extracted, the amplitude varies greatly through time, and a reliable phase marker is absent.

Figure 2 shows a representative behavioral ►actogram for a rhythmic (i) and an arrhythmic (ii) rat. In addition, Chi-square ($X^2$) periodograms are also displayed for both animals (iii). Both will be described in detail below.



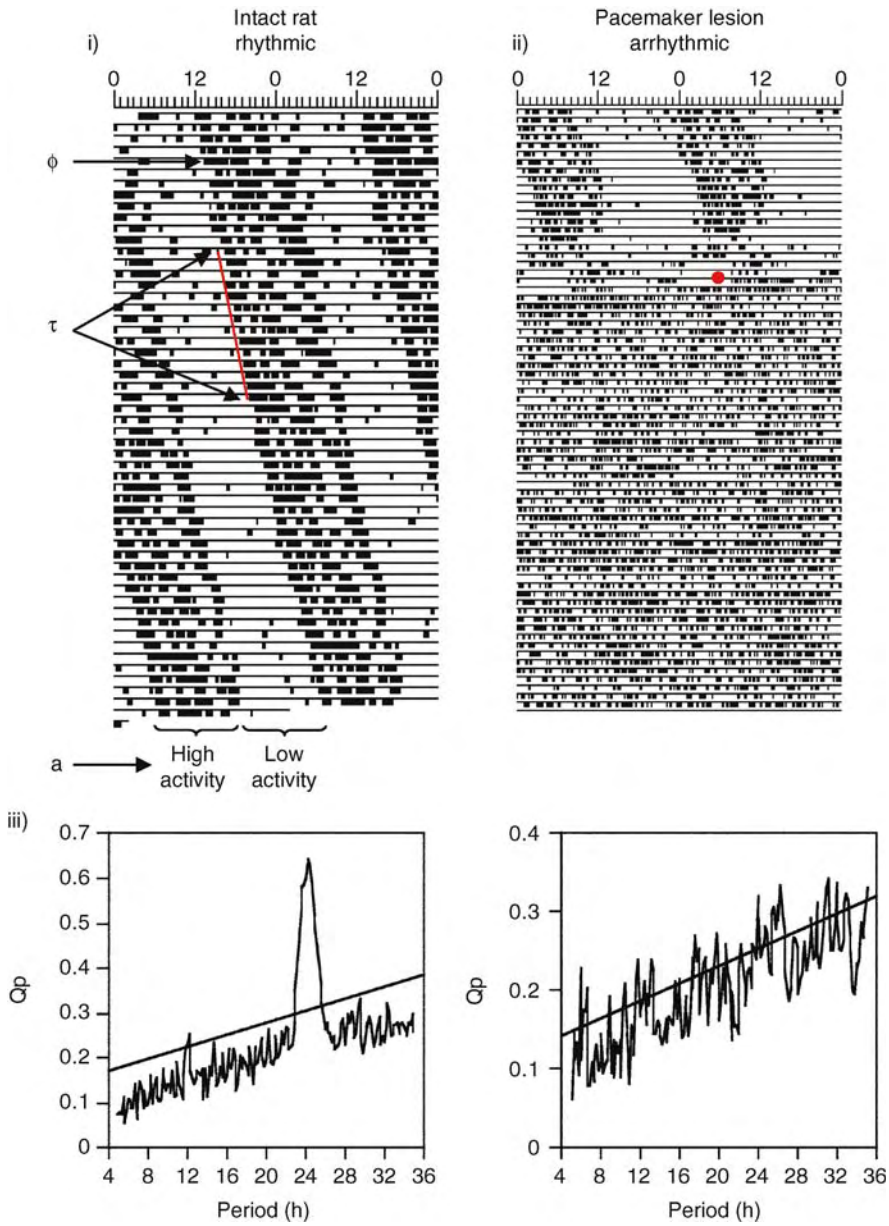
**Arrhythmicity/Rhythmicity. Figure 1** The circadian oscillation.

The preferred graphical representation for circadian rhythms is the actogram (Fig. 2 i, 2 ii). Actograms display time of day on the abscissa, and consecutive days on the ordinate. Activity counts are usually summed into 6 or 10 min intervals, or activity bins, and are represented as black ticks along the abscissa. Double-plotted actograms display 48 h of circadian activity on each line, facilitating the visualization of the rhythm. Although actograms were originally designed to graphically represent the locomotor activity rhythm of an organism, they can be used to plot other physiological variables such as temperature, pupal eclosion, cell firing, or gene expression. The actogram on the left shows running wheel activity of a rat housed in complete darkness (Fig. 2 i). From this actogram, one can easily determine the phase of the rhythm: in this case (and by convention) locomotor activity onset; the period of the rhythm (the slope of the eye-fitted line of best fit that passes through successive activity onsets); and the amplitude of the rhythm (high activity at subjective nighttime (►subjective day/night), low activity at subjective daytime). In contrast, the actogram on the right shows arrhythmicity in a rat following a lesion of the central ►circadian pacemaker (Fig. 2 ii). Following the lesion (red dot on the actogram), no clear phase, period, or amplitude of the rhythms can be measured.

The Chi-square periodogram (Fig. 2 iii) is a statistical test that is commonly used to extract the presence, and compute the value, of circadian periods within a given time series data set. This procedure was first developed by Enright [2] and later refined by Sokolove & Bushnell [3]. Typically, a minimum of 10 consecutive days of activity data is required for the accurate computation of circadian periods using the Chi-square periodogram. Significant periods present in the sample are observed as peaks above the significance level of the Chi-square statistic. As can be seen in the periodogram in Fig. 2 iii, there is one significant and dominant period very close to 24 h in the rhythmic animal (Fig. 2 i) and a multitude of different periods in the arrhythmic animal (Fig. 2 ii). The Chi-square periodogram has the advantage of reducing experimenter bias in the computation of the period of circadian rhythms compared to the eye-fitted regression line used in the actogram. However, the precision of the Chi-square periodogram is affected by the size of the bins used to collect the activity data, and by very short data sets.

## Dependence on the Circadian Clock

Circadian rhythmicity in all organisms is driven by a small set of ►putative clock genes that are interlinked into one or more transcription-translation ►feedback loops [4]. These genes are expressed in various cell types, tissues, organs and organisms [1]. In animals with a central nervous system, a central pacemaker is responsible for the generation of circadian rhythms. For example, in mammals, the primary circadian pacemaker is localized within the hypothalamic ►suprachiasmatic nucleus (SCN). In *Drosophila melanogaster*, a small set of lateral neurons (LN) in the fly brain are responsible for circadian rhythmicity. Lesion of the mammalian SCN or the *Drosophila* LN will abolish rhythmicity. Mutations in the molecular mechanism driving the circadian oscillation will also lead to altered rhythmicity and/or arrhythmicity. For example, the ►*tau*



**Arrhythmicity/Rhythmicity. Figure 2** The actogram and periodogram as ways to analyze rhythmicity and arrhythmicity.

mutation in hamsters, which affects a key regulatory enzyme, leads to a circadian period of about 20 h [5]. The genes *cryptochrome, period, and bmal1* in mammals are considered essential components of the molecular clock and mutating or knocking-out these genes will lead to drastic changes in period and arrhythmicity [4]. In flies, the *timeless* gene is an essential component of the circadian machinery and its absence leads to arrhythmicity [6]. In *Neurospora*, the circadian oscillation relies on the expression of the *frequency* and *white-collar* genes [7].

## Environmental Causes for Arrhythmicity

Circadian arrhythmicity can occur through several ways. As described previously, destruction of the central pacemaker or mutations in key genetic elements will lead to immediate loss of circadian rhythmicity at the behavioral and physiological levels (see Fig. 2 ii). However, environmental signals can cause arrhythmiciy as well. The best known exogenous stimulus that will severely affect circadian rhythmicity and often lead to arrhythmicity is light. Constant bright light exposure will initially affect the period of the circadian oscillation

(see ►Aschoff's Rules). Over time, constant light will lead to disruptions of circadian rhythms. ►Splitting, the fragmentation of the ►activity phase into two components 180° out of phase, occurs in mice and hamsters housed in constant bright light. Constant light can eventually lead to complete arrhythmicity, similar to what can be observed after destruction of the central pacemaker (Fig. 2 ii). Interestingly, the disruptive effects of constant light are slow to appear and typically necessitate weeks or months of constant exposure. The effects of constant light are also intensity-dependent. Constant light of low intensity is less disruptive than high intensity constant light. Importantly, the effects of constant light on rhythmicity cannot be attributed to a destruction of the pacemaker, because rhythmicity is restored upon transfer to complete darkness or a light/dark cycle.

# Articular Cartilage

Walter Herzog
Professor, Faculty of Kinesiology , University of Calgary, Calgary, Canada

## Definition

Articular cartilage is a thin layer of fibrous connective tissue on the articular surfaces of bones in synovial joints (Fig. 1).

It consists of cells (2–15% in terms of volumetric fraction) and an intercellular ►matrix (85–98%) that is made up of 65–80% water.

## Characteristics

### Function

The major functions of articular cartilage are to transfer forces between articulating bones, to distribute forces in joints and to provide a nearly frictionless surface for joint movement.

### Description of the Structure

Articular cartilage is heterogeneous and its material properties change as a function of depth. Although theses changes are continuous, articular cartilage is typically divided into four zones (Fig. 2).

- Superficial zone
- Middle (or transitional) zone
- Deep (or radial) zone
- Calcified zone

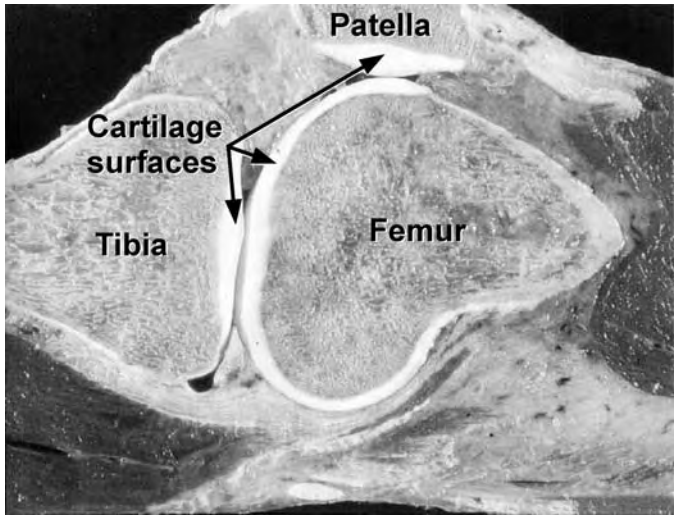
The superficial zone is the thinnest, most superficial region that provides the gliding surface for joints. It contains a superficial layer (►*lamina splendens*) of about 2 μm thickness that is made up of randomly aligned ►collagen fibrils and a deep layer of collagen fibrils aligned parallel to the cartilage surface following the so-called "split line" pattern [1], which follows the direction of normal joint movement.

The collagen fibrils of the superficial zone show a wave-like pattern referred to as ►*crimp*. The deep layer of the superficial zone contains articular cartilage cells (►*chondrocytes*) that are flat and metabolically relatively inactive [2], contains little proteoglycan, but has the highest water concentration of all zones (about 80%) [3].

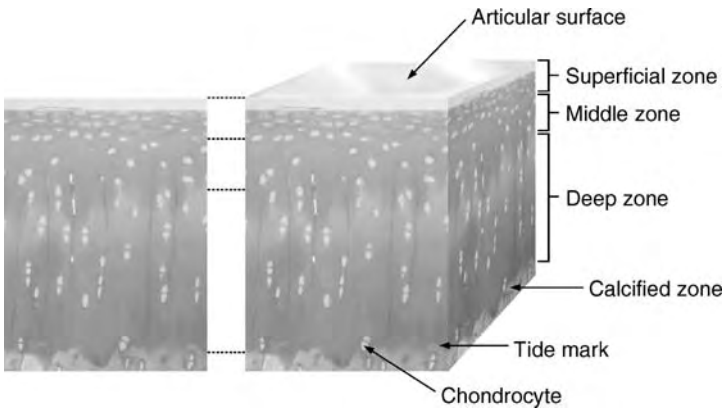
The middle (or transitional) zone is typically thicker than the superficial zone. Collagen fibrils have a greater diameter in this zone than in the superficial zone and are oriented randomly. The proteoglycan content is greater and aggregate complexes are larger than in the superficial zone. The chondrocytes are nearly spherical and are thought to be metabolically more active than those in the superficial zone.

The deep (or radial) zone contains the largest diameter collagen fibrils. They are oriented perpendicularly to the subchondral bone and the cartilage surface. The chondrocytes tend to be aligned in radial columns and are thought to be metabolically highly active.

The calcified zone provides the mechanical transition that separates the relatively soft cartilage tissue from the stiff subchondral bone. It is characterized by hydroxyapatite, an inorganic constituent of the bone matrix. The calcified zone is separated from the deep (radial) zone by the ►*tidemark*, an undulating line of a few micrometers thickness. Collagen fibers from the deep zone penetrate the tidemark and anchor the calcified zone, thereby adhering cartilage to bone. The calcified zone contains metabolically active



**Articular Cartilage. Figure 1** Sagittal plane section through a human knee showing the femur, tibia, and patella and associated articular cartilage.



**Articular Cartilage. Figure 2** The four zones of articular cartilage. The superficial zone provides the sliding surface of joints with collagen fibrils aligned parallel to the surface and flat, relatively metabolically inactive cells. The middle (or transitional) zone contains collagen fibrils that are oriented randomly, and cells that are nearly spherical. The deep (or radial) zone contains collagen fibrils that are oriented perpendicular to the subchondral bone (and articular surface) and the cells are typically aligned in radial columns. The calcified zone provides a mechanical transition that separates the relatively soft cartilage tissue from the stiff subchondral bone.

chondrocytes, serves for structural integration and is considered important for nutrition and cartilage repair arising from the underlying bone [4].

## Composition

Articular cartilage consists mostly (85–98%) of *matrix* and a sparse population of cells (2–15%). It is avascular, aneural and alymphatic.

*Chondrocytes* are metabolically active cells in articular cartilage that are responsible for the synthesis and degradation of the matrix. They are isolated, lie in lacunae and receive nourishment through diffusion of substrates. The volumetric fraction, shape and metabolic activity of chondrocytes vary as a function of cartilage depth. Chondrocytes are soft compared to the surrounding matrix, but they are surrounded by a protective cover that consists of a pericellular matrix and capsule, called a ►*chondron*.

The *intercellular matrix* consists of structural macromolecules and fluid. Fluid comprises the greatest part of the extracellular matrix and its volume fraction decreases from the superficial (80%) to the deep zone (65%). Macromolecules, which are produced by the chondrocytes, comprise the remaining 20–35% of the matrix. Of the macromolecules, collagens are the most abundant (50%), while ►proteoglycans make up about 20–35%, and non-collagenous proteins/glycoproteins contribute 15–20% to the tissue dry weight [5].

There are at least 18 different types of *collagen*. However, in articular cartilage, type II collagen is by far the most abundant (about 80–85% of all collagens). Other types of collagen (V, VI, IX, X and XI) are also found in articular cartilage and have been associated with specific functional roles [6, 7]. Collagen molecules are comprised of three α-chains that are interwoven in a helical configuration. Each chain has a high hydroxylysine content and covalently bound carbohydrates that make it readily adhere to proteoglycans.

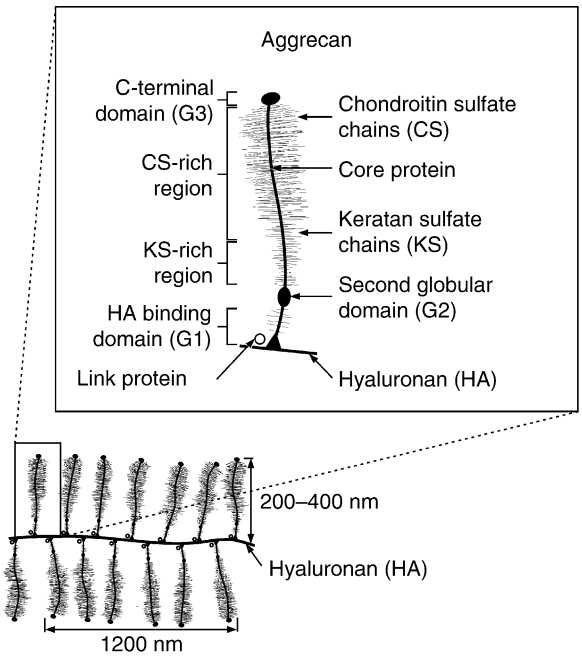
Collagens form a structural network that gives cartilage its tensile strength. Because of the characteristic orientation of the fibrillar network, collagens are associated with providing resistance to compressive loading through their coupling with fluid pressurization. Collagens are cross-linked for further strength [8] and are connected to proteoglycans via molecular chains arising from glycosaminoglycans and polysaccharides. Thus, collagens are intimately connected to other macromolecules and so make up a tough tissue that can withstand high repetitive loading effectively.

*Proteoglycans* are large molecules composed of a central core protein with glycosaminoglycan side chains covalently attached. The side chains contain sugars with a negative charge. When cartilage is loaded, proteoglycans are compressed and the repulsive forces from the negatively charged side chains are increased compared to the natural pre-tensed state.

Articular cartilage contains large aggregating proteoglycans (aggrecan and versican) and small interstitial proteoglycans (biglycan, decorin, fibromodulin and lumican). Aggrecan is the major proteoglycan. It consists of a core protein and up to 150 chondroitin and keratin sulfate chains (Fig. 3).

The core protein's N-terminal G1 domain interacts with link proteins and hyaluronan and these components form stable macromolecular complexes.

Changes in proteoglycan structure and decreased density often accompany articular cartilage degeneration



**Articular Cartilage. Figure 3** Macromolecular aggregate formed by aggrecan molecules (*inset-blown up*) binding to a chain of hyaluronan through a link protein. The aggrecan molecule consists of a core protein with several domains: hyaluronan binding G1 domain, G2 domain, keratin sulfate-rich region, chondroitin sulfate-rich region and C-terminal domain, G3.

and aging [9, 10]. These changes are associated with increases in water content, decreased stiffness and reduced resistance to withstand mechanical loading. They are often the first signs of ►osteoarthritis.

*Non-collagenous proteins* play a role in the assembly and integrity of the extracellular matrix. They form links between chondrocytes and matrix. Non-collagenous proteins include adhesive glycoproteins such as fibronectin, thrombospondin, chondroadherin and other matrix proteins such as the link protein, cartilage matrix oligomeric protein, cartilage matrix protein and proline/arginine-rich and leucine-rich repeat proteins.

Articular cartilage tissue *fluid* consists of water and dissolved gas, small proteins and metabolites. Loading of the articular cartilage produces fluid pressurization and movement. The tissue fluid is closely associated with the ►synovial fluid of the joint, which is essential for virtually frictionless movement of the articulating surfaces.

### Osteoarthritis

Osteoarthritis is a joint degenerative disease that affects about 50% of all people above the age of 60 in North America. It is associated with a thinning and local loss of articular cartilage from the joint surfaces, osteophyte formation at the joint margins, swelling of the joint and pain. The causes for osteoarthritis are not well understood, although it is agreed that they are multi-factorial. Acknowledged risk factors include age, injury, weakness and obesity.

### Definition

Neural network modeling is a powerful research tool based on the combination of theoretical methods, including mathematical analyses and computer simulations, and is complementary to experimental techniques in neuroscience research. Neural networks are used to understand how actual neuronal networks in a particular brain area represent and process information, and how they perform specific computations such as planning and execution of movements.

### Description of the Theory

#### General Frameworks

The relationship between theory and experiment plays an important role in neural network modeling and creates a wide spectrum of approaches [1–3]. Some models are heavily based on the anatomical and electrophysiological properties of the actual neuronal networks involved. Studies along this line usually proceed from the detailed description of single cells to the behavior of the network. This approach is most useful when accurate experimental data at the morphological and physiological levels are available, the function of the neuronal network is already known, and the network itself is relatively small. Such models can determine whether existing data are sufficient to explain observed network behavior, and intend to pinpoint drawbacks and missing components in the model. The alternative to this *data-driven/bottom-up* approach is a *theory-driven/top-down* approach. Here, the emphasis shifts to descriptions of higher-level functions such as a perceptual ability. Based on the theoretical analysis, an algorithm that performs the desired function is developed first and then embedded into a simplified network while imposing known biological constraints. This kind of approach tends to be more loosely bound to particular experimental data. However, by sacrificing specificity, the theory-driven approach attempts to address fundamental and puzzling questions, and can help in formulating and testing what kind of computational algorithms the brain is using in different tasks. In the long run, this approach is expected to suggest new experiments and research directions.

Whereas the data-driven and theory-driven approaches represent two opposite extremes, there are varieties of other approaches that combine different proportions of the "abstract" and "realistic" components of the modeling and fill in the gap between these two extremes. Anyhow, biologically plausible models must not contain all the known features of the target system; they need to include only those features that are necessary to accurately simulate a particular phenomenon under study.

In this essay, only basic concepts relevant to the modeling of large-scale neural networks are considered. For further readings on the theory-driven approaches, see the book by Hertz et al. [4] and the review by Ermentrout [5] that focus not so much on biological modeling as on general theoretical approaches and algorithms. In contrast, the monograph by Anderson [6] and the textbook by Dayan and Abbott [7] consider neural networks from a broad neuroscience perspective, with an emphasis on the biology behind the assumptions of

models, as well as on for what the models might be used. Finally, the link between the theoretical studies and experimental approaches is the main concern of the book by Koch and Segev [2]. It has an excellent collection of papers for those interested in biophysical mechanisms of computation in neurons and networks.

## Network Architecture and Operation

### Units and Connections

Depending on the complexity of a target neuronal system and the desired level of realism, each unit of the model network may simulate either a single neuron or a set of similar neurons with coherent functional properties. The communication of activity from one neuron to another is modeled by means of a connection between a corresponding pair of units. The entire set of units and the pattern of connections between them define the architecture of the network. The realistic design of architecture requires knowledge of the underlying neural structure from neuroanatomical studies. When such data are not available, which is often the case, an educated guess based on other indirect studies could be useful.

### Types of Units

Each unit can be classified as input, output, or hidden depending on the role that it plays in the operation of the network. ►Input units receive external signals that may represent sensory signals, signals from other networks, or some events in the external environment of an organism. The stimulation of input units may then change the activities of ►hidden units to which they are connected. This perturbation may further propagate across the whole network through connections to other hidden units and ultimately reach the ►output units. The role of the latter is to provide an input to another network or simulate events at the behavioral level, for example, a motor action. Depending on the network architecture and its interpretation, the input, hidden, and output units may overlap partially or completely.

### Types of Architecture

There are two prevailing network architectures in neural networks. Fig. 1a shows an example of layered ►feed-forward network. The role of the input units is to feed external signals to the rest of the network.

All connections are feed-forward. There are no connections between units in the same layer. Units in the intermediate layers are considered as hidden units, whereas the last layer represents the output units.

Networks that are not strictly feed-forward but include feedback connections are called recurrent networks. An example of a fully ►recurrent network is presented in Fig. 1b. Unlike the feed-forward architecture, there is no explicit distinction between input, hidden and output units.

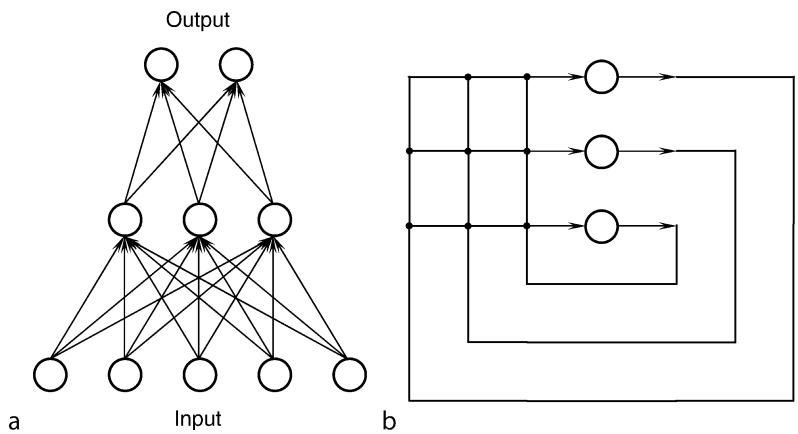
### Dynamical Rules

The specification of architecture is necessary but not sufficient for the complete definition of network operation. One also needs to define the dynamical rules that stipulate how and when the state of each neuron is updated. Once the network is fully specified its operation is to transform the input signals into output ones.

## Single Neuron Models and Synaptic Interactions

### Integrate-and-Fire Model

A simple single-neuron model that generates action potentials is known as ►integrate-and-fire neuron. The basic idea is to divide the operation of a neuron $i$ into



**Artificial Neural Networks. Figure 1** (a) Network architecture. *Circles* represent units, whereas *lines* show connections between them. *Arrows* indicate the directions of connections. (a) Feed-forward network with one hidden layer. (b) Fully recurrent network with three units.

two qualitatively different modes. In the first mode, the neuron builds up its membrane potential starting from a specific value $u_i^{\text{rst}}$, called the reset potential, by temporally integrating its inputs. During this mode, the membrane potential $u_i(t)$ at an instant of time $t$ obeys the dynamical rule given by a resistor-capacitor circuit charging equation:

$$\tau_i \frac{du_i}{dt} = -u_i(t) + R_i I_i(t). \tag{1}$$

Here, the time constant $\tau_i = R_i C_i$ depends on the resistance, $R_i$, and capacitance, $C_i$, properties of the cell membrane; the term $-u_i(t)$ is the trans-membrane leakage, whereas $I_i(t)$ is the total synaptic current charging the spike emitting part of the cell, soma. Once the potential $u_i(t)$ reaches a specific threshold value $u_i^{\text{thr}}$, the neuron enters into its second mode of operation by instantaneously firing a spike and resetting the potential to $u_i^{\text{rst}}$. After an absolute refractory period, during which the cell cannot emit spikes, the neuron restarts its operation in the first mode. Thus, the outcome of the model is the alteration of the prolonged period of integration and instantaneous firing.

In the framework of integrate-and-fire model, the effective synaptic current $I_i(t)$ charging the soma can be modeled in several ways. The dynamics of $I_i(t)$ depends on a set of synaptic time constants $\{\tau_{ij}^{\text{syn}}\}$. Each $\tau_{ij}^{\text{syn}}$ characterizes the temporal variation of the synaptic conductance of neuron $i$ invoked by arriving spikes fired by neuron $j$. In the approximation $\tau_{ij}^{\text{syn}} << \tau_i$, i.e. when the characteristic time of the synaptic current changes is much shorter than that of the charging of the soma, the effective total current $I_i(t)$ is represented by a sum of elementary contributions made at the time of arrival of individual spikes [8]:

$$I_i(t) = \tau_i \sum_j w_{ij} \sum_k \delta(t - t_j^k - \Delta_{ij}), \tag{2}$$

where $t_j^k$ is the time when neuron $j$ emitted the k-th spike, $\Delta_{ij}$ is the delay in the arriving time at synapse $i$ of spikes fired by neuron $j$, and $\delta(x)$is the Dirac delta function. The synaptic efficacy, $w_{ij}$,is expressed in units of the current.

### Conductance-Based Models

A more realistic approach to representing the effective charging current $I_i(t)$ utilizes a ►conductance-based model that accounts for a variety of transmembrane ionic currents. In this framework, (1) is usually given in the following form:

$$C_i \frac{du_i}{dt} + I_i^{\text{ion}}(t) = 0. \tag{3}$$

Here, $I_i^{\text{ion}}(t)$ designates the net transmembrane ionic current, including the leakage. It is assumed that all ionic current flow occurs through membrane channels, and the instantaneous voltage-current relationship obeys Ohm's law. The ionic current through channels of a particular type *chn* is then given by a linear expression:

$$I_i^{chn}(t) = g^{chn}(u_i(t) - E^{chn}), \tag{4}$$

whereas the net ionic current $I_i^{\text{ion}}(t)$ is a simple sum of the currents through different types of channels: $I_i^{\text{ion}}(t) = \sum_{chn} I_i^{chn}(t)$. Here, $g^{chn}$ is the conductance associated with the specific type of channel *chn*. The sign of the expression in (4), which indicates whether the current is outward or inward, depends on whether the membrane potential $u_i(t)$ is above or below the channel reversal potential $E^{chn}$. It is usually assumed that $E^{chn}$ does not explicitly depend on time or potential. The known ion channels can be divided into three distinct types: passive or leak, synaptic, and active. Depending on the type of the channel, the corresponding conductance $g^{chn}$ may have a mathematical description that ranges from very simple to very complex. For example, the passive channels are represented by a constant (time- and voltage-independent) conductance. Other channels, such as those located at synapses, change their conductance to certain ions when the appropriate chemical agents (e.g. neurotransmitters or second messengers) bind to their receptors. As the release of chemical agents is triggered by a presynaptic action potential, the conductance of the synaptic channels is modeled as a time-dependent but voltage-independent function that has a sharp peak at the spike arrival time. The active channels have conductances that are both voltage- and time-dependent. The model neuron that incorporates these types of nonlinear channels may produce responses that mimic not only a subthreshold mode but also the generation of action potentials. Unlike the integrate-and-fire model, in which spikes are discontinuous in time, here the spike generation occurs in a continuous-time fashion. Therefore, the model neuron of this type, often referred to as Hodgkin and Huxley [9] or biophysical model, may produce action potentials that have a shape similar to those observed in experiments.

### Compartmental Approach and Realistic Modeling

The models considered so far are *single-point models* that disregard the underlying spatial structure of the neuron. The application of cable theory to nerve axons and dendrites, as well as the introduction of a ►compartmental approach, made it possible to develop increasingly realistic models of a single neuron. Advanced biophysical models of this kind, which are trying to incorporate as much morphological and physiological data as possible, represent a neuron as a set of electrically coupled isopotential compartments. The basic assumption is that the continuously distributed system can be divided into small segments,

called compartments. The geometry of compartments is modeled as an ellipsoid (soma) or cylinder (dendritic or axonal branch) of various sizes. Electrically, each compartment is modeled as a resistance-capacitance pair. Adjacent compartments are connected by series resistances. One must be aware, however, that detailed biophysical models incorporate a vast number of adjustable parameters. While these models are adequate for studying the behavior of a single neuron or a neuronal circuitry composed from a few cells, their application to large-scale networks may be inappropriate.

## Learning and Generalization

The performance of a neural network, which is the relationship between the input signals and the output units' activities produced by the network in response, depends on several factors such as the connectivity pattern, number of neurons, synaptic interactions, etc. Traditionally, the network performance is adjusted by varying only a set of parameters **w** that, in the framework of the underlying model, effectively control the strengths of synaptic connections (e.g. synaptic efficacies in integrate-and-fire model, or synaptic conductances in conductance-based models). Such an approach is consonant to numerous experimental observations, indicating that during relatively short time periods the key mechanism, by which neuronal networks change their behavior, is the modification of the conductivity of pre-existing synapses (i.e. modification of the strength of connections) rather than the variation of the number of neurons or formation of new connections between them (i.e. modification of the network size and the connectivity pattern, respectively). For the sake of certainty, we shall refer to the parameters **w** as the connection weights.

A fixed set of **w** corresponds to a specific input-output transformation task implemented by the network. As the values of individual weights change, the same signals acting on the input units generate different activities of the output units. Therefore, by varying **w**, one can force the network to implement different transformation tasks. This also means that the network memorizes the task that it implements in the set of connection weights **w**. A key question in the theory of neural networks concerns the problem of *learning*: "How do we choose the connection weights so the network implements a specific task of interest?" The systematic adjustment of the connection weights, the goal of which is to find such a set **w** that implements the desired task, is called training or learning and is described by a corresponding ►learning algorithm.

The common approach to network learning is formulated as follows. The known examples (i.e. input-output pairs) of a particular transformation task to be learned are divided into two subsets: the training set and the testing set. The former is used to train the network to produce an appropriate output for each input in the set by applying a specific learning algorithm. It is expected that after training, the network will generate correct (or nearly correct) responses for all examples in the training set. Next, one would like to check whether the network indeed has learned the transformation task or whether it has simply memorized examples in the training set. For that purpose, examples from the testing set are presented to the network. If the responses to the novel examples of the same task are correct, then it is said that a *generalization* has taken place. If, however, the number of correct responses is at a chance level then there is no generalization.

### *Types of Learning Paradigms*

Two types of learning paradigms are generally distinguished: supervised and unsupervised. ►Supervised learning requires the knowledge of correct output responses for all examples in the training set. In this approach, which is also known as learning with a teacher, a direct comparison of the produced outputs against the correct responses provides a feedback to the network about its performance. The comparison is done in terms of the error function E(**w**) that is, as a rule, a simple quadratic form of differences between the produced and correct outputs. The learning algorithm is an iterative procedure that adjusts the connection weights based on the feedback error E(**w**). Its ultimate goal is to find such a set of the connections **w** that minimizes the error function. Thus, supervised learning, in essence, is an optimization problem. ►Back propagation and ►simulated annealing (see [4,6]) are two examples of supervised learning algorithms commonly used in neural networks.

Unlike supervised learning, in ►unsupervised learning there is no teacher and corresponding algorithms do not require any feedback about the performance. Therefore, unsupervised learning can be used when correct responses to the inputs in the examples are not known, or the learning goal at the neural level is not explicitly defined. In the course of unsupervised learning, the network is expected to detect features and regularities in the input signals by itself, and represent them in the output in some appropriate way. In the framework of this approach, during the presentation of an example in the training phase, the modification of an individual connection weight is influenced only by the states (activities) of the two units that it is linked to and by its own state (value). Thus, in unsupervised learning, changes in connection weights are affected only by local events whereas in supervised learning, due to the global character of the feedback error, those changes are affected by remote events (i.e. activities of the output units). In contrast to supervised learning, the unsupervised learning paradigm could

therefore provide a suitable framework for studying biological mechanisms of learning. A well-known example of unsupervised learning is ►Hebbian learning rule, which stipulates that concurrent firing in the pre- and post-synaptic neurons strengthens the synaptic connection.

## Ascending Neuromodulatory Projections

### Definition

This collective term is used to describe a number of varyingly loosely aggregated collections of neurons occupying the brainstem or basal forebrain that are characterized by long projections that ascend to innervate, usually diffusely, the cerebral cortex and certain of the deep telencephalic nuclei. Such projections are further characterized on the basis of their major neurotransmitters, among which are included epinephrine, norepinephrine, dopamine, serotonin, histamine, orexin and acetylcholine. Consistent with the typically neuromodulatory effects of such projection systems on telencephalic functions, they have also been referred to as "state-setting projections."

## Ascending Nociceptive Pathways

Steve Davidson, Glenn J. Giesler, Jr
Department of Neuroscience, University of Minnesota, Minneapolis, MN, USA

### Synonyms

Anterolateral pathway; Pain system; Ascending pain pathways

### Definition

Nociceptive neurons in the spinal cord and trigeminal nuclei send their axons to terminate within a large number of regions in the upper cervical spinal cord, brainstem and diencephalon. These neurons provide a link between peripheral nociceptors and pain perception in the brain. Precise roles for each ascending pathway in nociception have not yet been established with certainty and it is likely that their roles vary among species. This overview presents a summary of prominent findings on several of the most thoroughly examined ascending nociceptive projections.

### Characteristics

#### Spinothalamic Tract (STT)

Several early clinical cases in which injury to the spinal cord blocked the sense of pain suggested that axons carrying nociceptive information crossed within the spinal cord and then ascended within the anterior white matter [1]. These observations led to the first surgical

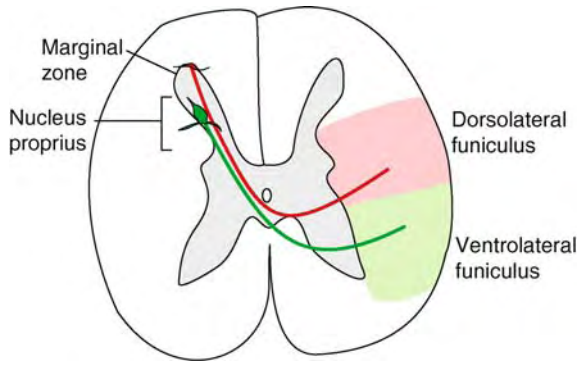
attempts to relieve chronic pain by ►cordotomy, i.e., cutting the anterolateral quadrant of the spinal cord, the area now known to carry an overwhelming majority of ►spinothalamic tract (STT) axons. Cordotomy can very effectively eliminate pain for patients, but the positive effects are short lived and pain frequently returns within several months. It is not known which tracts begin to carry the nociceptive information following a cordotomy.

Anatomical studies in a variety of species including primates demonstrated that lesions of the spinal cord caused degeneration of axons within the thalamus. Both ►anterograde and ►retrograde tracing studies have since determined the locations and numbers of the cells of origin of the STT, as well as the areas of termination of STT axons within the thalamus. ►Antidromic activation and extracellular recording techniques have been used to identify and functionally characterize the stimulus-response properties of STT neurons to mechanical, thermal, and chemical stimuli.

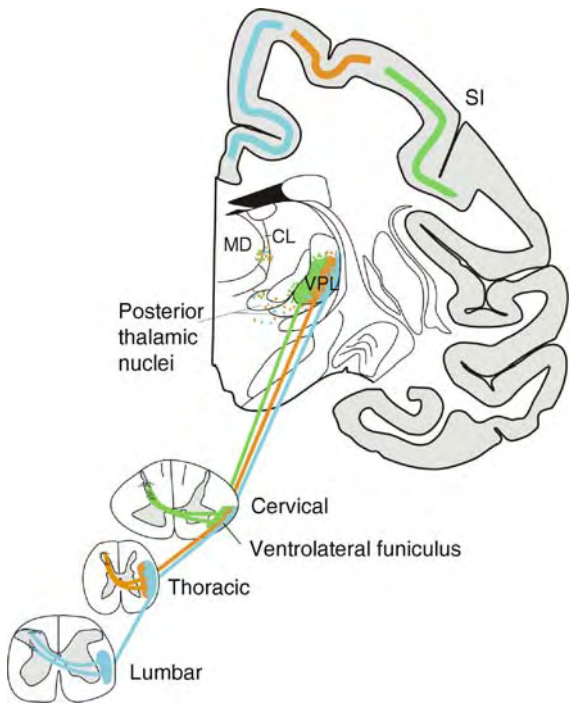
The cells of origin of the STT are found within the spinal gray matter at all levels of the cord. STT cell bodies and dendrites receive glutamatergic and several types of peptidergic inputs. It has been estimated that there are between 15 and 20 thousand STT neurons on one side of the spinal cord of primates [1,2]. The upper cervical segments have been shown to contain 1/3 of all cells of origin of the STT. Within the gray matter, STT neurons are concentrated in the marginal zone (lamina I) and within the deep dorsal horn (lamina V). STT neurons are also found within the intermediate gray zone and the ventral horn. Most axons of STT neurons decussate at a level near the cell body and then turn to ascend within the ►ventrolateral funiculus. STT axons originating from marginal zone neurons ascend in a position that is dorsal to STT axons originating from neurons within the deep dorsal horn. Within thoracic levels, STT axons of marginal zone neurons are generally located dorsal to the denticulate ligament in the dorsal lateral funiculus, whereas the axons of lamina V neurons are found within the ventral part of the lateral funiculus ([2], Fig. 1). There is a somatotopic organization of ascending STT axons such that axons from lumbosacral levels ascend on the periphery of the lateral funiculus, whereas STT axons from progressively rostral levels are located closer to the gray matter ([3], Fig. 2).

STT axons continue to ascend through the lateral and ventral brainstem. Collateral branches are frequently given off by these axons supplying nociceptive sensory information to a number of nuclei, particularly within the reticular formation.

STT axons terminate in three principle regions of the thalamus including the ventral posterior lateral (VPL), central lateral and adjacent parts of the medial dorsal nucleus, and posterior thalamic nuclei [1,4]. STT terminations within VPL are somatotopically organized.



**Ascending Nociceptive Pathways. Figure 1** Axons os spinothalamic tract neuron cross to the contralateral side of the spinal cord and ascend the white matter within the antero–and dorsolateral funiculi.

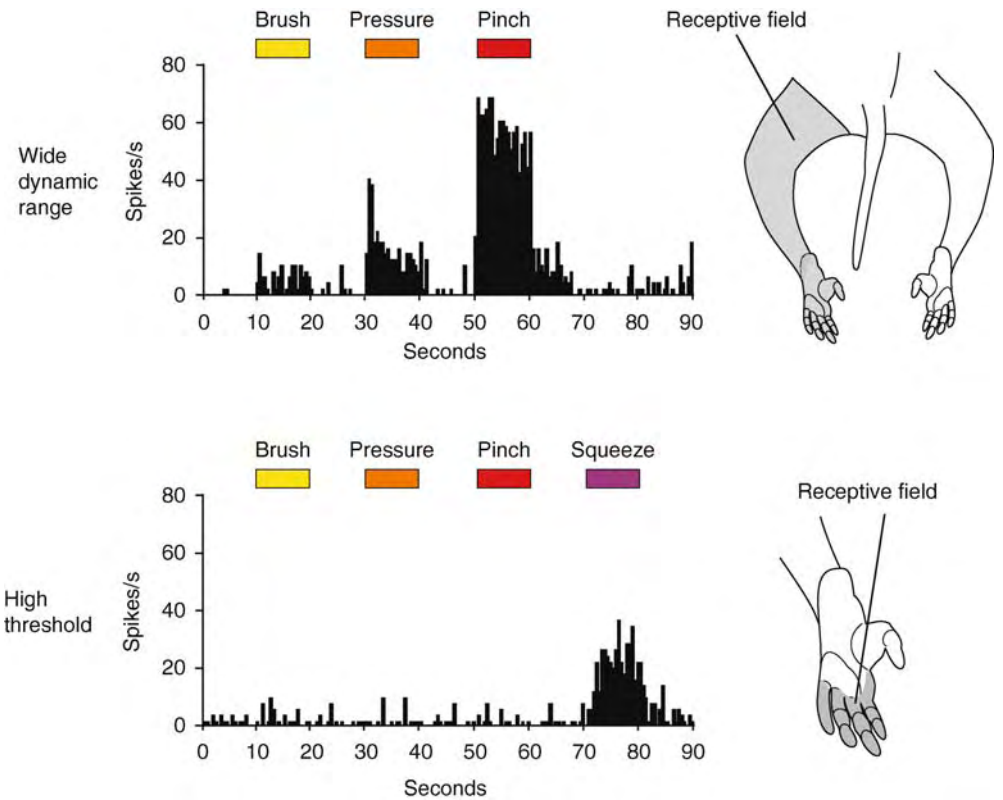


**Ascending Nociceptive Pathways. Figure 2** The spinothalamic tract is somatotopically organized. Axons from neurons in rostral segments of the spinal cord ascend medially relative to axons orginating from caudal segments. The somatotopy is maintained within the major target nucleus of the thalamus, the ventroposterior lateral nucleus. Primary sensory cortex is somatotopically organized with lumbar segments (e.g. leg) represented medially within the post–central gyrus and cervical segments (e.g.arm) represented laterally.

Axons ascending from lumbosacral levels terminate within the lateral part of VPL; those from cervical levels end within the medial part of the nucleus. Within VPL of primates, STT terminals are concentrated within small

areas that are surrounded by large regions that are dominated by the endings of medial lemniscal axons. A high percentage of nociceptive neurons within the primate VPL can be antidromically activated from primary somatosensory cortex, indicating that nociceptive input to VPL neurons via STT axons is transmitted to the cortex (Fig. 2). A second area of termination of the STT is the central lateral nucleus and the adjacent lateral region of the medial dorsal nucleus. STT neurons projecting to this region are often located within the intermediate zone and ventral horn of the spinal cord. Many of the nociceptive neurons within this area of the thalamus have large, bilateral, even whole-body receptive fields. Thus it is unlikely that this region is involved in localization of nociceptive stimuli, and instead may be involved in the production of affective/emotional responses to nociceptive stimulation. STT axons that terminate in the posterior thalamic nuclei appear to arise predominantly from neurons of the marginal zone. A recently described area of primate thalamus, the posterior part of the ventral medial nucleus, is suggested to receive a large proportion of STT inputs [4]. Nociceptive information originating from receptors on the face in the oral and nasal cavities is carried to the ventral posterior medial nucleus of thalamus by trigemino-thalamic tract projections.

Responses of STT neurons to a variety of somatic and visceral stimuli have been examined [1]. In primates, the vast majority of STT neurons have been classified as nociceptive, responding either preferentially (wide dynamic range, WDR) or specifically (high threshold, HT) to mechanical noxious stimuli (Fig. 3). In most studies, higher percentages of HT-STT neurons have been found in the marginal zone and more WDR neurons within the deep dorsal horn. Cutaneous receptive fields of neurons in the marginal zone tend to be smaller, sometimes being restricted to a single toe. The receptive fields of deeper neurons often cover much of the ipsilateral leg. Many STT cells are activated by noxious thermal stimulation of their receptive fields. Response thresholds to noxious heat stimuli are often between 45 and 55°C. Repeated applications of noxious heat stimuli lead to sensitization, including reduced response thresholds, increased response magnitude



**Ascending Nociceptive Pathways. Figure 3** Spinothalamic tract neurons are typically classified as one of two types: Wide Dynamic Range or High Threshold. Wide Dynamic Range neurons are responsive to innocuous stimuli applied to their receptive fields as well as noxious stimuli. High Threshold neurons do not respond to innocuous mechanically stimuli. Both types may respond to thermal and/or chemical stimuli.

to identical noxious heat stimuli, and the production of ongoing activity. STT neurons also receive nociceptive input from muscles and joints, and they can be activated by stimulation using noxious chemicals such as Capsaicin, mustard oil and histamine.

STT neurons also can be activated by noxious stimulation of visceral tissues. In almost all cases, STT neurons that respond to stimulation of a visceral organ have somatic receptive fields as well. Frequently, somatic receptive fields are located in areas to which noxious stimulation of an organ would produce ►referred pain in human. STT axons are therefore capable of carrying nociceptive visceral information, and the convergence of somatic and visceral nociceptive input probably contributes to the phenomenon of referred pain.

## Spinohypothalamic Tract (SHT)

Burstein [5] noted that spinal cord neurons could be antidromically activated using small amplitude current pulses delivered through electrodes located within the hypothalamus of rats. In addition, injections of anterograde tracers into the spinal cord labeled axons within several areas of the hypothalamus, including the lateral, posterior, and ventromedial hypothalamus. Injections of retrograde tracers that were restricted to the hypothalamus labeled thousands of neurons within the spinal cords of rats. Spinohypothalamic tract (SHT) cell bodies were located in the marginal zone and the deep dorsal horn. SHT axons have been shown to ascend to the posterior thalamus, then turn ventrally to enter the supraoptic decussation. These axons continue to ascend in a position just dorsal to the optic tract and enter the hypothalamus (Fig. 4). Many SHT axons ascend to the level of the optic chiasm where they decussate a second time, turn posteriorly, and then descend within the supraoptic decussation on the side ipsilateral to the cell body form which they originated. SHT axons have been shown to terminate in the ipsilateral hypothalamus, posterior thalamus, and brainstem. Some have even been shown to descend as far as the level of the medulla. SHT neurons are frequently nociceptive. Some also receive an apparent input from innocuous thermoreceptors. It has been suggested that through their complex, bilateral projections and frequent branches, SHT axons could provide nociceptive input to a variety of areas of the brainstem and forebrain that are involved in nociceptive processing. SHT neurons have also been identified and characterized in monkeys. Large numbers of neurons within all divisions of the trigeminal complex and upper cervical segments similarly send axonal projections to the hypothalamus.

## Spinoreticular Tract (SRT)

The spinoreticular tract (SRT) is a direct projection from spinal cord neurons to the reticular formation of medulla, pons and midbrain ([1,6], Fig. 4). Regions that receive these direct spinal afferent fibers include the nucleus gigantocellularis and nucleus dorsalis, both within the medulla, and the cuneiform nucleus of the midbrain. Because several of these regions in the reticular formation in turn send ascending nociceptive projections to the forebrain, it is believed that the SRT is part of a multisynpatic projection system to the thalamus and probably is involved in providing nociceptive information that is used in producing cortical arousal.

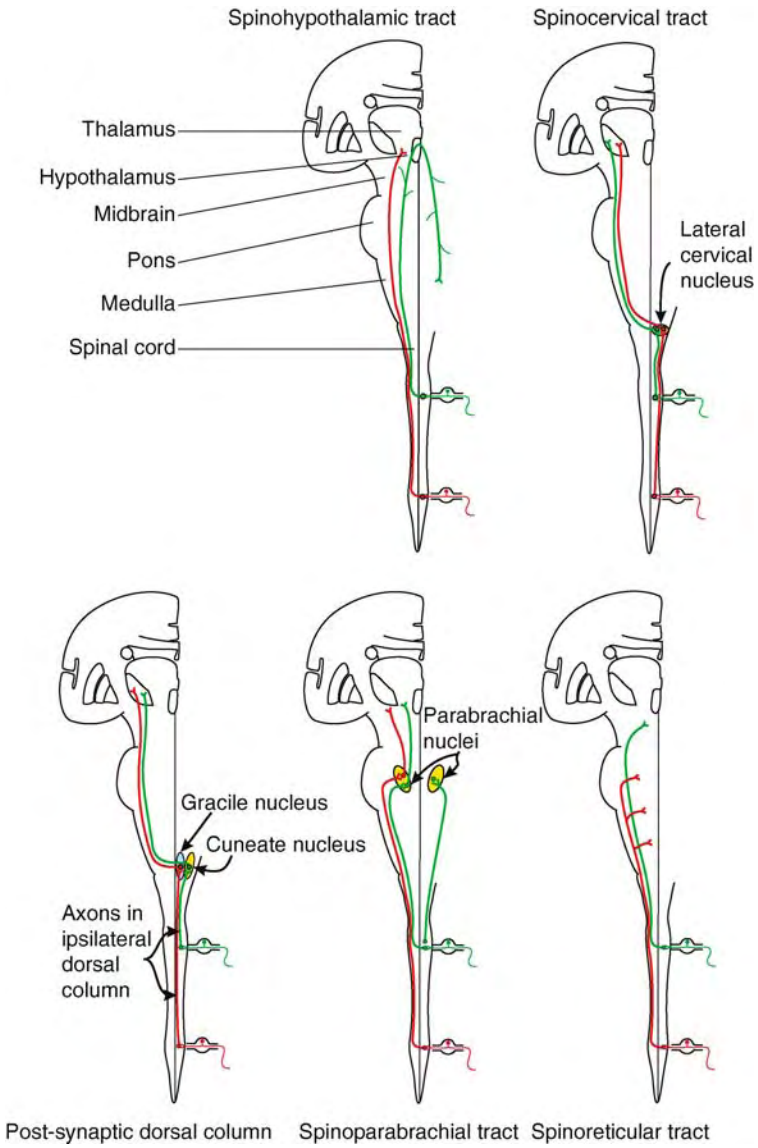
Studies in which antidromic methods have been used to demonstrate direct projection to the reticular formation have shown that many SRT neurons are nociceptive. These neurons have been frequently recorded deep within the spinal gray matter and have large complex receptive fields frequently including the face. Retrograde tracing studies indicate that SRT neurons are found within the marginal zone and deep dorsal horn, but a large percentage are located within the intermediate zone and ventral horn.

## Spinoparabrachial Tract

Somatic sensory and nociceptive information ascends directly from the spinal cord to several sub-nuclei of the parabrachial nucleus, which is located lateral to the superior cerebellar peduncle within the rostral pons and caudal midbrain ([7], Fig. 4). The locations of the cells of origin of the spinoparabrachial tract have been established using electrophysiological and anatomical techniques. Injections of retrograde tracers that are restricted to the parabrachial nucleus label a large number of spinal neurons at all levels of the spinal cord of rats and cats. Although spinoparabrachial tract neurons are found throughout much of the gray matter, the fact that they are highly concentrated within the marginal zone has generated a great deal of interest in this projection. Anterograde tracing studies indicate that neurons in the marginal zone send a large projection via the dorsal part of the lateral funiculus to the parabrachial nuclei on both sides. Studies in which antidromic activation has been used to identify spinoparabrachial tract neurons in cats indicate that the overwhelming majority is activated by noxious stimuli. The parabrachial nuclei are known to have large projections to several areas of the forebrain that are involved in nociception, including the hypothalamus and the amygdala. Therefore, this projection appears well suited for providing nociceptive information that is used for producing cognitive, emotional or affective responses to pain.

## Spinocervicothalamic Tract (SCT)

Spinocervical tract neurons are located throughout the length of the spinal cord. Many SCT neurons receive powerful afferent input from innocuous mechanoreceptors and as many as half of SCT neurons also receive nociceptive input [8]. These neurons send their ascending axons into the dorsal part of the ipsilateral lateral



**Ascending Nociceptive Pathways. Figure 4** Illustrations of other ascending nociceptive pathways.

funiculus. SCT axons ascend to upper cervical segments where they terminate within the lateral cervical nucleus (LCN), an island of neurons extending from segment C3 through C1 that is located with the dorsal lateral funiculus (Fig. 4). The number of neurons that form the LCN varies greatly among species, but in carnivores may be as many as 10,000 neurons. The LCN is comparatively small in monkeys, although precise cell counts are not available. In humans the LCN has been reported to be highly variable. Some individuals appear to have a prominent LCN on one side and few if any LCN neurons on the other. Other individuals appear to have a clear LCN on both sides, and some have no LCN on either side. These findings suggest a lesser, variable role for the SCT in nociception in humans.

Roughly half of LCN neurons in carnivores are nociceptive and these have been shown to respond specifically or preferentially to noxious mechanical stimuli. Many of these neurons can also be activated by noxious heat stimuli. LCN neurons that receive mechanoreceptive or nociceptive input are somatotopically organized; neurons in the lateral LCN receive input from lumbosacral segments, whereas neurons in the medial LCN receive input from cervical levels. A small number of neurons in the medial LCN have nociceptive whole-body receptive fields. Axons of LCN neurons decussate in upper cervical spinal cord and ascend to terminate in the contralateral VPL. As many as half of ascending axons of LCN neurons give off branches that terminate within the midbrain.

### Postsynaptic Dorsal Column Projection (PSDC)

Injections of retrograde tracers into the dorsal column nuclei of cats, rats and monkeys label large numbers of neurons throughout the length of the spinal cord [9]. Many of these are located in nucleus proprius (laminae III and IV). A smaller number are found near the central canal. Anterograde tracing studies indicate that most axons of this type ascend within the ipsilateral dorsal columns, but some appear to ascend within the dorsal lateral funiculus (Fig. 4). In cats, PSDC axons frequently terminate in the periphery of the dorsal column nuclei while primary afferent fibers often terminate in the cores of the two nuclei. In rats, the terminations of these projections appear to overlap more substantially. In cats, roughly half of PSDC neurons can be driven exclusively by innocuous mechanical stimulation and the remainder can be classified as WDR neurons, indicating that this projection is capable of conveying nociceptive information. PSDC cells have been shown to be powerfully activated by noxious mechanical and heat stimuli. Several lines of evidence indicate that nociceptive visceral information is carried by this projection in rats, monkeys and possibly humans. An elegant series of studies show that PSDC neurons convey nociceptive visceral information that reaches the thalamus [10]. These authors have also pointed out that surgical section of the medial area of the dorsal columns relieves chronic visceral pain in patients.

## Aschoff's Rules

Christian Beaulé
Department of Biology, Washington University, St. Louis, MO, USA

### Definition

Aschoff's Rules are a set of three statements used to describe, and predict, the circadian behavior of animals housed under ►constant lighting conditions. These rules were attributed to the circadian biologist Jürgen Aschoff (1913–98), based on his observations of the spontaneous frequencies (free-running periods) of several animal species.

### Aschoff's First Rule

States that the endogenous free-running circadian period (*tau*, τ), observed in complete darkness (DD), will shorten for ►diurnal animals and lengthen for ►nocturnal animals when they are exposed to constant light (LL). The effects of LL are intensity dependent with brighter light enhancing these effects. Thus, Aschoff's First Rule predicts that $\tau_{LL} < \tau_{DD}$ for diurnal animals and $\tau_{LL} > \tau_{DD}$ for nocturnal animals.

### Aschoff's Second Rule

States that under constant bright light, ►activity time (*alpha, α*) increases compared to ►rest time (*rho*, ρ) for diurnal animals and decreases for nocturnal animals. As a result, the duration of daily activity in constant conditions increases with increasing light intensity for diurnal animals and decreases with increasing light intensity for nocturnal animals. Thus Aschoff's Second Rule predicts that $\alpha_{LL} > \rho_{LL}$ for diurnal animals and $\alpha_{LL} < \rho_{LL}$ for nocturnal animals.

### Aschoff's Third Rule

States that the ►free-running period in DD is longer than 24 h for diurnal animals and shorter than 24 h for

nocturnal animals. Thus Aschoff's Third Rule predicts that: $\tau_{DD} > 24$ h for diurnal animals: $\tau_{DD} < 24$ h for nocturnal animals.

## Characteristics

### Historical Perspective

"Aschoff's Rule" is a term that was originally coined by Colin S. Pittendrigh (1918–96) in 1960 during the Cold Spring Harbor Symposia on Quantitative Biology (Vol XXV, Biological Clocks, 1960). During his symposium, Jürgen Aschoff presented a summary of the circadian behavior of diurnal and nocturnal animals housed under constant conditions (DD and various intensities of LL). Within the species reviewed, diurnal animals (finches, starlings, lizards) shortened their free-running period in LL and nocturnal animals (house mice and white-footed mice) lengthened their free-running period in LL compared to their period in DD. Pittendrigh, who was presenting after Aschoff, made several major empirical generalizations about circadian rhythms; one of these generalizations was "XII: $\tau_{FR}$ is light intensity dependent. There is evidence of a fairly strong further generalization which I propose to call *Aschoff's Rule*. This can be summarized by $\tau_{LL} > \tau_{DD}$ in nocturnal animals; $\tau_{LL} < \tau_{DD}$ in diurnal animals" (where $_{FR}$ means free-running) [1]. Because of this, the first rule is often referred simply as Aschoff's Rule. The other two of Aschoff's rules were not as explicitly stated by Pittendrigh in this article, but nonetheless became part of the circadian nomenclature.

The effects of constant light on the circadian behavior of animals have long been recognized, but Aschoff was among the first to systematically analyze and describe them [2]. At that time, the circadian research field was still in its infancy and the exact conditions that would affect the circadian ►oscillator, or even the nature of such an oscillator, were unknown. A conceptual framework was needed in order to establish whether the circadian oscillator was endogenous or exogenous. For an endogenous oscillator to be revealed, one had to find conditions where extraneous entraining signals (see ►Zeitgebers) were kept constant. Light is the most important Zeitgeber affecting circadian rhythms. In order to prevent its entraining role, light level was held constant, from complete darkness (DD) to LL of different intensities. The free-running circadian behavior could then be studied in an unperturbed system.

### Behavioral Characteristics of Aschoff's Rules

In the absence of any light cues (DD), circadian rhythms persist with a spontaneous frequency of about one cycle per day, or a free-running period of approximately 24 h. This spontaneous frequency is species specific, with individuals within a given species showing some variability in their free-running periods. Free-running also occurs under constant illumination, suggesting that constant light does not provide any entraining cue to the circadian clock. However, LL does affect the frequency of the circadian oscillation (period of circadian rhythms). Aschoff's observations showed that diurnal animals gradually increased the frequency of their circadian oscillation as the LL intensity increased (shortened free-running period), and that nocturnal animals decreased their spontaneous frequency (lengthened free-running period; Aschoff's First Rule). In addition to its effects on frequency, Aschoff observed that LL led to an increase in general locomotor activity for diurnal animals and to a suppression of locomotor behavior of nocturnal animals (Aschoff's Second Rule). Finally, based on a small initial sample of different animal species, Aschoff proposed that the free-running period in constant darkness is longer than 24 h for diurnal animals (finches, starlings, and lizards) and shorter than 24 h for nocturnal animals (house mice and white-footed mice (Aschoff's Third Rule).

### Violation of Aschoff's Rules

Like every good rule, or set of rules, Aschoff's Rules have their exceptions. The initial summary and description of the behavior of animals in constant conditions made by Aschoff in 1960 surveyed a small number of animal species (finches, starlings, lizards, and mice). In a follow-up article, Aschoff reviewed practically all the available data on the behavior of a wider range of animal species under DD and LL of various intensities [3]. This review article covered the behavior of close to 80 species of diurnal and nocturnal birds, mammals, reptiles, fishes, and arthropods [3]. Although, in general, most species seemed to follow Aschoff's Rules, there were a few exceptions. Some arthropods (e.g. some species of ground beetles) and some diurnal mammals (e.g. some species of squirrels) violate Aschoff's First Rule. The effects of increasing intensities of LL do not produce the predicted changes in their free-running rhythms. Arthropods also seem to violate Aschoff's Third Rule: both diurnal and nocturnal species have free-running periods shorter than 24 h. However, these observations and the generalizations derived from them are complicated by the fact that prior lighting history will change ►pacemaker properties of the circadian ►oscillator, and cause ►after-effects [4]. These history-dependent effects on the circadian period can last for a relatively long time and affect the observed compliance with Aschoff's Rules. It is unclear if all the species reviewed by Aschoff had the same lighting history.

### Mechanisms Underlying Aschoff's Rules

There has been surprisingly little research aimed specifically at determining the physiological, anatomical, or molecular mechanism (s) underlying Aschoff's Rules. There is, fortunately, some evidence from attempts that were made (directly or not) at explaining the

mechanism through which constant light will accelerate (diurnal) or decelerate (nocturnal) the circadian oscillator (Aschoff's First Rule). However, the evidence comes mostly from nocturnal rodents, species that tend to follow Aschoff's Rules. These are discussed below.

## Genetic Components of Aschoff's First Rule

When inbred strains of mice are compared for their expression of Aschoff's First Rule under ►dim red light versus LL, one can observe different magnitudes of the lengthening effect of LL on the spontaneous frequencies of the circadian oscillation. Because inbred mice are all species variants of the Genus *Mus*, this suggests that differences in genetic makeup, ability to perceive light, and/or circadian clock gene expression might account for these differences in the manifestation of Aschoff's First Rule in mice.

There is evidence that the ►clock gene *Period2* might be involved in the expression of Aschoff's First Rule. It has been shown that constant bright light, which increases the free-running period of mice, will also alter *Period2* protein levels. In rhythmic mice under LL, *Per2* mRNA is still rhythmic, but PER2 protein is elevated and non-rhythmic in the ►suprachiasmatic nucleus (SCN, the mammalian central circadian pacemaker) [5]. This is in contrast to mice kept in DD where both *Period2* mRNA and protein are rhythmic. In addition, mice bearing a mutation in the *Period2* gene violate Aschoff's First Rule. The free-running rhythm of *Period2* mutant mice is shorter in LL than it is in DD [6]. Thus, a differential regulation of putative clock genes (*Period2* or other) in mice appears to correlate with the differences in circadian behavior under LL.

## Anatomical Components of Aschoff's Rule

The pathway through which light reaches the circadian clock in mammals, the ►retinohypothalamic tract (RHT), has been very well studied. This monosynaptic projection from the retina to the SCN conveys the photic information necessary for the effects predicted by Aschoff's Rules. The transduction of the light signal starts in the ►retina where specialized ►photoreceptor cells convert light into a neuronal signal that is then transmitted through the optic nerve towards the SCN and other brain centers. The classical ►photoreceptors (rods and cones) are not required for the transmission of light signals to the SCN. Mice lacking rods and cones entrain normally to ►light-dark cycles and show normal lengthening of their free-running period under LL [7]. This suggest that there are other means of ►phototransduction in rodless-coneless mice. Indeed, the novel ►photopigment melanopsin, exclusively expressed in ►retinal ganglion cells has been shown to be sufficient for the transmission of photic information to the circadian system. In melanopsin knockout mice, the lengthening effect of LL on the free-running period is reduced [8]. This suggests that melanopsin-containing retinal ganglion cells that project to the circadian system participate in the expression of Aschoff's First Rule.

Besides the SCN, there is another structure that is part of the larger circadian system in mammals: the ►intergeniculate leaflet (IGL) of the thalamus. The IGL receives direct retinal inputs and sends information back to the SCN. Lesions of the IGL will reduce the lengthening effects of LL on the free-running period, but only in hamsters, not mice [9,10]. This suggests that, at least in hamsters, the IGL integrates part of the light information required for the increase in free-running period induced by LL.

Even after nearly 50 years, the observations made by Aschoff are still effective tools for the description of the effects of constant conditions on the spontaneous frequency of the circadian oscillator. Their real value for circadian biologists include: (i) they established that specific circadian behaviors are conserved across species and highly reproducible, (ii) that the circadian period is "plastic" and influenced by lighting history, and (iii) that, when combined with entrainment theory, they can be explained, at least in a qualitative way, to result from the effects of light on the ►phase-response curve of two coupled-circadian pacemakers (see ►morning/evening oscillators).

## Aseptic Meningitis

### Definition

Aseptic meningitis is an illness mainly characterized by inflammation of the linings of the brain (meninges) and is not caused by bacteria.

## Aspinous Neuron/Cellular

### Definition

Neurons that do not have spines on their dendrites are classified as aspinous neurons.

## Association Cortex

### Definition

Refers to cerebral cortex other than the primary sensory and motor areas and, thus, most of the cortical mantle. The hallmark of association cortex is dominant cortico-cortical input-output relationships, thus suggesting the function of combining and recombining cortically processed information in the service of increasingly elaborate cortical representations of the internal and external environments in relation to memory, mood and motivation. Unimodal association areas flanking the primary sensory areas are concerned with the elaboration of modality specific sensory processing. Multimodal association areas merge information arising from more than one sensory modality. Speech areas in the inferior frontal and parietotemporal regions comprise high-order multimodal association areas. High-order association areas involved in behavioral synthesis and sequencing and the emotional, motivational and mnemonic content of behavior, sometimes referred to as "limbic association cortex," occupy parts of all of the cortical lobes, but culminate in the prefrontal, insular and medial temporal lobes.

## Association Tracts

### Definition

Commissures are fibers which exchange information between the hemispheres. Association pathways are fiber bundles within a hemisphere, while fibers between cerebral cortex and subcortical centers are called projection pathways.

►General CNS

## Associative Learning

### Definition

Associative learning is the learning of associations between events. In associative learning, a subject learns the relationship between two different stimuli or between the stimulus and the subject's behavior.

Classical conditioning and operant (or instrumental) conditioning are typical examples of the associative learning.

## Synonyms

Associative long-lasting potentiation; Associative long-term facilitation; LTP

## Definition

Long-lasting increase in the efficacy of synaptic transmission, induced in an input that is active when LTP-inducing high-frequency stimulation is applied to another independent strong input.

In a weak input, high-frequency stimulation (e.g. 100 Hz for 1s) often fails to induce LTP; however, when the weak input is stimulated simultaneously with high-frequency stimulation of another independent strong input, the weak input can also exhibit Long-term potentiation (LTP) (►Long-term potentiation, ►Gene expression). This type of LTP is called "associative LTP."

## Characteristics

### Quantitative Description

LTP is usually induced in a relatively strong input, and is not induced in a weak pathway. This characteristic of LTP is referred to as "cooperativity," and LTP induction requires activation of the sufficient number of afferent fibers that enables the postsynaptic cell to depolarize beyond a certain threshold level. However, a weak pathway can be potentiated when it is activated simultaneously with a strong pathway, because the strong pathway can provide sufficient depolarization of the postsynaptic cell. This characteristic of LTP is referred to as "associativity," and is regarded as the most fundamental property for associative learning.

### Higher Level Structures

Associative LTP of excitatory synaptic transmission can be observed in the ►hippocampus and cerebral cortex.

### Lower Level Components

Associative LTP is a form of synaptic plasticity (►Synaptic plasticity, ►selectivity) observed in certain kinds of excitatory central synapses.

### Higher Level Processes

Associative LTP is regarded as a cellular model for associative learning, which is observed in brain regions such as the hippocampus and cerebral cortex.

### Lower Level Processes

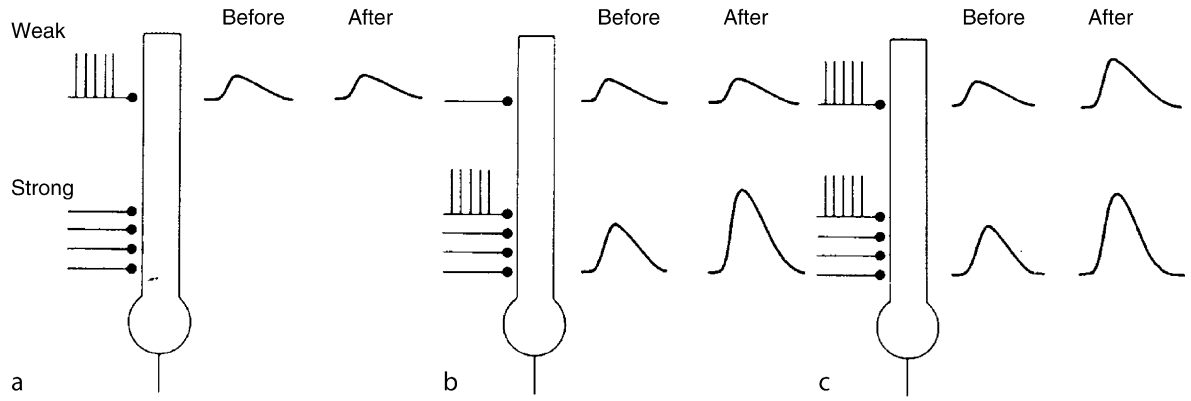
Associative LTP is usually observed at the synapse that exhibits NMDA receptor-dependent LTP (►NMDA-LTP). Standard tetanic stimulation at sufficiently strong stimulus strength causes depolarization in the postsynaptic cell, which is sufficient to relieve the $Mg^{2+}$ block of NMDA receptor channels and to allow $Ca^{2+}$ to flow into the postsynaptic cell. When one input is stimulated with a pattern that does not induce LTP by itself during the strong depolarization caused by tetanic stimulation of another independent input, the NMDA receptors of the former input become active and LTP is induced in both inputs. The LTP induced in this way in the former input is called "associative LTP" and the NMDA receptor plays an essential role in this process. In other words, the release of the neurotransmitter glutamate from the presynaptic terminal must occur simultaneously with the postsynaptic depolarization in order to induce LTP, and this is called a "►Hebbian rule."

### Process Regulation

The timing of synaptic activation and postsynaptic depolarization is extremely important for associative LTP. In order for associative LTP to occur, two independent pathways must be activated closely in time. A weak pathway must be active simultaneously with a strong pathway in order for the weak pathway to be potentiated. However, this process seems to be more complicated when we observe this phenomenon more carefully. As reviewed by Dan and Poo [1], associative LTP may be a type of spike-timing dependent plasticity: when the postsynaptic depolarization follows the synaptic activity, the synaptic response is potentiated. In contrast, when the synaptic activity follows the postsynaptic depolarization, the synaptic response is depressed. Thus, the sequence of the events, as well as the timing, may be a critical factor for associative LTP.

### Function

Figure 1 demonstrates the three rules observed in synaptic plasticity in general [2]. In order to exhibit LTP, the strength of an input must be strong enough to depolarize the postsynaptic cell and activate NMDA receptors (Fig 1a). In other words, a relatively large



**Associative Long-Term Potentiation. Figure 1** (a) Cooperativity. A weak input fails to exhibit LTP even if it receives tetanic stimulation. (b) Specificity (selectivity). LTP is restricted to the input that receives tetanic stimulation. (c). Associativity. A weak input can be potentiated if it is concurrently active when LTP is induced in another strong input. (cited from Nicoll et al. 2).

number of afferent fibers must be stimulated to include LTP, and this property is called "cooperativity" (Fig 1b). Figure 1b also indicates that the input that does not receive tetanic stimulation fails to show LTP, even if the other input in the same cell exhibits LTP. This property is called "selectivity" or "specificity." This type of LTP is referred to as "►homosynaptic LTP" because LTP is restricted to the tetanized pathway. Another important property is "associativity," which is shown in Figure 1c. In some sense, these properties are common to those of learning and memory, and associativity especially may be a cellular process underlying the formation of associative memory.

However, there are some exceptions. Strictly speaking, in some condition, synapse specificity of LTP breaks down locally at short distances [3,4]. Thus, ►heterosynaptic facilitation and depression (►heterosynaptic depression) can occur, and in some case, ►heterosynaptic LTP can be observed in the hippocampus. Furthermore, LTP and ►Long-term depression (LTD) can interact heterosynaptically [5]. These phenomena are regarded as "non-Hebbian."

# Associative Memory

Makoto Hirahara
Faculty of Engineering, Hosei University, Tokyo, Japan

## Synonyms

Associatron; Content-addressable memory; Hopfield model

## Definition

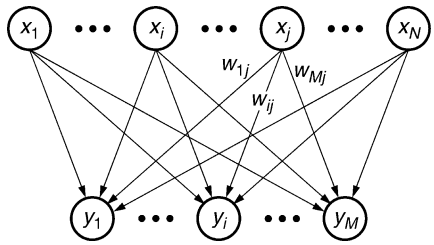
Associative memory is one type of neural network model for human memory. The network stores input–output pattern pairs to recall a stored output pattern when a noisy or incomplete version of a stored input pattern paired with it is presented.

## Characteristics

### Heteroassociative Memory

When looking at a banana, someone might recall a monkey. Human memory system probably represents the two different entities as two distinct firing patterns of neurons. So, it is possible that the associative recall is a transformation from the pattern "banana" to the different pattern "monkey."

A neural network model that performs such a transformation from a pattern to a different pattern is referred to as ►heteroassociative memory (Cross-associative memory). The most simplified model is a two-layer feedforward network as shown in Fig. 1. Let $\{\xi_i^\mu\}$ $(i = 1, \ldots, N)$ and $\{\eta_i^\mu\}(i = 1, \ldots, M)$ be the $\mu$th $(\mu = 1, \ldots, Q)$ of a $N$-dimensional input and a $M$-dimensional output pattern, respectively. It is often assumed that each component of the patterns takes a value of either +1 (firing) or –1 (not firing) independently with



**Associative Memory. Figure 1** Two-layer feedforward network for heteroassociative memory. Input–output pattern pairs are stored in the weights, $w_{ij}$, which connect the input units $\{x_j\}$ to the output units $\{y_i\}(i = 1, \ldots, M;\ j = 1, \ldots, N)$.

equal probability. Then, the network stores (learns) the $Q$ pattern pairs (associations) as follows

$$w_{ij} = \frac{1}{N} \sum_{\mu} \eta_i^{\mu} \xi_j^{\mu},$$

where $w_{ij}(i = 1, \ldots, M;\ j = 1, \ldots, N)$ is the weight from the $j$th unit (neuron) in the input layer to the $i$th unit in the output layer (Fig. 1).

When an input pattern is presented, the state of the input layer, $\{x_i\}$ $(i = 1, \ldots, N)$, is set to that pattern and is fed through the weights to the output units $\{y_i\}$ $(i = 1, \ldots, M)$

$$y_i = \text{sgn}\ (h_i), h_i = \sum_j w_{ij} x_j,$$

where $\text{sgn}(h)$ is +1 for $h > 0$ and −1 otherwise.

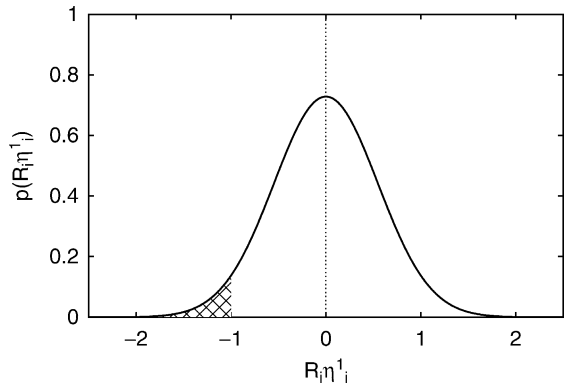
If an input is one of the stored patterns, say, $\{\xi_i^1\}$, we hope that $\{y_i\}$ would coincide with the target output pattern $\{\eta_i^1\}$. To see this possibility, we rewrite the activity $h_i$ by putting $\{x_i\} = \{\xi_i^1\}$ and have

$$h_i = \sum_j \frac{1}{N} \sum_{\mu} \eta_i^{\mu} \xi_j^{\mu} \xi_j^1 = S_i + R_i,$$

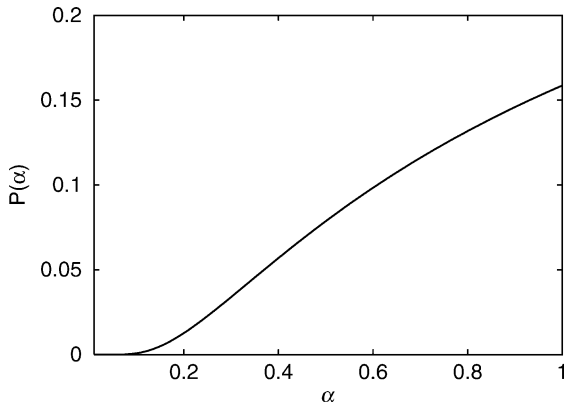
$$S_i = \frac{1}{N} \eta_i^1 \sum_j \xi_j^1 \xi_j^1 = \eta_i^1,$$

$$R_i = \frac{1}{N} \sum_{\mu \neq 1} \eta_i^{\mu} \sum_j \xi_j^{\mu} \xi_j^1, \qquad (1)$$

where $S_i$ is the signal to stabilize the target $\eta_i^1$, and $R_i$ is known as cross-talk noise arising from the correlations of the stored patterns $\{\xi_i^{\mu}\}(\mu \neq 1)$ with the input $\{\xi_i^1\}$. The cross-talk noise often hinders the model from recalling the target, $\{\eta_i^1\}$: an error occurs at the $i$th output unit when $R_i$ is of opposite sign to $\eta_i^1$ and has an absolute value larger than 1 (i.e., $R_i \eta_i^1 < -1$). Since the quantity $R_i \eta_i^1$ is the sum of many $(= N(Q-1) \approx NQ)$ independent random variables, each of which takes a value of $+1/N$ or $-1/N$ with equal probability, the central limit theorem guarantees that it has a Gaussian distribution with mean zero and variance $Q/N$. The fraction $Q/N$ is often referred to as load level (hereafter denoted as $\alpha$). Figure 2 shows a Gaussian $(\alpha = Q/N = 0.3)$ where the hatched area (integral from $-\infty$ to $-1$ with respect to $R_i \eta_i^1$) gives the error probability $P(\alpha)$ for one output unit.



**Associative Memory. Figure 2** Distribution of cross-talk noise $R_i$ times target $\eta_i^1$, when an original input pattern $\{\xi_i^1\}$ paired with $\{\eta_i^1\}$ is presented. The hatched area gives the error probability $P(\alpha)$ for one output unit.



**Associative Memory. Figure 3** Error probability for one output unit as a function of load level $\alpha$. A higher $\alpha$ causes a wider distribution of cross-talk noise, resulting in a higher error probability (see Fig. 2).

Rising load level $\alpha$ widens the Gaussian, resulting in a higher error probability $P(\alpha)$ as shown in Fig. 3.

Since the network has the $N$ output units, the probability that the network recalls the target with no error is given by $(1 - P(\alpha))^N$. Perfect recalling is thus a severe condition, so we need to allow the network to make some errors. A different type of learning algorithm is needed to prevent the cross-talk noise [1,2], though we in this case have to present input–output pairs repeatedly during learning.

It is also important to see the ability to eliminate external noise. Let $\{\rho_i\}$ $(i = 1, \ldots, N)$ be a noise pattern, each component of which takes a value of either +1 with probability $(1 + d)/2$ or −1 with probability $(1 - d)/2$ $(0 \le d \le 1)$. Then, a noisy version of a stored input pattern $\{\xi_i^1\}$ can be expressed as $\{\xi_i^1 \rho_i\}$. Since the sign of $\xi_i^1$ is reversed when $\rho_i = -1$, $\{\rho_i\}$ acts as external noise embedded in $\{\xi_i^1\}$. The similarity between the original pattern and the noisy version (overlap at the input layer or initial overlap) can be evaluated as

$$m = \frac{1}{N} \sum_i \xi_i^1 \xi_i^1 \rho_i = \frac{1}{N} \sum_i \rho_i \approx d.$$

Thus, $m$ is approximately equal to the parameter value $d$ for generating external noise.

When such a noisy input is given, the network should eliminate the noise so that the overlap of the target output pattern $\{\eta_i^1\}$ and the output state $\{y_i\}$ (overlap at the output layer), $m'$, is larger than the initial overlap $m$. To evaluate this possibility, we present a noisy input $\{\xi_i^1 \rho_i\}$ to the network and have

$$y_i = \mathrm{sgn}(S_i + R_i),$$

$$S_i = \frac{1}{N} \eta_i^1 \sum_j \xi_j^1 \xi_j^1 \rho_j = m \eta_i^1,$$

$$R_i = \frac{1}{N} \sum_{\mu \neq 1} \eta_i^\mu \sum_j \xi_j^\mu \xi_j^1 \rho_j.$$

Then, the overlap at the output layer can be expressed as

$$m' = \frac{1}{M} \sum_i \eta_i^1 y_i = \frac{1}{M} \sum_i \mathrm{sgn}(S_i \eta_i^1 + R_i \eta_i^1)$$
$$= \frac{1}{M} \sum_i \mathrm{sgn}(U_i),$$

$$U_i = m + R_i \eta_i^1.$$

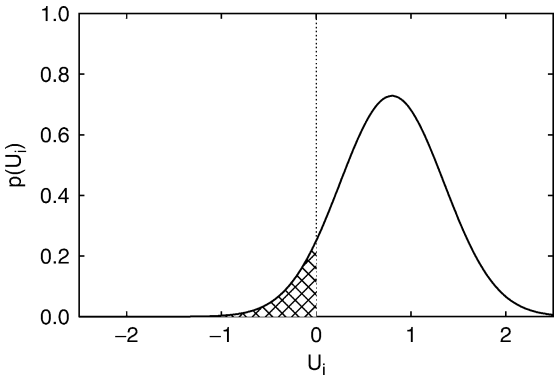
The quantity $R_i \eta_i^1$ has a Gaussian distribution with mean zero and variance $\alpha$ $(= Q/N)$ for the same reason as above, and hence $U_i$ is normally distributed with mean $m$ and variance $\alpha$ as shown in Fig. 4.

Since $\mathrm{sgn}(U_i)$ takes a value of either −1 with probability $P(\alpha, m)$ (indicated by the hatched area) or +1 with the remaining probability, the overlap $m'$, given as the sum of a large number $(= M)$ of sgn $(U_i)$ divided by $M$, should converge to the average

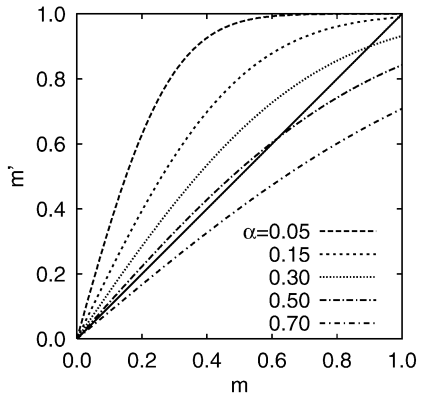
$$m' = (-1)P(\alpha, m) + (+1)(1 - P(\alpha, m)) = 1 - 2P(\alpha, m).$$

Figure 5 shows $m'$ as a function of $m$ for various values of load level $\alpha$.

The network has a good performance to eliminate external noise $(m' > m)$ if the initial overlap $m$ does not exceed a critical value $m_c(\alpha)$, which is the intersection of each curve with the solid line $(m' = m)$. The critical value decreases with increasing $\alpha$ (e.g., $m_c(0.05) \approx 1.0$, $m_c(0.3) \approx 0.9$). Far more increase in $\alpha$ results in the disappearance of the intersection (e.g., $m_c(0.7) \approx 0.0$).



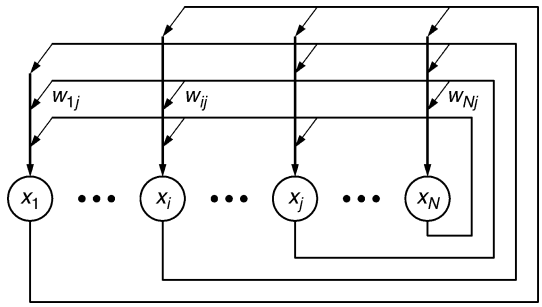
**Associative Memory. Figure 4** Distribution of $U_i$ (see text). The hatched area gives the probability of sgn($U_i$) = −1.



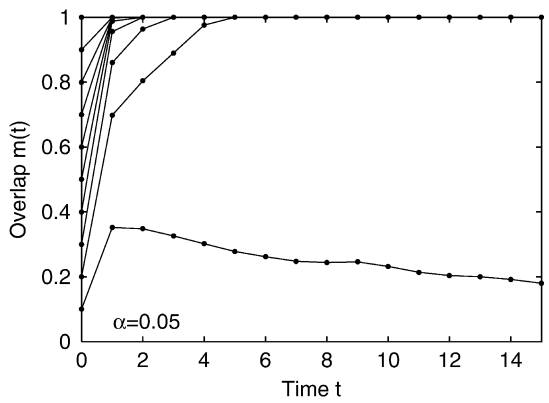
**Associative Memory. Figure 5** Noise reduction ability of heteroassociative memory for various values of load level $\alpha$. Overlap at the output layer, $m$, is plotted as a function of overlap at the input layer, $m$.

## Autoassociative Memory

A neural network is referred to as ▶autoassociative memory, when input and output patterns to be stored are the same. The network recalls the whole of a stored pattern when receiving a part (or a noisy version) of it as one might recall the whole concept of "apple" when smelling the scent of it. If we substitute $\{\xi_i^\mu\}$ for $\{\eta_i^\mu\}$ in the section of heteroassociative memory described earlier (and set $w_{ii} = 0$ and $M = N$), then we obtain a two-layer feedforward network for autoassociative memory storing $\{\xi_i^\mu\}$. This network has the same characteristics as the heteroassociative memory.



**Associative Memory. Figure 6** One-layer recurrent network for autoassociative memory. The $N$ units are mutually connected through the weights $W_{ij}$ $(i \neq j)$.



**Associative Memory. Figure 7** Time courses of overlap $m(t)$ for various values of initial overlap $m(0)$, when $\alpha = 0.05$. If the network recalls a target pattern successfully, $m(t)$ takes a value of 1.

Here, we consider the case where the network has feedback connections to receive the current output as the next input (i.e., $\{x_i\} = \{y_i\}$). Then the network keeps updating its state (output), which may have more overlap with $\{\xi_i^1\}$ than a previous state does. Such a recurrent neural network for autoassociative memory can be constructed with only one layer of units as shown in Fig. 6.

Let $\{x_i(t)\}$ $(i = 1, \ldots, N)$ be the state of the network at time $t$. The initial state $\{x_i(0)\}$ is set to a given input pattern, after which $\{x_i(t)\}$ develops at every discrete time step according to the following dynamics

$$x_i(t+1) = \mathrm{sgn}(h_i), h_i = \sum_{j \neq i} w_{ij} x_j(t), \qquad (2)$$

where $w_{ij}$ $(i,j = 1, \ldots, N)$ is the weight of the connection from the $j$th to the $i$th unit. If we again assume that each component of patterns to be stored, $\xi_i^\mu$ $(\mu = 1, \ldots, Q; i = 1, \ldots, N)$, takes a value of either +1 or −1 independently with equal probability, the learning algorithm can be written in the form

$$w_{ij} = \frac{1}{N} \sum_{\mu} \xi_i^\mu \xi_j^\mu. \qquad (3)$$

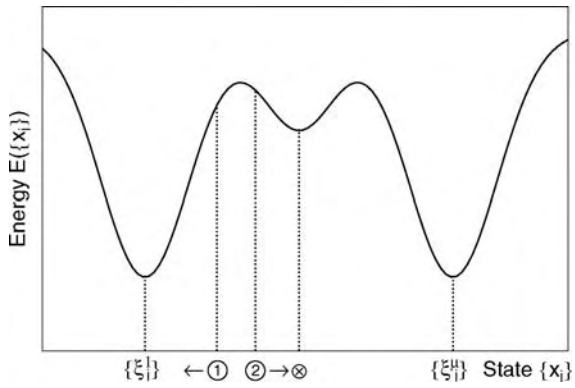
Now, the network keeps changing its state $\{x_i(t)\}$. The time evolution of $\{x_i(t)\}$ could be captured in part by the overlap $m(t)$ with a stored pattern, say, $\{\xi_i^1\}$

$$m(t) = \frac{1}{N} \sum_{i} \xi_i^1 x_i(t).$$

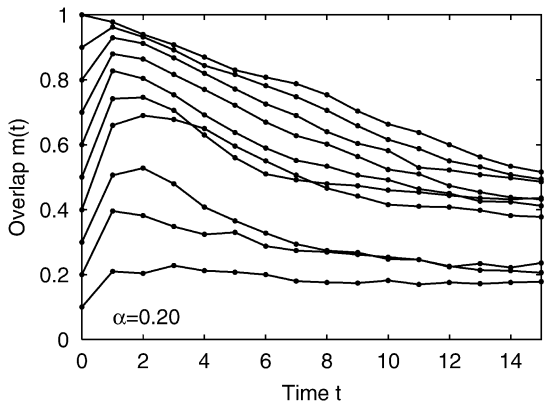
Figure 7 shows simulation results for load level $\alpha = 0.05$, where the curves demonstrate the time courses of $m(t)$ for various values of initial overlap $m(0)$.

When starting from 0.2 or more, the overlap $m(t)$ converged to 1 after several steps. This means that the network was successfully attracted to a stable state (an attractor), which was just the target $\{\xi_i^1\}$. When $m(0) = 0.1$, $m(t)$ once went up, then went down, and finally converged to a small value (not shown). The increase in $m(t)$ at time $t = 1$ indicates that the network once approached to the target $\{\xi_i^1\}$. This initial phenomenon could be understood from the curve for $\alpha = 0.05$ shown in Fig. 5 where $m' = m(1) \approx 0.35$ when $m = m(0) = 0.1$. After the initial increase, the network state gradually moved away from $\{\xi_i^1\}$ and finally converged to an attractor that was different from $\{\xi_i^1\}$ (see [3] for estimation of $m(t)$ at time $t \geq 2$). One may think that another stored pattern was recalled, but this was not the case. This attractor, not intended to be stored in the network, is called a spurious state (a spurious memory or a spurious attractor).

Thus, the network seems to converge to an attractor, regardless of whether the attractor is $\{\xi_i^1\}$ or not. In fact, the convergence is guaranteed if the state of only one unit is updated at one time (although in the above simulation the states of all units were updated synchronously). This is because the network is governed by a lower bounded energy function, $E(\{x_i\})$, associated with its state $\{x_i\}$, and the dynamics given as Eq. 2 alters $\{x_i\}$ so as to reduce the value of $E(\{x_i\})$ [4]. The learning algorithm given as Eq. 3 is the process to make the intended patterns $\{\xi_i^\mu\}$ be local minimum points (states with local minima of the energy function). In addition to this, the algorithm implicitly forces states closer to $\{\xi_i^\mu\}$ to have lower energies and also creates additional local minima at unintended points (spurious states). The resulting landscape of the energy function is as shown in Figure 8. Since Eq. 2 always decreases the energy, the network atate starting with the initial state starting with the initial state ① a noise version of $\{\xi_i^1\}$ moves toward and stops at the target $\{\xi_i^1\}$ (successful recall), whereas the state starting with ② a more noisy version of $\{\xi_i^1\}$ moves away from $\{\xi_i^1\}$ and reaches a spurious state ⊗. In the case of high load level $\alpha$, however the possibility of stopping at $\{\xi_i^1\}$ becomes low: rising $\alpha$ increases the number of spurious states and reduces the size of the basins of attraction (the width



**Associative Memory. Figure 8** Landscape of energy function $E(\{x_i\})$. The network alters its state $\{x_i\}$ so as to reduce the value of $E(\{x_i\})$. The network state starting with the initial state ① (a noise version of $\{\xi_i^1\}$) moves toward and stops at the target $\{\xi_i^1\}$ (successful recall), whereas the state starting with ② (a more noisy version of $\{\xi_i^1\}$) reaches a spurious state ⊗.



**Associative Memory. Figure 9** Time courses of overlap $m(t)$, when $\alpha = 0.2$.

of valleys) around the intended patterns. It is known that the stored patterns are no longer stable states (local minimum points) if $\alpha$ is above about 0.15 [4,5]. The critical value of load level, $\alpha_c$, is often called ►memory capacity (storage capacity). Figure 9 shows the time courses of $m(t)$ for load level $\alpha = 0.2$. Even if just a target $\{\xi_i^1\}$ was presented ($m(0) = 1$), the network state moved away from the target.

## Associative Memory for Storing Unbiased Patterns

Up to now, we assumed that each component of patterns to be stored took either +1 (firing) or –1 (not firing) independently with equal probability. Thus, the patterns are unbiased in the sense that the number of pattern components taking +1 is almost the same as that of components taking –1. This implies that single neurons respond to about one-half of stimuli.

However, this assumption would be physiologically implausible. Many physiologists have reported that neurons in the brain have selectivity for stimuli (e.g., face and object) or stimulus properties (e.g., orientation, shape, color, motion direction). It seems better to assume that, for a given stimulus, a small number of neurons are activated while the others are not.

The introduction of this alternative assumption allows an associative network to have a large memory capacity. Let $\{\xi_i^\mu\}(\mu = 1, ..., Q; i = 1, ..., N)$ be a biased pattern whose components take values of either +1 with probability $(1 + b)/2$ or –1 with the remaining, where $-1 < b < 0$ (unbiased patterns if $b = 0$). Patterns with $b \approx -1$ are especially referred to as sparsely encoded patterns. The network stores the $Q$ biased patterns according to the following covariance learning rule

$$w_{ij} = \frac{1}{N(1-b^2)} \sum_\mu (\xi_i^\mu - b)(\xi_j^\mu - b).$$

We also need to modify the dynamics as follows

$$x_i(t+1) = \mathrm{sgn}(h_i), h_i = \sum_j w_{ij}(x_j(t) - b) + b.$$

Note that, if $b = 0$, this network is reduced to the associative memory for storing unbiased patterns (Eqs. 2 and 3).

If we input a stored pattern $\{\xi_i^1\}$ as did previously, we get

$$h_i = \sum_{j\neq i} \frac{1}{N(1-b^2)} \sum_\mu (\xi_i^\mu - b)(\xi_j^\mu - b)(\xi_j^1 - b) + b = S_i + R_i,$$

$$S_i = \frac{1}{N(1-b^2)} (\xi_i^1 - b) \sum_{j\neq i} (\xi_j^1 - b)(\xi_j^1 - b) + b \approx \xi_i^1,$$

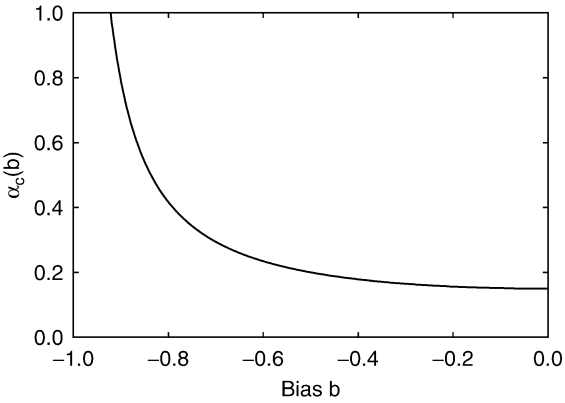
$$R_i = \frac{1}{N(1-b^2)} \sum_{\mu\neq 1} (\eta_i^\mu - b) \sum_{j\neq i} (\xi_j^\mu - b)(\xi_j^1 - b).$$

The cross-talk noise $R_i$ follows a Gaussian with mean zero and variance $Q(1-b^2)/N$, which decreases with increasing $b$. The network storing biased patterns thus has smaller cross-talk noise than the network storing unbiased patterns ($Q/N$), while the two networks have almost the same signal $S_i$.

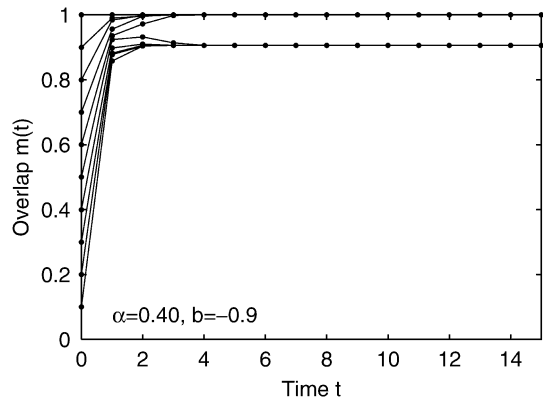
It is known that the memory capacity for biased patterns can be roughly estimated by

$$\alpha_c(b) = \frac{\alpha_c(0)}{1-b^2},$$

where $(\alpha_c(0) \approx 0.15)$ is the memory capacity for unbiased patterns [6]. Figure 10 shows $\alpha_c(b)$ as a function of $b(-1 < b < 0)$. The capacity $\alpha_c(b)$ increases with decreasing $b$. Figure 11 demonstrates the time courses of overlap $m(t)$ when $b = -0.9$ and $\alpha = 0.4$. Even if the network is at double the load level



**Associative Memory. Figure 10** Memory capacity of autoassociative memory, $\alpha_c(b)$, as a function of bias *b* of stored patterns.



**Associative Memory. Figure 11** Time courses of overlap $m(t)$ for autoassociative memory storing biased patterns ($b = -0.9$, $\alpha = 0.4$).

as the network storing unbiased patterns (Fig. 9), the target $\{\xi_i^1\}$ was recalled after several steps $(m(t) = 1)$ if the initial overlap $m(0)$ was 0.6 or above. When $m(0)$ was small, $m(t)$ converged to about 0.9. This means that all the units took $x_i(t) = -1$ $(m(t) = N^{-1}\sum \xi_i^1 x_i(t) \approx 0.9)$.

## Associative Memory for Storing Hierarchically Correlated Patterns

The patterns treated above are independent of one another, which is a prerequisite for many conventional networks such as the earlier network to work properly. The independent patterns are distributed over the pattern space such that each pattern is located at almost the same distance from all the others. In other words, similarities between any two patterns are the same (i.e., $N^{-1}\sum \xi_i^\mu \xi_i^\nu \approx b^2$ for $\mu \neq \nu$).

However, it seems better to suppose that similar things are encoded into similar patterns. Since a neuron, in general, responds not only to an optimal stimulus but also to stimuli close to the optimal, presenting similar stimuli would yield similar firing patterns. Moreover, there are a plenty of (living and nonliving) things similar to one another, and we make use of their similarity in our daily life. For example, one would acquire a one's own concept "bird" (in part) by finding common (similar) properties among previously encountered instances (such as pigeons, sparrows, and crows), and the concept would, in turn, help us to recognize (categorize) a novel creature flying with wings as a member of that concept (the category represented by that concept). If the novel instance should be represented as an independent pattern, which is similar to neither patterns of the previous instances nor a pattern of the concept, we might be unable to identify it or may miscategorize it as a member of a different category such as "airplane," "ice cream," and "book." To begin with, we could not acquire concepts (similarities) from independent patterns of instances.

Hierarchically correlated patterns are often used to represent concepts and their instances (the second level concepts in a two-level hierarchy). Let $\{\xi_i^\mu\}$ $(\mu = 1, ..., Q_1; i = 1, ..., N)$ be the $\mu$th concept pattern (representative of the $\mu$th category), which is not given to but acquired by the network (see later). For simplicity, each component of $\{\xi_i^\mu\}$ is assumed to take either +1 or −1 independently with equal probability. Each category $\{\xi_i^\mu\}$ has $Q_2$ instances $\{\xi_i^{\mu\nu}\}(\nu = 1, ..., Q_2; i = 1, ..., N)$. Each component $\xi_i^{\mu\nu}$ takes either the same value as $\xi_i^\mu$ with probability $(1 + c)/2$ or the different value from $\xi_i^\mu$ (i.e., $\xi_i^{\mu\nu} = -\xi_i^\mu$) with the remaining probability $(0 < c < 1)$. In this case, the similarity between an instance and its concept is given by $N^{-1}\sum \xi_i^{\mu\nu}\xi_i^\mu = c$. So the instances are distributed around their concepts with equal distance $1 - c$. The similarity between any two instances of the same category is $N^{-1}\sum \xi_i^{\mu\nu}\xi_i^{\mu\nu'} = c^2$ $(\nu \neq \nu')$, so that, in each category, each instance is located at the same distance $1 - c^2$ from all the others. The similarity between any two instances of different categories is of zero.

Here, we consider the case where only the instances are given in learning phase. If we use the network given as Eqs. 2 and 3, we get

$$w_{ij} = \frac{1}{N}\sum_{\mu,\nu} \xi_i^{\mu\nu}\xi_j^{\mu\nu}.$$

When one of the instances, say, $\{\xi_i^{11}\}$, is input to the network, the activity of the *i*th unit is given by

$$h_i = \sum_{j\neq i}\frac{1}{N}\sum_{\mu,\nu}\xi_i^{\mu\nu}\xi_j^{\mu\nu}\xi_j^{11} = \xi_i^{11} + \frac{1}{N}\sum_{\nu\neq 1}\xi_i^{1\nu}\sum_{j\neq i}\xi_j^{1\nu}\xi_j^{11} + \frac{1}{N}\sum_{\mu\neq 1,\nu}\xi_i^{\mu\nu}\sum_{j\neq i}\xi_j^{\mu\nu}\xi_j^{11}.$$

The first term is the signal to stabilize the target $\xi_i^{11}$. The second and third terms are cross-talk noise arising from correlations of the input pattern $\{\xi_i^{11}\}$ with the other instances of the same category $\{\xi_i^1\}$ and of the different categories $\{\xi_i^\mu\}(\mu \neq 1)$, respectively. If we suppose that $N$ and $Q_2$ are large enough, the mean values of the second and third terms are estimated as about $Q_2 c^3 \xi_i^1$ and zero, respectively. This suggests that when $Q_2 c^3 > 1$, the network comes to recall not the target instance $\{\xi_i^{11}\}$ but the concept $\{\xi_i^1\}$ to which the target belongs.

Thus, the network given as Eqs. 2 and 3 has the potential ability to acquire concepts by learning instances [2]. In return for this ability, however, the ability to recall instances is lost.

One way to overcome this problem is to introduce so-called nonmonotonic units to the network [7,8]. A usual monotonic unit emits an output value whose sign is always the same as that of an activity $h_i$ (e.g., Eq. 2), whereas a nonmonotonic unit outputs a value opposite in sign to $h_i$ if $|h_i|$ is above a threshold $T$ and outputs a value with the same sign as $h_i$ otherwise. Thus, units whose activities are large in absolute value are destabilized so that their contributions to state transition would be reduced. Since the activities are, on average, larger in absolute value when a concept $\{\xi_i^\mu\}$ is presented than when an instance $\{\xi_i^{\mu\nu}\}$ is presented, setting $T$ at high and low level leads the network to recall a concept and an instance, respectively [8]. It is also known that a network with nonmonotonic units is effective for storing unbiased patterns [7]: it has a large memory capacity [9], large basins of attraction around stored patterns, and a small number of spurious states.

Another way to recall instances is to use a cascade of two associative networks [10]. The first network acquires concepts by learning instances, just described above. The second network stores difference patterns defined by $\{\eta_i^{\mu\nu}\} \equiv \{\xi_i^{\mu\nu}\xi_i^\mu\}$. Since $\eta_i^{\mu\nu} = 1$ for $\xi_i^{\mu\nu} = \xi_i^\mu$ and $-1$ otherwise, $\{\eta_i^{\mu\nu}\}$ contains information only on the difference of $\{\xi_i^{\mu\nu}\}$ from $\{\xi_i^\mu\}$, thus interpreted as distinctive features of the instance $\{\xi_i^{\mu\nu}\}$. Because they are biased patterns ($N^{-1}\sum \eta_i^{\mu\nu} = c$) independent of one another ($N^{-1}\sum \eta_i^{\mu\nu}\eta_i^{\mu'\nu'} = c^2$), we can use the above network for storing biased patterns as the second network. Therefore, the second network has a large memory capacity (Fig. 10). Combining a concept $\{\xi_i^\mu\}$ recalled by the first network and a difference pattern $\{\eta_i^{\mu\nu}\}$ recalled by the second, the cascade network outputs (recalls) a target instance $\{\xi_i^{\mu\nu}\}$ $(= \{\xi_i^\mu\eta_i^{\mu\nu}\})$. This cascade network is applicable, even if instances $\{\xi_i^{\mu\nu}\}$ each have their own similarity $c_{\mu\nu}$ $(= N^{-1}\sum \xi_i^{\mu\nu}\xi_i^\mu)$ to their concepts $\{\xi_i^\mu\}$ (i.e., $c_{\mu\nu} \neq c_{\mu\nu'}$ for $\nu \neq \nu'$). In this case, a concept $\{\xi_i^\mu\}$ is more similar to an instance $\{\xi_i^{\mu\nu}\}$ than to another instance $\{\xi_i^{\mu\nu'}\}$ as a concept "bird" might be more similar to "pigeon" than to "owl." In other words, instances of the same category are ordered with respect to their similarity $c_{\mu\nu}$. It is known that, when being stored in the cascade network, the instance patterns are ordered with respect to stability: rising load level $\alpha$ destroys (destabilizes) memories of the instances in ascending order of their similarity. Moreover, when a concept pattern (instead of an instance pattern) is presented as an input, the network recalls an instance having a higher similarity to the concept with a higher probability and in a shorter period of recall time, which seems to be consistent with human behavior (known as the typicality effect). When we are asked to recall an instance of "bird," "pigeon" would be more probable and faster to be recalled than "owl."

# Associative Priming

## Definition

A form of priming in which the prime and test are associated due to the experience of repeated pairing between the two concepts or stimuli. Although many associatively related words are semantically related, association measured as free association norms can be distinguished from a more direct form of semantic relation such as object category.

►Latent Learning

## Astrocyte

### Definition

Also known as astroglia, astrocytes are characteristic star-shaped glial cells in the brain. Astrocytes are irregularly shaped with many long processes. They are the largest and most numerous neuroglial cells in the brain and spinal cord. They regulate the extracellular ionic and chemical environment. "Reactive astrocytes" along with microglias respond to injury and amyloid plaques.

## Astrocytoma

### Definition

The most common primary glial brain tumor. It can be found throughout the central nervous system (CNS). It is characterized by diffuse (infiltrating) or circumscribed growth. Astrocytomas can be classified by their histologic appearance and by their malignant potential.

The most commonly used grading system was developed by World Health Organization (WHO). It recognizes four different grades of astrocytoma; grade I describes low grade slow growing tumors while grade IV the most aggressive and deadly form (glioblastoma).

Grades II and III correspond to intermediate levels of malignancy.

## Asynergia

### Definition

Lack of coordination and poor harmony among various components of a complex motor task.

## Asynthesia

### Definition

Failure to bind visual features together into the perception of an object. For example, a patient suffering from a stroke had lost color vision as well as the ability to recognize faces. His main problem was that he could perceive the local features of an object, but could not bind them together into a coherent object that consequently could not be recognized, although drawing it went quite well. He could also fluently describe objects he had known before his stroke.

## Ataractic Drug

►Antipsychotic Durgs

## Atasia-Abasia

### Definition
Inability to stand or walk.

## Ataxia

### Definition
Impaired motor coordination (= incoordination) usually related to disorders of the cerebellum or its connections with the brain and spinal cord. Ataxia [Greek, a (negative article) + taxi (order)] is characterized by slurred speech (ataxic dysarthria), nystagmus, dysmetria (undershooting or overshooting a target with trajectory limb movements), poor dexterity in performing rapid alternating movements (dysdiadochokinesis), and wide based gait (truncal ataxia). The term ataxia is also used to describe degenerative diseases of the cerebellum, most of them hereditary.

### Definition
Absence of muscle tone (an extension of hypotonia, which is reduced muscle tone) seen in the acute phase of

spinal cord injury, or in disorders of the peripheral motor system, such as lower motor neuron disease, peripheral nerve disease, neuromuscular junction disorders, or myopathy. Atonia also occurs during ►rapid eye movement (REM) sleep.

## Atonic Seizures

### Definition

Brief losses of consciousness and postural muscle tone without muscular contractions, such that the patient (usually a child) drops to the floor ("drop attack"); the ►electroencephalogram (EEG) shows sequences of spikes and slow waves.

►Electroencephalography

## ATP

### Definition

Adenosine triphosphate: a high energy compound used by cells predominantly for metabolic purposes. ATP hydrolysis also provides the energy for muscular contraction.

►Sliding Filament Theory

## ATP-sensitive $K^+$ Channel(s)

### Definition

►Neuronal Potassium Channels

## Atrial Fibrillation

### Definition

Abnormal heart beat caused by an irregular and fast activity in the atria that is irregularly conducted to the ventricles. This may be consistent or episodic (paroxysmal atrial fibrillation). Raises the risk of ischemic stroke five times over.

►Stroke
►Ischemic Stroke

## Attention

Peter Klaver
Department of Psychology, University of Zurich, Zurich, Switzerland

### Definition

Attention represents a set of cognitive abilities that allow living beings to cope with the enormous amount of information flooding the sensory system, and to use this information in goal directed and adaptive behavior. More than one hundred years of research distinguished several major aspects of attention. One refers to selective attention, which is the ability to filter relevant from irrelevant information. The second refers to divided attention, which is the ability to cope with more than one task at the same time. The third refers to the ability to move attention and therefore select stimuli. The fourth refers to the ability to sustain attention to a task. This essay describes these aspects of attention and discusses the neural systems that support these attentional mechanisms and pathologies that impair them.

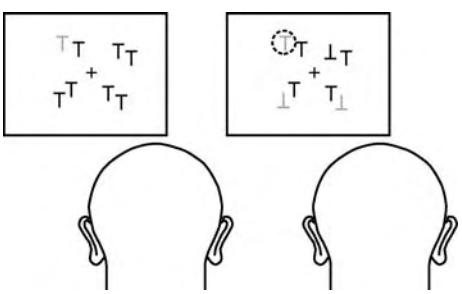
### Characteristics

#### Selective Attention

Selective attention refers to the ability to preferentially process relevant above irrelevant information. This is a fundamental cognitive process and can occur for example at the perceptual level when attention is directed to locations in space, objects or object features such as color or shape, auditory pitch or any other sensory information. Selection can also occur at higher levels of processing, for example when semantic categories such as natural and man-made objects need to be distinguished. Two crucial issues in selective attention studies will be discussed here. The first concerns the question how information is selected. What determines the relevance of information? Is selection determined by perceptual features such as salient object features (bottom-up processes) or by top-down processes such as task instructions, memory, or cues that initiate a selection process? The second issue concerns the question where and when information is selected. Particularly at the perceptual level many studies investigated whether selection takes place in the

low level sensory system (early selection), or after the processing of sensory information (late selection). This is called the "early-late selection debate." For both the "how" and "when" question of selective attention one has to distinguish between spatial and non-spatial attention. Spatial attention is assumed to affect the sensory system and is guided by top-down processes, whereas non-spatial attention may not. When stimuli are spatially segregated it is presumed that spatial attention works as a spotlight or zoom focusing on a location. When attention is directed to a particular location, objects within the focus of attention are preferentially processed as compared with conditions in which attention is divided between locations or when attention is directed to another location. Human brain imaging and animal neurophysiological studies suggested that spatial attention directly operates at the sensory system, and increases the sensitivity of perception by means of competition between stimuli in relevant and irrelevant locations (sensory gating). Spatial selection may also be biased by top-down processes, even before a stimulus is presented on the attended location [1].

Mechanisms of spatial selective attention are thought to be a prerequisite of object perception. It is thought that all object features within the focus of attention are selected in parallel. This may be intuitive, since an object requires space but can contain different features within this space, such as luminance, color, texture, orientation, or motion direction. In order for selection to occur all information coming from feature specific processing areas needs to be integrated within this space, and conjoined with other features at different locations that build an object. The visual search paradigm is often used to study the selection of objects within space (Fig. 1).



**Attention. Figure 1** An example of a spatial attention task including a virtual spotlight of attention. On the left a pop-out condition is displayed, in which a target object can be detected on the basis of a salient feature without much attention. On the right side a serial search condition is displayed in which detecting a target object requires reorienting of attention over the display. Here, the target distinguishes from distractors on the basis of a specific conjunction of object features (upright grey "T").

The paradigm uses displays with arrays of objects with multiple features such as colors or shapes. Many studies using this paradigm suggested that much less attention is required when an object can be recognized on the basis of a salient feature. The object then seems to pop-out of the display and attention is automatically directed to the target object. When, however, objects need to be detected on the basis of a conjunction of features, the search process is time consuming and depends on the number of irrelevant objects [2]. It is then assumed that the spatial focus attention searches through the display. Findings that "illusory conjunctions" between features are made due to a lack of spatial attention suggested that spatial attention is needed to detect an object with multiple features. Such and other evidence supported the idea that object features are bound together within the focus of attention. Taken together, ample evidence showed that selective attention within the visual domain differs between spatial and non-spatial attention. Whereas selection of locations is determined by top-down processes that accompany the competition between relevant and irrelevant locations and the increase of perceptual sensitivity, the selection of objects relies upon both bottom-up and top-down processes. Salient object features may capture attention by a bottom-up process, whereas top-down processes guide spatial attention, perceptually integrate object features and bias locations or object features by task instructions in favor of behaviorally relevant objects.

## Characteristics: Divided Attention and Executive Control

The second aspect of attention deals with the cognitive resources that are available to allocate attention. The attentional resources are limited. For example, when two tasks are performed simultaneously performance may be impaired (driving a car in Cairo while using a mobile phone is virtually impossible). Subjects then have to deal with the coordination of goals. This is accompanied with a switch cost and can be attributed to limitations in ►attention control system. A large amount of research investigated how attentional resources are organized, which processes require attention and which do not, how much time it takes to switch between tasks, and whether there is one central limited attentional resource or several resources in different sensory systems. An influential model of the executive control system assumes that most behavior is controlled by a contention scheduling system that coordinates goals and actions and is determined by previous experience and memories of responses to stimuli [3]. Executive control only then interferes and inhibits concurrent goals when the situation requires an alternative response. Such an alternative response is

required during decision making, planning, correcting errors, during coping with novel situations or responses, when overcoming habitual responses or when a situation is considered difficult or dangerous. This executive control has a limited capacity. A typical task demanding executive control is the Wisconsin card sorting task. In this task, the examiner places four cards with symbols that differ in number, shape or color in front of the subject, who is given a set of response cards with similar symbols on them. The subject is then asked to place an appropriate response card in front of the stimulus card based on a sorting rule established, but not stated, by the examiner (i.e. sort by color, number or shape). The examiner then indicates whether the response is "right" or "wrong." After 10 consecutive correct responses, the examiner changes the sorting rule simply by saying "wrong." The subject must then ascertain the new sorting rule and perform 10 correct trials. The sorting rule is then changed again, until six cycles have been completed. In this task, the change of situation demands a new response to a similar stimulus. Hence, the response that was previously tagged to a stimulus must be inhibited and changed to a new response. The Stroop task is also often used to test executive processes [4]. Here, a simpler process is required when solving a response conflict. For example, if the word "red" is printed in blue and subjects are required to pronounce the color of the printed word, there is a strong tendency to pronounce red instead of blue. In other words, the irrelevant information competes with the relevant information for a response. Attention is then required to suppress the tendency to respond to the irrelevant information. The mechanisms underlying selection of the relevant verbal response above the conflicting irrelevant response is thought to be similar to the perceptual selection process. Many studies showed that neurons in the prefrontal cortex have the possibility to perform such a selection process. These neurons show selective responses to either response information if the stimuli are presented separately, but if they are presented together the neural response to the irrelevant stimulus decreases [5]. Brain lesion studies and neuroimaging studies have shown that the brain areas responsible for executive control are located in the frontal lobe, the cingulate cortex and prefrontal cortex. Prefrontal neurons have been related to this ability. These neurons are decision sensitive rather than stimulus sensitive and are capable to adapt to new situations.

## Characteristics: Orienting Attention

Orienting of attention is particularly needed when searching in the environment for relevant information or during the tracing of stimuli through space. Searching in the environment is usually associated with the foveation of a stimulus. This overt focusing with the eye can also be replaced by covert orienting of attention. As discussed under the term selective spatial attention that focusing attention improves detection of a stimulus. Moving a spotlight of attention from one stimulus location to another can also occur overtly and covertly by moving the eye or moving the "inner" eye. Several brain imaging and neurophysiological studies have shown that the neural mechanisms underlying overt and covert orienting of spatial attention has been associated with overlapping systems. Orienting attention has been associated with a network of at least three brain areas working strongly together, the posterior parietal lobe, the superior colliculus and the lateral pulvinar of the thalamus, representing the so called posterior attentional system [6]. These brain areas have been shown to contain representations of a spatial map that contain location sensitive neurons with relatively fixed relations among spatial locations and some more flexible spatial relationship to the body or the focus of attention. Neural activity in these neurons also suggests their capability to maintain and change the focus of attention. These three neural systems are thought to cope with subprocesses in orienting attention and in visual search. The movement of the attentional focus can be separated in at least three subprocesses; it requires the unlocking of attention to the old location (disengagement of attention), a shift of attention toward the new target location, and tagging to a new focus (engagement of attention). Lesions in the posterior parietal lobe have been associated with the disengagement of attention. Lesions in the superior colliculus have been associated with deficits in shifting the attention. These lesions not only result in slower shifts of attention and reduced capability to calculate the new target location, but patients with such lesions also return to a new location as easily as to a previously attended location. In healthy subjects, returning attention to a previously attended location is inhibited, in order to prevent searching at the same place again (inhibition of return). Finally, lesions in the lateral pulvinar of the thalamus have been associated with difficulties in engaging attention to a new location on the contralateral side of the lesion or to sustain attention to a location in particular when distracting stimuli are present in the ipsilateral visual hemifield. Indeed, this network of brain areas has been shown to be involved in visual search tasks. However, this network does not explain which stimulus locations are relevant and which stimuli draw and guide attention. Here, selective attention mechanisms are needed to distinguish relevant from irrelevant information. As discussed above, such selection mechanisms may be regulated in the occipital and temporal lobe. Thus, spatial orienting can be divided in several subprocesses and neural correlates, but this network does not operate without other

attentional processes and brain areas when coping with spatial attention demanding task.

## Characteristics: Arousal and Vigilance

Arousal represents the state of cortical activity or wakefulness. Cortical activity is accompanied with a desynchronization of slow rhythmic activity in the encephalogram. Arousal is regulated by different neurotransmitters in the brain stem, particularly noradrenaline, which innervate different patterns of cortical structures via the thalamus along ascending pathways. Yet, the relation between arousal and attentional functions, such as vigilance, remain under investigation. Vigilance or sustained attention represents the ability to detect and respond to small changes occurring at infrequent random time intervals in the environment. A typical vigilance test is the Continuous Performance Task, which is a 15 minute letter discrimination task. Performing this task requires at least durable (tonic) and momentary (phasic) attention and possibly arousal, that is vigilance requires maintaining a durable state without overt behavior while initiating sudden behavior once a target occurs. Vigilance can be measured by increased error rates and longer reaction times as a function of time (usually at least 5 min). The decrease in performance over time can be due to both a reduced tendency to judge a stimulus as a target and to a reduced sensitivity to discriminate between targets and distracters. Vigilance is thought to be controlled by the cholinergic system and noradrenergic system in the nucleus locus coerulus of the brain stem, the intralaminar thalamic nuclei and the right prefrontal cortex [7].

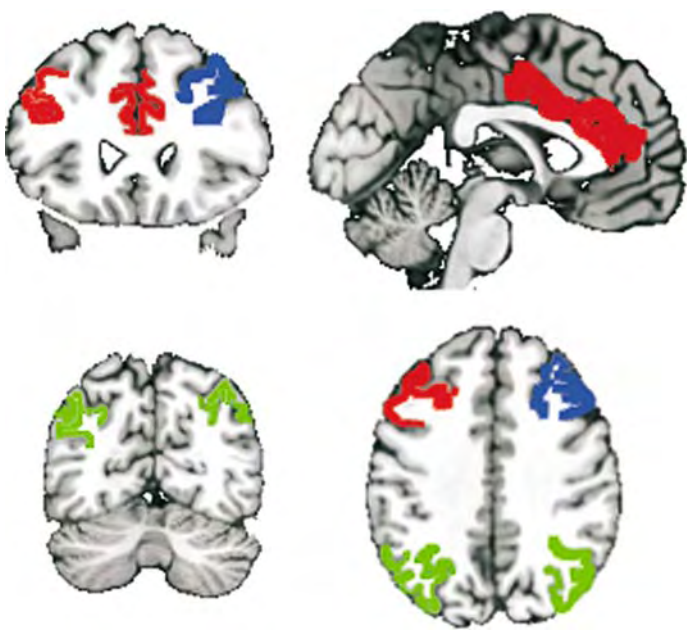
## Neural Networks of Attention

The brain areas that are involved in the attentional functions described above form a neural network that strongly interact and are coactive in many task situations (Fig. 2).

One of the most influential neural models of attention [6] consists of three subsystems. The posterior attention system (parietal cortex, superior colliculus, pulvinar) is concerned with spatial attention, the anterior attention system (anterior cingulated, basal ganglia and dorsolateral prefrontal cortex) with target detection and executive control, and the vigilance system (right prefrontal cortex, intralaminar thalamic nuclei and brainstem nuclei) with sustained attention.

## Pathology

Many patients with cognitive disorders also have attentional deficits. ►Attention deficit disorder is similar to the hyperactivity diagnosis in children and is referred to under the term ADHD (attention deficit/hyperactivity disorder). These diagnoses often have co-morbidity with disturbances in social behavior and the processing of emotions. Patients (children) are less persistent in performing a task, are overactive, impaired in short-term memory performance, and are often prone to make speeded errors and are less able to make decisions. These symptoms of ADHD can



**Attention. Figure 2** A neural network of attention according to Posner & Petrides (1994). This model highlights brain regions that are involved in the attentional control system (red), orienting of attention (green) and vigilance (blue).

be summarized under sustained attention, selective attention and executive control. These deficits correlate with impairments in neural networks of the right frontal (vigilance), posterior parietal (orienting/selective attention), and respectively anterior cingulate cortex (executive control) [8]. Other pathologies with attention deficits have often been associated with damage to the prefrontal cortex or with an imbalance in the neurotransmitter system. Patients with lesions in the prefrontal cortex can be impaired in sensory gating operations, in discriminating between old and new items and a disability to sustain attention. Deficits to discriminate between old and new stimuli or a lack of inhibition to previous responses may also lead to dysfunctions in executive control. Patients with schizophrenia have also been associated with attention deficits. Schizophrenia is often associated with sensory gating dysfunctions and the disability to inhibit interference of irrelevant information, inhibiting previously relevant but currently irrelevant responses or stimuli. Though the neural underpinnings of schizophrenia are largely unknown, a frontal dysfunction and neurotransmitter imbalance of dopamine and noradrenalin may play a role [9]. Patients with hemispatial neglect suffer from lesions in the right parietal or right prefrontal lobe. Some of the heterogeneous dysfunctions of these patients may be related to attention. The disorder of orienting that impairs awareness of stimuli located on the side of space opposite to the lesion in one cerebral hemisphere may be related to a disinhibited orienting to the ipsilesional field or deficits in disengaging attention to the contralesional field [10]. Thus, a variety of attentional deficits have been related to different pathologies. We now begin to understand how specific attentional functions are impaired in different pathologies. However, knowledge about the relation between pathology and specific attention functions is far from complete.

# Attention Deficit

## Definition

Many psychiatric and neurological diagnoses include deficits in attention. These diagnoses are, for example, neglect, attention deficit disorder, hyperactivity, schizophrenia, closed head injuries. Lesions in the prefrontal cortex, or deregulations of neurotransmitters may also accompany attention deficits. Patients with these diverse disorders suffer from a wide spectrum, yet specific patterns, of attention deficits. The spectrum may include impaired vigilance, concentration deficits, short-term memory, decision making, hyperactivity, perceptual, orienting deficits.

# Attention Deficit Hyperactivity Disorder (ADHD)

## Definition

►Attentional Disorder

# Attention Demanding Process

## Definition

An attention demanding process is a process that involves cognitive resources, so another simultaneously performed task would suffer. For example, counting

backward is made increasingly demanding by counting backward in steps of two or three. Performing such a task impairs performance of the covert or overt rehearsal of numbers or words. Attention demanding tasks are suitable to demonstrate the limited capacity of attention.

►Attention

## Attention Shifts

### Definition

Attention can switch between tasks. If two tasks have to be performed simultaneously and processing resources are not able to perform the task in parallel, attention has to be divided and switched between the tasks. Task switches are accompanied with costs in processing in at least one of the tasks. It is assumed that the cost of processing is due to limitations in attentional resources.

Coping with task switches is thought to be part of the attentional control system.

►Attention

## Attentional Control System

### Definition

An influential model of the attentional control system consists of a set of brain regions that cope with the orienting of attention (posterior attentional control system, which includes the posterior parietal cortex, superior colliculus and lateral pulvinar of the thalamus), executive attention (anterior attentional control system, including the cingulate cortex and dorsolateral prefrontal cortex) and vigilance or alerting system (right prefrontal cortex). This model developed by Posner and

Petersen (1990) covers about all attentional functions.

►Attention

## Attentional Disorder

### Definition

Many psychiatric disorders also include attentional deficits, while one percent of children suffer from attention deficit disorder. Attention deficit disorder is not equivalent with hyperactivity, though attention deficit hyperactivity disorder (ADHD) is used as a common psychiatric diagnosis. The diagnosis includes impaired controlled processing of information, short-term memory, learning and decision making. The children are impaired in sustaining attention, are not able to focus long on a task, are disinhibited and overactive and reactions are less controlled. There is often a co-morbidity with social and emotional disorders.

►Attention

## Attentional Filtering

### Definition

Represents a particularly strong attentional effect, in which the context gates sensory input in an all-or-none fashion.

## Attractive Stimulus

### Definition

An attractive stimulus is a signal or a cue that is appealing and draws the receiver to the source of stimulation. The same stimulus can be attractive or aversive depending on physical features such as its intensity (for instance, concentration of an odor) or the behavioral context in which it is perceived.

►Aversive Stimulus
►Odor Coding

## A-type $K^+$ Current (IA)

### Definition

Voltage-dependent $K^+$ current, showing relatively rapid inactivation and contributing to action-potential repolarization in cortical neurons.

►Neuronal Potassium Channels
►Action Potential

## Atypical Depression

### Definition

This is a sub-type of dysthymia and major depression characterized by mood reactivity – being able to experience improved mood in response to positive events. It is also characterized by reversed vegetative symptoms, namely over-eating and over-sleeping. Leaden paralysis and sensitivity to personal rejection may also be observed.

►Major Depressive Disorder

## Atypical Neuroleptic Drugs

### Definition

Relatively newer neuroleptic drugs with less severe adverse effects on movements.

►Antipsychotic Drugs

## Audiogenic Seizures

### Definition

Seizures evoked by loud sound often beginning in the inferior colliculus.

►Inferior Colliculus

## Audiogram

### Definition

A chart showing the amount of hearing loss (in decibels) at each frequency.

►Hearing Aids

## Auditory Brainstem Response (ABR)

### Definition

An early latency sound-evoked event-related potential.

Typically elicited by clicks or tone bursts, and more recently by complex stimuli such as speech, the ABR has a distinctive pattern of neural waves arising within the first 10 ms after stimulation. Uses of the ABR include hearing assessment, tumor detection, intraoperative monitoring. Also known as Brainstem Auditory Evoked Response (BAER).

►Auditory Evoked Potentials

## Auditory Cortical Areas

Christoph E. Schreiner[1], Jeffery A. Winer[2]
[1]Coleman Memorial Laboratory, W.M. Keck Center for Integrative Neuroscience, Department of Otolaryngology-Head and Neck Surgery, School of Medicine, University of California at San Francisco, San Francisco, CA, USA
[2]Division of Neurobiology, Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA, USA

### Definition

Auditory cortical (AC) areas are structurally and functionally distinct regions in the temporal lobe that process acoustic information. Parcellation of these regions and the identity of areas are based on joint considerations of structural and functional properties, including cytoarchitecture, myeloarchitecture, neuro- and histochemistry, connectivity, electrophysiology and functional imaging. The number of AC areas is a matter of debate and may be species specific.

### Characteristics

#### Higher Level Structure

AC contains many areas as defined by tonotopic representations, i.e., an orderly progression of characteristic frequency (CF) or its absence; areas devoid of CF gradients are identified by their connectional affiliations or cytoarchitectonic attributes.

AC has a high degree of internal order, a stereotyped neuronal organization and intricate local microcircuitry. It is organized in all spatial axes. Thus, in cat AC, CF gradients are found in many (five of thirteen) areas, while other areas are polymodal (six) or limbic-related

(two) [1,2]. The CF gradient differs among areas, with local expansions or reductions of particular frequencies that may serve specific behavioral or ecological roles.

A further axis is laminar organization, which segregates afferent input systems to specific layers (e.g., thalamic projections preferentially end in layers III and IV, while corticocortical input targets layers II and III) and output (corticofugal projections to the midbrain arise exclusively from layer V, while those to the thalamus concentrate in layer VI). Even in areas without a CF representation, there is connectional order on a laminar and topographic basis [1]. Thus, all areas have a topographic connectional order, even if the physiological expression is area specific.

## Lower Level Components

Like all brain structures, AC has an intricate array of neuron types and connections that allow it to generate specific physiological responses by combining and recombining inputs in many ways. An elementary form of such order is in the membrane profile of cortical neurons, which is a consequence of genomic and ion channel-related features and endows cells with fundamental properties related to intrinsic excitability and filtering. A second basic level of this specialization is cell shape and chemical anatomy, which is diverse, ranging from glutamatergic pyramidal cells whose apical dendrites may be up to 2 mm long and which subserve vertical columnar organization within cortex, to tiny gamma-aminobutyric acid (GABA)-containing basket cells whose dendritic domain is confined completely to a cortical layer and whose range of synaptic action is a few hundred micrometers. Between these extremes a host of subtypes exist which endow AC with a multitude of processing regimes, including the ability to segregate and integrate streams of information entering it or exiting from it. Thus, even among pyramidal neurons there are subvarieties (giant versus small, classical versus. inverted, single-spiking versus bursting, spinous versus smooth, corticothalamic versus corticotectal versus corticocortical) that confer diversity to intracortical intralaminar descending feedback and feedforward connections. Rather than serving as the final terminus for connections and processing, the cortex redistributes streams of information to the forebrain, thalamus, midbrain and medulla, enabling ongoing processing and filtering of ascending information and deconvolving an auditory stream into its constituent elements [1,2].

## Higher Level Processes

Segregation and integration are two fundamental aspects of cortical organization that must interact to enable functional processes. Cortical processes can be characterized as a combination of highly localized and specific processes within areal subregions and global computational procedures and algorithms that reflect operations common to all areas. A basic operational principle is the systematic representation of behaviorally relevant attributes of proximity, similarity or dissimilarity within an organized parameter space. This requires detecting relevant features of the acoustic biotope, performing computed correlations and organizing perceptual space to implement behavior. Cognitive processes that occur in AC entail the analysis and interpretation of the environmental scene based on higher order correlations and in comparison with previously stored information regarding the behavioral relevance of objects, backgrounds and events.

In a mixed set of hierarchical and parallel processes, global groupings of auditory cortical fields can be distinguished [3]. These areas may be broadly subdivided into families that subserve and elaborate specific functional relations (Fig. 1).

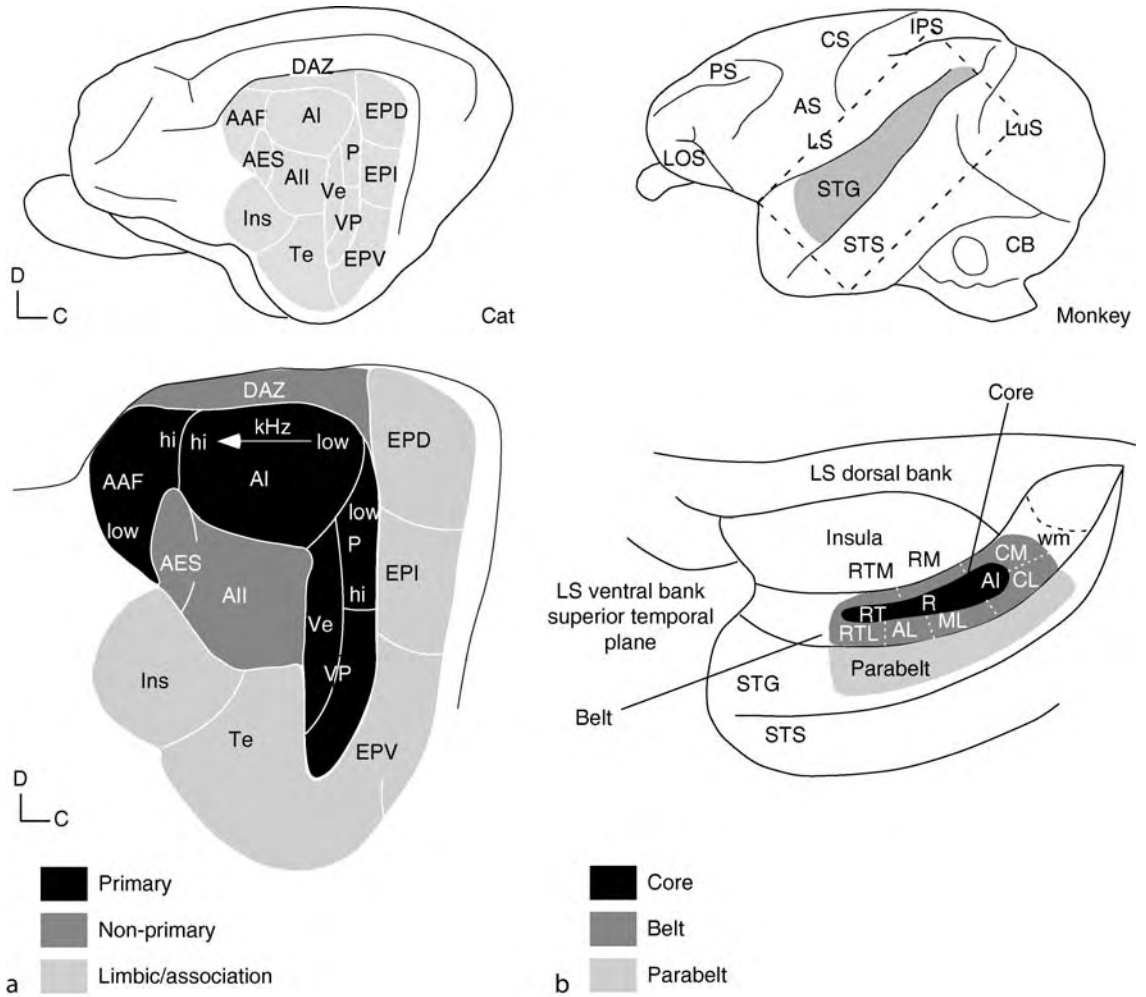
Primary (first order or core [5]) areas represent intermediate stages in the synthesis of percepts after brain stem analysis and precede higher cortical tasks. The primary cortical regions represent auditory information topographically and with receptive field parameters tightly coupled to stimulus aspects [2]. Neurons typically respond to pure tones with a relatively short latency, prefer a restricted range of frequencies and have a global tonotopic organization preserving CF [6]. Other functional properties, such as spectral integration bandwidth, preferred sound intensity or binaural interactions are multiplexed on the tonotopic map and have systematic local organizations [2,6,7].

Secondary (second order, non-primary or belt) areas probably participate in discrimination, categorization and integration of information. Neurons in these areas show high local variability in frequency organization, response latencies and spatial and spectral integrative properties. Responses to pure tones are often reduced and complex sounds elicit stronger responses. Extreme examples are echolocation-specific maps in the AC of some bats [7]. Systematic representations of highly specific parameter-combinations of biosonar sounds and their echoes reflect distance or velocity information.

Multimodal (association, parabelt) areas include the parabelt regions and may process complex multimodal percepts and contribute to the foundation of concepts (for perceptual unity and consistency in decision-making and behavior). Their receptive field properties are poorly understood. A role in the analysis of communication and non-communication sound categories and in speech perception is plausible.

Supramodal areas are involved in the executive control of cognitive networks including language.

Limbic areas receive extralemniscal auditory input, show little regional specificity for particular stimulus aspects and convey auditory information to subcortical



**Auditory Cortical Areas. Figure 1** Subdivisions of cat (a) and macaque (b) auditory cortex in a lateral view of the hemisphere (*upper panels*) and with the principal subdivisions indicated (*lower panels*). The macaque subdivisions are redrawn from [4]. For cat primary and macaque core areas, the local tonotopic gradient from low to high frequencies is indicated (*arrows*). A potential correspondence between cat primary, non-primary and limbic/association areas and macaque core, belt and parabelt areas remains to be established. Abbreviations: *AAF* anterior auditory area, *AES* anterior ectosylvian area, *AI* primary auditory cortex, *AII* second auditory cortical area, *AL* anterolateral belt area, *AS* arcuate sulcus, *CB* cerebellum, *CL* caudolateral belt area, *CM* caudomedial belt area, *CS* central sulcus, *D* dorsal, *DAZ* dorsal auditory zone, *EPD* dorsal area of the posterior ectosylvian gyrus, *EPI* intermediate area of the posterior ectosylvian gyrus, *EPV* ventral area of the posterior ectosylvian gyrus, *Ins* insular area, *IPS* intraparietal sulcus, *L* lateral, *LOS* lateral orbitofrontal sulcus, *LS* lateral sulcus, *LuS* lunate sulcus, *ML* mediolateral belt area, *P* posterior auditory area, *PS* principal sulcus, *R* rostral core area, *RT* rostrotemporal core area, *RTL* lateral rostrotemporal, *RTM* medial rostrotemporal, *STG* superior temporal gyrus, *STS* superior temporal sulcus, *Te* temporal area, *Ve* ventral auditory area, *VP* ventral posterior area, *wm* white matter.

structures (amygdala and central gray) implicated in the control of smooth muscle.

## Lower Level Processes

A key feature of core areas is a gradual change in neurons' preferred frequency, creating a fundamental cochleotopic axis across AC. Within the continuous CF map are smaller pools of neurons with functional roles other than tonotopic organization, contributing to specific representations of binaural differences, temporal patterns, stimulus intensity or sharpness of frequency tuning, which in turn are superimposed upon and integrated with CF maps [2]. Such representations could coordinate perceptual processes for binding and streaming, two prime functions for which AC is responsible, following processing in the brain stem. The functional organization of belt and parabelt regions is less well understood; however, they may have a local

order as demonstrated by the object-oriented maps in higher cortical areas of bats [2,7].

In the vertical axis, systematic functional distinctions between cortical laminae coexist with a columnar organization principle, i.e., with receptive field properties, such as CF, that are shared by neurons across the six layers. Lamina specific ensembles of cell types, modular microcircuits, thalamic and cortical inputs, as well as cortical and subcortical output targets, each suggest a fine-grained representation of functional properties within a column [1,6].

Neuromodulatory influences from many chemically specific subcortical sites, including cholinergic, serotoninergic, noradrenergic and dopaminergic sources, converge onto AC areas and regulate cortical excitability, gate information processes, enhance signal-to-noise ratios and modulate receptive field synaptic plasticity [8]. These modulatory inputs can modify cortical function based on state, experience and behavioral context.

## Function

Communicative, predatory and reproductive behaviors rely critically upon AC to combine, transform and distribute acoustic information. AC interfaces hearing and higher order communication and cognitive networks, including human language areas. Transformations of auditory information in the thalamus and cortex support representations of the auditory environment for essential perceptual tasks. The neural algorithms for such transformations are common to all sensory systems but can also involve unique, modality-specific processes. Different AC subregions contribute to task-related computations and probably serve object specific analyses, suggesting the cortical emergence of processes that are either object related or embody processing stages and streams dedicated to specific features of the auditory environment [9]. Functional differences underlying these processes are created by thalamic and cortical circuits and by local diversity and specialization in synaptic and cellular mechanisms.

AC areas create distinct streams for cortical sound representation [6,9]. They may be less concerned with the representation of specific auditory attributes (a task which we suggest is largely completed in the brain stem) and more with the conjunction and coordination of acoustic, multisensory and limbic frames of reference, each contributing globally to auditory behavior and communication. The computed entities probably serve several central processing tasks, construction of a global representation of the acoustic world, determining object features such as form, texture and position, generating a reliable and stable feature representation, allowing subsequent multisensory integration, permitting the assignment of significance to particular environmental constellations and ultimately, the emergence of unique perceptual attributes and concepts that trigger behavior.

Functional properties of neurons and neural networks of auditory cortical areas can be dynamically modified through experience. Critical behavioral decisions can reflect the contextual influences within the acoustic scene and their modification by experience. Thus, limbic circuits influence auditory processing, auditory stimuli can modulate behavioral arousal level and sound content and meaning can be assessed based on context and memory.

## Pathology

Dysfunction of AC results from many causes, including perinatal asphyxia, cerebrovascular disease (stroke), tumors, trauma, infection and developmental misadventures. In humans, consequences can range from minor auditory sensory disturbance, to auditory agnosia (impaired recognition of non-verbal sounds), to pure word deafness (impaired recognition of speech sounds), to cortical deafness (inability to recognize auditory stimuli). In human cases and infrahuman studies of AC lesions [10], perceptual deficits can involve discrimination of tone duration, auditory sequences and interaural order as well as impaired sound localization and reduced auditory speech perception. Often, tone detection and discrimination are unaffected. AC lesions also affect the construction of auditory objects, assessment of behavioral stimulus significance and decision-making in a learned stimulus/response contingency.

### Synonyms

Auditory event-related potentials; ERP

### Definition

The firing of neurons results in small but measurable electrical potentials. The specific neural activity arising from acoustic stimulation, a pattern of voltage fluctuations lasting about one half second, is an auditory evoked potential (AEP). With enough repetitions of an acoustic stimulus, signal averaging permits AEPs to emerge from the background spontaneous neural firing (and other non-neural interferences such as muscle activity and external electromagnetic generators), and they may be visualized in a time-voltage waveform. Depending upon the type and placement of the recording electrodes, the amount of amplification, the selected filters, and the post-stimulus timeframe, it is possible to detect neural activity arising from structures spanning the auditory nerve to the cortex.

### Characteristics

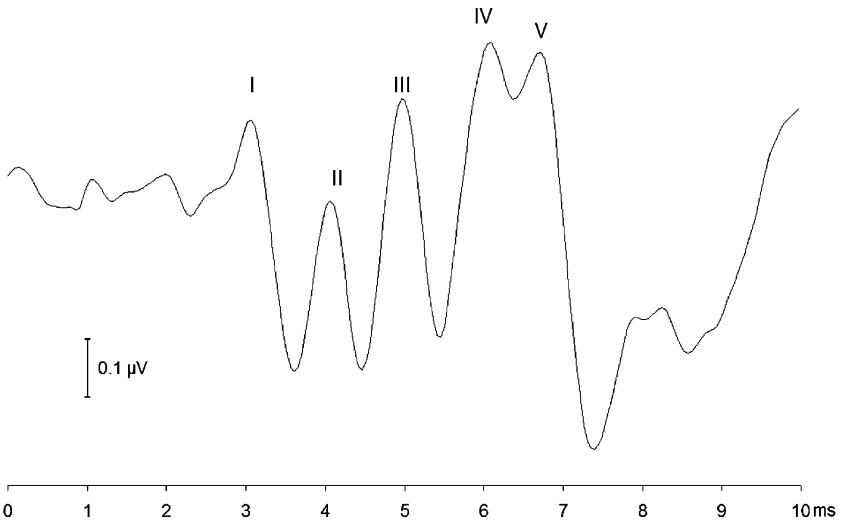
In general, as the time after stimulation (►latency) of a response increases, the neural generator becomes more central. In far field recordings from humans, the three typically used response classifications, based on response latency, are: early (the first 10 ms), middle (10–80 ms) and late (80 ms to 500+ ms). In terms of generators, these classes correspond roughly to brainstem, thalamus/cortex and cortex, respectively [1].

#### Early Latency

Waves arising in the first ten ms after stimulation include both receptor potentials from the cochlea and neurogenic responses arising from the auditory nerve and low midbrain structures. With a near-field recording technique known as ►electrocochleography (►ECochG), two receptor potentials, originating in the cochlea's hair cells, can be recorded from the vicinity of the ear drum: the cochlear microphonic and the summating potential. They are AC and DC potentials, respectively, have an effective latency of zero, and last the duration of the stimulus. A millisecond and a half later, the dual-peaked neurogenic compound action potential of the distal auditory (eighth cranial) nerve can also be seen with ECochG. In contrast, using far-field electrodes, neurogenic responses known as the ►auditory brainstem response (ABR), can be recorded from the scalp (Fig. 1) [2].

These waves depend upon synchronous firing in the first relays of the afferent auditory pathway. For a given stimulus type (often an abrupt broadband click) and intensity level, the expected latency of ABR peaks falls within a very tight range (less than half a millisecond). Deviations from this range are useful in clinical diagnoses.

In particular, the ABR is a valuable objective measure of hearing. With decreasing stimulus intensity, wave latencies increase systematically until the hearing threshold is reached, below which the response is absent. Thus, an accurate measure of hearing threshold is possible in individuals who are unable to be tested behaviorally. Although there is a developmental time course (adult-like responses are attained by age two),



**Auditory Evoked Potentials. Figure 1** Early-latency auditory evoked potentials. The auditory brainstem response.

it is possible to test hearing in newborns with age-appropriate norms. Importantly, the ABR is unaffected by sleep or sedation, so obtaining hearing thresholds in babies or other uncooperative individuals is possible.

A second major clinical use of ABR is in the detection of lesions, tumors, demyelinization, or conditions that cause increased intracerebral pressure (e.g., hydrocephalus, hematoma). ABR morphology, peak and interpeak latencies can have distinctive patterns that alert skilled clinicians to neural damage (e.g., eighth nerve tumors). Another major use of ABR is intraoperative monitoring. During neurosurgery, monitoring of ABR enables an immediate indication of whether any of the structures involved in the auditory pathway have been put at risk. Finally, the brainstem response provides a measure of neural synchrony necessary for normal perception of sound [3].

### *Brainstem Responses to Complex and/or Long Stimuli*

Typical recordings employ short duration, relatively simple stimuli. However, complex sounds, some quite long in duration, are increasingly being used. Brainstem response to speech sounds can be used as a biological marker of deficient auditory processing associated with language and learning disorders [4]. A brainstem response whose nature depends on a long-duration stimulus is the ►frequency-following response (►FFR). The FFR, also known as auditory steady-state response, is an index of phase locking to a periodic stimulus. Examples of FFR-inducing stimuli are pure or modulated tones, tone complexes, modulated noise and speech [5]. Recorded from the scalp in humans, the FFR is a phase-locked response that, depending on electrode placement and stimulation and recording techniques, originates from as early in the auditory pathway as the auditory nerve or as late as the rostral brainstem. It is a measure of both spectral and periodicity encoding, and because it is readily detectible in individuals, it has utility as a clinical measure of those processes as well as of hearing level. Brainstem responses are influenced by lifelong and short-term auditory experiences [6].

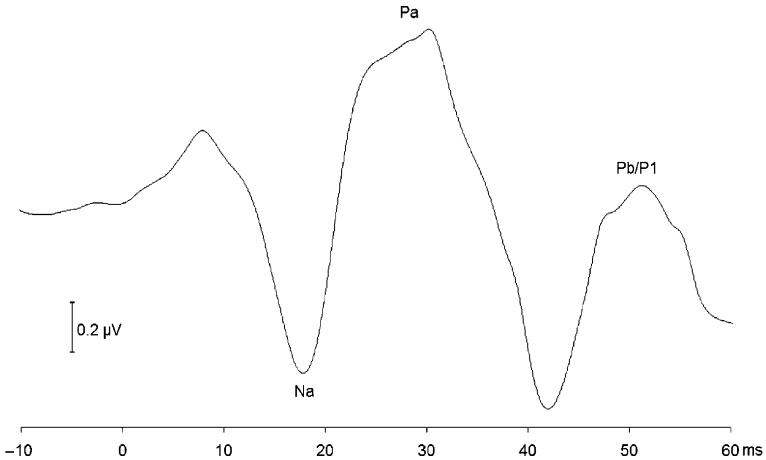
### Middle Latency

The waves following the ABR, up to roughly 80 ms, are collectively known as the middle-latency response (MLR) (Fig. 2) [7].

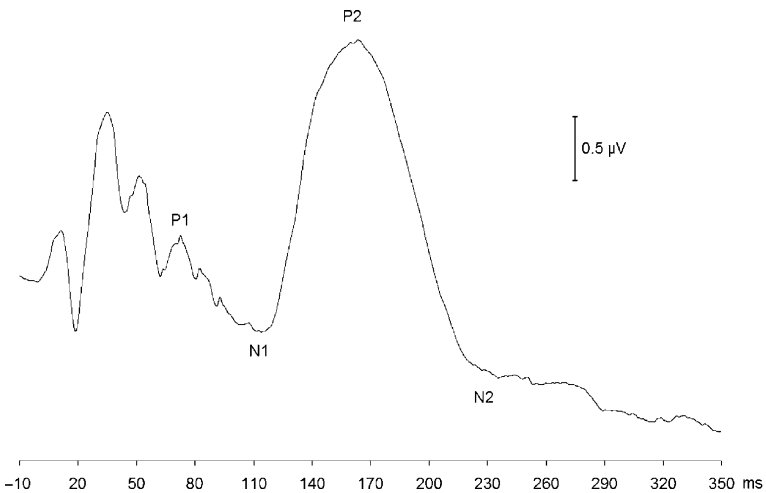
Although responses in this time frame are less mappable to specific neural generators than the earlier ABR waves, the thalamus (P0, Na) and cortex (Pa, Nb, P1) are involved. (Note: Unlike ABR waves, the names of middle- and late-latency responses typically begin with P or N indicating positive or negative polarity.) As ABR requires a high degree of neural synchrony, individuals with certain neurological disorders may exhibit absent ABRs despite normal hearing. Thus, MLR can be useful in assessing hearing sensitivity. For this same reason, a lack of sufficient synchrony in response to low frequency signals often makes MLR superior to ABR in assessing low-frequency hearing. Two major caveats in MLR as a hearing measure is that it does not reach its mature morphology until adolescence, and in children, there is a strong influence of sleep state.

### Late Latency

Late-latency (>80 ms) AEPs, historically the first discovered, are cortical in origin and are much larger and lower in frequency than early and middle-latency potentials. Highly dependent upon stimulus type, recording location, recording technique, patient age and state, the late-latency responses may differ dramatically in morphology and timing and may overlap one another. Thus, categorization of responses



**Auditory Evoked Potentials. Figure 2** Middle-latency auditory evoked potentials.



**Auditory Evoked Potentials. Figure 3** Late-latency auditory evoked potentials. Exogenous responses.

into two broad types, exogenous and endogenous, is useful in describing these late potentials. Exogenous responses, which also describe early and middle-latency potentials, are more-or-less obligatory responses to a sound. Endogenous responses typically require a stimulus manipulation or the performance of a task by the patient.

### *Exogenous Responses*

The archetypal late-latency exogenous responses are illustrated in Fig. 3.

Beginning with P1 (which is sometimes classified as middle-latency) at about 80 ms through to N2 at about 250 ms, all are cortical in origin and maximal in amplitude at the central top of the scalp. The maturational time course of the various components varies. Late cortical responses do not reach maturity until post-adolescence. They have value in assessing cortical auditory processing. In addition to the classic pattern of responses to stimulus onset, changes within an ongoing stimulus also evoke a response called the acoustic change complex (ACC) [9]. Tones or tone complexes changing in frequency, complexity or intensity and speech syllables are typical stimuli. The response can be evoked by an acoustic change that is very near threshold.

Bridging the exogenous and endogenous categories is the ►mismatch negativity (►MMN). MMN is an acoustic change detector. It is evoked by a sequence of identical sounds that is interrupted occasionally by a different sound. This stimulus presentation technique is termed “oddball paradigm.” The response to that infrequent stimulus differs from that to the main stimulus, and appears as a slow negative deflection in the 150–300 ms time frame. The types of stimulus manipulations that evoke MMN include intensity,

frequency and complexity, and the contrasting stimuli can be at (or even below) perceptual threshold.

### *Endogenous Responses*

Endogenous (literally "born within") potentials are those that, while induced by external stimuli, originate not as an obligatory consequence of the inducing sound, but rather due to some level of cognitive processing. Examples of endogenous AEPs are the P300 and N400. Sequentially occurring later in time, the P300 and N400 represent successively higher levels of sound processing. Evoked using the oddball paradigm, the classic P300, unlike MMN, only occurs when the listener is consciously attending to the stimulus aberration. P300, which is also evoked by other sensory modalities, is considered an index of cognition because stimulus evaluation and classification must take place [10]. The response is further divided into P3a and P3b components. P3a either appears to a distracter stimulus which is presented along with the targets and non-targets within the oddball presentation, or, if stimulus differences are large enough, with no task at all. This component has more frontal lobe contribution than the classically elicited parietal-centered P3b. A higher level of cognition is required for the N400 response [11]. It requires a speech stimulus, and occurs in response to semantic incongruity and thus is an indication of language processing.

## Considerations

A number of considerations and caveats are involved in the recording of reliable auditory evoked potentials. No response is monolithic, either in its etiology or in interpretation. A thorough description of stimulus factors alone could fill a volume: the length, intensity, complexity and repetition rate of the stimulus all affect the responses. Some responses differ dramatically depending upon whether the stimulus is delivered to one or both ears or whether there is accompanying visual stimulation; others are relatively unaltered by these factors. Characteristics of the recording device, particularly filters, also have an effect on response recording. Successively later responses have increasing low-frequency content and high-pass filters must correspondingly be opened. However, with increasingly more energy being passed on the low end, recordings are more prone to contamination by non-stimulus related activity: artifacts. Artifacts fall under two categories, those internal to and external to the testee. Internal artifacts include eye blinks, movements, muscle contractions including the involuntary sound-evoked postauricular muscle (PAM) reflex, and brain activity that is unrelated to the sound stimulus. External artifacts are those arising from electrical sources such as AC power line and the electrical signal traveling through the earphone or loudspeaker cables (stimulus artifact). The degree to which artifacts adversely affect response recordings depends upon how alike in frequency the artifact and the response are. For example, eye blinks are very low in frequency, and thus are more damaging to low-frequency late-latency responses. Most artifacts are random in time of occurrence. Two exceptions are stimulus artifact and PAM. Stimulus artifact lasts as long as the stimulus. Therefore, it is not a concern if the stimulus is a 100 μs click and the response of interest is the middle-latency Pa. However, the stimulus artifact from a 5 ms tone burst may obliterate an early-latency brainstem response. PAM reflex occurs in response to the stimulus in the 15 ms timeframe and thus most affects middle latency responses.

Much information can be gleaned from AEPs for both clinical and theoretical purposes. As the power and speed of computers increases, multiple-channel recordings and advanced signal processing techniques are better able to inform us about the underlying neural processes that are signified by these minute perturbations in the electroencephalographic activity resulting from auditory stimulation. Together with advances in neural imaging, the exquisite timing resolution of AEPs can help us approach a better understanding of the biological bases of auditory function responsible for human communication such as speech and music.

# Auditory Maps

►Tonotopic Organization (Maps)

# Auditory-Motor Interactions

Walter Metzner
UCLA Department of Physiological Science,
Los Angeles, CA, USA

## Definition

Interactions between hearing and various motor functions, such as protective reflexes and vocal behavior.

## Characteristics

Auditory signals guide a multitude of behavioral responses from simple reflex motor patterns for orientation to complex vocal communication behaviors in virtually all vertebrates and insects. Hence, auditory stimulation can elicit anything from simple motor patterns, such as head/neck turns or ear movements, to complicated, highly coordinated interactions of several motor patterns, such as calling, breathing, and postural changes that occur, for example, during birdsong. In turn, certain motor patterns, especially those associated with vocal behavior, can also affect how the brain processes auditory signals.

### Auditory Orientation Reflexes

Orienting movements of the head, neck and/or eyes in response to auditory signals are generally thought to be controlled by auditory input to the superior colliculus in mammals, or its homologue structure in birds, the optic tectum. Most of our knowledge about what controls head movements in response to external signals is based upon studies of visually guided orienting responses, where the topographic representation of the stimulus that ultimately guides the motor response is naturally determined by the retinotopic organization of the visual system. Auditory input to the superior colliculus/optic tectum is topographically organized only in barn owls. In mammals, the representation of auditory space appears to be less developed, and is often even more complicated by movements of the external ears, or pinnae. Very little is therefore known about the neuronal basis of acoustically elicited orienting responses. It appears that output from the superior colliculus/optic tectum to small areas in the midbrain tegmentum mediate the sensory-motor transformation of stimulus location into a direction-specific pre-motor command. This in turn gives rise to a directed behavioral response through activation of the various pools of motor neurons in the brainstem and spinal cord that control head/neck turns, turns of the body axis, and/or eye movements.

#### *Pinna Movements in Mammals*

The mammalian pinna plays an important role in sound localization, especially for sources in the midsagittal plane, which generate minimal interaural disparities. In species with mobile external ears, the pinnae can be oriented independently of the head's position, thus aiding in sound localization by allowing the animal to obtain multiple samples of an acoustic object. In such mammals, auditory targets elicit stereotyped pinna movements that typically consist of two parts: a short-latency component that is time-locked to the onset of the sound and a second long-latency component that is highly correlated with eye movements and is probably part of the animal's general orientation behavior. The second, slower response most likely involves the superior colliculus, and might be mediated by pathways linking the superior colliculus with the facial nucleus, either via the reticular formation (tectoreticular–facial pathway) or via the paralemniscal area (tectoparalemniscal–facial pathway). In particular, the paralemniscal area, situated in the lateral midbrain tegmentum, supplies an elaborate network of monosynaptic excitatory and inhibitory inputs to the medial portion of the facial nucleus, where the motoneurons that innervate the muscles of the pinna are located. It is not clear, however, if the superior colliculus is also involved in mediating the initial, faster response. This component of auditory-evoked pinna movements might be driven directly via the paralemniscal area, which receives multiple, binaural inputs from the ascending auditory pathway, notably from the dorsal nucleus of the lateral lemniscus.

### Acoustic Startle Response

The startle response is a fast reflexive response to intense, unexpected acoustic, tactile or vestibular stimuli and protects the animal from injury by blows or predatory attacks. The acoustic startle response (ASR) of mammals, including humans, consists of a quick eyelid-closure and a contraction of facial, neck

and skeletal muscles, an arrest of ongoing behaviors, and an increased heart rate. This results in a brief stiffening of the limbs, dorsal neck, and body wall before the animal can perform directed evasive or defensive actions [1]. The ASR can be modulated by various experimental manipulations, expressing habituation, sensitization, and fear conditioning. ASR has thus been used as a behavioral assay to examine the neuronal basis of behavioral plasticity, and to model neuropathological dysfunctions of sensorimotor information transfer.

The ASR is phylogenetically widespread and can also be found in fish and aquatic amphibians where it is expressed as "►C-start escape" and is mediated by the ►Mauthner cell system [2]. An ASR is even present in some insects [3]. Its neuronal implementation is therefore rather diverse, although it has been suggested that the most fundamental mechanisms for rapid motor control by the Mauthner system may even be shared between fish and mammals.

The behavioral latency of the ASR in mammals is very short (5–10 ms in rats), indicating that a simple circuit with very few synapses underlies this reflex response. The neuronal elements linking the cochlear nucleus to motoneurons controlling neck and limb muscles are found within the reticular formation. All current models proposed for the neuronal implementation of the ASR include an initial central relay in the cochlear nuclear complex leading to a central, integrating brainstem element within the reticular formation, which relays its output to motor neurons in brainstem and spinal cord. A small cluster of giant neurons in the caudal pontine reticular nucleus (PnC) represents the key component of this sensory-motor circuit, and is involved in sensory-motor integration and its modulation by other central-nervous inputs. Auditory information reaches the PnC via different nuclei of the central auditory pathway, such as the dorsal and ventral cochlear nucleus, the lateral superior olive and neurons of the cochlear root nucleus, a ganglion located within the auditory nerve.

## Middle Ear Muscle Reflex

The middle ear muscle reflex (MEMR) in mammals consists of contractions of two middle ear muscles, the ►stapedius and ►tensor tympani, respectively, in response to intense sound signals, thus protecting the inner ear from damage. Between the two muscles involved, the contraction of the stapedius contributes more to the overall MEMR. Measurements of the MEMR have become an important tool in audiologic examination and for detecting hearing loss in children and newborns [4].

In normal hearing humans, MEMR thresholds are approximately 95 dB SPL for tones and 75 dB SPL for wideband noise. As a result of the MEMR, hearing thresholds increase between 15 and 20dB in all mammals tested, including humans. The short latencies for the MEMR of only 3–6 ms, with those for the tensor tympani reflex being slightly longer, suggest a simple underlying circuitry. However, the exact reflex pathways are still unknown. There is evidence for both, interneurons within or near the superior olivary complex (most likely in the medial superior olive) and direct projections from cochlear nucleus neurons to facial and trigeminal motor neurons, which ultimately innervate stapedius and ►tensor tympani muscles, respectively.

A MEMR is also found in birds and involves a ►stapedius muscle (also called "musculus columellae"), which is, like its mammalian counterpart, innervated by facial motor neurons. Further details of the underlying circuitry are not known. Reptiles and ►anuran amphibians also possess a set of middle ear muscles that are attached to various structures in the middle ear, however, relatively little is known about their function(s) and the underlying neuronal control. It has recently been suggested that the middle ear muscle system in anuran amphibians (the so called "opercular system"), in addition to protecting the inner ear from sound shocks, might also play a protective role by reducing the large pressure changes that occur in the inner ear fluids during ambulatory or ventilatory movements.

## Auditory Feedback Control of Vocalizations

### *Mammals*

While the importance of auditory feedback for vocal learning in birds and mammals is well documented, its role in adulthood is much less understood [5–7]. Whereas auditory experience affects the overall structure of a species' vocal repertoire on a large scale only in humans and songbirds, but not in non-human primates, more recent data indicate that subtle modifications of a fixed template indeed occur in a wide variety of call types in every major primate group. It appears, therefore, that vocal learning in non-human primates consists mostly of subtle spectro-temporal changes of an inherited basic call structure [8]. In certain songbirds, it has been demonstrated that auditory feedback also plays a major role in the maintenance of the bird's acquired song throughout its life (see below). Although the evidence is patchy, among adult mammals, only humans, bats, and possibly cetaceans appear to require auditory feedback for the maintenance of basic parameters of species-specific vocalizations.

In humans, the detrimental effects of deafness on human language are well known, even when deafness was acquired postlingually. In addition, language dysfluencies and stuttering in hearing human subjects appear to be caused by a malfunction of the auditory feedback circuit that controls the production of

vocalizations. Apart from these complex effects on human language, basic vocal parameters, such as the fundamental frequency are also affected. Speaking deaf humans tend to speak in a voice that contains higher fundamental frequencies than in hearing human speakers. When adequate auditory feedback is provided, as with a cochlear implant, however, the fundamental frequency is one of the earliest acoustic features to approach normal values again. Numerous psychoacoustic experiments in adult humans also demonstrate that the fundamental frequency of their voice changes when artificially modified auditory feedback is presented, such as frequency-shifted formants.

Auditory feedback is also essential in echolocating bats [9]: the dynamic, temporal, and spectral pattern of their echolocation cries crucially depends on the information contained in the returning echo signal.

Reports on neural interactions between auditory processing and vocalization control are scarce, and few studies have addressed this issue at the level of single neurons. Auditory stimulation can affect neural activity in certain motor structures in various mammals, such as the paralemniscal area in bats, the parabrachial nucleus in cats, bats, and monkeys, the nucleus ambiguous, which controls laryngeal activity, and the laryngeal nerve in bats and rats. Neurons with dual vocal premotor and auditory function occur in the bat and monkey midbrain. So far, however, no coherent concept of what mechanism might underlie auditory feedback control of call production has emerged.

Conversely, vocalization has been shown to affect processing of auditory information in the superior olivary complex and adjacent areas (including the nucleus of the central acoustic tract), in the vicinity of the nuclei of the lateral lemniscus (within the paralemniscal area), adjacent to or within the inferior colliculus, in the medial geniculate body, and in the auditory cortex. This has been reported in several species of bats and in primates. In most cases, auditory responses were markedly suppressed during vocalization.

### *Songbirds*

Songbirds are one of the best-studied examples for the role of auditory feedback in vocal learning: young male songbirds learn to produce their species-typical song patterns by first forming a song memory or "song template" (normally resembling the father's song), and then shaping their vocal output by comparing auditory feedback from their own vocalizations with this template. In addition, more recent work has shown that auditory feedback is not only needed to acquire song, but that in adults of some species, hearing their own song is also required for maintaining proper song patterns during adulthood well beyond the age at which song is learned. As many components of the brain circuitry that mediates song learning have been identified, birdsong provides a powerful model system for studying the neural mechanisms of auditory-guided vocal learning [6], including various aspects of human speech [7].

Birdsong research focuses mainly on the neuronal sites and mechanisms that underlie song memory and auditory feedback. So called "song-specific neurons", which respond selectively to playbacks of the bird's own song, or in some cases the tutor's song, but not to song produced by other males of the same species, appear to play a key role. Such song-specific responses are created within a forebrain nucleus (the "High Vocal Center", HVC) and are then relayed to other nuclei throughout the song system; they were even found in the hypoglossal nerve that innervates the bird vocal organ, the syrinx. One particular pathway, the "anterior forebrain pathway", which is strikingly similar to the mammalian cortical-basal ganglia circuit, may be a key player in the auditory feedback control of song during vocal learning, as well as during adulthood [6]. Various lesion experiments indicate that this pathway is essential to the vocal plasticity necessary for song learning.

Many neurons in the song system show both premotor and auditory function. Currently, however, we still have little knowledge of what song feedback information reaches the sensory-motor structures of the song control system, or how sensory and motor activity interact at the cellular level. For instance, how can these neurons distinguish self-generated sounds from those emitted by external sources? A neural mechanism involving a ►corollary discharge (or "►efference copy") might play a role in solving this problem. Such a mechanism entails subtracting a motor copy of the vocal command signal from the sensory input, thus canceling out anticipated sensory feedback from the bird's own song. The plasticity in the processing of auditory feedback also appears to depend upon other behavioral states, such as wakefulness or sleep.

### *Fish*

Sound communication is not unique to mammals or songbirds but rather is a trait shared with most vertebrates. ►Teleost fishes include many species that hear and also produce sounds for communication purposes, such as midshipman, toadfish, and weakly electric mormyrid fish [10]. Playback of sounds produced by these fish evokes calling behavior and ►phonotaxis. The vocal control system extends from forebrain to hindbrain levels and shares several organizational features with the vocal systems of birds and mammals. Various studies have also pinpointed sites where the auditory and vocal systems interface with

the ►neuroendocrine axis of the brain. Thus, the vocal and auditory feedback mechanisms identified in these simple systems are essential for producing vocal communication behaviors within the context of more complex social and reproductive behaviors.

### Cerebellar Learning

Cerebellar computation has recently been portrayed as a straightforward example of feed-forward processing of inputs in order to improve movement accuracy. In the context of auditory stimulation, the cerebellum plays a major role in temporally specific learning that occurs in rhythmic motor entrainment, for example, movements observed in musicians in response to auditory feedback from the instrument they are playing.

Similar to the fact that vocal motor patterns can also affect the processing of auditory signals, cerebellar processing also appears to be able to affect sensory information processing. This has been demonstrated, for example, for the perception of pitch in humans. Neuroimaging studies have shown that fine auditory discrimination depends critically upon non-motor sensory support functions of the cerebellum.

A

# Auditory Nerve

Jonathan Siegel
Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL, USA

### Synonyms

Cochlear nerve; Auditory division of the statoacoustic nerve; Cochlear division of the vestibulocochlear nerve; Eighth cranial nerve

### Definition

The auditory nerve is the peripheral pathway comprised of the central processes of the sensory ►spiral ganglion neurons of the cochlea that project to the ipsilateral cochlear nucleus, as well as the axons of the neurons of the ►olivocochlear efferent system that originates in the superior olive.

### Characteristics

#### Quantitative Description

The number of spiral ganglion neurons in mammals ranges from about 10,000–50,000, 80–95% of which are classified as Type I, while the remainder are (Fig. 1) Type II. Type I neurons receive input from inner hair cells, while outer hair cells provide the input to Type II cells [1]. There are between about 475 and 2,500 olivocochlear efferent neurons in a range of mammals, approximately one-quarter to one-third of which belong to the medial olivocochlear system that contacts outer hair cells, while the remainder belong to the lateral olivocochlear system which projects primarily to the dendrites of the Type I spiral ganglion neurons within the organ of Corti [2].

#### Higher Level Structures

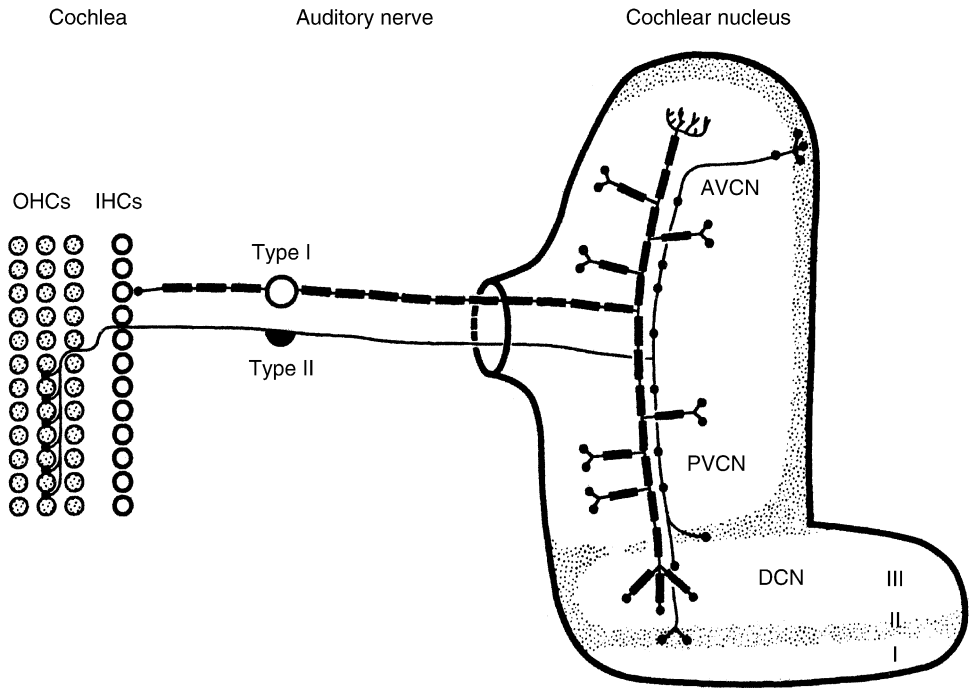
The auditory nerve is the beginning of the afferent auditory pathway that ascends through the brainstem and midbrain to reach the auditory cortex in the temporal lobe. The olivocochlear efferent system is the common final descending auditory pathway to the cochlea.

#### Lower Level Components

The auditory nerve is a subdivision of the ►statoacoustic nerve, the eighth cranial nerve, the other being the vestibular division. The nerve carries both afferent and efferent axons between the cochlea and the medulla.

##### *Afferent*

The spiral ganglion, located in Rosenthal's canal, coiled around the modiolus of the cochlea, gives rise to the



**Auditory Nerve. Figure 1** Diagram of the peripheral and central connection patterns of the spiral ganglion neurons. The type I neurons receive input exclusively from inner hair cells and bifurcate to terminate in ventral and dorsal regions of the cochlear nucleus that in turn project to other brainstem auditory nuclei. The type II neurons, which receive input exclusively from outer hair cells, follow the course of the type I neurons, but terminate in granule cell regions of the cochlear nucleus. (Reprinted from Fig. 2.19 of reference [1] with kind permission of Springer Science and Business Media).

afferent component of the auditory nerve. Two classes of bipolar ganglion cells provide separate sensory innervation for the inner and outer hair cells. The larger type I cells, which are 80–95% of the total, send mostly unbranched peripheral processes through the osseous spiral lamina to form small bouton endings on the inner hair cells. The remainder of spiral ganglion cells are generally smaller and their peripheral processes branch within the organ of Corti to form multiple small endings on outer hair cells.

Each inner hair cell typically contacts from about 10 (in the apical turn) to 25 (mid basal turn) different type I spiral ganglion cells. Each bouton ending is opposed by a specialized presynaptic complex in the hair cell typified by a presynaptic dense body that tethers synaptic vesicles via filamentous links. This synaptic organization, in which a single active zone provides the entire excitatory drive to a sensory neuron, is unique in the nervous system and undoubtedly exerts a strong influence on how auditory signals are encoded. On entering the cochlear nucleus the axons of the type I spiral ganglion cells bifurcate, with branches running rostral (ascending) and caudal (descending). The ascending type I axons terminate in the anteroventral cochlear nucleus (AVCN), forming large end-bulbs of Held on the somas and small bouton endings on both the somas and dendrites of AVCN neurons. The descending branches form small to intermediate size endings on cells in both the posteroventral (PVCN) and dorsal (DCN) divisions of the cochlear nucleus.

The peripheral processes of the type II ganglion cells take a characteristic basal spiral course in the outer spiral bundles underneath the outer hair cells, before branching to form as many as 60 terminals on outer hair cells along their spiraling course. The type II cells and their processes are smaller than their type I counterparts and are far less heavily myelinated. While the central processes of type II ganglion cells follow the same course as the type I cells that originate in the same region of the cochlea, they terminate exclusively within the superficial granule cell regions of both the ventral and dorsal cochlear nucleus and thus do not appear to project to the same cochlear nucleus neurons that receive input from the type I spiral ganglion cells [1].

### *Efferent*

The olivocochlear system provides the efferent component of the auditory nerve. Here too, there is specialization, with the medial division terminating on the basal somas of outer hair cells, while the lateral division terminating primarily on the peripheral processes of the type I spiral ganglion cells underneath the inner hair

cells. The cell bodies of the medial olivocochlear neurons are in the medial periolivary regions of the superior olivary complex. The majority of their large, myelinated axons cross the midline to project to the contralateral cochlea, but some project ipsilaterally. The relatively small somas of the more numerous lateral olivocochlear neurons are located in and near the lateral superior olivary nucleus and project primarily to the ipsilateral cochlea. Their axons are small in diameter and unmyelinated. Before leaving the brainstem, the axons of both medial and lateral olivocochlear neurons join to form the olivocochlear bundle, which leaves the brainstem in the vestibular division of the vestibulocochlear nerve, before crossing at the vestibulocochlear anastomosis into the cochlear division to enter the modiolus. Within the modiolus, the olivocochlear bundle forms the intraganglionic spiral bundle within Rosenthal's canal next to scala tympani of the cochlea. On entering the organ of Corti, the lateral olivocochlear neurons join the inner spiral bundle, running beneath the inner hair cells, where they terminate on the unmyelinated dendrites of the type I spiral ganglion cells. The medial olivocochlear neurons terminate in multiple large vesicular endings at the base of outer hair cells. The density of medial efferent terminations is greatest in the basal half of the cochlea, the region where the mechanical cochlear amplifier function of outer hair cells appears strongest [2].

## Process Regulation

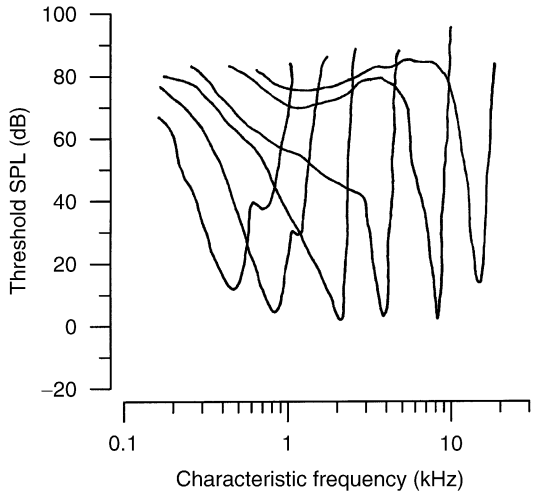
The process of afferent auditory nerve signaling can be considered to be under regulation by the olivocochlear efferent system, as well as the acoustic reflex activity of the middle ear muscles. The physiology of the lateral olivocochlear efferent subsystem is largely unknown. The small size of the unmyelinated lateral olivocochlear neurons and their axons has made recordings impractical. Because of its innervation pattern, this system undoubtedly must regulate the transmission of afferent information to the brain via the type I spiral ganglion cells. The medial efferent neurons are generally tuned to the same frequencies as their type I afferent neighbors, suggesting a highly tonotopic central reflex arc. Because this system terminates directly on outer hair cells, it is likely to regulate their role in amplifying vibrations of the basilar membrane, referred to as the cochlear amplifier. There is evidence that this action may optimize performance in detecting signals in background noise and in selective attention to auditory stimuli in the presence of competing visual stimuli [3].

## Function

All sharp electrode recordings of responses to sound from single units in the auditory nerve reported thus far have been from the type I spiral ganglion cells which receive input exclusively from inner hair cells. No recordings have been reported from the type II spiral ganglion neurons, likely because of their small size. Auditory nerve fiber single units discharge action potentials in the absence of stimulation, quantified as an average spontaneous rate (SR). There are two distinct classes of auditory nerve fibers, one with relatively low SR (less than 15 spikes/s) and with relatively high SR with a broad distribution centered around 60 spikes/s. The majority (85% or so) are high SR. These two classes of neurons exhibit different relations between stimulus sound pressure level (SPL) and the average rate during a tone burst stimulus. The minimal SPL that produces a detectable rate increase above the SR is defined as the threshold level. Thresholds are somewhat higher for low SR than for high SR neurons. High SR neurons tend to reach a saturating discharge rate of ~300/sec with increasing stimulus level within 30 dB of threshold. Low-SR neurons can exhibit much more shallow rate-versus-level relations and may not saturate until much higher stimulus levels are reached [4].

The neural ►tuning curve is constructed by measuring the thresholds for the entire range of tone frequencies to which the neuron responds (Fig. 2).

The frequency at which the lowest threshold SPL is measured is called the characteristic frequency (CF). The characteristic frequency is determined by the location along the cochlear spiral where the type I neuron receives its input from an inner hair cell. The rapid rise of threshold above CF is due to the steep decline in vibration of the traveling wave apical to the peak. The region of the tuning curve that dips



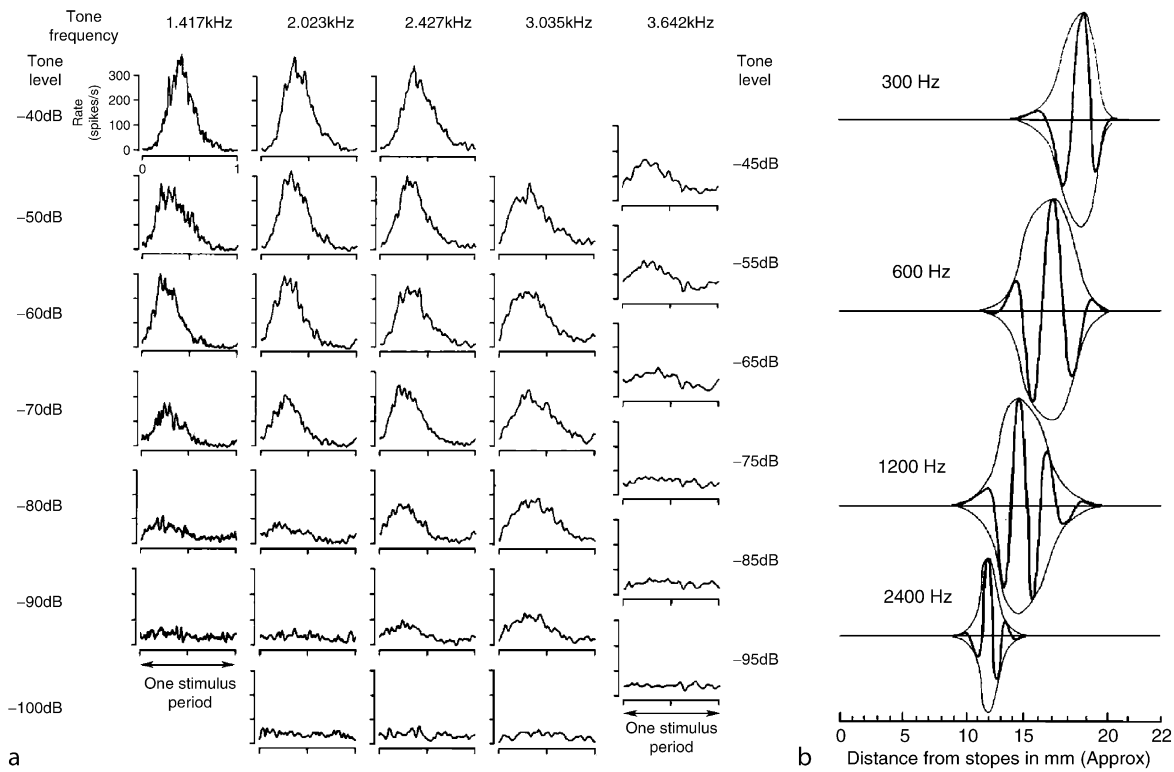
**Auditory Nerve. Figure 2** Schematic representation of ►auditory nerve tuning curves measured from type I spiral ganglion neurons that receive input from hair cells in different regions of the cochlea, as indicated by the characteristic frequency, the frequency of minimum threshold.

down to the CF is called the tip of the tuning curve, while the shallow low-frequency region is called the tail. The tuning curve resembles an inverted version of the low-level basilar membrane response because the amplitude of vibration of the hair bundle of the hair cells that contact the auditory neurons is determined fairly directly by the local vibration amplitude of the basilar membrane. In fact, the basilar membrane vibration threshold tuning curve closely resembles the tuning curves of both hair cells and the cochlear afferent neurons in the corresponding region of the cochlea. For stimulus level and frequency combinations above threshold the average rate of action potentials grows with increasing level and saturates as described above. So the neural threshold tuning curve allows us to know whether or not a particular neuron will respond to a stimulus with a given frequency and intensity, but nothing about how strongly it responds [4].

One of the most striking aspects of auditory nerve physiology is the ability of single neurons to encode the temporal waveform of acoustic stimuli, a phenomenon referred to as ►phase locking. This basic attribute is illustrated in Fig. 3. Figure 3a, reproduced from a study by Don Johnson [5], shows histograms representing the relative probability that an action potential will be recorded at different phases of a single cycle of a sine wave stimulus tone.

The CF of the neuron was 2.5 kHz and the responses to tones ranging from 1.4 to 3.6 kHz all demonstrate a continuous modulation of discharge probability that corresponds to the temporal waveform of the stimulus. Note that the time axis (x-axis) for the 1.4 kHz tone represents 0.7 ms, while that of the 3.6 kHz tone is only 274 ms (the time of one period = 1/frequency), yet a modulation of probability within this short time is clearly seen. Phase-locked responses of auditory nerve units to tones have been used to demonstrate a neural version of the space-time pattern of basilar membrane vibration first described by von Békésy as a traveling wave (Fig. 3b) [6].

While fascination with temporal precision is understandable, Fig. 3a also demonstrates the equally significant feature that the encoded waveform remains remarkably undistorted, despite a change of stimulus



**Auditory Nerve. Figure 3** Phase-locked responses of auditory nerve units. (a) Period histograms measured from a neuron with characteristic frequency of 2.5 kHz for tones of different frequencies and intensities. Each histogram represents one period of the stimulus, which decreases from left to right. The waveform is preserved from stimulus amplitudes near threshold to several orders of magnitude larger (*bottom to top*). amplitude of three or more orders of magnitude. Much of this high-fidelity dynamic range is probably the result of the relatively mild compressive nonlinearity that originates in the cochlear amplifier. But it is still amazing that a signal passing through the essentially instantaneous and strongly saturating nonlinearity of the hair cell transducer, as well as what would be expected to be a highly nonlinear cascade of synaptic transmission and action potential generation, were this synapse typical of others in the nervous system. Such extreme timing precision and waveform preservation is undoubtedly essential to account for temporal auditory perceptual abilities including sound localization and the ability to extract speech from noisy backgrounds, or form mental images of auditory objects in three-dimensional acoustic space.

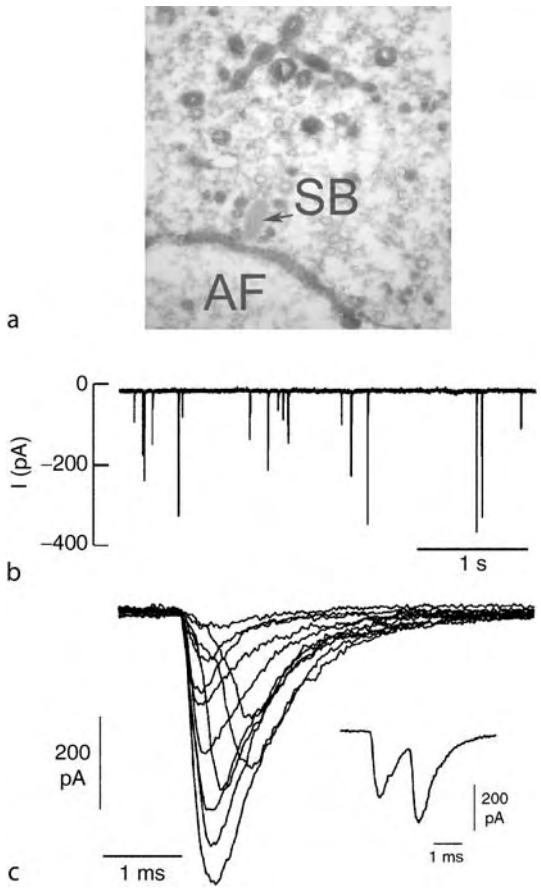
The cellular and molecular mechanisms that underlie this amazing performance of cochlear afferent neurons have been the focus of a spate of recent studies. Applying whole-cell patch-clamp recording techniques to hair cells has allowed presynaptic neurotransmitter release to be quantified as small cell capacitance changes caused by the fusion of synaptic vesicles with the hair cell membrane [7] at specialized active zones. The characteristic ►presynaptic dense body appears to be a temporary storage site to rapidly replenish a limited number of release sites with readily-releasable synaptic vesicles (Fig. 4a).

The dark reaction product filling the synaptic cleft and numerous vesicles and other membranous compartments within the hair cell in Fig. 4a indicates that the synaptic vesicles are derived from the cell surface. These synapses appear share basic mechanisms with other excitatory glutamatergic synapses with some important exceptions.

First, these synapses are each capable of unlimited sustained release of around 500 vesicles per second, a rate that would be expected to produce pronounced synaptic depression in conventional chemical synapses. This means that one inner hair cell can release around 10,000 vesicles per second at its ~20 afferent synapses for an indefinite period of time. This profound specialization of the inner hair cell for synaptic transmission compliments the outer hair cell's specialization for its participation in the process of amplifying sound-induced vibrations of the basilar membrane.

Second, this synaptic organization appears essential for the temporal precision and waveform preservation discussed above. Elisabeth Glowatzki has recorded spontaneous and stimulated synaptic currents from mammalian type I nerve terminals on inner hair cells using patch-clamp [8]. Even though most of her recordings represented activity of a single hair cell active zone, individual synaptic events appeared to have far too much amplitude variation to be explained by a single population of unitary quanta with a normally



**Auditory Nerve. Figure 4** Ultrastructural and functional basis for auditory nerve stimulus encoding. (a) electron micrograph of an active zone at the synapse between an inner hair cell and a type I spiral ganglion neuron (AF). A characteristic presynaptic dense body (SB), with attached synaptic vesicles, is seen in the hair cell. (b) Excitatory postsynaptic currents recorded from an afferent terminal on an inner hair cell using patch-clamp show large amplitude variation. (c) Higher time resolution of postsynaptic currents reveals evidence for synchronized multiquantal release. (b and c Reprinted by permission from [5], Copyright 2002).

distributed amplitude distribution (Fig. 4b, c). Instead, synaptic events appeared to represent highly synchronized subunits that could sometimes be resolved when synchrony was not perfect (Fig. 4c). This finding confirmed preliminary measurements made by this author using sharp electrodes, but has provided the ability to address synaptic mechanisms with much greater power. This group has subsequently verified that the pronounced rate adaptation seen in the auditory nerve following the onset of a tone burst is due to synaptic depression caused by depletion of transmitter. Depolarizing voltage steps within the normal

physiological range for hair cell receptor potentials yielded a fairly linear relation between presynaptic calcium currents and the rate of synaptic transmission [9]. This near-linearity appears to arise from an interaction between the voltage-dependence of calcium channel activation, reduced driving force for calcium with depolarization and cooperativity of 3–4 calcium ions to activate exocytosis. Since the synchronized multiquantal postsynaptic potentials usually exceed the threshold for action potential initiation in the sensory neuron, there is a nearly 1:1 relation between the rate of postsynaptic action potentials and presynaptic release events. So the strong saturation of average rate observed in most auditory nerve units in the intact system is very likely due to saturation of the dc component of the hair cell receptor potential. The dc receptor potential saturates due to a combination of the compressive growth of the basilar membrane response for stimuli near CF, along with the saturating nature of the hair cell transducer function. By extension, the waveform preservation in phase-locked auditory nerve responses described above would be expected, as long as the probability of transmitter release is modulated by cycle-by-cycle variations in presynaptic calcium currents that are controlled by calcium channels with gating rate constants modulated extremely rapidly by changes in membrane voltage. Molecular mechanisms of hearing loss specifically related to synaptic transmission by the inner hair cells are beginning to be identified [10].

The implications are clear: extreme temporal precision is achieved in this system by generating excitatory postsynaptic potentials with extremely short rise-times which may reach action potential threshold in less than 50 μs. At least for most synaptic events, this means that the statistics of action potential discharge of the postsynaptic neurons is determined by the statistics of presynaptic neurotransmitter release, which is largely determined by the statistics of presynaptic voltage-gated calcium channels at the active zones. Thus, the hair cell receptor potential temporal waveform appears to be encoded in individual type I spiral ganglion action potentials in a way very similar to that of an analog-to-digital converter with a pulse code modulation scheme. The presence of as many as 20–30 statistically independent synapses per hair cell assures a sufficient bit rate to encode the hair cell receptor potential waveform with reasonably good fidelity.

# Auditory Neuroscience – Introduction

Armin H. Seidl, Edwin W. Rubel
Virginia Merrill Bloedel Hearing Research Center, University of Washington, Seattle, WA, USA

## Definition

All animals, including man, must interact with their environment to survive. Such interaction is dependent on sensory information obtained from the environment, which is then processed by the brain and elicits specific motor and mental reactions. Amongst all types of sensory information, the perception of sound is one of the most important tasks the human brain has to accomplish. Sound allows us to communicate through speech (see essay on ►Speech perception), to detect prey or localize a predator. In higher and more complex life forms, sound can also be perceived as music. Sound enables us to process information about our environment in total darkness and over long distances, where visual and olfactory information might not be available.

Sound consists of pressure waves in the air or in any substrate that can transmit such waves (e.g. water). The

exact nature of sound is described by a branch of physics called acoustics (see essay on ►Acoustics).

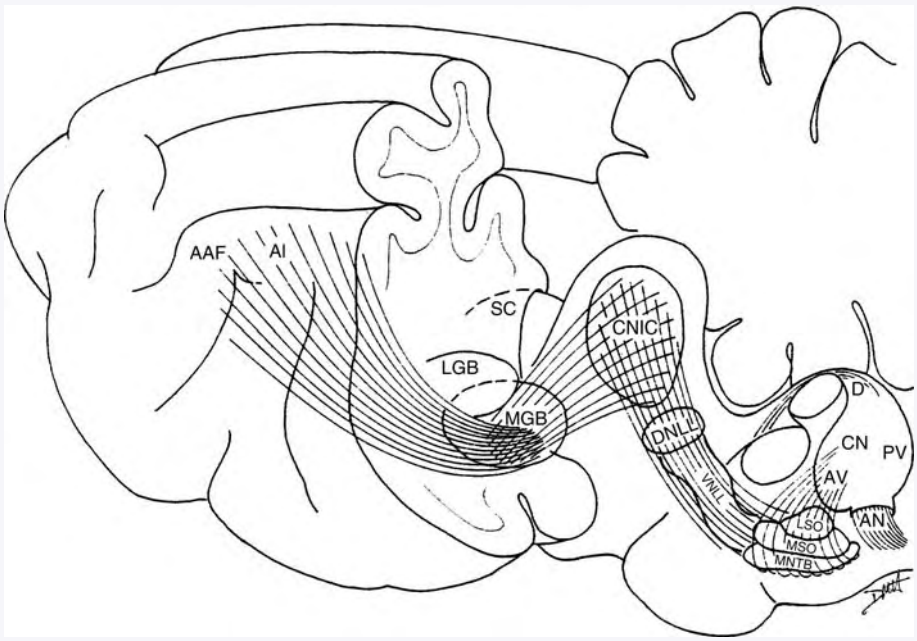
The Auditory Neuroscience section consists of a series of essays describing how acoustic information reaches the brain, where it is processed in the brain and some fundamental properties on how we believe the information is coded. While the main focus of this section lies on the mammalian brain, it also makes references to hearing in birds as well as several invertebrates. Two chapters also touch on clinical applications, where scientifically acquired knowledge can be used to treat certain hearing-related disabilities (Fig. 1).

## Ears and Auditory Brain Areas

The external ear, called the auricle, directs sound waves towards the tympanic membrane and middle ear. Within the middle ear, a set of mechanical structures functions as a transformer to increase the force of the pressure waves such that more of their energy can be transmitted into an aqueous medium. This aqueous substrate is contained in a structure called the inner ear. The inner ear contains the organs of balance, the vestibular epithelia, and the organ of hearing, called the cochlea (see essay on ►Cochlea). Within the cochlea, a sensory epithelium translates pressure waves into electrical activity that is then passed on to higher auditory centers in the brain. The cochlea is also the first place in the auditory system where incoming sound information is sorted according to spectral components or frequency bands (see essay on ►Tonotopic organization), a characteristic of the auditory system that is preserved throughout all levels in the brain as acoustic information is passed on to higher areas. From the cochlea, acoustic information is transferred to the brain via the auditory nerve (see essay on ►Auditory nerve). The auditory nerve also carries efferent information from the brain to the cochlea, presumably to fine-tune the cochlea for specific signals.

As in other parts of the brain, neurotransmitters are responsible in the auditory system for transmitting information from one neuron to another, or from sensory cells to neurons (e.g., hair cells to cells in the cochlear nucleus) (see essay on ►Neurotransmitters in the auditory system).

The first area within the brain to receive sound information from the auditory nerve is the cochlear nucleus, which serves as a relay station for ascending auditory information, but also executes a fair amount of information processing. The cochlear nucleus itself is divided into three subnuclei (see essay on ►Cochlear nucleus). These subnuclei have remarkably different characteristics in terms of the synaptology of auditory nerve afferents, cellular phenotypes, afferents from other locations and efferent projections.



**Auditory Neuroscience – Introduction. Figure 1** Afferent auditory pathways in the cat brain. AN auditory nerve, CN cochlear nucleus (D dorsal, AV and PV anterior and posterior ventral), LSO lateral superior olive, MSO medial superior olive, MNTB medial nucleus of the trapezoid body, VNLL and DNLL ventral and dorsal nucleus of the lateral lemniscus, CNIC central nucleus of the inferior colliculus, MGB and LGB medial and lateral geniculate body, SC superior colliculus, A1 primary auditory cortex, AAF anterior auditory field (drawing by David M. Harris).

Coming from the cochlear nucleus, the information is distributed to nuclei located in the auditory brainstem (see essay on ►Superior olivary complex, ►Nuclei of the Lateral lemniscus). The auditory brainstem is the first area within the brain where sound information from the two ears is compared, a phenomenon of critical importance for sound localization and hearing in noisy environments (see essay on ►Binaural pathways and processing). Neurons in both the cochlear nucleus and the auditory brainstem have specialized functional properties for the initial processing of sound signals (see essay on ►Intrinsic properties of auditory neurons).

From the brainstem, afferent information is conducted to the auditory midbrain (see essay on ►Inferior colliculus) and to the superior colliculus (see essay on ►Superior colliculus and hearing). The inferior colliculus, which comprises the auditory midbrain, acts as an integrative station as it receives input from virtually every auditory area in the brain. The superior colliculus is where acoustic information is integrated with other sensory information, such as visual and somesthetic cues.

The medial geniculate body, the principle thalamic target of neurons in the inferior colliculus is the source of auditory information to the neocortex, specifically the regions of the auditory cortex (see essay on ►Medial geniculate body, ►Auditory-motor interactions).

Eventually sound information arrives in the auditory cortex, where the conscious perception of sound is thought to be created (see essay on ►Auditory cortical areas). The perception of sound can be described with psychoacoustical experiments (see essay on ►Psychoacoustics).

As a whole, neuronal activity in the brain caused by an auditory stimulus can be detected by auditory evoked potentials. This method records patterns of voltage changes due to acoustic stimulation that can be detected with electrodes placed on the head (see essay on ►Auditory evoked potentials).

The brain areas described here are by no means static: Auditory brain centers can change their structural and functional properties in response to changing stimuli. These changes are an active process and are described as plasticity (see essay on ►Plasticity in the central auditory system).

## Hearing in Birds and Invertebrates

While structurally very similar, the auditory system of birds possesses several specializations in order to process the very complex bird songs (see essay on ►Avian Auditory System). Two properties are particularly interesting. First, in contrast to the mammalian auditory system, the sensory epithelium of the hearing system in birds can regenerate sensory cells after damage, leading to functional recovery. Second, the forebrain areas related to the production of acoustic information are hypertrophied and show remarkable seasonal plasticity in some species of songbirds.

Insects are, apart from a few species of crustacea, the only invertebrates that have been shown to exhibit a sense of hearing. The hearing mechanism in insects can be very different from the mammalian hearing system, although the basic feature of pressure wave detection is preserved (see essay on ►Invertebrate ears and hearing). Characteristic for the hearing of insects is the widespread use of substrate sound.

## Clinical Applications

Two essays on clinical applications related to hearing loss are also included in this volume: Hearing Aids and Cochlear Implants. Hearing Aids amplify sound to make it more accessible, e.g. in the case of presbycusis. Cochlear Implants on the other hand stimulate a functional auditory nerve directly. This can restore hearing when the sensory epithelium is not functional or irreparably damaged (see essays on ►Hearing aids, ►Cochlear implant).

## Epilogue

To conclude, it is worthy of note that the hearing system, in contrast to the visual or the sensory system, cannot rely on a spatial representation of stimuli on its receptor surface. Frequency is extracted by the sensory epithelium via a matching of the physical properties of the sound waves to unique structural and functional properties of the sensory epithelium. It is solely because of an elaborate computational mechanism that a sound source can be understood and localized.

While often in the shadow of the literally more colorful visual system, the field of auditory neuroscience is a fascinating subject to study and unique in terms of its complexity.

### Acknowledgments

## Auditory System

### Definition

The network of auditory centers and auditory pathways of the brain involved in processing mainly information from the ears. The auditory system divides into two parts, the ascending part and the descending part. The ascending system starts in both ears and ends in the highest auditory representations, which are the auditory cortex where mammals including humans are concerned. The descending system starts with projections from the auditory cortex to lower centers and ends with nerve fiber terminals in the inner ear.

## Autapse

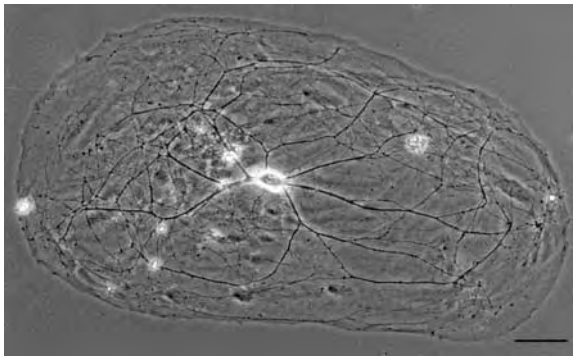
Kazuhiko Yamaguchi
Laboratory for Memory and Learning, Brain Science Institute, Riken, Japan

### Synonyms

Self-synapse, recurrent synapse

### Definition

►*Autapse*: ►Synapse formed by the axon of a neuron on its own dendrites *in vivo* or *in vitro*. Autapses of solitary neuron grown on a micro-island of collagen or non-neural cells utilized widely as a simple, useful



**Autapse. Figure 1** Solitary hippocampal neuron cultured on a glial micro-island that has many autapses, synapses formed by the axon of a neuron on its own dendrites. Bar, 50 μm.

model of synaptic transmission (Fig. 1). Originally, autapse was defined in rabbit cortical neuron impregnated with Golgi methods [1].

## Characteristics

Functional autapse was found in solitary neuron cultured on a micro-island (diameter, 300–500 μm) of cardiac myocytes [2]. Acetylcholine (ACh) released from synaptic terminal onto itself, at autapses, evoked fast nicotinic excitatory postsynaptic potentials (►EPSPs). Autapse provides an advantageous model to investigate factors affecting differentiation and development of a single neuron. In addition, autapse is adequate for image-analysis of single neurons using fluorescent dyes. Especially, autapse has a unique value to investigate the heterogeneity of presynaptic terminals belonging to one neuron.

## Purpose

Autapse provides the simplest model of epilepsy [3]. If a solitary hippocampal neuron grown in the micro-island culture has excitatory autaptic connections, it generates paroxysmal depolarizing shifts (PDSs) and sustained depolarizations, characteristic epileptiform activities. Thus, kynurenate, a non-specific blocker of glutamate receptors, is required to be added in culture medium. Washout of kynurenate elicits large depolarizing events or sustained depolarization with repetitive firings. Both NMDA- and AMPA-receptors are involved in the generation of these epileptiform activities. The generation mechanism for such epileptiform activities is attributable to self-regenerative excitatory pathway through autaptic connection. The autapse of excitatory neurons provides the opportunity to study in a very simple context the pharmacology of the initiation, continuation and termination of epileptiform activities [3]. A computational approach to examine conditions for long-lasting firing of autapse is also performed.

To widely utilize autapse as one of the standard models of the central synapse, basic characteristics of autaptic transmission should be proved normal. Electrophysiological characteristics of autaptic transmission of hippocampal neurons are analyzed by using the patch-clamp method [4]. Using this voltage-clamp method, epileptiform discharge is suppressed by controlling the membrane potential. For excitatory autapse, excitatory post-synaptic current (►EPSC) amplitude is changed depending on the holding voltage of the cell body, and the estimated reversal potential is –4 mV, which is almost the same as that for glutamate receptor channels in a usual synapse. This indicates that both autaptic and synaptic glutamate receptor channels have common ion-selectivity. Some excitatory autaptic transmission, like some excitatory synaptic transmission, is dual function: an early, rapid non-NMDA component and a prolonged NMDA-component, the latter is blocked by $Mg^{2+}$ in a voltage-dependent manner. Some neurons make inhibitory autapse, which shows similar physiological and pharmacological properties to those of usual inhibitory synapse. Under a condition of low ►release probability, amplitude of autaptic EPSC shows probabilistic fluctuation. In the tail of stimulus-evoked large EPSC, spontaneous mini-EPSCs (►asynchronous EPSCs) appear, which are attributable to the ►quantal release of glutamate. The probability of recording an autaptic current of a particular size is well described by the quantal theory of transmitter release, like physiological synapse. In general, autaptic transmission is considered the same as the normal synaptic transmission. Therefore, autapse provides a simple and reliable model for the synaptic transmission in mammalian CNS. Especially, autapse contributes to the analysis of synaptic properties of CNS neurons cultured from gene knocked-out animals.

Functional analysis of proteins relating to ►presynaptic exocytosis are difficult in the mammalian central synapse, because the size of the pre-synaptic terminal of the mammalian central synapse is very small (usually, less than 1 μm), and synaptic exocytosis is composed of several sub-steps and each step involves various types of proteins. A reconstruction system such as *Xenopus* oocyte for ion channel is not available for presynaptic exocytosis. Furthermore, presynaptic exocytosis is a very fast process. Time between spike arrival at the presynaptic terminal and transmitter release is less than half of a millisecond. Therefore, biochemical analysis of protein-protein interaction *in vitro* alone is not sufficient for the understanding of the molecular mechanism of the presynaptic exocytosis. To investigate the molecular mechanism in the presynaptic exocytosis, autapse of central neurons cultured from a gene knocked-out animal is widely utilized as one of the standard tools [5,6]. Presynaptic exocytosis consists

of several sub-steps such as docking, priming, membrane-fusion and endocytosis. Autapse has the advantage of estimating the total size of the ►readily releasable pool, a physiological counterpart of the docked vesicle pool, of each neuron. The total RRP size of autapses of one neuron is around several thousand quanta, estimated by hypertonic sucrose methods. Each action potential elicits release of a few hundred quanta from one neuron. Release probability, estimated from the released vesicle number divided by the readily releasable pool size, is several percent of the readily releasable pool [6]. Applying such a quantitative analysis to the autaptic transmission of a gene knocked-out animal, physiological function of a particular protein is assigned to some particular substeps of presynaptic exocytosis. For example, neurons lacking complexins, presynaptic proteins, show a remarkable reduction in release probability, while the readily releasable pool size is normal. Reduction in transmitter-release is attributable to decreased $Ca^{2+}$ sensitivity of the membrane fusion process. Complexins are demonstrated to be acting at or following the $Ca^{2+}$ triggering step of fast synchronous transmitter release by regulating the exocytosis $Ca^{2+}$ sensor, its interaction with the core complex fusion machinery, or the efficiency of the fusion apparatus itself [5].

Autapse provides a model system for investigating the presynaptic type of synaptic plasticity. In the micro-island culture, one neuron has a few hundred presynaptic sites where synaptic vesicles are accumulated. These presynaptic sites, identified as synaptophysin- or synapsin I-immunoreactive sites, are not homogeneous in functional features. In autapses of cultured dentate gyrus neurons, about one third of the synaptophysin-positive sites are functional release sites that are visualized with styryl fluorescent FM dyes. FM dyes are up-taken by synaptic vesicle membranes through endocytosis following membrane-fusion at the functional autaptic terminals, but not at silent presynaptic sites. The presence of silent presynaptic sites is also demonstrated electrophysiologically. Some cortical neurons in the micro-island culture show spontaneous autaptic mini-EPSCs, but no evoked EPSC, which indicate silent presynaptic site [7]. In autapses of cultured dentate gyrus neurons, silent presynaptic sites are converted into functional ones by activation of the PKA cascade, which would be the underlying mechanism for the synaptic plasticity at the mossy fiber terminal in the hippocampus [8].

Autapse of central neuron cultured on a glial micro-island is utilized to address glial cell – neuron interaction in synaptic transmission. Evoked synchronous release of glutamate from an autaptic terminal activates rapid electrogenic glial glutamate-transporter currents, while clearance of released glutamate by glial cells may affect the decay time-course of autaptic EPSC [9].

Neuronal synaptogenesis is enhanced by the glial cell in the co-culture system; however, it is unclear whether diffusible or membrane-bound astrocyte-derived factors are responsible for the increase in synaptogenetic efficiency. To address this question, autapse provides an advantageous experimental system [10]. Under the condition of continual supplementation of astrocyte-diffusible factors from the rims of culture dishes, solely grown hippocampal neurons on a micro-island of collagen also forms autapses. After 8–9 days in culture, neurons may or may not be overlaid with astrocytes. Local contact with astrocytes enhances autaptic synaptogenesis robustly via integrin receptor elicited PKC activation [10]. Autapse is a useful model system for exploring both soluble and cellular factors affecting synaptogenesis.

## Principles

Though autaptic connection exists in normal cortical neurons *in vivo* [1], autapse in cultured neurons is formed under rather artificial conditions, the micro-island culture. A solitary neuron is grown on the micro-island and forms an autapse. However, neurons in the multi-cellular culture of the micro-island rarely form autapses.

To make the micro-island culture [3], the cover glass is coated with agarose and then attached to the bottom of a holed-plastic culture dish by Sylgard. Collagen solution is then sprayed from a glass micro-atomizer onto a dried film of agarose. The collagen is cross-linked by ammonium gas. The diameter of the micro-island distributes 50–500 μm. The exposed agarose surface is resistant to cell attachment. Glial cells, plated 1–2 days before neural cell plating, grow to cover the micro-island. Hippocampal neurons of newborn rat, isolated by papain-treatment, are plated at a low density (2,000 cells per $cm^2$). Soluble glial factors are supplied from glial cells grown on the outer rims of the plastic bottom. After 7–9 days in culture, neurons solely grown on the micro-island form an autaptic connection. A blocker for glutamate receptors (kynuranate) or NMDA receptor (APV) is required to obtain healthy autaptic responses.

## Advantage and Disadvantage

### *Advantage*

As a simple model of synaptic connection, autapse provides the following advantage; first, all autaptic terminals belonging to one cell share common basic properties, such as excitatory or inhibitory, though there are heterogeneity in detail. Cell types are selected by means of electrophysiology, pharmacology, immunocytochemistry and GFP-tag methods. Selective culture of the neurons from a specific brain region, such as "hippocampus CA3" or "dentate gyrus" is also available. Second, quantification of synaptic terminals per one neuron is possible in the autaptic system. Thus, autapse

provides a reliable assay system to examine synaptogenesis-ability of various chemicals or cells [10]. Third, unlike conventional approaches, in which pairs of neurons and electrodes are required (one presynaptic, the other postsynaptic), physiological experiments using autapse require only one electrode. Furthermore, we can inject chemicals into the cell through a whole-cell recording electrode. Fourth, since all presynaptic terminals contact on one neuron, it is possible to estimate the size of the total releasable pool belonging to one neuron [5,6]. Fifth, autapse provides a unique system to address heterogeneity among synaptic terminals from one neuron.

### *Disadvantage*

Though autaptic connection in cultured neurons provides a useful assay system to elucidate the roles of proteins and other chemicals in synaptic transmission, synaptogenesis and so on, it has a limitation. The age of the animal is restricted to be very young, since neurons should be cultured. Basic physiological properties of autapse and physiological synapse are proved the same [4], but this does not mean that all properties of autapse are necessarily the same as those in normal synapse. Even though autaptic connection exists in mammalian cortical circuits *in vivo*, most axon collaterals terminate to other neurons. In autapse, all axon terminals contact on one cell. Therefore, possible effects of a retrograde signal on a synaptic terminal could be different between autapse and normal synapse. In excitatory autapse, synaptic activities are restricted to some extent during culture. This restriction may affect autaptic synaptogenesis. Nevertheless disadvantage, autapse provides very useful and the simplest model of the neuronal circuit for investigation of synaptogenesis, synaptic transmission, plasticity and modulation.

# Autism (Autistic Disorder, Childhood Autism)

## Definition

Autism is classified as a pervasive neurodevelopmental disorder including key characteristics such as abnormal communication skills and social interactions as well as repetitive and stereotyped patterns of behavior. Autism is thought to result from defective neuronal circuitry.

# Autoantibodies

## Definition

Serum immunoglobulins that react to self-antigens (own body).

# Auto-associative Memory

## Definition

A neural network that associates patterns with themselves to recall a stored pattern by receiving a noisy or incomplete version of that pattern.

►Associative Memory

## Auto-associative Network

### Definition

A neural circuit in which the outputs of a region feedback as input onto elements within that same region.

## Autobiographical Memory

### Definition

Remote memory is classified into autobiographical memory and public memory. Autobiographical memory is a recollection of the earlier events of one's own life.

It includes factual knowledge about oneself (e.g., addresses where lived, names of teachers/friends/colleagues) so-called personal semantics, and one's personal memory of events or episodes specifiable time and place so-called autobiographical incidents.

►Long-Term Memory

## Autocellular Septate Junctions

### Definition

Septate junctions are formed between the plasma membrane of the same glia cells.

►Alternative Splicing and Glial Maturation

## Auto-Covariance Function

### Definition

The cross-covariance is a linear measure of the relationship between two functions of time (variables), one taken at time t and the other at time $t_{-i}$. The cross-covariance is computed as the average of the products of the deviations of each variable from their respective mean. The auto-covariance is the cross-covariance of a function at time t and itself at time $t_{-i}$.

►Signals and Systems

## Autocrine Feedback Control

### Definition

A series of molecular events that originate on the same cell secreting neurotransmitters or hormones and possessing membrane receptors selective for these molecules (autoreceptors). The activated autoreceptors mediate a sequence of reactions, which usually compensate the original triggering event.

## Autogenetic Excitation and Inhibition of Motoneurons

### Definition

Excitation and inhibition of the motoneurones innervating the muscle from which the afferents eliciting the excitation and inhibition originate. Autogenetic inhibition was originally described as a disynaptic inhibition of motoneurones evoked by activation of Ib afferents from muscle tendons belonging to the muscle innervated by the motoneurones. The interneurones in the pathway (Ib inhibitory interneurones) receive input from a number of sensory modalities (including gr. Ia afferents and cutaneous afferents) in addition to descending motor tracts and the transmission in the pathway may therefore be greatly modulated in relation to movement. Subsequent experiments have demonstrated that the inhibition is depressed during functional tasks such as walking, whereas transmission in excitatory Ib pathways is facilitated. These excitatory pathways include at least a disynaptic autogenetic excitatory pathway in addition to a longer (polysynaptic) pathway.

►Integration of Spinal Reflexes

## Autografting

Synonym: autotransplantation

Transplantation of tissues or organ pieces between the different parts of the same individual or animal.

# Autoimmune Demyelinating Disorder (ADD)

Autoimmune Demyelinating Disorder (ADD) is an autoimmune disorder affecting nervous system, leading to neurodegeneration.

►Autoimmune Demyelinating Disorders: Stem Cell Therapy

# Autoimmune Demyelinating Disorders: Stem Cell Therapy

## Synonyms

Autoimmune demyelinating disorder ADD; Multiple sclerosis; Experimental autoimmune encephalomyelitis; Neuroprotection; Remyelination; Neural stem cells; Cell transplantation

## Definitions

### Stem Cell Transplantation

Medical procedure in the field of hematology, oncology or regenerative medicine that involves transplantation of ►stem cells (►stem cell transplantation) of different origin (e.g., ►neural stem cells, hematopoietic stem cells, mesenchymal stem cells, cord blood stem cells, etc.). It is most often performed on people with diseases of the blood or bone marrow, certain types of cancer or diseases of the central nervous system [e.g., ►multiple sclerosis (MS), Parkinson's disease (PD), Huntington's disease (HD), etc.]. Transplanted stem cells are usually administered either locally (e.g., intraparenchymally), intravenously or intrathecally (e.g., through the cerebrospinal fluid circulation). The main aims of the procedure are either: the repopulation of the host bone marrow and the production of new blood cells, the replacement of lost and/or injured neural cells or the induction of peripheral immune tolerance.

### Stem Cells

Stem cells are primary cells common to all multi-cellular organisms that retain the ability to ►self-renew through asymmetric cell division and can differentiate – both in vitro and in vivo – into a wide range of specialized (post-mitotic) daughter cells (►cellular potency). Two major categories of stem cells exist in mammals: ►embryonic stem (ES) cells, derived from blastocyst, and adult (somatic) stem cells, which are found in adult tissues.

### Neuroprotection

Cellular and molecular mechanisms spontaneously taking place – or being fostered by a given therapy – within the central as well as peripheral nervous system by which neural cells are protected from apoptosis and/or degeneration (for example following a brain injury or as a result of chronic neurodegenerative diseases) (►neuroprotection).

### Multiple Sclerosis

Chronic disease of the central nervous system (CNS) occurring as a consequence of an autoimmune attack against certain (*self*) myelin antigens. ►Multiple sclerosis (MS) primarily affects young adults, with an age of onset typically between 20 and 40 years, and is more common (2:1 ratio) in women than in men. Distinctive characteristics of MS is the presence of multifocal perivascular inflammatory infiltrates in the CNS white matter, mainly composed of cells of the immune system (e.g., macrophages and lymphocytes), that cause demyelination and secondary axonal degeneration. Symptoms of MS include changes in sensation, visual problems, muscle weakness, depression, difficulties with coordination and speech, severe fatigue, and pain. More severe MS cases can also be associated with impaired mobility and disability.

### Experimental Autoimmune Encephalomyelitis (EAE)

Widely used animal model of the human demyelinating disease MS. ►Experimental autoimmune encephalomyelitis (EAE) is generally induced in rodents or primates by either immunization with myelin antigens [e.g., myelin oligodendrocyte glycoprotein (MOG), proteolipidic protein (PLP), myelin basic protein (MBP), etc.] in adjuvant (►active induction) or adoptive transfer of myelin-specific T cells (►passive induction). Induction of EAE typically results in ascending flaccid paralysis of limbs with inflammation and tissue damage primarily targeting the spinal cord.

### Neural Stem Cells

Heterogeneous population of mitotically-active, self-renewing, multipotent cells of both the developing and the adult central nervous system (CNS). Neural stem cells (NSCs) have been successfully isolated from the entire embryonic as well as adult CNS. The ganglionic eminence(s), in the embryo, and both the subventricular zone (SVZ) of the lateral ventricles and the sub-granular zone (SGZ) of the hippocampus dentate gyrus (DG), in the adult, have been shown to consistently contain

stem-like cells capable of driving neuro- and gliogenesis. These regions are then defined as highly specialized ►CNS germinal niches. Protocols to obtain in vitro large-scale numbers of NSCs are available, thus supporting the concept that these cells might represent a renewable source of uncommitted ready-to-use cells for transplantation purposes.

## Characteristics

Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system (CNS) (►Autoimmune Demyelinating Disorder (ADD)), whose aetiology is still unknown. MS pathology is characterized by the presence within the CNS of perivascular lympho/mononuclear inflammatory infiltrates inducing patchy demyelination, axonal loss and reactive astroglial scarring.

Substantial proportion of demyelinated lesions within the CNS from MS patients are fully or partially remyelinated. Furthermore, in some MS cases the clinical course appears to be benign with no long-term accumulation of disability. Characteristic sclerotic plaques are identified in individuals without neurological disability, suggesting the existence of "►clinically silent" MS.

In this context, spontaneous remyelination may spontaneously occur and some axons may recover their capacity to conduct action potentials [1]. However, spontaneous repair is inefficient over time and, in the vast majority of MS cases, neurological disability progresses as irreversible axonal loss and neuronal damage accumulates [1].

### Remyelination Failure in MS

The most likely causes of remyelination failure in MS may be summarized as follows: (i) selective depletion of oligodendrocyte progenitor cells (OPCs) around demyelinating areas; (ii) failure of the recruitment of OPCs to the demyelinated areas; (iii) failure of recruited OPCs to differentiate into remyelinating oligodendrocytes; (iv) inhibition of remyelination as a net result of protective vs. detrimental effects of cytokines; (v) anatomical and molecular inhibition of remyelination associated with astroglial scarring; and (vi) acute and/or chronic axonal loss and/or dysfunction [1,2].

## Cell-Based Therapies for Myelin Repair in Autoimmune CNS Demyelination

The intrinsically complex nature of MS poses great challenges for cell-based remyelinating therapies. Two major requirements have to be satisfied: (i) an unlimited source of cells; and, (ii) the possibility of accessing several CNS damaged areas at the same time. Current studies are mostly aimed at addressing some preliminary issues that need to be solved before prospecting any potential human application of cell-based therapies such as (i) the ideal stem cell source for transplantation; (ii) the route of cell administration; (iii) and, the differentiation and persistence of cells transplanted into the targeted tissue.

Several experimental transplantation procedures aimed at restoring the myelin architecture within CNS demyelinated areas have been developed so far. Different types of myelin-forming cells have been transplanted into rodent models of either genetic, chemical or autoimmune CNS demyelination. These approaches show serious limitations. In particular, lineage-restricted myelin-forming cells – either OPCs, Schwann cells or olfactory ensheathing cells – posses in vitro limited growth and expansion characteristics and, once transplanted, may drive remyelination only within restricted CNS areas close to the transplantation site [3].

The functional and morphological properties of stem cells might therefore represent a promising alternative for transplantation approaches in MS [4].

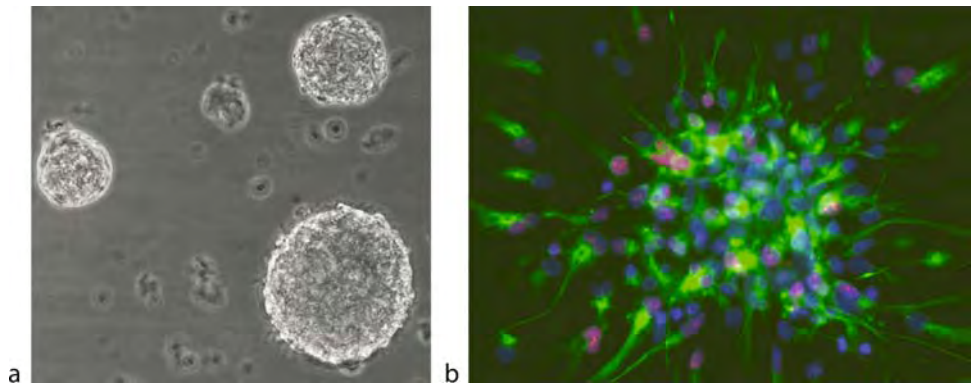
The therapeutic use of embryonic stem (ES) cells is still constrained by some key issues – such as feeder-independent growth (expansion) and in vivo teratocarcinoma formation – which need to be solved before proposing any ES cell-based therapy for human applications.

Adult stem cells represent a ready-to-use cell source for cell-based therapies, since they can be obtained by different tissues (e.g., bone marrow, brain, etc.) and have been widely used in experimental and clinical settings in vivo without causing tumor formation and overt toxic/side effects.

### Neural Stem Cells

Mammalian neural stem cells (NSCs) support neurogenesis and gliogenesis within restricted areas (germinal niches) of the CNS throughout adulthood, can undergo extensive in vitro expansion and possess the capacity to generate a progeny of daughter cells which can integrate into and repair the tissue of origin. These cells show: (i) growth factor (GF)-dependent proliferation and stable growth rate; (ii) capacity for ►self-renewal; (iii) multipotentiality; and, (iv) functional plasticity either over serial in vitro passaging or after several freezing-thawing cycles [4] (Fig. 1).

The route of cell administration represents a major constraint for NSC transplantation and appears to be dependent on the CNS lesion site(s). The anatomopathological features of certain focal CNS disorders, such as Parkinson's disease (PD) or acute spinal cord injury (SCI), might suggest that direct local (*intralesional*) cell transplantation might facilitate tissue regeneration, while the multifocality of other CNS disorders – such as MS and epilepsy – would represent a major limitation for *intralesional* cell-transplantation approaches. In multifocal CNS disorders,



**Autoimmune Demyelinating Disorders: Stem Cell Therapy. Figure 1** In vitro characteristics of NSCs used for transplantation in CNS autoimmune demyelinating disorders. Upon continuous mitogen stimulation in serum-free growth media, NSCs appear in vitro as free-floating neurospheres (A, phase contrast). After plating on proteic substrates (e.g., poly-L-lysine, matrigel, etc.), display chain-like radial migration, still undergo cell cyle and express Ki67 (B, red) while maintaining immunoreactivity for nestin (B, green). Nuclei in B have been counterstained with dapi (blue). Magnification in A and B 40 X.

systemic (e.g., intravenous, intrathecal) transplantation of NSCs can be therapeutically efficacious owing to the ability of transplanted cells to follow, via the blood stream or cerebrospinal fluid circulation, a gradient of chemoattractants (e.g., pro-inflammatory cytokines and chemokines) occurring at the site of inflammatory lesions [4,5]. Specific homing of transplanted NSCs has been shown in SCI, epilepsy, and stroke. However, the exact molecular mechanism sustaining this phenomenon has been detailed, so far, only in experimental autoimmune encephalomyelitis (EAE). Tethering, rolling, and firm adhesion to inflamed endothelial cells and extravasation into inflamed CNS areas are sequentially mediated by the constitutive expression of functional cell adhesion molecules (CAM) (e.g., CD44), integrins (e.g., α4, β1), and chemokine receptors (e.g., CCR1, CCR2, CCR5, CXCR3, CXCR4) on NSC surface [4,5].

### *Therapeutic Functions of Transplanted NSCs*

Irrespective of the characteristics of the experimental disease and type of inflammation, functional recovery obtained by NSC transplantation barely correlates with absolute numbers of transplant-derived newly generated terminally differentiated neuronal cells. Transplantation of NSCs into rodents with experimental PD or Huntington's disease (HD), very scarcely differentiate into tyrosine hydroxylase (TH)-immunoreactive neurons despite significant behavioral improvement. Mice with SCI, acute stroke and intracerebral hemorrage do improve despite pathological evidence of preferential astroglial fate of transplanted NSCs. The large majority of NSCs injected into mice with experimental cerebral hemorrage or with acute ischemic stroke, express markers of undifferentiation (e.g., nestin) when surrounding damaged CNS areas. In EAE, very low differentiation of transplanted NSCs into myelin forming oligodendrocytes is accompanied by striking neurophysiological evidence of axonal protection and remyelination. In the very same context, more than 20% of transplanted cells reaching inflammatory demyelinated areas do not express differentiation markers. This limited terminal differentiation and propensity for maintaining an undifferentiated phenotype within the host tissue, suggests that transplanted NSCs might also be therapeutic efficacious via a bystander mechanism(s) alternative to cell replacement. Indeed, transplanted NSCs reduce the scar formation and/or increase survival and function(s) of endogenous glial and neuronal progenitors surviving to the pathological insult. This neuroprotective effect is accompanied by increased in vivo bioavailability of major neurotrophins [e.g., nerve growth factor (NGF), brain-derived growth factor (BDNF), etc.]. Also, transplanted NSCs promote bystander immunomodulation as they release soluble molecules (e.g., cytokines and chemokines), express immune-relevant receptors (e.g., chemokine receptors, CAMs), capable of profoundly altering the inflammatory environment and up-regulate membrane expression of certain functional death receptor ligands (e.g., FasL, TRAIL, Apo3L) by which they induce programmed cell death (apoptosis) of inflammatory T lymphocytes [5]. Transplanted NSCs also significantly and specifically contribute to the down-regulation of effector functions of inflammatory T cells and macrophages within both the target tissue as well as within draining lymph nodes [6]. Major NSC transplantation studies in animal models of CNS disorders are summarized in Table 1 (reproduced from [4]).

**Autoimmune Demyelinating Disorders: Stem Cell Therapy. Table 1** Neural stem cell (NSC) transplantation studies in animal models of CNS disorders

| Neural stem cell source | Route of cell administration | Disease model | Mechanism(s) of therapeutic efficacy | | Outcome |
|---|---|---|---|---|---|
| | | | Cell replacement | Bystander effect | |
| *Demyelinating disorders* | | | | | |
| Adult brain SVZ NSCs (mouse) | Icv and iv single cell injection | Chronic EAE in mice | Oligodendroglial and neuronal differentiation | Rescue of endogenous OPCs and modulation of NGFs in vivo | Attenuation of clinical, neurophisiological and pathological parameters of EAE |
| Adult brain SVZ NSCs (mouse) | Iv single cell injection | Relapsing EAE in mice | Not tested | Induction of apoptosis of CNS-infiltrating T lymphocytes | Attenuation of clinical, and pathological parameters of EAE |
| Adult [19–64 years] brain NSCs (human) | Intralesional (*epicentre*) cell transplantation | EB-X focal demyelination of the thoracic (T10) spinal cord dorsal column in rats | Schwann cell-like driven remyelination (P0 immunoreactive cells) | Not tested | Functional restoration of peripheral nerve conduction |
| Adult brain striatal NSCs (rat) | Icv neurosphere injection | Acute EAE in rats | Not tested | Inhibition of MOG-specific lymphocyte proliferation | Attenuation of clinical and pathological parameters of EAE |
| *Traumatic brain injury* | | | | | |
| Neonatal cerebellum C17.2-CD NSCs (mouse) | Stx intraparenchimal (*ipsi or contralateral*) cell transplantation | Parieto-temporal CCI brain injury in mice | 60% neuronal and 40% astroglial differentiation | Not tested | Improved coordination and vestibulomotor functions |
| Embryonic [E14.5] brain NSCs (mouse) | Stx ipsilateral intrastriatal neurosphere transplantation | Fronto-parietal CCI brain injury in mice | No neuronal or astroglial differentiation, 85% of NG2 immunoreactivity | Not tested | Improvement of motor and learning performances No effects on necrotic cavity size or hippocampal degeneration |
| *Stroke* | | | | | |
| Neonatal cerebellar C17.2-CD NSCs (mouse) | Intralesional (*infarction cavity*) transplantation of PGA-NPC complex | Transient (*3 hours*) unilateral CCAO in mice | Neuronal, astro- and oligodendro-glial differentiation | Decrease mononuclear cell infiltration and astrogliosis | Not tested |
| Embryonic [E14] hippocampal MHP36 NSCs (mouse) | Stx unilateral striatal cell graft | Transient (*17 min.*) bilateral CCAO in mice | 50% neuronal differentiation | Rescue of endogenous neurons | Not tested |
| Foetal [15 weeks] brain immortalized [clone HB1.F3]NSCs (human) | Iv single cell injection | Stx intrastriatal administration of bacterial collagenase in mice | 10% neuronal and 75% astroglial differentiation | Increase of viable NGFs | Improvement of motor performances |

**Autoimmune Demyelinating Disorders: Stem Cell Therapy. Table 1** Neural stem cell (NSC) transplantation studies in animal models of CNS disorders (Continued)

| Neural stem cell source | Route of cell administration | Disease model | Mechanism(s) of therapeutic efficacy | | Outcome |
|---|---|---|---|---|---|
| | | | Cell replacement | Bystander effect | |
| Foetal [15 weeks] brain immortalized [clone HB1. F3] NSCs (human) | Iv single cell injection | Transient (*90 min,)* MCAO in mice | 20% neuronal and 60% astroglial differentiation 20% undifferentiation | Decreased atrophy Increase of viable NGFs | Lower sensory motor deficits |
| Fetal [16–20 weeks] brain NSCs (human) | Stx multiple cortical cell deposits | Transient (*1 hour*) distal MCAO in rats | 50% neuronal and 15% astroglial differentiation | Less macrophage/ microglial cell infiltration at lesion borders | Not tested |
| *Parkinson's disease* | | | | | |
| Neonatal cerebellar C17.2-CD NSCs (mouse) | Stx unilateral cell graft in the SN-VTA | MPTP-induced nigrostriatal degeneration in mice | 10% neuronal differentiation | Rescue of endogenous $TH^+$ neurons Increase of viable GDNF | Decrease of amphetamine-induced turns |
| Foetal [10–12 weeks] brain NSCs (human) | Stx bilateral (CN) and unilateral (SN) cell graft | MPTP-induced nigrostriatal degeneration in monkeys | Low neuronal differentiation | Rescue of endog-enous $TH^+$ neurons | Not tested |
| Foetal [12–20 weeks] brain NSCs (human) | Stx unilateral intrastriatal neurosphere graft | MPTP-induced nigrostriatal degeneration in mice | Infrequent $TH^+$ immunoreactivity | Not tested | Not tested |
| Foetal [P3] brain SVZ NSCs (mouse) | Stx unilateral intrastriatal graft of VM neurons/ NPCs (1:1 and 1:8 ratios) | 6-OHDA-induced nigrostriatal degeneration in rats | No evidence of neuronal differentiation. 12.5–31% increased neuronal survival, decrease of caspase-$3^+$/$TH^+$ neurons, less cell debris, | increase of viable Shh | Decrease of amphetamine-induced turns |
| Foetal [22 weeks] brain NSCs (human) | Stx unilateral intrastriatal neurosphere graft | 6-OHDA-induced nigrostriatal de-generation in rats | Low neuronal differentiation, predominant astroglial differentiation | Not tested | Weak behavioral improvement |
| Embryonic [E14.5] brain NSCs (rat) | Stx unilateral cell graft into the MBF | 6-OHDA-induced nigrostriatal degeneration in rats | 13–16% doublecortin immunoreactivity, 20–25% GFAP immunoreactivity, infrequent $TH^+$ immunoreactivity | Not tested | Not tested |
| Embryonic [E12] brain NSCs (rat) | Stx unilateral cell graft into the SN | 6-OHDA-induced nigrostriatal degeneration in rats | Poor integration, infrequent $TH^+$ immunoreactivity | Not tested | No behavioral differences |

**Autoimmune Demyelinating Disorders: Stem Cell Therapy. Table 1** Neural stem cell (NSC) transplantation studies in animal models of CNS disorders (Continued)

| Neural stem cell source | Route of cell administration | Disease model | Mechanism(s) of therapeutic efficacy | | Outcome |
|---|---|---|---|---|---|
| | | | Cell replacement | Bystander effect | |
| Adult brain SVZ NSCs (rat) | Stx unilateral intrastriatal cell graft | 6-OHDA-induced nigrostriatal degeneration in rats | No evidence of NeuN and Tuj1 immunoreactivity, nestin immunoreactivity. DAT immunoreactivity | Increase of viable neuroprotective and neuroregenerative factors | Decrease of amphetamine-induced turns |
| *Huntington's disease* | | | | | |
| Foetal [12 weeks] brain NSCs (human) | Stx unilateral intrastriatal cell graft | QA-induced striatal degeneration in rats | 1% NeuN, 3.5% GFAP immunoreactivity, ki67 immunoreactivity (in vivo *proliferation*). | 26% greater striatal volume Increase of viable CNTF, BDNF, GDNF | Improvement of motor function |
| Foetal [15 weeks] brain NSCs (human) | Stx unilateral intrastriatal cell graft | 3-NP-induced striatal degeneration in rats | Predominant nestin immunoreactivity, low NeuN and GFAP immunoreactivity, certain calbindin and GAD immunoreactivity | Extensive survival of striatal neurons, increase of viable BDNF | Improvement of motor function |
| *Acute spinal cord injury* | | | | | |
| Neonatal cerebellar C17.2-CD NSCs (mouse) | Intralesional transplantation of PGA-NPC complex | Lateral thoracic (T9-T10) spinal cord hemisection in rats | Majority of cells immunoreactive for nestin | Major contribution of NPCs as trophic support | Improvement of motor function |
| Neonatal cerebellar C17.2-CD NSCs (mouse) | Intralesional (*epicentre*) cell transplantation | Dorsal cervical (C3) Kopf microwire knife-mediated spinal cord lesion in rats | No evidence of differentiation | In vivo secretion of NGF, BDNF, GDNF | Not tested |
| Foetal [15 weeks] brain NSCs (human) | Multiple (n = 4) intraspinal cell deposits | Dorsal thoracic (T9) spinal cord spinal cord weight drop injury in NOD-*scid* mice | 2.9% astroglial, 26.3% neuronal, 64.1% oligodendroglial differentiation | Not tested | Improvement of coordinated forelimb-hind limb motor function |
| Embryonic [E15] hippocampal NSCs (rat) | Iv single cell injection | Dorsal thoracic (T7) spinal cord weight drop injury in rats | 4.7% neuronal, 47% astroglial, 48% oligodendroglial differentiation | Cell accumulation within the injured spinal cord lesion, | Not tested |
| Adult spinal cord NSCs (rat) | Multiple (n = 4) intraspinal cell deposits | Dorsal thoracic (T8-T9) spinal cord weight drop injury in rats | 74% astroglial, 17% oligodendroglial and 3% neuronal differentiation | Not tested | Improvement of motor function |

**Autoimmune Demyelinating Disorders: Stem Cell Therapy. Table 1** Neural stem cell (NSC) transplantation studies in animal models of CNS disorders (Continued)

| Neural stem cell source | Route of cell administration | Disease model | Mechanism(s) of therapeutic efficacy | | Outcome |
|---|---|---|---|---|---|
| | | | Cell replacement | Bystander effect | |
| *Epilepsy* | | | | | |
| Foetal [15 weeks] brain NPCs (human) | iv single cell injection | Lithium cloride/ pilocarpine seizures model in rats | Hippocampal distribution of transplanted cells, ~60% neuronal (26% $GABA^+$, 31% $PV^+$, 3% $GluR^+$ immunoreactivity), 21% astroglial differentiation, ~25% undifferentiation | Not tested | ~85% decrease of generalized convulsive seizure frequency and severity, increase of GABAergic synaptic inhibition |

*Neural stem cells includes cells derived from embryonic, foetal, neonatal, and adult tissues. Abbreviations used: 3-NP, 3-nitropropionic acid; 6-OHDA, 6-hydroxydopamine; BDNF, brain-derived neurotrophic factor; CCAO, common carotid artery occlusion; CCI, controlled cortical impact; CN, caudate nucleus; CNS, central nervous system; CNTF, ciliary neurotrophic factor; DAT, dopamine transporter; EAE, experimental autoimmune encephalomyelitis; EB-X, -X irradiation and ethidium bromide-induced focal demyelination; GAD, glutamic acid decarboxylase; GDNF, glial-derived neurotrophic factor; GFAP, glial fibrillary acidic protein; icv, intracerebroventricular; iv, intravenous; MBF, medial basal forebrain; MCAO, middle cerebral artery occlusion; MOG, myelin-oligodendrocyte glycoprotein; MMP-2, matrix metalloprotease-2; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; NeuN, neuronal nuclear antigen; NGF, nerve growth factor; NGFs, neurotrophic growth factors; Ngn-2, neurogenin-2; NOD-scid, non-obese diabetic-severe combined immunodeficient mice; NPCs, neural stem/progenitor cells; OPCs, oligodendrocyte-progenitor cells; P0, peripheral nerve myelin protein P0; PGA, poly-glicolic acid; QA, quinolinic acid; SN, subtalamic nucleus; Shh, sonic hedgehog; Stx, stereotaxic; SVZ, subventricular zone; TH, tyrosine hydroxylase; VM, ventral midbrain; VTA, ventral tegmental area.

## Hematopoietic Stem Cells

The transplantation of hematopoietic stem cells (HSCs) from autologous or allogeneic bone marrow, umbilical chord or peripheral blood is a widely utilized form of therapy for patients with hematopoietic malignancies and solid tumors. Evidence suggests that HSCs may contribute to the generation of new neurons in the adult brain by means of (i) trans-differentiation; and/or (ii) cell fusion, thus suggesting that HSC transplantation might in principle be useful as a therapeutic tool for brain repair [7]. Other results indicate that in rats with a demyelinated lesion of the spinal cord, HSC transplantation – upon either intravenous or intraparenchimal cell injection – results in varying degrees of remyelination which appears proportional to the number of injected cells [7].

In addition to mechanism aiming at replacement of damaged CNS cells, HSC transplantation is successfully utilized to target the autoimmune response at the peripheral level in several autoimmune diseases including MS [8]. The efficacy of HSC transplantation (following intense chemotherapy) is likely to be based on the intense immune suppression, which ends up in the eradication of most autoimmune cells, followed by the successful engraftment of the transplanted stem cells leading to the reconstitution of the immune system representing a recapitulation of ontogenesis and thus accompanied by the acquisition of self-tolerance [9]. Moreover, HSC transplantation induces immune tolerance in rodents with EAE, as sustained by increased numbers of circulating regulatory T cells, a shift in T cell epitope recognition and a strong reduction of autoantibodies [9].

## Mesenchymal Stem Cells

The adult bone marrow contains a non-haematopoietic cell lineage which is capable of differentiating into osteoblasts, adipocytes, and chondrocytes. Due to their preferential capacity of differentiating into cells of the mesodermal lineage, these cells are currently defined as "mesenchymal" stem cells (MSCs). MSCs constitute the stromal scaffold providing the appropriate microenvironment for maturation and differentiation of blood-derived progenitor cells possibly by means of the release of survival factors [10].

MSCs can also be induced to differentiate in vitro into cells with biochemical, anatomical, and electrophysiological characteristics of neuronal cells [10]. Upon intravenous injection, MSCs engraft into different tissues – including the brain – where they escape immune surveillance and differentiate expressing some microglial and astroglial markers [9]. Migration of intravenously-injected MSCs to the brain may well depend upon tissue injury, as demonstrated by their

minimal engraftment when transplanted into healthy non-human primates [9]. In contrast, in rodents with cerebral ischemia and traumatic brain injury, systemically-injected MSCs migrate to the injured CNS. These migratory properties are regulated by cell adhesion molecules and receptors for inflammatory chemokines, such as CXCL12, which plays a key role in the migration of CXCR4-positive mesenchymal stem cells to peripheral tissues [9].

MSCs can also significantly modulate many immune functions. MSCs inhibit T cell proliferation and induce T cell energy [9]. MSCs also affect dendritic cell maturation both in vitro and in vivo, thus resulting in the generation of tolerogenic antigen presenting cells (APCs) [9]. Interestingly, proof of MSC-dependent induction of $CD4^+$ T cell subsets with a regulatory phenotype has recently been provided in vitro. Human MSCs also affect B lymphocyte proliferation and maturation to antibody secreting cells [9].

In vivo, transplantation of syngenic MSCs ameliorates chronic EAE in mice. Moreover, systemically-injected MSCs also improve relapsing-remitting EAE and migrate to the CNS where they promote BDNF production and induce proliferation of endogenous oligodendrocyte progenitor cells [9].

All together these results consistently challenge the view that stem cells therapeutically work exclusively throughout cell replacement. Indeed, NSC transplantation may also promote CNS repair via intrinsic *neuroprotective* bystander capacities, mainly exerted by undifferentiated stem cells releasing, at the site of tissue damage, a milieu of *neuroprotective* molecules once temporally and spatially orchestrated by environmental needs. The intrinsic nature (*pleiotropism and redundancy*) of these molecules as well as their "►constitutive" characteristics, might represent a *stem cell signature* that also reconciles data showing that other sources of somatic stem cells (e.g., HSCs, MSCs), may efficiently promote CNS repair despite very low capabilities of neural (trans) differentiation.

The exact knowledge and the potential impact of *non-conventional* stem cell-mediated therapeutic mechanisms might result, in certain circumstances, in more efficacious curative alternatives.

# Autoimmune Disease

## Definition

Diseases caused by immune responses targeting a self component that leads to subsequent tissue/organ damage and dysfunction. Autoimmune diseases can be organ/tissue specific or systemic depending on the distribution of the self components attacked by the immune system. Both cell-mediated and humoral (antibody mediated) immune responses are involved in tissue damage. Susceptibility of autoimmune disease is controlled by both environmental and genetic factors.

►Anti-DNA Antibodies against Microbial and Non-Nucleic Acid Self-Antigens

# Autoimmune Neuroinflammation

## Definition

Inflammation caused by immune reactivity towards self antigens within the nervous system. Multiple sclerosis

and its animal model experimental autoimmune encephalomyelitis are prototype diseases for autoimmune neuroinflammation.

►Multiple Sclerosis
►Experimental Autoimmune Encephalomyelitis

## Autoimmune Response

### Definition

Humoral (antibody) or cellular (T cell) immune responses against self antigens (autoantigen). Autoimmune diseases are caused by autoimmune responses, and can be divided into organ specific and systemic autoimmune diseases. For example, among neurological diseases, myasthenia gravis is mediated by autoantibody against the acetylcholine receptor. Although multiple sclerosis has been suggested to be mediated by autoimmune responses against myelin and/or oligodendrocytes, no single myelin antigen has been identified as the autoantigen.

►Multiple Sclerosis
►Myasthenia Gravis

## Autoimmune T Cells

### Definition

T cells that recognize specific self-antigens. These T cell subpopulations mediate an autoimmune response (i.e. a response to self-antigens), which can be either protective (e.g. fighting off cancer cells or neurodegenerative conditions) or – if not properly regulated – destructive (causing an autoimmune disease).

►Autoimmune Response

## Autoimmunity

### Definition

A condition in which the body produces an immune response recognizing its own proteins. Autoimmune responses can be mediated by either T or B lymphocytes.

►Autoimmune Response

## Autologous Macrophage Therapy for Spinal Cord Injury

### Definition

A treatment for acute spinal cord injury, in which systemic monocytes withdrawn from the patient's own blood are activated ex-vivo and reintroduced into patient for the purpose of carrying out their innate therapeutic functions.

►Autologous Macrophages for Central Nervous System Repair

## Autologous Macrophages for Central Nervous System Repair

Michal Schwartz[1], Eti Yoles[2]
[1]The Weizmann Institute of Science, Rehovot, Israel
[2]Proneuron Biotechnologies, Beit-Gamliel, Israel

### Synonyms

Blood-borne monocytes for CNS repair

### Definition

Restoration of damaged neural (brain and spinal cord) tissues by the peripheral immune system; specifically, by blood derived monocytes injected following activation, into the margins of the lesion site, or by boosting of adaptive immunity as away of enhancing recruitment of blood-borne monocytes injected autologous activated macrophages or by endogenous innate immune cells recruited via T cell-based vaccination.

### Characteristics

Recovery from acute central nervous system (CNS) injuries requires recruitment of blood-borne monocytes whose numbers, activity, and localization are rigorously controlled. CNS-resident microglia also participate in the recovery process, but their ability to acquire the needed activity is limited. Spontaneous recruitment of blood-borne monocytes is also limited, but can be boosted either by vaccination (with T cell-specific antigens or dendritic cells loaded with such antigens) or by exogenous application of specifically activated autologous macrophages. The cells are harnessed for restoration of homeostasis by removing cell debris, balancing exogenous ionic and neurotransmitter concentrations, providing growth factors, attracting reparative cells, and supporting tissue recovery and renewal.

Based on the realization that peripheral monocytes are needed for CNS repair, a number of ▶immune-based approaches have been developed. One such therapy for spinal cord injury makes use of specifically activated autologous macrophages [1–3]. Macrophages are prepared from the patient's blood, activated on the patient's skin to adopt a phenotype that promotes repair, and then reintroduced into the patient. The activated macrophages, unlike "classically" activated macrophages programmed to dispose of hostile invading organisms, express the cell-surface markers CD80, CD86, and CD54, as well as class II major histocompatibility complex molecules (MHC-II). All of these features are characteristic of antigen-presenting cells (APCs) reminiscent of 'alternatively activated macrophages' rather than classical pro-inflammatory macrophages [1]. In addition, they secrete the growth-promoting brain-derived neurotrophic factor but not the cytokine tumor necrosis factor-α. The abundant presence of the former coupled with the absence of the latter is suggestive of beneficial neuroprotection. The cellular features of these activated macrophages are reminiscent of those of microglia/macrophages recruited or activated by the adaptive immune system [4].

## Background

Up until about 10 years ago, activated macrophages were viewed simply as cells that secrete the inflammatory mediators needed to kill intracellular pathogens. Data accumulated over the last decade suggested, however, that monocytes are multi-talented cells that are capable of expressing different functional programs in response to distinct micro-environmental signals. The differentiation of monocytic phenotypes is profoundly affected by microbial products and cytokines. Microbial products are associated with the "classical" activation that turns monocytes into potent effector cells that kill microorganisms and tumor cells. At the other extreme are the "alternatively" activated macrophages, conditioned by APC-secreted cytokines to control local inflammation (shechter, London, unpublished observations), [5] promote angiogenesis, tissue remodeling, and repair [1].

Over the last decade, the activities of blood-borne macrophages and resident microglia in the CNS, which formerly were considered to be wholly detrimental, began to be viewed in a different light. It is now widely accepted that immune cells are essential players in CNS repair (See review). Experiments in rats with completely transected optic nerves or spinal cords demonstrated that local application of macrophages preincubated with fragments of sciatic nerve (a peripheral nerve, and thus capable of regeneration) promotes motor recovery [3]. Similar results were reported by Benowitz and his colleagues, who showed that macrophage-derived factors stimulate growth [6].

The early experiments in which autologous activated macrophages were locally injected into the injured optic nerve were repeated in a paradigm of rat spinal cord contusion in which blood-borne monocytes were activated by preincubation with autologous skin [1]. In these and subsequent experiments the macrophage phenotypes were characterized, and parameters such as the site of injection, dosage, regimen, and therapeutic window were established. Specifically, macrophages are needed at the margin of the lesion site, not at the hyperacute phase, and express factors needed for scar resolution and for controlling inflammation.

These and related studies made it clear that the reparative role of activated macrophages which exert beneficial effects on the injured spinal cord differs from that of the resident microglia. This raised an important question: are such macrophages spontaneously recruited after a CNS insult? Addressing this question became feasible with the introduction of chimeric mice in which a visible marker, green fluorescent protein, is expressed by bone marrow-derived monocytes [5,7] shecter et al., Rolls et al. unpublished observations. Studies showed that the majority of innate cells accumulating at the site of injury were the resident microglia, while hardly any blood-borne monocytes were seen to infiltrate the damaged CNS. Recruitment of blood-borne monocytes turned out to be a key factor in recovery from any CNS injury [8].

### *Quantitative regulation*

#### *When Are Macrophages Needed?*

In studies aimed at establishing the optimal time for macrophage intervention after spinal cord injury it became clear that in the CNS, as in any other tissue, repair and restoration are dependent not only on context, but also on timing. The following time windows were examined in a rat model of spinal cord injury, each representing a different post-injury physiological stage: (i) 3–4 days after spinal cord injury, a period characterized by decline in primary infiltration of neutrophils participating in inflammation and a high incidence of apoptotic cells (ii) 7–10 days after injury, a period of maximal proliferation and/or accumulation of ED1-positive cells (activated microglia/macrophages), T cells, and progenitor glial cells (iii) 14 days after injury, when the numbers of ED1-positive cells and T cells are still very high, while cytokines and chemokines in the injured tissue are decreasing or disappearing; and (iv) 21 days after injury, by which time many of the injury-induced biochemical and cellular activities in the spinal cord have peaked and begun to return to normal. The best effect was observed when cells were implanted 7–9 days after the injury.

The outcome, assessed in terms of recovery of motor function, is also critically affected by the choice of injection site. Injection close to the caudal margin of a

contusive spinal injury was found to be beneficial. Injections one or three segments below that level yielded no significant improvement in recovery [9].

## Other immune-based therapies

Macrophages that beneficially affect recovery resemble APCs [1]. Studies of immune system participation in recovery from CNS insults disclosed that the peripheral immune system, traditionally viewed as being affected only in a passive way by CNS injury, in fact, plays an active role in CNS repair and is an integral part of it. That discovery led to a series of studies that culminated in formulation of the seminal concept of "►protective autoimmunity" [10,11]. According to this concept, T cells that react with specific CNS autoantigens ("autoimmune" T cells), by locally controlling the activity of resident microglia, play a central role in the physiological processes of CNS protection and repair. Active vaccination (using specific T cells) and passive vaccination (using myelin-derived peptides or dendritic cells loaded with those peptides) yielded similar results, manifested by better locomotion and reduced scar tissue. Recovery was accompanied by changes in the behavior of microglia/macrophages at the margins of the lesion, such that they were found to express the phenotype reminiscent of that of the activated macrophages.

It was further discovered that a principal role of the T cells has to do with shaping microglial behavior and recruiting blood-borne monocytes [5,12]. The activated microglia can act as APCs, produce growth factors, and scavenge neurotoxins such as excessive quantities of glutamate. Thus, not only do they support neuronal survival but they also promote neurogenesis and oligodendrogenesis, as well as axonal sprouting from adult neural stem cells [4]. It also became clear that not only resident microglia but also bone marrow-derived blood-borne monocytes can be induced to undergo a switch in phenotype, so that the activity they express is similar to that of transplanted growth-promoting macrophages [7]. Blood-borne innate immune cells that are recruited as a result of a T cell-based vaccination reside mainly at the margins of the lesion site.

Recognition that adaptive immune cells confer local immunity capable of supporting cell renewal by supporting an ectopic stem-cell niche raised another important question: after CNS injury, can the ►local immune response be controlled in a way that allows exogenously applied stem cells to be harnessed for promotion of recovery? Investigation of this possibility disclosed that a T cell-based vaccination given on the day of spinal cord contusion, if supplemented 1 week later by injection of neural stem cells into the CSF, results in significantly better recovery than that attained by vaccination alone. No effect was observed with the stem-cell injection alone. Moreover, in the vaccinated injured mice (but not in mice that were not vaccinated after injury), stem cells that are injected into the CSF find their way to the lesion site, supporting the contention that the local immune response helps to create a niche which recruits not only stem cells but also additional immune cells for repair. The injected stem cells apparently do not undergo local differentiation into any of the neural lineages; rather, their functions appear to be related to immune activity and creation of a regulatory niche [13].

Taken together, the blood-borne monocytes, play a major role in CNS repair. They can be recruited in various ways, including bone-marrow transplantation, active or passive vaccination, and administration of autologous macrophages.

## Automatic Postural Response

### Definition

The automatic postural response is a muscular response to a postural perturbation that is thought to be mediated by brainstem centers. The response can be modulated in amplitude by many factors, including habituation, anticipation, prior experience, etc. However, it is "automatic" because it cannot be completely suppressed and is therefore neither completely fixed nor completely voluntary.

## Autonomic Control of Sensory Receptors

Magda Passatore, Silvestro Roatta
Department of Neuroscience – Physiology Division, University of Torino, Raffaello, Torino, Italy

### Definition

The autonomic nervous system consists of three divisions: sympathetic, parasympathetic and enteric nervous system, however, only the sympathetic system is considered relevant in the context of vegetative-sensory interaction. The sympathetic nervous system (SNS) is activated during states of arousal and, in general, by physical, psychological and psychosocial stress as part of a complex neuro-hormonal body adjustment. In particular SNS governs the so-called ►*defense reaction* that contributes at rapidly mobilizing body resources for a ►fight or flight response. In addition, or probably within the same adjustment procedures, SNS modulates the discharge of several ►sensory receptors. Among them are several types of cutaneous ►mechanoreceptors, ►muscle spindle receptors, pain receptors, some visceral ►chemo- and mechanoreceptors. As a consequence, also the reflex actions mediated by the affected receptors may be modified.

A list of the ►receptors affected by enhancement of sympathetic flow is presented in Table 1 [see also 1,2]. We will focus on muscle spindle receptors that have been studied more extensively, due to their relevance in control of skeletal muscle function. Pain receptors, which are affected by ►catecholamines only under particular circumstances, are given more extended treatment elsewhere, in chronic pain mechanisms.

### Characteristics

#### General Considerations

Claude Bernard in 1851 first suggested that sensory input can be modulated by the activation of the SNS, on the basis of the observation of changes in cutaneous sensitivity following the extirpation of the cervical ganglion in the cat. A large number of old and recent electrophysiological and pharmacological data show that the SNS modulates the discharge of numerous types of mechanical and chemical receptors, at least in a percentage of them. The electrical stimulation of the relevant sympathetic nerve and local administration of catecholamines affect the firing properties of these receptors, in terms of both resting discharge and excitability, as recorded from ►primary afferents in several animal species [1,2]. The majority of data available in the literature are in fact collected in *acute* experiments performed on animal models, or in *in vitro*

Data obtained following sympathetic activation induced by either electrical stimulation of sympathetic supply (1–10 Hz) or application of catecholamines or through specific manoeuvres, in the species indicated. Effects reported are obtained by recording afferent discharges from primary neurons; symbols indicate the prevalent response: activation of the resting discharge and/or facilitation of the test response (+), inhibition and/or depression (–), diphasic response (+ − or − +), no effect (0).

preparations. Few studies are available on humans based on microneurography during sympathetic activation tests.

The mechanisms responsible for this action are still debated. For some of the reported actions, there is in fact some disagreement on whether they are due to the *direct* effect exerted by catecholamines on the sensory receptors or rather they are *indirect,* i.e., secondary to metabolic, mechanical or thermal changes induced in the receptor-bearing tissue by the concomitant sympathetically induced ►vasoconstriction. For some cutaneous receptors, micromovements induced by contraction of adjacent ►piloerector muscles has been also suggested. An action exerted directly on the sensory receptors, rather than secondary to vasoconstriction, is suggested by: (i) functional studies in which the sympathetic effect on the receptors was not mimicked by ischemia; (ii) morphological studies proving the existence of noradrenergic fibers in close contact with a number of receptors, such as Pacini corpuscles, muscle spindles and cutaneous hair receptors. Conclusive contribution to the debate should be provided by immunohystochemical investigations proving or disproving the presence of specific adrenoceptors on the various sensory receptor terminals. The studies listed in Table 1 attribute the sympathetically induced effect to a direct action on the receptors, except for some of them, i.e., Freeman & Rowe (1981), Edwall & Scott (1971), Eldred et al. (1960), Eyzaguirre & Fidone (1980) and Elam & Macefield (2004).

It must be added that the sympathetically induced action on the same sensory receptors is likely to be different or more pronounced after "sensitization" processes develop in the affected area; this possibility has been particularly investigated for nociception (see below, under *Pain receptors*).

## Overview

Increase in sympathetic outflow and locally-applied noradrenaline is reported to elicit or enhance the resting discharge and/or to increase the sensitivity to the relevant stimuli, in various types of cutaneous mechanoreceptor. The effect was shown, in some case, to be mediated by increased amplitude and rate of rise of the generator potential, and possibly by an action at the level of the ►encoding site. In general excitatory actions seem to predominate on slowly adapting mechanoreceptors while depressant actions are more commonly observed in rapidly adapting receptors. Besides characteristics of adaptation, sympathetic effects seem to depend on the ►afferent fiber type (see Table 1).

Sympathetic stimulation enhances ►Pacini corpuscle activity in experimental animal models, although some depressant effect is also reported. In some of these receptors, in humans, Hallin & Wiesenfeld [3] evidence a clear relationship between extent of stress/sympathetic outflow and spontaneous discharge frequency of the receptor. A similar interaction is reported in their experiments for the discharge of slowly adapting type I receptors in response to light mechanical stimuli (see Table 1).

The two studies performed on periodontal mechanoreceptors show excitatory and depressant sympathetic actions on rabbit and cat models, respectively, while excitation occasionally followed by inhibition is reported for tooth pulp receptors, having nociceptive function.

An increase in visceral perception of intestinal distension is evidenced in humans during increase in sympathetic outflow (Table 1) while, in the same experimental condition, somatic sensitivity (cutaneous) appears scarcely affected. Sympathetic activation was elicited in this study by means of lower body negative pressure that produces venous pooling in lower extremities (which activates the sympathetic nervous system directly via cardiovascular reflexes).

### Muscle Spindles

Stimulation of peripheral sympathetic pathways has been shown to profoundly affect the resting discharge rate, as well as the stretch sensitivity of both Ia and II spindle afferents. However the results from different studies performed on various muscles and animal species are not uniform [1,2,4], the mechanisms of such modulator action are still disputed, and so is the functional relevance of the sympathetic action on spindles. In particular, the effects observed in hindlimb muscles of experimental animals were either considered secondary to vasoconstriction or exerted directly on spindles but having small magnitude, therefore scarce functional relevance [2]. By contrast, more recent studies performed on masticatory and neck muscles in several experimental models show that sympathetic activation exerts, in the large majority of muscle spindle afferents, a consistent depression of the response to muscle length changes, possibly preceded by a transient enhancement of variable magnitude. This response consists of a reduction in the ►static and dynamic sensitivity, observed in both Ia and II units innervating bag and chain ►intrafusal muscle fibers. This response was found to be mediated by $\alpha_1$-adrenoceptors and to be independent of sympathetically induced vasoconstriction [2,5]. To the action exerted by the sympathetic outflow on muscle spindle afferents is attributed the sympathetically-induced transient enhancement followed by remarkable decrease in the magnitude of both jaw ►jerk and ►tonic vibration reflex in jaw elevator muscles lasting throughout the stimulation and longer [6]. In fact these effects parallel, in relative magnitude and time course, the ones induced by the

sympathetic stimulation on spindle afferent discharge recorded from jaw elevator muscles. Thus the main action induced by the sympathetic stimulation consists of a considerable decrease in the quality of proprioceptive information. This should impair the ability of motor system both to correct perturbations, i.e., decrease the ►feedback control of muscle length, and to tune the motor program according to current constraints (►feed-forward control of movement).

Besides affecting muscle spindle afferents sensitivity to muscle length changes, sympathetic stimulation also affects their resting discharge, such effect ranging from enhancement to strong depression of firing. Even though the origin of this difference is not clarified, such action is of obvious importance since baseline activity is an important excitatory input that may affect ►muscle tone, through spindle support to α-►motoneurons. The different time course exhibited by the effect on spontaneous discharge rate and sensitivity to stretch suggests that more than one mechanism is involved in the sympathetic action on spindles. Recent findings indicate that intrafusal muscle fibers are among the possible targets of sympathetic innervation. Bombardi et al. [7] report, in rabbit masseter muscle, the presence of sympathetic fibers, visualized by immunohystochemical fluorescent labeling of the noradrenaline-synthesizing enzymes tyrosine hydroxylase and dopamine beta-hydroxylase, along the entire length of the spindles, within the capsule wall, in periaxial fluid space and in close apposition to intrafusal fibers, confirming previous findings obtained, using traditional techniques, on limb muscles [8]. In addition $\alpha_{1a}$-adrenoreceptors are detected at the polar region of a large percentage of spindles, both bag and chain intrafusal fibres [7]. Recent work from the same group demonstrates the presence of $\alpha_{1a}$-adrenoceptors, with the same localization, in spindles of several muscles i.e., trapezius, splenius, triceps (caput longum) and gastrocnemius muscles in rabbits (Bombardi, personal communication). Localization of the $\alpha_{1a}$-adrenoreceptors in the polar regions of the spindles suggests that the sympathetic mediator may modulate the spindle afferent discharge by altering the mechanics of both types of intrafusal fibers.

The functional implications of the sympathetic action on muscle spindle receptors are of considerable interest since this signal contributes to a number of body functions, such as control and coordination of ongoing movements, maintenance of postural control, perception of position and movement of our body (kinaesthesia), and learning of stereotyped movements and motor skills. Therefore, any system able to modulate the spindle receptors is liable to affect those functions. The action of sympathetic innervation on spindle receptors still needs to be confirmed in humans.

### *Pain Receptors*

The large majority of studies agree in showing that, under normal conditions, increase of sympathetic outflow does neither activate nociceptors nor affect their ongoing discharge (see Table 1). However, the sympathetic action may become powerful under pathological conditions, when some "precipitating factor" intervenes, such as peripheral nerve lesions resulting from injury or compression, trauma of soft tissues, inflammatory processes or previous sensitization of the relevant receptors. Under these conditions, in which pain problems are disproportional to the initial injury, some ►nociceptive receptors develop sensitivity to catecholamines, which may initiate or enhance the ongoing discharge [9] (see Table). The reasons suggesting that the SNS system plays a role in certain painful states are the following: (i) the control of the sympathetically innervated structures in the affected area is abnormal (sweating, temperature dysregulation, trophic changes); (ii) pain is exacerbated by emotionally arousing stimuli; (iii) pain is temporarily relieved by sympathetic blockade (α-adrenoreceptors) and is rekindled by injecting small amounts of catecholamines or of α-adrenergic agonists.

It has been hypothesized that this peripheral sympathetic-sensory coupling is one of the mechanisms involved in initiation and maintenance of a symptom defined ►sympathetically-maintained pain, that may be common to several diseases [4,9,10].

## Final Remarks

As reported above, the sympathetic nervous system exerts a widespread modulation of several receptors. It is well known that the central nervous system can control the inflow of sensory information at different spinal and supra-spinal levels, the aim being either to amplify or filter out specific signals, thus selecting the ones that are most relevant in a particular context. It is tempting to speculate that the SNS takes part to this aim/action acting directly at the receptor level, thereby constituting the peripheral branch of a general system controlling and processing afferent information.

# Autonomic Dysfunction

## Definition

Autonomic dysfunction is an impairment of autonomic function which may be caused by disease or degeneration of the central or peripheral nervous system. The effects may be focal or widespread and tend to increase in prevalence with age, affecting the cardiovascular and thermoregulatory systems in particular.

►Autonomic Insufficiency

# Autonomic Effects on Skeletal Muscle

Silvestro Roatta, Magda Passatore
Department of Neuroscience – Section of Physiology, University of Torino, Torino, Italy

## Definition

The autonomic nervous system is generally considered to control "vegetative functions". However, since the end of nineteenth century cathecolamines ("adrenal extracts" at that time) were shown to increase the force developed by skeletal ►muscle twitches in the dog. Besides this ►inotropic action, catecholamines have been shown to affect many other processes at the muscle fiber level that also impact on relevant aspects of muscle function, like fatigability, energy consumption and metabolism. Given that skeletal muscles receive no parasympathetic innervation (with possible exceptions, like the rat masseter muscle in which a vascular parasympathetic innervation is reported), the autonomic effects appear to be exclusively sympathetic in origin, mediated either by the neurally released noradrenaline or indirectly through circulating adrenaline released in the blood by the adrenal medulla. The issue was extensively reviewed by Bowman [1] and is here resumed and updated. The anatomical basis for autonomic effects on skeletal muscles is first introduced, then the different effects are dealt with separately, being grouped in the following categories:

1. Effects on contractility.
2. Effects on excitability.
3. Effects on glucose and protein metabolism.
4. Effects on neuromuscular transmission.

## Characteristics

### Anatomical Basis

Besides innervating blood vessels, post ganglionic unmyelinated sympathetic fibers have also been reported to lay interspersed and in neuroeffective association with skeletal muscle fibers [2]. However, most effects on the skeletal muscle appear to be mediated by the circulating adrenaline rather than by the noradrenaline released by sympathetic fibers. This results from experiments in which the effects observed by local or systemic injection of adrenaline were not reproduced by stimulation of the relevant sympathetic pathways and is explained by the following considerations: (i) among the increasing list of ►adrenergic receptors (ARs) ($\alpha_1$, $\alpha_2$, $\beta_1$, $\beta_2$, $\beta_3$, and relative subtypes), $\beta_2$-ARs mediate most adrenergic effects on skeletal muscle fibers; (ii) at difference from $\alpha_1$-ARs, the ubiquitous vascular receptors mediating vasoconstriction, $\beta_2$-ARs are not located in tight correspondence with sympathetic ►varicosities releasing noradrenaline; (iii) $\beta_2$-ARs are the preferential target of circulating adrenaline, which has for these receptors a much higher affinity than noradrenaline.

$\beta_2$ receptor density on the ►sarcolemma may depend on the ►muscle fiber type and has been reported to be higher in type-I, as compared to type-II. Conversely, $\alpha_1$- and $\beta_1$-ARs have been detected pre-juctionally in the motor endplate (see below) and are usually not found in skeletal muscle fibers. However, exceptions and differences may occur in different muscles and different animal species. For instance $\alpha_1$ effects have

been reported in the rabbit masticatory muscles [3] and in rat muscles, where their expression in the sarcolemma was shown to increase in particular conditions like motor denervation, chronic ipokalemia and aging [1,4]. Finally, cotransmitters of adrenaline like NPY may also play a role [3].

### Effect on Contractility (Inotropic Effect)

Cathecolamines affect the force developed by skeletal muscle fibers, the effects being different depending on the muscle fiber type. The effects on contractility are classically described through the modification exhibited by the muscle twitch: it generally results increased and longer lasting in fast contracting muscle fibres (type-II) while it is decreased and shorter lasting in slow-contracting fibres (type-I) [1]. The potentiating effect on type-I fibres, that in the masticatory muscles was shown to be partly mediated by the noradrenaline co-transmitter NPY [3], was also observed in limb muscles. However, the fact that in limb muscles such effect was observed at relatively high doses of injected adrenaline or at relatively high frequencies of splanchnic sympathetic nerve stimulation (which stimulates secretion of catecholamines from the adrenal medulla) has cast doubts on its actual physiological significance. On the contrary, the inhibitory effect on slow-twitch muscle fibres could be evoked with much lower doses of injected adrenaline, as well as by stimuli reflexly increasing the sympathetic outflow, and is therefore expected to have an impact in physiological conditions [1].

More recently, an increase in twitch amplitude was also described for type-I muscle fibres, in *in vitro* preparations exposed to $\beta_2$ ARs agonists [5]. These experiments led to clarify that the contractility of the muscle fiber can be modulated by controlling the release/reuptake of calcium ions from/into the intracellular calcium store (the sarcoplasmatic reticulum), through the following mechanisms: (i) increased $Ca^{++}$ release from the sarcoplasmatic reticulum mediates the increase in twitch amplitude in both fiber types; (ii) increased $Ca^{++}$ re-uptake in the sarcoplasmatic reticulum decreases the twitch duration (slow fibres only). These effects would be achieved by phosphorylation of both ryanodine receptors and the sarcoplasmic pump regulatory protein *phospholamban*, respectively, via the cAMP-PKA pathway [5]. The same pathway exists in cardiac muscle fibers and contributes to the increase in force and rate of relaxation produced by catecholamines via $\beta_1$ ARs.

From the functional point of view, the potentiation of amplitude and/or duration of the twitch occurring in type-II muscle fibers would result in an increase in the force level developed by ►subtetanic contractions. Interest for these effects has recently emerged in sports physiology where the relevance of the positive inotropic effect and the *anti-fatigue* effect (see below) is investigated to ascertain any possible improvement in muscle performance or endurance by administration of $\beta_2$ agonists. However the most pronounced effect concerns type-I muscle fibers. It generally consists in a weakening of subtetanic contractions, due to the fact that the effect of twitch shortening overcomes the effect of amplitude increase. In response to $\beta_2$-agonists administration the developed force may decrease to less than 40% of the original value, the magnitude of such decrease depending on the experimental setup and on of stimulation frequency of the muscle fibers. The functional implication is not evident in this case. One possible interpretation is that, under the effect of adrenaline, the speed of contraction is privileged, rather than the force, so that slow-twitch (type-I) muscle fibers behave more similarly to the fast-twitch (type-II) fibers. This effect may improve the performance of fast movements in a ►*fight or flight response.*

### Effect on Excitability

Cathecolamines, via $\beta_2$ ARs, potentiate the activity of the ►Na/K pump located in the sarcolemma thus promoting a hyperpolarizing effect. This effect is not consistently observed in resting conditions but may become important in preserving muscle function (force) during exercise. During intense muscle activity a relevant outflow of potassium ions from muscle fibers to the interstitial fluid takes place. The ensuing decrease of concentration gradients across the sarcolemma (particularly at the level of T-tubules) leads to decreased excitability of muscle fibers and impaired force production, and constitutes a major peripheral mechanism of ►muscle fatigue.

An *anti-fatigue* effect of catecholamines has been demonstrated in several *in-vitro* and *in-vivo* preparations; these experiments show that the force level decreased by iperkalemia or fatigue could be partially restored by infusion of adrenaline or of $\beta_2$-agonists (e.g., salbutamol, terbutaline) [6], as well as by electrical stimulation of the lumbar sympathetic chain (Orbeli effect).

It may be worth considering the adrenergic stimulation of the Na/K pump in a systemic perspective. During exercise, the potassium loss from active fibers generally leads to a substantial increase in plasma potassium concentration that may rise from 4 mM to more than 8 mM, depending on exercise intensity and muscle mass involved. It is interesting to observe that, in steady-state exercising muscles, potassium efflux from active fibers is not affected by pharmacological blockade of $\beta_2$-ARs.

This suggests that the Na/K pump in active fibers cannot be further potentiated by the circulating adrenaline, being already stimulated by the locally altered ionic gradients. However, adrenaline may still effectively operate in all non-exercising muscles,

thereby stimulating a general potassium uptake. This attenuates the exercise-induced rise in plasma potassium concentration, thus preserving excitability of active fibers and delaying fatigue. An increased rise in plasma potassium concentration is in fact observed when this action is prevented by β-blockade.

Through the adrenergic modulation of the Na/K pump activity and the control on blood flow redistribution (via α- and β-ARs) the sympato-adrenergic system operates a central control of plasma potassium concentration in exercise [7].

## Effect on Glucose and Protein Metabolism

Adrenaline, again through the $\beta_2$-ARs – cAMP – PKA pathway, modulates important metabolic functions in the skeletal muscle cells, that will be here briefly summarized.

Adrenaline and $\beta_2$-agonists were shown to reduce the release of amino acids (mainly alanine and glutamine) from isolated muscle preparations and to increase muscle mass when orally administered in different animal species. This anabolic effect is specific to striated muscle (smooth muscles are not affected); it appears within two days after $\beta_2$-agonists administration and is attenuated 14 days afterwards, possibly because of β receptors down-regulation. This *protein sparing* was recently shown to be mediated by inhibition of proteolysis (through a mechanisms involving PKA-activation of *calpastatin* which specifically inhibits the proteolytic enzyme *calpain*), although potentiation of protein synthesis may also occur [8].

Cathecolamines promote glucose uptake and glycogenolysis in skeletal muscle, however some of the underlying mechanisms remain unclear.

As for glucose uptake, it is potentiated, particularly by noradrenaline, via unspecified β-ARs (it is debated whether $\beta_3$ receptors are implicated). Adrenaline instead, via $\beta_2$-ARs, antagonizes the insulin-mediated glucose transport. Again, in antagonism with insuline adrenaline inhibits glycogen synthesis and promotes glycogenolysis, this latter process appears to be not particularly relevant in resting muscles, being conditioned to the simultaneous occurrence of muscle activity. These actions, however, result in increased lactate outflow from the muscle fibers; lactate diffuses out of the cells and may be then reconverted to glucose by the liver. These effects may contribute to the adrenaline-induced increase in ►glycemia [9].

The sympatho-adrenal system plays an important role in the processes of storage and release of energy substrates by coherently modulating the activity of skeletal muscles, liver, pancreas and adipose tissue.

## Effects on Neuromuscular Transmission

In addition to the modulation of several intracellular processes, another action of cathecolamines may be of interest in this context, i.e., the modulation of acetylcholine release at the ►motor end plate, through an action exerted on the motor terminal. This presynaptic modulation appears to be (i) rather complex, being mediated by both α- and β-ARs; (ii) difficult to study, given the concomitant postsynaptic effects on cell excitability (see above); and (iii) not particularly relevant in physiological condition, given the intrinsically high reliability and effectiveness of neuromuscular transmission. In fact, the effects of ►sympathomimetics were evidenced under partial curarization, i.e. an experimental model in which neuromuscular transmission is weakened in all motor end plates and blocked in some of them. In this condition both adrenaline and noradrenaline improve the efficacy of neuromuscular transmission, to the extent that neuromuscular blockade is overcome in some fibers (so called *anti-curare* effect) [1]. The hypothesized involvement of β-receptors has been confirmed in recent studies indicating that presynaptic $\beta_1$-ARs may potentiate the postsynaptic effect by increasing synchronization of vesicles exocytosis [10].

## Function

The autonomic nervous system affects several important functions of the skeletal muscle fiber primarily through the action of adrenaline via $\beta_2$ ARs, although other ARs may be implicated in the modulation of neuromuscular transmission and in processes related to glucose uptake. Secretion of adrenaline increases during exercise and most of its actions on muscle fibers can be considered as part of a general strategy aimed at increasing muscle performance in terms of developed force, movement velocity, availability of energy substrates and protection from fatigue. However, it should be taken into account that adrenaline secretion also occurs in stressful conditions, possibly in the absence of relevant muscle activity; in this condition adrenergic effects on skeletal muscle may be inappropriate. A possibly similar situation occurs when $\beta_2$-agonists are systemically administered, e.g., for the treatment of asthma ($\beta_2$-ARs mediate broncho-dilation). No broncho-specific sympathomimetics have been devised, as yet, and a number of side-effects of these drugs, such as ipokalemia (see above), hyperglycemia (see above) and ►tremor, can partly be attributed to activation of $\beta_2$-ARs in skeletal muscles. Increased physiological tremor (in the range 8–12 Hz) due to administration of adrenaline was attributed to its negative inotropic effect on type-I muscle fibers: decreased fusion of subtetanic contractions (see above) implies increased oscillations in force/position in the limbs.

However, the involvement of muscle spindles in physiological tremor was also hypothesized, the oscillations having been attributed to instability of the ►feedback control of muscle length. Catecholamines might also affect this feedback control through their modulating action on muscle spindle receptor activity (►Autonomic control of sensory receptors).

## Synonyms

Terms sometimes used to describe exercise and related phenomena include muscle contraction, muscular work, and physical activity

## Definition

Exercise can be defined as the voluntary activation of skeletal muscles for recreation, rehabilitation, or participation in sport. Since it is possible to evoke muscle contraction via electrical stimulation or segmental reflexes, this definition emphasizes the voluntary component of exercise and CNS involvement in the contractions. Terms like physical activity include exercise as defined above but also voluntary muscular contractions directed toward occupational and other activities of daily living.

Exercise has been categorized as "static," "dynamic," or "intermittent." Static exercise refers to exercise associated with limited muscle shortening, and is the human analog to "isometric" contractions in isolated muscle preparations. Dynamic exercise describes rhythmic shortening and/or lengthening contractions and is exemplified by running or cycling. Intermittent exercise describes things like ball games where variable bursts of activity with varying muscle mass and forces are used. The basic mechanisms that govern the autonomic responses to static, dynamic and intermittent exercise are similar. In this chapter only "static" and "dynamic" exercise will be discussed further.

## Characteristics

### Quantitative Description

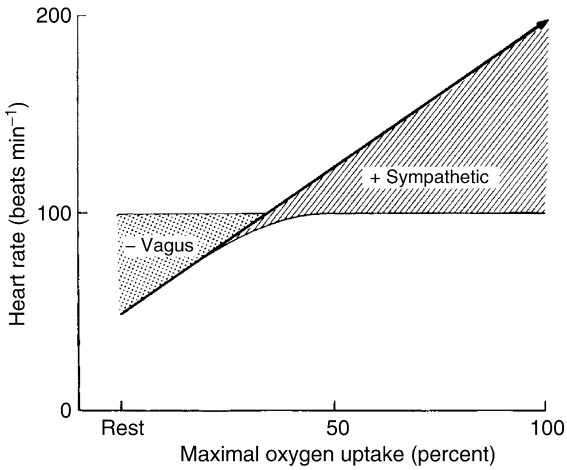
Exercise of all types is associated with several physiological responses governed by the autonomic nervous system:

- An increase in heart rate.
- An increase in blood pressure, especially systolic blood pressure.
- An increase in ventilation.
- Exercise lasting more than a few minutes also evokes autonomic responses directed at metabolism and thermoregulation.

The magnitude of these responses can be highly variable depending on the intensity and duration of the exercise along with subject specific variables. However, the direction of change across conditions is similar.

At the onset of exercise, heart rate (HR) rises instantaneously [1,2]. During heavy or maximal dynamic exercise in the young, values increase from around 60 beats/min at rest to about 200 beats/min. With a static handgrip, heart rate usually rises 10–20 beats per minute (depending on the fraction of maximal voluntary contraction), but with prolonged or fatiguing contractions larger increases occur. The rise in HR from rest to 100 beats/min is mainly due to withdrawal of vagal tone to the heart. As HR increases to values above 100 beats/min, the cardiac sympathetic nerves become increasingly engaged (Fig. 1).

At the onset of exercise there is also an instantaneous rise in arterial blood pressure [1,2]. During dynamic



**Autonomic Function and Exercise.**
**Figure 1** Schematic showing the contributions of vagal withdrawal and sympathetic activation to the rise in heart rate (HR) with exercise. At rest, vagal control of heart rate predominates. As exercise intensity increases to 30–40% of maximal, vagal tone is withdrawn and HR increases to about 100 beats per minute. At this exercise intensity, sympathetic traffic to the heart increases and is responsible for the further rise in HR as exercise intensity increases. (Figure from Rowell, LB: "Human Cardiovascular Control," Oxford 1993.)

exercise, systolic pressure rises due to increases in stroke volume and heart rate that eject more blood into the aorta and large conducting vessels. The effects of dynamic exercise on diastolic pressure are more variable due to vasodilation in the active skeletal muscles. In young healthy subjects and trained athletes diastolic blood pressure does not change or falls. In older subjects and those with conditions like hypertension diastolic pressure can rise with exercise. The net effect of these changes is a modest to marked increase in mean arterial pressure.

During static exercise both systolic and diastolic pressure rise. The rise in systolic pressure is due to increased cardiac output (due primarily to an increased HR) and peripheral vasoconstriction caused by the sympathetic nervous system. Static muscle contractions also compress blood vessels in the active muscles [2,3]. With large muscle mass exercise this causes diastolic pressure to rise. In severe forms of large muscle mass static exercise or during very heavy weight lifting, systolic arterial pressure can rise to values above 300 mmHg.

Like heart rate and blood pressure, ventilation increases instantaneously at the onset of exercise. During heavy dynamic exercise values in excess of 100 L/min can be seen, and in some elite athletes values in excess of 150–200 L/min are common. With static exercise, the rise in ventilation is usually much less.

The autonomic nervous system also maintains metabolic homeostasis during exercise (especially prolonged dynamic exercise), when the metabolic rate can increase by 10-fold or more. This is accomplished by mobilizing fuel from the liver and fat cells via the sympathetic nerves and release of epinephrine and other hormones [4]. During prolonged dynamic exercise core temperature can rise several degrees and engage autonomic thermoregulatory responses that evoke sweating and can cause skin blood flow to rise from very low levels to as much as 5–7 L/min [2].

The main structures that regulate the cardiovascular and respiratory responses are in or near the nucleus of the solitary tract, and for metabolic and thermoregulatory control they reside in the hypothalamus [1–3,5]. These structures receive descending commands from CNS centers (especially the sub-thalamic locomotor center) that are involved in the planning and execution of the contractions.

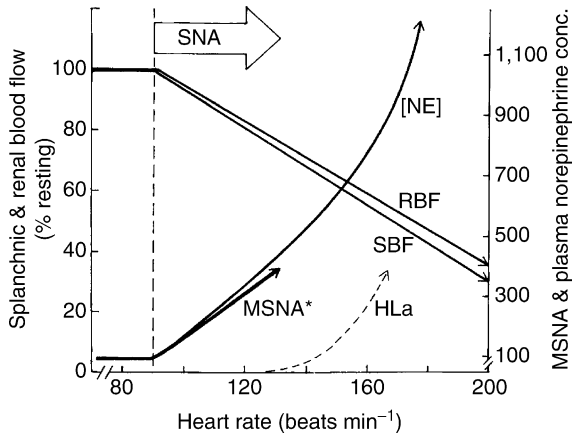
## Lower Level Components

The cardiovascular and respiratory centers receive continuous input from afferents located throughout the body. The primary afferent information affecting cardiovascular function during exercise comes from arterial baroreceptors and chemoreceptors located in the aortic arch and carotid sinus, and carotid body along with group 3 and 4 afferents in the active skeletal muscles [1–3,6,7]. There are also thermal sensors located throughout the body (but most notably in the hypothalamus), and sensory neurons in the hypothalamus also monitor blood glucose [2,4].

## Higher Level Processes

In general, a signal proportional to the central motor command provides "feed-forward" information to the brainstem cardiovascular and respiratory centers (and probably the centers that govern metabolism and thermoregulation). This "central command" evokes the instantaneous increase in heart rate, blood pressure and ventilation seen at the onset of exercise [1,2]. It permits substantial physiological adjustments to be made before there are vast increases in muscle metabolism that might overwhelm traditional feedback regulatory mechanisms. Central command clearly causes:

- Vagal withdrawal from the heart and a rapid increase in heart rate
- An increase in renal sympathetic nerve activity
- An increase in ventilation prior to any changes in arterial blood gases that might be sensed by chemoreceptors
- A resetting of arterial baroreflexes so that blood pressure and heart rate can rise with exercise [7]



**Autonomic Function and Exercise. Figure 2** Schematic representation of how various indices of sympathetic outflow change with exercise intensity. Splanchnic and renal blood flow are 100% at rest and as exercise intensity increases vasoconstrictor outflow to these vascular beds can reduce blood flow to ~30% of resting values. The curvilinear line shows the rise in plasma norepinephrine, (NE) an index of whole body sympathetic activation. The rise NE does not start until exercise intensities become moderate. Muscle sympathetic nerve activity (MSNA) also rises during moderate and heavy exercise. Vasoconstriction in the visceral beds permits a higher fraction of the cardiac output to perfuse the contracting muscles. The rise in MSNA limits blood flow to inactive muscle and restrains metabolic vasodilation to maintain blood pressure. (Figure from [1].)

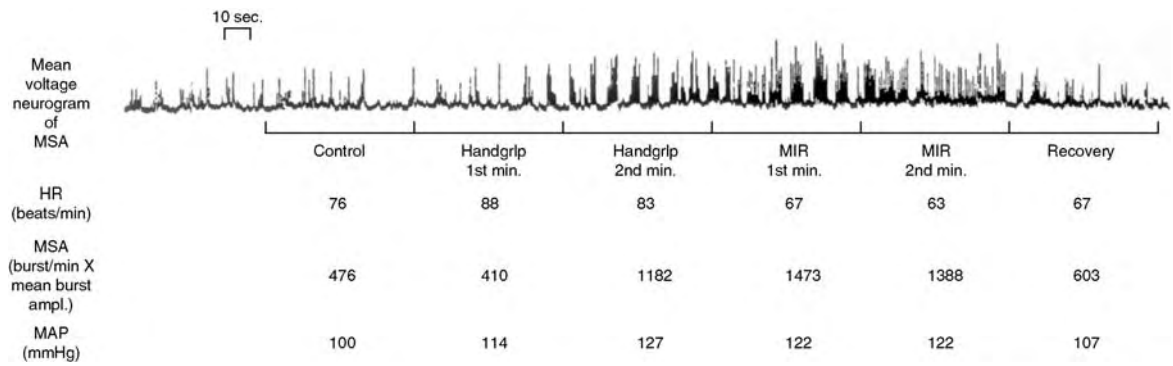
However, central command does not evoke "mass sympathetic" discharge to most organ systems, but provides discrete and targeted changes in autonomic outflow Figure 2 [1–3,5].

## Lower Level Processes

Arterial baroreceptors respond to mechanical deformation in the aortic arch and carotid sinus. Increased deformation results in increased afferent firing and is related to changes in arterial pressure. Changes in arterial blood $pCO_2$ and $pO_2$ are sensed by the aortic and carotid chemoreceptors that are close to the baroreceptors. During mild and moderate dynamic exercise changes in any of the variables sensed by the arterial chemoreceptors are minimal, and it is unclear if these receptors are obligatory for the regulation of ventilation during exercise under most circumstances.

In skeletal muscle group III and IV afferents evoke cardiovascular and respiratory responses based on exercise-induced changes in the skeletal muscle, and thus provide the autonomic nervous system with information about the contracting skeletal muscle [1–3,5,6]. At rest the group III afferents are primarily mechanosensitive and the group IV afferents respond primarily to metabolic stimuli, especially acidosis. However, during exercise chemosensitive afferents can respond to mechanical stimuli and vice versa (Fig. 3).

As blood glucose declines, epinephrine is released from the adrenal medulla and (in conjunction with other hormonal adaptations) mobilizes glucose from liver glycogen and liberates free fatty acids from adipocytes



| | Control | Handgrip 1st min. | Handgrip 2nd min. | MIR 1st min. | MIR 2nd min. | Recovery |
|---|---|---|---|---|---|---|
| HR (beats/min) | 76 | 88 | 83 | 67 | 63 | 67 |
| MSA (burst/min X mean burst ampl.) | 476 | 410 | 1182 | 1473 | 1388 | 603 |
| MAP (mmHg) | 100 | 114 | 127 | 122 | 122 | 107 |

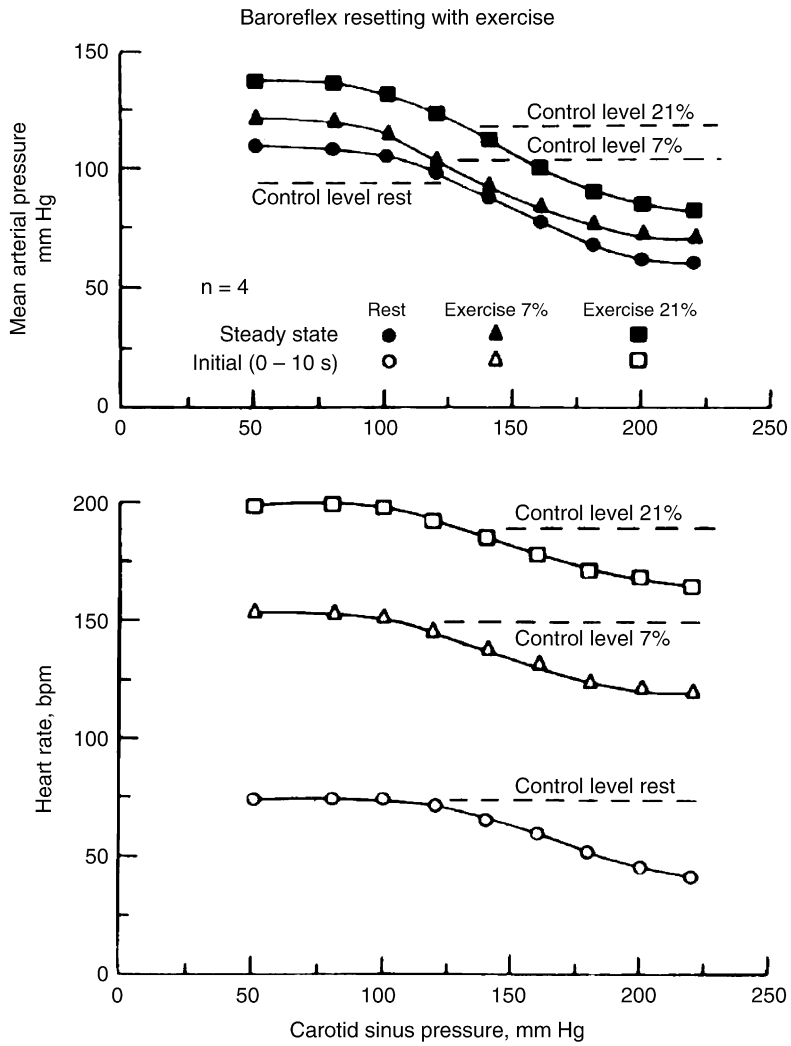
**Autonomic Function and Exercise. Figure 3** Change in Muscle Sympathetic Nerve Activity (MSNA) during a forceful handgrip lasting several minutes followed by muscle ischemia produced by inflation of an arm cuff to supersystolic levels. From rest to exercise there is a rapid rise in HR and blood pressure, however, MSNA does not rise for about a minute. Additionally, blood pressure and MSNA, but not heart rate, remains elevated during the muscle ischemic response (MIR). These data show that central command can cause HR and blood pressure to rise before MSNA is increased. During handgripping, the rise in MSNA is thought to occur when muscle acidosis acts locally to stimulate chemosensitive muscle afferents. This stimulation continues during the MIR when the acidotic metabolites are trapped in the previously active muscles. Experimental paradigms like this have been used to study the interplay between central command and feedback from muscle in regulating the autonomic responses to exercise. (Figure from [3].)

to support muscle metabolism during prolonged heavy dynamic exercise like marathon running.

Temperature sensitive neurons located in the preoptic/anterior hypothalamus monitor central temperature. This area also receives feedback from temperature sensitive afferents throughout the body. When core temperature falls there is an increase in vasoconstrictor activity to skin to conserve heat. When core temperature rises there is a withdrawal of vasoconstrictor activity, followed by activation of sympathetic cholinergic nerves to sweat glands and cutaneous blood vessels [2].

## Process Regulation

The current concept is that central command evokes changes in autonomic outflow that prepare the organism for exercise. However, the old idea of "mass sympathetic discharge" at the onset of exercise has been superseded. In this context, central command is thought to operate in two basic ways [1–3,6,7]. First, central command directly influences the cardiovascular and respiratory centers. Second, it is also thought to re-set feedback mechanisms so that the "operating point" and gain of the response facilitates the physiological

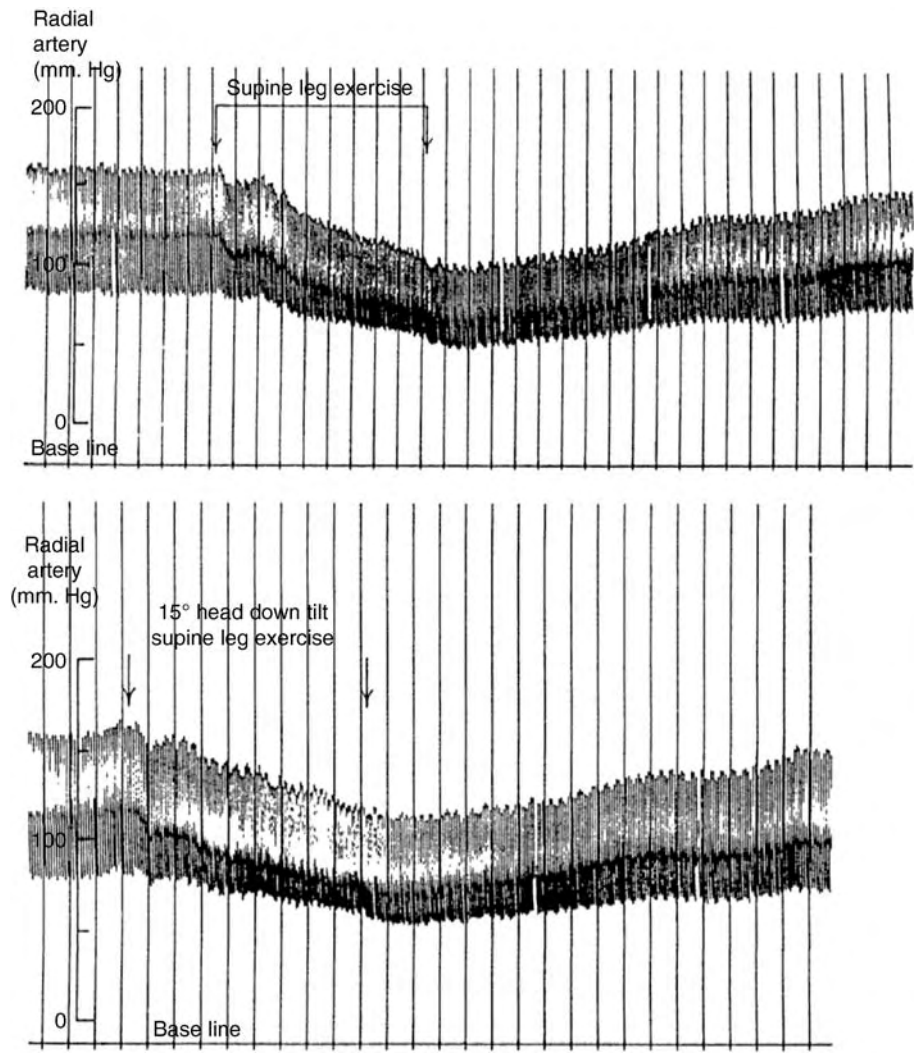


**Autonomic Function and Exercise. Figure 4** Effects of altering pressure in a surgically isolated carotid sinus preparation in a conscious dog during rest and several levels of exercise. This preparation permits manipulation of pressure in the carotid sinus and measurement of systemic responses. A rise in carotid sinus pressure will evoke a baroreflex mediated fall in systemic pressure and HR. By contrast, a fall in carotid sinus pressure will evoke a baroreflex mediated rise in systemic pressure and HR. During exercise, the ability of baroreflexes to regulate arterial pressure and heart rate are maintained, but their operating point is shifted upward so that a rise in BP and HR are permitted. Central command is thought to cause baroreceptor "resetting" in the brainstem cardiovascular centers. (Figure from [7].)

adjustments needed for exercise. For example, blood pressure and heart rate rise during exercise, but recent evidence suggests that baroreflexes operate normally but are re-set to defend a higher blood pressure during exercise [7] (Fig. 4).

The group III and IV afferents contribute to overall blood pressure and respiratory regulation by providing the brain with information about the metabolic and contractile state of the active muscles. When skeletal muscle becomes acidotic, Group IV afferents can evoke a robust pressor (and modest ventilatory) response and signal a "mismatch" between blood flow and metabolism so that blood pressure rises to increase blood flow to the active skeletal muscles [1–3,5,6].

Normally, when core temperature increases by 0.5–1°C there is withdrawal of vasoconstrictor tone to the skin, and then activation of sudomotor (and vasodilator) nerves to the skin. The sudomotor nerves evoke sweating which increases evaporative heat loss and cools the skin. At about the same time there is marked neurally-mediated cutaneous vasodilation which transports heat from the core to the periphery. With exercise, the threshold for sweating and cutaneous dilation is shifted to a higher temperature [1].



**Autonomic Function and Exercise. Figure 5** Total failure of arterial pressure regulation during exercise in a patient with autonomic failure. This patient had undergone extensive surgical sympathectomies for malignant hypertension before antihypertensive drugs were available. In the upper panel blood pressure falls as soon as supine exercise starts and continues to fall as it continues. A second trial of exercise was then attempted with a 15% head down tilt to augment venous return. However, blood pressure also fell during this trial. This demonstrates the essential role of the sympathetic nervous system in redistributing cardiac output and restraining vasodilation in the active muscles to regulate blood pressure during exercise. (Figure from [9].)

With the onset of exercise there is an increase in sympathetic outflow to visceral organs to mobilize glucose from the liver and suppress the release of insulin [4]. Additionally, with heavy, large-muscle-mass exercise, epinephrine is released from the adrenal medulla and also contributes to these and related responses. During prolonged, moderate exercise, these responses are more modest, and are important after one or two hours of exercise when glucose homeostasis is threatened by depletion of liver and intramuscular glycogen.

### Function

The overall function of the autonomic nervous system during exercise is to maintain whole body homeostasis in the face of potentially huge increases in skeletal muscle metabolism. With static exercise fuel for skeletal muscle and temperature regulation are not major problems, and the respiratory consequences are generally not limiting. The main problem is that high skeletal muscle forces compress blood vessels to the active muscles and contribute to skeletal muscle acidosis. A combination of relative or absolute skeletal muscle underperfusion and high levels of metabolic demand lead to autonomic responses designed to increase arterial blood pressure, and hence blood flow to the active muscles.

With large muscle mass dynamic exercise, skeletal muscle metabolic activity can increase to 10-fold in untrained healthy subjects and up to 20-fold in trained athletes. The first physiological "problem" is that there is a marked (up to 50- to 100-fold) vasodilation in the active skeletal muscles and without vasoconstriction of visceral organs, increases in heart rate, and some sympathetic restraint of metabolic vasodilation in the active skeletal muscles blood pressure will fall [1,2,8]. Additionally, if there is not a prompt and adequate increase in minute ventilation, potentially lethal changes in blood gases might occur. So, the increase in minute ventilation (probably evoked largely by central command) is essential to avoid exercise-induced asphyxia. A third main problem posed by dynamic exercise to homeostasis is thermoregulation.

However, when a large increase in skin blood flow is superimposed on the rise in skeletal muscle blood flow with exercise the vasodilation can threaten arterial pressure regulation [2].

### Pathology

There are many pathophysiological conditions associated with the autonomic nervous system that influence the physiological adjustments to exercise. Figure 5 shows the fall in blood pressure seen in patients with autonomic failure [9]. In these patients the sympathetic nerves do not restrain blood flow to the active muscles and visceral organs and exercise tolerance is severely limited. By contrast, in congestive heart failure, there is augmented sympathetic outflow to muscle at rest and during exercise, contributing to skeletal muscle underperfusion and limiting exercise tolerance.

### Therapy

Endurance exercise is a common and effective therapy for a variety of "lifestyle" related diseases including: hypertension, diabetes, dyslipidemia, obesity, and rehabilitation from heart attack. Exercise is also a key anti-aging strategy. While there are many beneficial effects of regular exercise, at least some are likely to relate to improved autonomic control of heart rate and blood pressure.

# Autonomic Function in Space

Tadaaki Mano
Gifu University of Medical Science, Seki, Gifu, Japan

### Synonyms

Neurovegetative function in outer space; Sympathetic and parasympathetic nerve activity in microgravity

## Definition

Autonomic function, also called neurovegetative function, is essentially important to regulate vital functions in humans and animals. This function is mainly dependent on the autonomic nervous system being composed of the sympathetic and parasympathetic nervous system. The autonomic nervous system regulates different kinds of vital organs and organ systems in the living body, including heart, blood vessels, sweat glands, adrenal gland and other hormone secretory organs, gastrointestinal tract, genitourinary organs, etc., by automatically and involuntarily using complex central commands and reflex mechanisms. This system plays indispensable roles in maintaining the homeostasis of blood pressure, blood glucose level, body temperature, and body fluid volume. Some of the autonomic functions are important for the maintenance of homeostasis of blood pressure and body fluid volume against terrestrial gravity. Gravity-dependent autonomic function should be altered in ►microgravity in space to adapt to this unusual condition. Autonomic function in space has been studied in Skylab, Spacelab, and more recently in ►Neurolab, using the space shuttle Columbia launched by NASA in USA [1–3], as well as in the Russian space station Mir [4]. This function is going to be investigated in the International Space Station, and also in interplanetary flights, for example to Mars, in the future. The same function has also been studied using various ground-based simulations of microgravity including ►parabolic flight [5], lower body positive pressure [6], head-out water immersion [7], dry immersion [8] and head-down bed rest [9].

## Characteristics

### Quantitative Description

Autonomic function has been evaluated in the living body using several different methods. Indirect and direct methods have been used for the quantitative evaluation of autonomic function. One of the indirect methods is to determine the plasma level of noradrenaline that is secreted at ►sympathetic nerve terminals. The plasma level of noradrenaline has been used as a good index of overall sympathetic nerve activity. More recently, noradrenaline spillover measurement became available to assess sympathetic nerve function in the organ levels. Another method often used is power spectral analysis of heart rate and blood pressure variabilities. Heart rate and blood pressure are modulated depending on sympathetic and parasympathetic neural regulation. Power spectral analysis of the heart rate reveals low (around 0.1 Hz) and high frequency (around 0.25 Hz) peaks. High frequency peaks in the power spectrum of heart rate variations is dependent on respiration and is considered to represent cardiac parasympathetic (vagal) nerve activity. The value of high frequency power divided by low frequency power is considered to represent cardiac sympathetic nerve activity; however, the assessment of this value is still under discussion. On the other hand, low frequency peaks in the power spectrum of blood pressure is related to so-called Mayer rhythm, and is considered to represent vasomotor sympathetic nerve activity. Based on these power spectral analyses of heart rate and blood pressure, quantitative analysis of autonomic functions has been possible in human subjects. In animals, direct recordings of sympathetic and ►parasympathetic nerve activity allows us a more precise and quantitative evaluation of autonomic function. Direct measurement of sympathetic nerve activity has also become possible in humans using a technique called ►microneurography. Microneurography has enabled us to record sympathetic nerve activity leading to muscle (►muscle sympathetic nerve activity; MSNA) and skin (skin sympathetic nerve activity; SSNA) from human peripheral nerves. Unfortunately, direct evaluation of parasympathetic nerve activity is not yet possible in humans, Autonomic function in space has been analyzed in humans using these different methods including measurement of the plasma level of noradrenaline, noradrenaline spillover measurement, power spectral analysis of heart rate and blood pressure, as well as microneurography.

### Higher Level Structures

The autonomic nervous system is composed of higher and lower level structures. Higher level structures include cerebral cortex, hypothalamus and brainstem. Hypothalamus plays a particularly important role in central control of autonomic function. Functions of these higher structures have been studied on earth, but poorly in space. These problems are expected to be resolved by future research under microgravity conditions in space.

### Lower Level Components

Lower level components of the autonomic nervous system include spinal cord, peripheral nerve, ►peripheral receptors and target effector organs. The descending commands from upper structures descend through brainstem and spinal cord to control target effector organs through peripheral sympathetic nerve with adrenergic α and β receptors, as well as parasympathetic nerves with cholinergic receptors. Peripheral ►target organs, also called effector organs, include pupils, heart, blood vessels, sweat glands, hormone secretory glands, gastrointestinal tracts, and genitourinary organs, etc., and react to efferent neural signals through peripheral receptors to maintain functional homeostasis against changes in environmental condition. Changes in efferent neural signals in peripheral sympathetic nerve leading to skeletal muscle (muscle sympathetic

nerve activity; MSNA) in humans have been studied using microneurography in ►simulated microgravity on the ground and also in space. MSNA was suppressed during exposure to short-term simulation of microgravity (parabolic flight [5], lower body positive pressure [6], and head-out water immersion [7]), but was enhanced after exposure to long-term simulation of microgravity (dry immersion [8], ►head-down bed rest [9]) and also after spaceflight of 17 days [1]. A lack of enhanced MSNA response after head-down bed rest of two weeks induced orthostatic hypotension.

## Structural Regulation

Structural regulation of the autonomic nervous system depends not only on descending commands from central structures, but also on different kinds of autonomic reflexes being composed of peripheral afferent (vagal and somatosensory) and efferent (sympathetic and parasympathetic) nerves, as well as reflex centers in spinal cord, brainstem and/or cerebral cortex. Autonomic reflexes play essential roles in maintaining homeostasis in the living body against changes in environmental conditions, including gravitational stress. For example, ►baroreflex is essentially important to maintain blood pressure homeostasis against terrestrial gravity. Changes in baroreflex and its components were studied in rats after exposure to spaceflight (Neurolab). The baroreflex sensitivity became lower with fewer unmyelinated nerve fibers, lower contraction ability and tension of the aorta, and a reduced number of smooth muscle cells in the aorta compared to preflight controls [3].

## Function

The function of the autonomic nervous system is highly complicated. Some of the autonomic functions are gravity-dependent. Gravity-dependent functions are more influenced by changes in gravitational loading and unloading. Some functional changes of the autonomic nervous system in space are comparable to age-related changes in autonomic function. For example, increases in basal MSNA after exposure to simulated (head-down bed rest) and real microgravity in space is similar to age-related changes in MSNA [10]. The MSNA increase induced by exposure to microgravity and aging may be related to similar compensatory mechanisms for changes in fluid volume, baroreflex, blood vessel and/or its receptors.

## Pathology

Different kinds of autonomic dysfunction occur in space. The autonomic disorder that appears at the early phase of spaceflight is ►space motion sickness. This disorder resembles motion sickness on earth, with symptoms such as nausea, vomiting, loss of appetite, vertiginous sensation, head heaviness, etc. Space motion sickness is caused by abnormal vestibulo-autonomic reflex related to brainward fluid shift and/or mismatching among sensations of different modalities, i.e., visual, vestibular and somatosensory information. Another important autonomic disorder is cardiovascular deconditioning in space. This deconditioning is induced by many factors including ►headward fluid shift, loss of blood volume, changes in baroreflex, changes in blood vessels and its receptor, loss of muscle pumping due to leg muscle atrophy and so on. Cardiovascular deconditioning is a kind of adapted condition to microgravity. The problem occurs when astronauts return to the earth. They often experience ►orthostatic intolerance with hypotension when standing. Orthostatic hypotension is one of important post-spaceflight dysfunctions in the human body that maintains upright posture against terrestrial gravity. The cause of post-flight orthostatic intolerance has been discussed and several hypotheses have been proposed; (i) reduced circulatory plasma volume due to fluid shift, (ii) reduced vascular responsiveness to sympathetic stimulation, (iii) cardiac hypofunction, and (iv) altered baroreflex and cardiopulmonary reflex.

## Therapy

For the therapy of space motion sickness, drugs used for motion sickness on earth such as antihistamine can be administered. Biofeedback treatment is also applicable for this disorder. To prevent post-spaceflight orthostatic intolerance, in-flight exercise and lower body negative pressure loading have been recommended. Water and salt intake before landing is also effective to prevent orthostatic intolerance. Artificial gravity applying short radius centrifuge is being developed to prevent orthostatic intolerance after long-term spaceflight. As medical therapy, a selective α-adrenoreceptor agonist midodorine hydrochloride and a peripheral noradrenaline competitor amezinium metilsulfate can be used for the treatment of orthostatic hypotension.

# Autonomic Ganglia

Elspeth McLachlan
Prince of Wales Medical Research Institute and the University of New South Wales, Randwick, NSW, Australia

## Synonyms

Sympathetic ganglia; parasympathetic ganglia

## Definition

Signals from the CNS to all peripheral tissues except skeletal muscle are transmitted, and in some cases modulated, within autonomic ganglia. Autonomic ganglia are aggregations of neurones that lie along peripheral nerve trunks where synapses are made by the axons of preganglionic neurones projecting from the brainstem and spinal cord.

## Characteristics

### General Description

The autonomic (Cross Ref) and somatomotor (Cross Ref) systems differ in that there is at least one autonomic synapse between the outflow from the central nervous system and the target organ. These synapses occur in swellings ("ganglia") along peripheral nerve trunks where the cell bodies of autonomic neurones aggregate during development. The ganglia differ somewhat between the divisions of the autonomic nervous system. These divisions were defined by John Langley at the end of the nineteenth century, primarily on anatomical grounds. Sympathetic preganglionic neurones lie in the intermediate zone of the thoracic and upper lumbar spinal cord, whereas ►parasympathetic preganglionic neurones lie in the cranial nerve nuclei and in the intermediate zone of the sacral spinal cord. ►Ganglia of the ►enteric nervous system are located within nerve plexuses in the gastrointestinal tract (cross ref to Enteric NS): the effects of the central nervous system on the gut are mediated via axons of sympathetic and parasympathetic origin, i.e., the enteric nervous system is a target of the other divisions.

Sympathetic and parasympathetic ganglia are mainly located separately. Preganglionic neurones project their axons in a segmental ventral root or in a cranial nerve to reach their target ganglia. Neurones within the ganglia ("ganglion cells," "postganglionic neurones") have axons projecting to specific functional targets, largely without any somatotopic organization. In a few cases, as in the pelvic ganglion of the male rat [1], sympathetic and parasympathetic ganglion cells intermingle in a single ganglion. The postganglionic axons project to their target organs in the peripheral nerve trunks.

Autonomic and sensory ganglia have a common origin in the neural crest, and share dependence on nerve growth factor(s) for survival during development and for maintenance in the adult [2]. Axotomy without regeneration leads to significant loss of both sympathetic and small sensory neurones. (Cross Ref to Neurotrophins and Degeneration/regeneration) The capillaries of these ganglia lack a significant barrier from the blood so that circulating hormones and toxins have ready access to modify neurones and synaptic behavior.

### Quantitative Description

The innervation of all peripheral tissues except skeletal muscle fibers is provided by autonomic pathways. There are many hundreds of thousands of autonomic neurones located in peripheral ganglia, which amplify spatially the signals emanating from the central nervous

system and, in some cases, modify the signals via feedback from the target tissue. Many of the properties of ganglia have been summarized previously [3] and only newer information is referenced here.

## Higher Level Structures

Sympathetic paravertebral chain, sympathetic prevertebral ganglia, parasympathetic ganglia.

## Lower Level components

### *Functional Anatomy of Autonomic Pathways*

*Sympathetic* ganglia are organized in two ways:

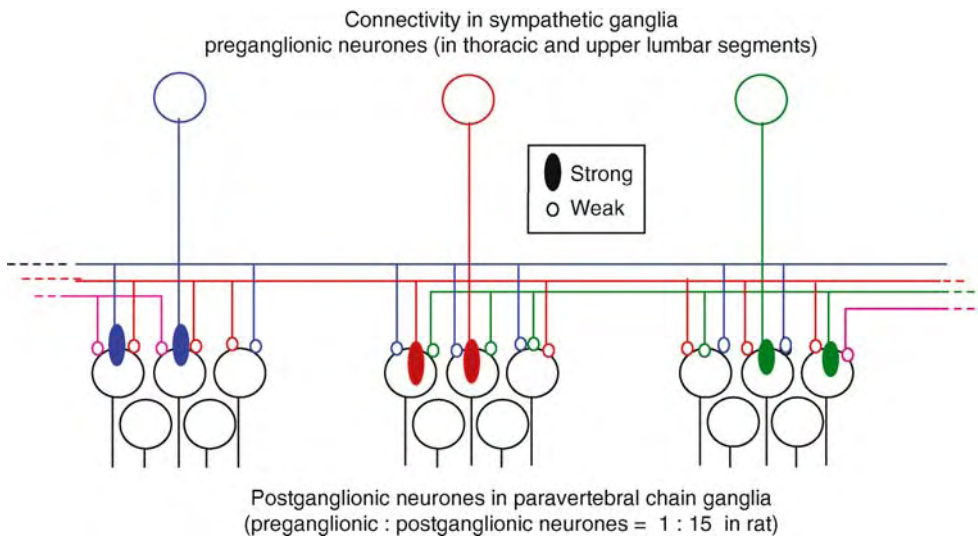
1. Bilateral paravertebral "chains" dorsal to the aorta extend to the base of the skull rostrally (to the superior cervical ganglion, SCG) and to the fused coccygeal ganglia (the ganglion impar) caudally. The segmental ganglia form beaded structures on either side that are more or less separate but often fuse at lumbar and sacral levels. Adjacent segmental ganglia may be fused (e.g., SCGs represent all cervical segments). Paravertebral ganglia are primarily involved with the innervation of blood vessels, sweat glands and erector pili in the trunk and limbs.

The neurones in each segmental ganglion project their axons to peripheral nerves via a grey ramus (reflecting the lack of myelination of postganglionic axons) or to the viscera via the splanchnic nerves. Each segmental ganglion between T1 and the most caudal sympathetic output for that species receives preganglionic axons via a white ramus (most preganglionic axons are myelinated). The preganglionic axons branch rostrally and/or caudally along the chain at thoracolumbar levels, so that each preganglionic axon forms synapses in several adjacent chain ganglia (Fig. 1), whereas cervical and lumbar chain ganglia receive axons arising from the rostral and caudal ends of the spinal outflow, respectively.

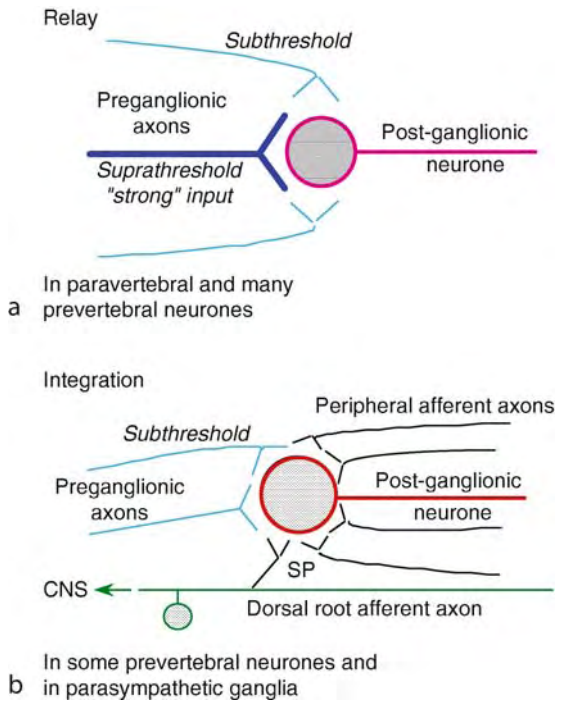
2. The preganglionic axons to the abdominal viscera cross the paravertebral chain in the splanchnic nerves which project to the prevertebral ganglia (e.g., coeliac-superior mesenteric and hypogastric ganglia). Postganglionic axons from these large ganglia project along the visceral nerves to the gastrointestinal tract and other viscera.

Paravertebral ganglia contain only preganglionic terminals, postganglionic neurones and associated supporting glia, with occasional "paraganglion cells" (small intensely fluorescent (SIF) cells) which have no axon but may release catecholamines into the vasculature. In contrast, prevertebral ganglia also contain the terminals of axons from enteric afferent neurons. Together with collateral branches of peptidergic primary afferent axons, these inputs excite ganglion cells involved with the inhibition of motility and secretion (Fig. 2, [4]). Finally, the sympathetic innervation of the enteric nervous system involves presynaptic modulation of enteric synapses rather than direct synapses on enteric neurones.

The *parasympathetic* ganglia project largely to cranial and visceral organs (not the limbs) and are less



**Autonomic Ganglia. Figure 1** Connectivity in sympathetic ganglia of the thoracic paravertebral chain. Preganglionic axons arising in each spinal segment pass into the chain where they form synapses with postganglionic neurones. Synapses are either suprathreshold (*"strong"*) or subthreshold (*"weak"*). Preganglionic axons tend to form strong synapses in the corresponding segmental ganglion. They send collateral branches to adjacent segmental ganglia where they generally form weak synapses. The weak synapses hardly ever contribute to the postganglionic discharge, but they can grow and take over the connection if the strong axon disappears (after e.g., injury to the spinal cord).



**Autonomic Ganglia. Figure 2** Function of synaptic transmission in ganglia. Transmission is by one of two mechanisms: (a) In most sympathetic ganglia, only one (occasionally two) of many preganglionic inputs activate the postganglionic cell, acting to relay precisely the CNS command via a suprathreshold cholinergic input. (b) In some prevertebral neurones and in parasympathetic ganglia, the postganglionic neurone integrates subthreshold information from many cholinergic inputs that arise both centrally and peripherally. Peptides such as Substance P (SP) released from collaterals of primary afferents act to potentiate the effects of the cholinergic inputs from other pathways by decreasing the conductance of the postganglionic cell.

organized. They resemble enteric ganglia in consisting of small clusters of neurones adhering to or lying within the walls of the viscera, e.g., salivary gland, heart, pancreas, bladder. Most of these ganglia contain sensory somata and interneurons as well as the postganglionic neurones that project to the target tissue. Thus, they have all the necessary components for reflex activity, although the precise function of the reflexes is largely unknown. The signals in parasympathetic pathways are more likely to be modified before they reach their targets than those in the sympathetic paravertebral chain (Fig. 2). Finally, parasympathetic neurones supplying the gastrointestinal tract directly innervate enteric neurones.

### *Structure of Autonomic Ganglion Cells and their Synapses*

Sympathetic neurones have large somata (~20–50 μm in diameter) and 0 to >20 dendrites that are relatively thin and sometimes varicose. The dendrites extend up to 500 μm from the soma (Fig. 3). The number of dendrites is proportional to the number of inputs that the neurone receives. Synaptic contacts (<1 $\mu m^2$) are made randomly by the varicosities of input neurones at a low density (<1/100 $\mu m^2$) over the soma, and dendrites and adjacent synapses can arise from distinct inputs [5]. About 50% of varicosities do not contact a ganglion cell, even with an intervening glial process. The number of synaptic contacts on a single guinea pig sympathetic paravertebral ganglion cell with ~10 dendrites is ~100. In contrast, parasympathetic neurones are usually monopolar and tend to be small with synapses that arise from one preganglionic axon, sometimes together with other peripheral inputs.

## Higher Level Processes

### *Connectivity*

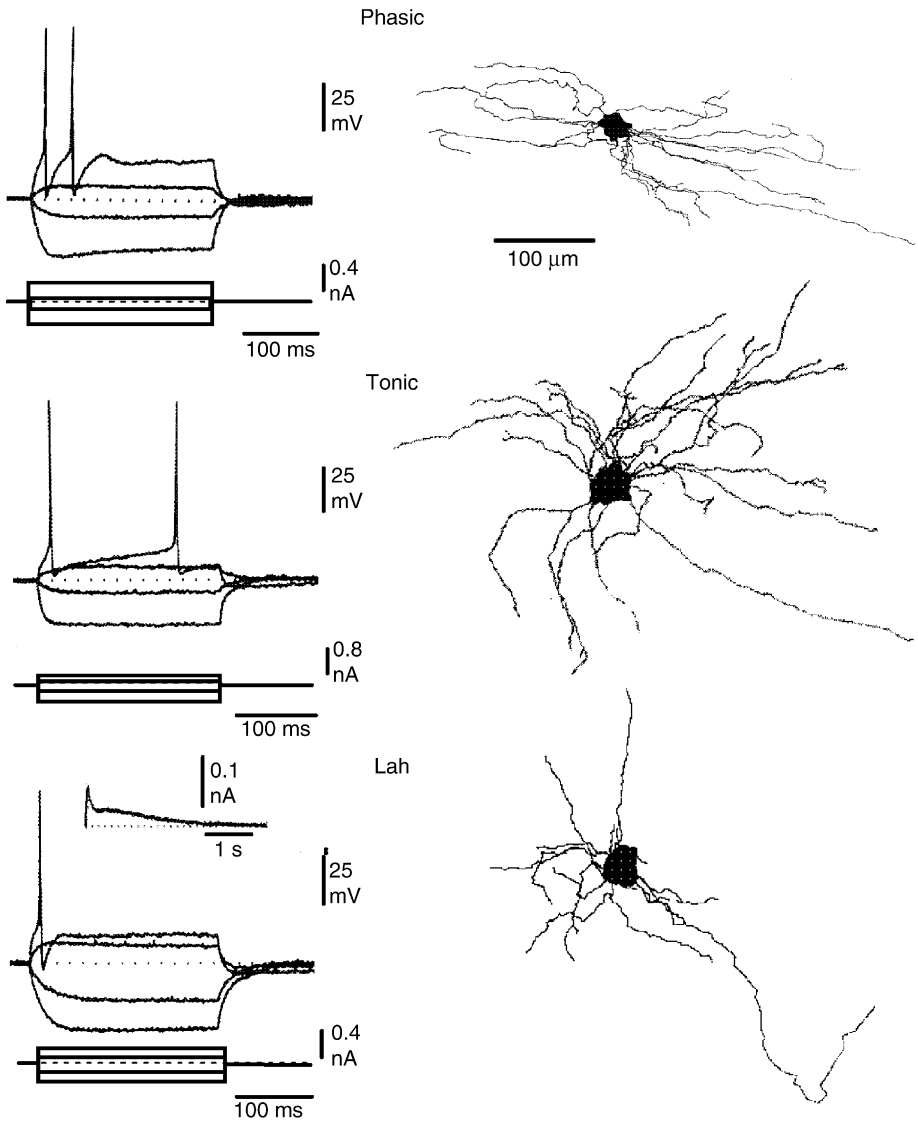
In both autonomic divisions, each preganglionic axon innervates a number of ganglion cells (divergence), while most ganglion cells receive synaptic inputs from multiple preganglionic axons (convergence).

1. *Divergence* is probably more important, at least in paravertebral ganglia, as only one (rarely two) of the several inputs is involved in discharging the postganglionic neurone. This "strong" input has a large safety factor for transmission, like the skeletal neuromuscular junction. The remaining inputs rarely summate due to the low firing frequencies of individual preganglionic axon. Thus, activity in each sympathetic preganglionic neurone discharges many postganglionic neurones (up to >200 or more in humans), amplifying the signal spatially and distributing it widely to the multiple innervated target tissues. Divergence is much less in parasympathetic ganglia (1: <10).
2. *Convergence* is essential for ganglion cells that integrate information from sensory and interneurons with preganglionic signals within sympathetic prevertebral and parasympathetic ganglia. The synaptic events must summate before these neurones discharge.

## Lower Level Processes

### *Synaptic Transmission*

Transmission in autonomic ganglia occurs via the ►quantal release of ►acetylcholine (ACh) from the preganglionic axons. These interact with nicotinic receptor channels (nAChR) composed of five subunits (α3, α5, α7, β2, β4 in different combinations), as at the skeletal neuromuscular junction. The α3/β4 heteromultimer is the main ganglionic nAChR, and various specific drugs antagonize the synaptic channels by both competitive and open-channel block. Single quanta produce ~0.1 nA peak inward postsynaptic current, whereas the strong input generates a synaptic current of 1 to >10 nA, reflecting the action of between



**Autonomic Ganglia. Figure 3** Three major classes of sympathetic ganglion cell can be distinguished in guinea pig ganglia by their discharge pattern when depolarized just above suprathreshold and by their distinctive morphology. The discharge depends primarily on the predominant expression and voltage-dependence of M-type K+ channels (phasic neurones), A-type K+ channels (tonic neurones) and a slow Ca-activated K+ conductance (LAH or long-after hyperpolarizing neurones; the conductance takes the time course of the current shown in the inset). The neurones shown are examples close to the average morphologies in terms of soma size, numbers and length of dendrites. Modified from Boyd et al., *Journal of Comparative Neurology* 369:372–387 (1996).

10 and >100 quanta. As this is similar to the number of synaptic contacts, it is likely that each contact releases at most one quantum and that there is a high probability of release. Subthreshold "weak" inputs release only a few quanta, although these also arise with a relatively high probability (>0.5), presumably from a limited number of varicosities. The synaptic current decay reflects average channel lifetimes of ~5 ms and ~25 ms, arising from the average duration of bursts of openings of two groups of nAChR channels.

The subtypes of voltage-dependent $Ca^{2+}$ channel that are involved in ACh release from preganglionic terminals vary between species, but are usually multiple. They also vary between inputs to the same neurone. For example, in the guinea pig, ~40% of transmitters released from a strong preganglionic input results from $Ca^{2+}$ influx through N-type channels, while the rest involves another channel (R-type, resistant to blockade by known antagonists). However, weak inputs to the same cell utilize N-type (35%), R-type (25%) and P-type (40%) channels

[6]. Sympathetic and parasympathetic inputs impinge on some guinea-pig pelvic neurones, but only the parasympathetic pathway is sensitive to N-type antagonists [7]. Across all ganglia, a major part of ganglionic transmission is resistant to selective $Ca^{2+}$ channel antagonists.

The postsynaptic nAChR channels permit the entry of both $Na^+$ and $Ca^{2+}$ ions, depolarizing the neurone to a threshold within a few ms. In the case of strong synapses, this leads to a postganglionic action potential. The weak post-synaptic potential lasts 30–100 ms because of the large input time constant of the ganglion cells (20–80 ms). Although this should assist the temporal summation of weak inputs, this rarely occurs as individual preganglionic axons discharge at <1.5 Hz. Even though axons in e.g., vasoconstrictor pathways fire with cardiac and respiratory rhythms, the low average frequency means that they rarely fire in consecutive cycles, so that the opportunity for summation is limited. Thus, the strong inputs dominate in firing the postganglionic cell, and the ganglia simply relay signals without modification in e.g., vasoconstrictor, pilomotor and sudomotor pathways but not in prevertebral ganglia (*see below*).

Evidence that synapses formed between cultured sympathetic neurones use adenosine 5′-triphosphate (ATP) has led to the idea that ATP contributes to synaptic transmission in normal autonomic ganglia. However, the evidence is against this at normal connections between preganglionic and postganglionic neurones [8], although it appears to be true for a subset of synapses in the enteric nervous system.

In addition to the preganglionic inputs, the synapses formed by peripheral afferent terminals in sympathetic prevertebral and parasympathetic ganglia are also ►cholinergic and utilize nAChRs, but these synapses release only a few quanta with a very low probability. Thus, individual axons release intermittently during repetitive stimulation, possibly due to a limited expression of synaptic proteins [9]. However, a barrage of weak synaptic potentials is generated during gut distension. At the same time, peptidergic primary afferents release Substance P within the ganglion. The activation of a variant NK-1 receptor on some ganglion cells decreases $K^+$ conductance, depolarizing the membrane, enhancing the concurrent weak synaptic potentials and triggering action potentials. This integrative function of ganglia occurs only in the extrinsic control of visceral motility and secretion.

### Neuronal Excitability and the AHP

The postganglionic action potential is readily blocked by tetrodotoxin leaving a residual inward $Ca^{2+}$ current. $Ca^{2+}$ entry during the action potential produces an afterhyperpolarization (AHP) lasting several hundred ms, which may be enhanced by $Ca^{2+}$ entry through nAChRs. The source of $Ca^{2+}$ to activate the underlying $K^+$ channels appears very localized. $Ca^{2+}$ entry through L-type channels activates Ca-dependent ►BK channels to determine the early peak of the AHP, while $Ca^{2+}$ entry through N-type channels activates ►SK channels that underlie the prolonged phase [10]. A small proportion of neurones also have a very slow Ca-dependent $K^+$ conductance dependent on Ca-induced $Ca^{2+}$ release. The long AHP limits the ability of the postganglionic neurone to fire at high frequency and may block inputs that are just suprathreshold at resting potential.

### Phenotypes of Autonomic Neurone

Sympathetic ganglion cells have been differentiated on the basis of their discharge pattern (phasic or tonic or with a long AHP), their expression of neuropeptides and of $K^+$, $Na^+$ and $Ca^{2+}$ channels and their morphology (Fig. 3).

Different sympathetic phenotypes have distinct distributions between ganglia and targets and have been identified in several species. Similarly, postganglionic neurones in parasympathetic ganglia can be distinguished from their companion neurones. The full range of this diversity has yet to be described, but clearly reflects the expression of distinct functional autonomic phenotypes.

## Function

Autonomic ganglia contain cholinergic synapses that either relay the central (preganglionic) signal directly to the target organ or, in other pathways, integrate central and peripheral inputs to provide control of visceral targets. The characteristics of synaptic transmission have been well defined, showing species, strain and pathway diversity in the subtypes of $Ca^{2+}$ channel and the subunit composition of nAChRs involved. Distinct neuronal phenotypes characterize different functional pathways.

# Autonomic Hyperactivity

## Definition

Autonomic hyperactivity may manifest as sympathetic hyperactivity, parasympathetic hyperactivity or both.

These most often occur in the context of acute brain injury resulting in loss of inhibition or irritation of excitatory foci within the central autonomic network.

Centrally mediated sympathetic hyperactivity is also seen in chronic spinal cord injury (Autonomic dysreflexia).

Sympathetic or parasympathetic hyperactivity are also occasional features of Guillain-Barré syndrome.

Patients may present with extraordinarily high blood pressure and heart rate – even a doubling of normal values – or conversely hypotension and bradycardia where vagal hyperactivity predominates.

These and other symptoms, such as salivary and bronchial hypersecretion, may place patients at immediate risk of cardiac or respiratory failure.

►Autonomic Insufficiency
►Guillain-Barré Syndrome

# Autonomic Insufficiency

## Synonyms

Autonomic failure

## Definition

Autonomic insufficiency refers to autonomic output which is not adequate to meet homeostatic needs. In clinical practice, this most often refers to syndromes in which there is widespread failure of autonomic output due either to central or peripheral disease.

## Characteristics

Autonomic insufficiency occurs in a great many disorders and so the spectrum of dysfunction is broad and individual presentations are varied. Some diseases cause symptoms throughout the body, while others appear restricted to particular organs [1]. Autonomic insufficiency may appear as a congenital disorder, and a number of inherited syndromes have been identified [2]. These include the hereditary sensory and autonomic neuropathies (HSANs), such as familial dysautonomia (FD). While such disorders are relatively uncommon, in later life attenuation of autonomic output occurs with increasing prevalence, either as a component of senescence (►Ageing) or secondary to other disease processes. Most often, autonomic insufficiency presents clinically as orthostatic intolerance (►Orthostatic intolerance) associated with syncope or presyncope. Other common complaints are anhidrosis (►Sweating disorders), impaired thermoregulation, impaired gastrointestinal motility, urinary dysfunction and impotence.

## Quantitative Description

The impact of autonomic diseases cannot be quantified in broad statements. In part, this is due to the insidious nature of many of these disorders which makes diagnosis problematic. Additionally, autonomic insufficiency is most often secondary to other disorders whose own prevalences may be changing rapidly due to the evolution of preventative and management strategies. Nonetheless, a few examples will serve to illustrate the importance of autonomic insufficiency from a global perspective. Orthostatic hypotension (orthostatic intolerance), the most common clinical presentation in autonomic insufficiency is defined as a fall of at least 20 mmHg in systolic blood pressure or at least 10 mmHg in diastolic blood pressure within 3 min of assuming an upright posture. The prevalence of this complaint increases with age such that, depending upon the population surveyed, it may be so common as to be the norm. Furthermore, its occurrence correlates with multiple drug use [3], another phenomenon which is on the rise, especially in more developed nations with aging populations. Similarly, in diabetes mellitus, estimates of the prevalence of autonomic abnormalities range from a few percent to the overwhelming majority of patients tested [4]. While there is great variation in the prevalence of diabetes mellitus, worldwide it is increasing so that autonomic complications may be

expected to be quite common in many societies in the near future. This contrasts with Chagas disease, which is largely restricted to Central and South America and has historically been a very important cause of disability and death [5]. At the beginning of the 1990s, Chagas disease, caused by the parasite *Trypanosoma cruzi* and spread by a number of insects, effected millions of people in endemic areas, with new cases numbering in the hundreds of thousands each year, and deaths in the tens of thousands. In some areas with vigorous vector control the incidence has dropped in a logarithmic fashion in recent years. In other areas, however, Chagas disease remains a common cause of gastrointestinal and cardiac disease among adults in their working years. A final example to illustrate the spectrum of autonomic insufficiency will be provided by Portuguese-type amyloidosis, also called famililal amyloid polyneuropathy type 1 (FAP-1). This inherited, autosomal dominant disorder is rare globally, but common in restricted areas [6], with a few percent of the population effected in some localities. Hence, in summary, autonomic insufficiency may be important both globally and locally as a cause of disability and death. Furthermore, the stage seems to be set for increased prevalence of some already common causes of this affliction.

## Higher Level Structures

Autonomic insufficiency may arise from disease of the central autonomic network (CAN), including stroke, trauma, infection and neoplasia (►Central regulation of autonomic function). However, since various components of the CAN also perform inhibitory functions, lesions to these areas may also result in disinhibition and consequent overactivity of the autonomic nervous system (►Autonomic/enteric dysreflexia). In many instances it is still not known which components of the CAN are involved or are most important in specific syndromes of autonomic insufficiency. Furthermore, as various diseases with autonomic involvement also result in impairment of cerebral circulation, it may be difficult to determine whether pathology in any given component of the CAN is primary or secondary. Notwithstanding these caveats, a few examples will serve to demonstrate the importance of particular higher level structures in representative disorders with autonomic involvement. A relatively common neurodegenerative disorder associated with autonomic insufficiency is Parkinson's disease [7], which is marked by degeneration of a number of nuclei including not only the substantia nigra but also the locus ceruleus (►Periaqueductal gray matter), the principle source of norepinephrine in the brain. Additionally, in both Parkinsonism and multiple system atrophy (MSA), loss of particular cell populations has been noted in the ventrolateral medulla [8]. With MSA, which normally develops insidiously late in life, there is also marked degeneration in the intermediolateral (sympathetic preganglionic) cell columns of the spinal cord. Hence, in addition to motor and sensory symptoms, patients with CAN disorders may experience a range of localized or generalized autonomic deficits.

## Lower Level Structures

In truth, many disorders defy classification as strictly central versus peripheral, or preganglionic (►Preganglionic neurons) versus postganglionic (►Postganglionic). However, pure autonomic failure (PAF), which like MSA most often effects older adults, is representative of those disorders which are primarily postganglionic. Outwardly, the patients may appear very much like those suffering from MSA, often demonstrating orthostatic hypotension and disorders of urinary or gastrointestinal function. However, the CAN is largely unaffected in PAF, while there is loss of postganglionic sympathetic function [9]. In a number of clinically similar syndromes manifesting as postganglionic autonomic failure, patients have been shown to possess antibodies to postganglionic neurons, including antibodies to ganglionic neurotransmitter receptors. Autoimmune damage is, in fact, one of the mechanisms responsible for peripheral nerve damage in diabetic ►autonomic neuropathy, the most common cause of postganglionic autonomic insufficiency in developed nations. There are, not surprisingly, many varieties of diabetic autonomic neuropathy, just as there are many varieties of diabetes mellitus. These autonomic neuropathies are most often accompanied by sensory and motor neuropathies which may demand more attention clinically. Nonetheless, the autonomic components of diabetic neuropathies are responsible for significant morbidity, and perhaps mortality. Signs and symptoms attributed to autonomic insufficiency include cold, discolored hands and feet due to loss of peripheral vascular tone. There is often asymmetrical loss of sweating, initially effecting the limbs. With loss of postganglionic vagal fibers, gastrointestinal motility is impaired and patients may experience complaints such as achalasia and constipation. Loss of autonomic, and particularly vagal, cardiac output may contribute to the increased risk of silent myocardial infarctions and sudden cardiac death in diabetic patients. Thus, diabetic autonomic neuropathies are commanding more attention, particularly as primary care increases the life expectancy of patients and allows autonomic dysfunction to manifest.

## Management

As autonomic insufficiency most often occurs as a secondary disorder, management commonly focuses on prevention or amelioration of the underlying disease. Additionally, autonomic insufficiency is sometimes successfully managed by supportive measures focusing

on strategies to minimize symptoms. These include modifying behaviors such as using supportive stockings, or altering eating and drinking patterns to control orthostatic hypotension. More recently, a number of neuroprotective drugs have appeared, and strategies such as stem cell transplantation show great promise in certain disorders. As the stage is set for an increase in autonomic insufficiency in more developed nations, it is most likely that there will be increasing research effort in these fields.

# Autonomic Interneurons

## Definition

Interneurons in the spinal cord or brain stem that form synapses with preganglionic neurons. These interneurons are segmental or intersegmental (propriospinal) interneurons in the spinal cord or equivalent in the brain stem (e.g., second-order neurons in the nucleus tractus solitarii receiving synaptic input from vagal visceral afferents).

►Autonomic Reflexes

# Autonomic Nervous System

## Definition

The autonomic nervous system is that part of the nervous system that regulates basic visceral processes, usually independently of voluntary control. The executing part of the autonomic nervous system is divided into a parasympathetic and a sympathetic branch. In many organs, these two branches have antagonistic effects, while in others (e.g. salivary glands), they act synergistically (even though not giving identical responses), and thereby enhance the effect of each system. In addition information about the functional condition of our organs is transmitted back to the brain via these two branches.

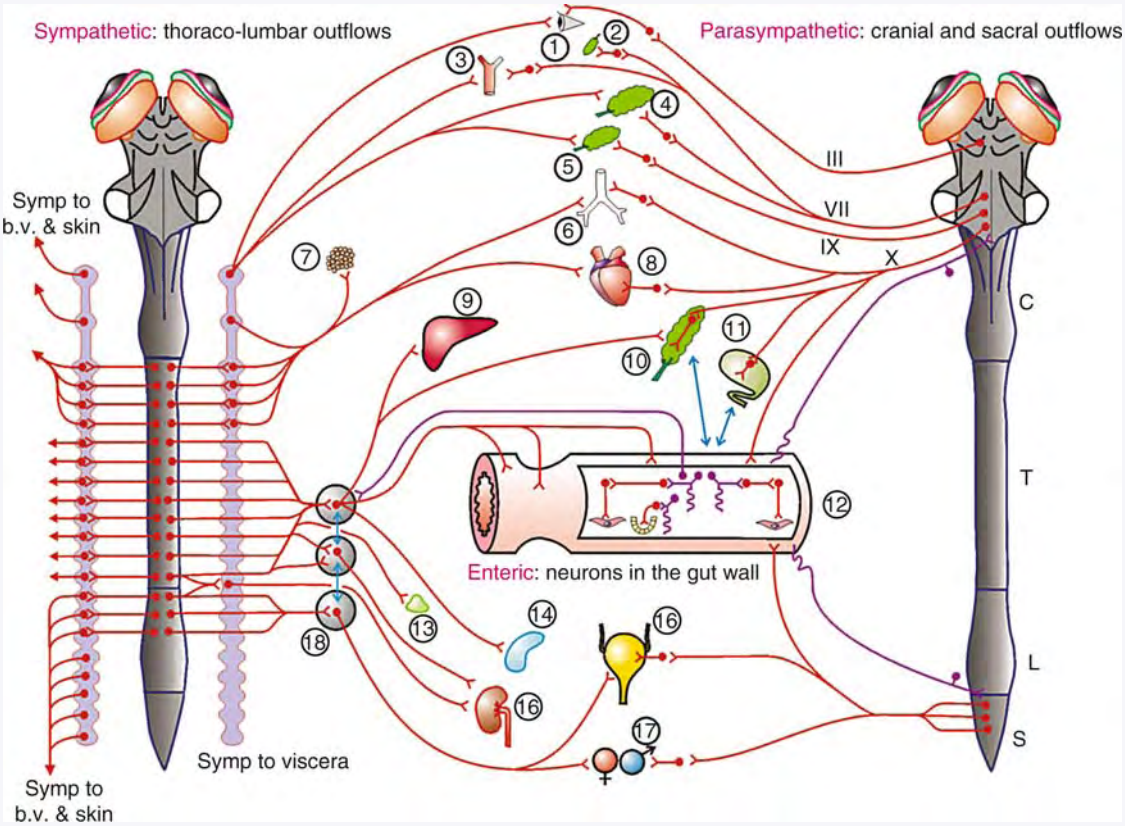
## Introduction

The autonomic nervous system (ANS) is that system of nerves that controls peripheral organs, other than striated muscle that is under voluntary control (Fig. 1). Thus it controls the visceral organs of the thoracic, abdominal and pelvic cavities, including the lungs, heart, digestive organs, kidneys, urinary bladder and internal generative organs. The autonomic nervous system also controls endocrine and exocrine glands throughout the body, the blood vessels that supply all organs, and, within the eye, ►neural regulation of the pupil. More recently, it has also become obvious that the autonomic nervous system can modulate the function of sensory receptors (see ►autonomic control



**Autonomic Nervous System and Its Divisions: Sympathetic, Parasympathetic and Enteric. Figure 1** Depiction of the organization of the peripheral pathways of the autonomic nervous system, showing its three parts, sympathetic, parasympathetic and enteric. The spinal cord and brainstem are pictured twice, at the left to show their sympathetic outflows and at the right to show parasympathetic outflows. Major organs that are supplied are numbered: 1 Eye; 2 Lacrimal gland; 3 Intracranial arteries; 4, 5 Salivary glands; 6 Respiratory tract; 7 Adipose tissue; 8 Heart; 9 Liver; 10 Pancreas; 11 Gallbladder and biliary tree; 12 Gastrointestinal tract; 13 Adrenal gland; 14 Spleen; 15 Urinary bladder; 16 Kidney; 17 Genital organs. 18 indicates prevertebral ganglia. Motor pathways are in red. The ANS also has associated afferent neurons. Some of these are shown in purple. Visceral afferents in fact supply all organs, but these are not shown, in order to simplify the diagram. Double-ended arrows indicate that there are neural connections between the pancreas and the gastrointestinal tract and between the biliary system and the gastrointestinal tract, as well as between pre-vertebral ganglia. Levels of the spinal cord are indicated, C, T, L and S.

of sensory receptors) and skeletal muscle (see ►autonomic effects on skeletal muscle).

## Autonomic Function

The functions of the autonomic nervous system are all related to ►homeostasis (Table 1), adjusting the activities of these organs so that the organs function at levels that are most favorable to the state of the body and to its environment (see [1]). This is achieved most often through reflex mechanisms which are largely involuntary. These ►autonomic/enteric reflexes particularly involve viscero-visceral reflexes. However, recently there has been a growing awareness that much autonomic function is also influenced by ►somato-autonomic reflexes [2] and entrained to circadian rhythms (see ►circadian rhythms of autonomic function). Thus, for example, physiological parameters such as blood pressure show daily rhythms appropriate to the sleep-wake cycle [3]. Furthermore, it is apparent that humans may exert varying degrees of voluntary control over autonomic function (see ►biofeedback of autonomic function). Thus, while ►tonic activity of autonomic nerves is always present to some degree, there are substantial adjustments to homeostatic challenges, such as those presented by exertion (see ►autonomic function and exercise) [4]. Additionally, information from visceral autonomic afferents may, via ►viscero-somatic reflexes, such as the ►Hering-Breuer reflex, modulate musculoskeletal function. The autonomic nervous system is thus one of two systems, the other being the endocrine system, that control the functions of the internal and surface organs (the skin is included as an organ). The two systems

**Autonomic Nervous System and Its Divisions: Sympathetic, Parasympathetic and Enteric. Table 1** A summary of major autonomically controlled functions

| |
|---|
| Heart rate and force |
| Arterial diameter (all vascular beds) |

| Piloerection |

would be better thought of as one, because they act in synergy to control the organs (see ►autonomic regulation of endocrine system). However, largely due to the history and pattern of basic and clinical investigation, autonomic and endocrine control are often separated in text-books.

Autonomic control of organs is through reflexes and through cortical control centers [5]. To elicit a reflex, the relevant states of organs must be detected. This detection is through ►visceral afferents that are properly regarded as part of the autonomic nervous system. Many visceral afferent neurons also communicate other information, for example pain from the viscera, satiety from the digestive tract or temperature. Thus visceral afferent neurons, while part of the autonomic nervous system, carry signals to the central nervous system that serve other functions [6].

## Structural Organization of the Autonomic Nervous System

Since the nineteenth century or early twentieth century, it has been common to divide the autonomic nervous system into three divisions, the sympathetic, parasympathetic and enteric divisions (see ►enteric nervous system). There were pragmatic reasons for this separation of parts of what is essentially one control system. The efferent (motor) autonomic outflows from the central nervous system are not distributed uniformly in the peripheral nerves; rather there are gaps. More precisely, there are some cranial, cervical and lumbosacral nerves that do not carry autonomic motor pathways (Fig. 1). Autonomic fibers are absent from the first two cranial nerves – the olfactory and optic nerves, they are then present in cranial nerves III, VII, IX and X. Then a gap in outflow occurs, with no autonomic contribution to cranial nerves XI and XII or the cervical nerves (there can rarely be a contribution from C7). The next group of nerve roots, T1 to L2 or 3 (the thoraco-lumbar outflows), all have autonomic components, and then there is a small gap where there are few autonomic fibers, which become prominent again in sacral roots 2–4. The outputs are thus considered as cranial, thoraco-lumbar and sacral.

Early studies of autonomic nervous system function particularly focused on ►cardiovascular reflexes, including ►blood volume regulation. It was noted that there are pathways that emerge from the cranial autonomics that slow the heart and dilate blood vessels, and that there are also dilator nerves in the sacral outflows. Thus, these were grouped together and called the cranio-sacral nerves. Conversely, there are cardio-accelerator and vasoconstrictor pathways in the thoraco-lumbar outflows. Furthermore, early investigations indicated that these opposite effects on cardiovascular function were elicited by two different ►postganglionic neurotransmitters, acetylcholine and norepinephrine. Because of the opposite effects on the cardiovascular system, and the thoraco-lumbar effects being "sympathetic" (in sympathy with the body) the two anatomical divisions became known as sympathetic and parasympathetic (the latter being associated with slowing or lowering cardiovascular function).

The division of the ANS into sympathetic and parasympathetic systems has led to enormous misconceptions, the most serious being the concept that the two divisions are somehow in opposition to each other. Thus it may be envisioned that, for example, an increase in sympathetic outflow to a particular organ is necessarily linked to a decrease in parasympathetic outflow. This

is quite a wrong idea. Autonomic nerves, whatever their anatomical origin, act in concert to control visceral organs and the vasculature [7].

The third division of the ANS is the enteric division, which is the system of autonomic ganglia and nerve fibers that is contained within the walls of the digestive organs [8]. This is given the status of a separate division because it contains complete reflex circuits which can operate in the absence of connections with the central nervous system. In terms of numbers of neurons, the enteric is the largest autonomic division. In humans, it contains 200–600 million neurons.

The motor pathways of the ANS that arise in the central nervous system pass through ►autonomic ganglia and generally make synapses on the way to the organs that they innervate [9]. The adrenal glands are exceptional in that they are innervated by preganglionic neurons with cell bodies within the spinal cord. Synaptic transmission in autonomic ganglia is mediated primarily by acetylcholine (ACh) that acts on nicotinic receptors. The use of nicotine and other drugs that block these receptors has been important in analyzing the nerve pathways. Neurons with cell bodies in the central nervous system that make synapses in peripheral ganglia are known as autonomic (sympathetic or parasympathetic) pre-ganglionic neurons. The neurons with which they connect are called post-ganglionic neurons; most of those of the sympathetic nervous system producing the classical neurotransmitter norepinephrine and those of the parasympathetic nervous system producing acetylcholine. Both classes of post-ganglionic neurons also produce a range of other neuroactive substances which modulate the effects of their primary neurotransmitters (see [10]). Enteric neurons are innervated by both parasympathetic pre-ganglionic neurons and sympathetic post-ganglionic neurons.

►Central regulation of autonomic function involves higher integrating centers but depends most immediately on a series of nuclei in the brain-stem (including the Edinger-Westfall nucleus, the nucleus of the facial nerve, the salivatory nuclei, the dorsal motor nucleus of vagus and the nucleus ambiguus) which contain the cell bodies of preganglionic neurons [11]. Within the spinal cord, autonomic cell groups are arranged in columns in the lateral funiculus, intermediolateral nuclei, intermediomedial nuclei and central autonomic nuclei. The central autonomic motor nuclei of the brain stem and spinal cord receive inputs from autonomic integrative cell groups, including the nucleus of the tractus solitarius, the Bezhold-Jarisch complex, the autonomic cell groups of the rostral ventro-lateral medulla, the paraventricular nucleus and other cell groups. At higher levels, important autonomic control is exerted through the amygdala and the cingulate cortex. At these higher levels, it is no longer possible to distinguish the centers as simply autonomic. They are also involved in endocrine control and affective behavior, both of which are closely related to autonomic function.

## Disorders of the Autonomic Nervous System

As homeostatic mechanisms normally manifest as subtle adjustments in physiology, the importance of the autonomic nervous system to human health is easily underestimated until we subject ourselves to extreme environments (see ►autonomic function in space) or encounter frank disease. In fact, disorders of the autonomic nervous system are numerous and diverse in their presentations (see [12]). ►Complex regional pain syndromes were recognized early in the evolution of our understanding of autonomic pathology. More recently, and especially with improvements in ►autonomic testing, it has been possible to differentiate disorders which, while similar in their presentations, actually have distinct etiologies and pathologies, and so warrant distinct treatment approaches [13]. Importantly, aging is associated with senescence of the autonomic nervous system [14] (see ►aging of autonomic/enteric function), although ►autonomic insufficiency is also a component of a range of disorders seen across the life cycle. Autonomic insufficiency is most apparent in its effects on cardiovascular function and frequently associated with orthostatic hypotension. However, insufficiency also has clinically important effects on digestive function (see ►salivary secretion control and ►bowel disorders), urogenital function (see ►micturition – neurogenic control and ►sexual reflexes) and sweating (see ►sweat gland control).

## Acknowledgement

This section of the Encyclopedia of Neuroscience is a tribute to the energy and foresight of the late Professor Akio Sato, whose scientific and personal contributions have substantially advanced understanding of the autonomic nervous system. His friendship and suport are sadly missed.

## Autonomic Neuropathy

### Definition

The autonomic neuropathies are disorders of peripheral autonomic function, and may manifest as autonomic hyperactivity, autonomic failure, or a mixture of both.

An exemplar of autonomic neuropathy is acute panautonomic neuropathy (pandysautonomia) in which there is often widespread and severe loss of sympathetic and parasympathetic function, but virtually no involvement of somatic fibers. At the other end of the spectrum is Guillain-Barré syndrome in which somatic nervous system dysfunction usually dominates, and there may be hypoactivity or hyperactivity of peripheral autonomic fibers.

## Autonomic Neurotransmitter

►Postganglionic Neurotransmitter

## Autonomic Premotor Neurons

### Definition

Neurons in brain stem, hypothalamus or even cerebral hemispheres that project to preganglionic neurons or autonomic interneurons associated with the preganglionic neurons and form synapses with these neurons are called autonomic (parasympathetic, sympathetic) premotor neurons.

►Autonomic Reflexes

## Autonomic Reflexes

Wilfrid Jänig
Department of Physiology, Christian-Albrechts-Universität zu Kiel, Kiel, Germany, Physiologisches Institut, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

### Definition

Reflexes are functionally defined by an efferent (motor) output system leading to a distinct effector response when activated and by the population of afferent neurons stimulated. They are fragments of more complex somatomotor behaviors and are used in the laboratory as tools to study experimentally the central organization of neural regulation of movement. In this isolated context they are experimental artifacts or fictions [1]. The same applies to ►autonomic reflexes when seen in this restricted experimental context. Systematic experimental studies of autonomic reflexes using measurements of effector responses, recording from functionally identified autonomic neurons, pharmacological interventions, histological techniques, tracer methods etc. have given and will continue to give invaluable insight into the central and peripheral neural mechanisms underlying regulations in which the autonomic nervous system is involved. The functions of many individual autonomic reflexes mediated by the spinal cord, brain stem or hypothalamus or by the peripheral nervous system may not always be obvious at first sight. This does not mean that these reflexes have no function or are left-overs from development. As in the somatomotor system, the function of most autonomic reflexes cannot be considered in isolation but becomes obvious when looked at in the context of neural regulations in which these reflexes are integrated.

In the somatomotor system, reflexes are the basic building blocks of the initiation and maintenance of movements whether occurring automatically, e.g., during locomotion or in posture, or being initiated by the telencephalon [2,3]. In the autonomic nervous system reflexes are the basic building blocks of autonomic regulations. Coordinated responses generated by the somatomotor, autonomic and neuroendocrine

systems constitute behaviors of the organism. In this sense autonomic reflexes are also fragments of behavior (see the interesting discussion in [4] "What do *reflex* and *voluntary* mean? Modern views on an ancient debate." For the autonomic nervous system this may be rephrased "What do *reflex* and autonomic *regulation* mean?").

## Characteristics

Autonomic reflexes mediated by the spinal cord, brain stem or hypothalamus are functionally defined by their afferent input and efferent output. They are di- or polysynaptic, organized at the segmental or propriospinal (propriobulbar) level and form the building blocks of ►autonomic regulations. The interneurons of the autonomic reflex pathways are important for the integration and coordination of different autonomic systems as well as of autonomic and somatomotor systems. Command signals from higher centers act primarily via these interneurons rather than directly with the final autonomic pathways in autonomic regulations.

### Categories of Autonomic Reflexes

Autonomic reflexes can be divided into three categories:

1. Autonomic reflexes mediated by CNS structures: spinal cord, brain stem or hypothalamus. These reflex pathways are either segmental (spinal, bulbar), intersegmental (propriospinal, propriobulbar) or supraspinal reflex loops (spino-bulbo-spinal, spino-hypothalamo-spinal, bulbo-hypothalamo-bulbar etc.).
2. Autonomic reflexes mediated by autonomic (non-enteric) ganglia outside the spinal cord (i.e., "extracentral"). For example, reflexes involved in regulation of motility or secretion of the ►gastrointestinal tract (GIT) are mediated by sympathetic postganglionic neurons of prevertebral ganglia. These neurons are physiologically activated by intestino-fugal neurons during distension of or other processes in the GIT leading to inhibition of motility and/or secretion ([5]; Chaps. 5 and 6 in [6]). Other extracentral reflexes may be mediated by parasympathetic postganglionic neurons in cardiac ganglia, by sympathetic postganglionic neurons in the stellate ganglion innervating the heart or by postganglionic neurons in the inferior mesenteric ganglion projecting to pelvic organs. However, the nature of the peripheral afferent synaptic input to these postganglionic neurons as well as the function of these peripheral reflexes during autonomic regulation of the respective target organs are unclear. Sympathetic postganglionic neurons in the paravertebral ganglia innervating target cells in the somatic tissues (blood vessels, glands, non-vascular smooth muscle cells) do not mediate peripheral autonomic reflexes (Chap. 6 in [6]).
3. Autonomic reflexes mediated by the enteric nervous system (ENS) are related to regulation of motility and secretion of the GIT involving smooth (non-vascular, vascular) muscle cells, secretory epithelia and endocrine cells. Several enteric reflexes can be defined by their intrinsic primary afferent neurons and their enteric motor neurons (defined by the target cells). These reflexes are monosynaptic, disynaptic or polysynaptic. They are the building blocks of the autonomic regulation of the GIT by the ENS and of its control by the brain ([5]; Chap. 5 in [6]).

I will concentrate on the first category of autonomic reflexes and here in particular on segmental spinal and propriospinal as well as autonomic reflexes in the brain stem. Table 1 lists characteristics of several basic autonomic reflexes related to autonomic regulation of pelvic organs, the cardiovascular system, functions of skin, gastrointestinal tract, airways, eye and pineal gland.

### The Autonomic Reflex Pathway in Spinal Cord and Brain Stem

The peripheral parasympathetic and sympathetic systems consist of many functionally discrete pathways that transmit impulse activity generated in the CNS to autonomic effector cells. The pre- and postganglionic neurons of each pathway exhibit a distinct reflex pattern to physiological stimulation of somatic or visceral afferents that is dependent on the central circuits connected to this peripheral autonomic pathway ([7]; Chap. 4 in [6]). The centrally generated signals are faithfully transmitted from the preganglionic neurons through autonomic ganglia to the postganglionic neurons and from the postganglionic axons to the effector cells at the neuroeffector junctions ([7]; Chaps. 6 and 7 in [6]). Thus these pathways are anatomically and physiologically separate from each other and functionally distinct with respect to the effector cells (e.g., vasoconstrictor neurons, vasodilator neurons, secretomotor neurons etc.).

Each peripheral autonomic pathway is connected to several basic reflex pathways organized in spinal cord or brain stem (Table 1). The common theme of the structure of practically all of these reflex pathways is shown for ►spinal reflexes in Fig. 1. Primary afferent neurons, most of them innervating visceral organs, but some also somatic tissues (skin, deep somatic), form reflex circuits with the preganglionic neurons. These reflex circuits are di-, tri- or polysynaptic. Each reflex circuit is primarily characterized by the type of afferent input and by the response elicited in the neurons of the autonomic pathways and therefore by the effector response. This basic structure of the autonomic spinal reflex applies to most autonomic reflexes in spinal cord. The reflexes are either spinal

**Autonomic Reflexes. Table 1** Autonomic reflexes mediated by spinal cord and brain stem[a]

| **Eye** | | | | | | |
| Iris | Mesencepalon (pupillary light reflex) | Retino-tectal tract (area pretectalis) | Pupilloconstrictor | Edinger-Westphal nucleus, lateral | Constriction of pupil | Pupil diameter |
| | Hypothal, spinal | Retino-hypothalamic tract | Pupillodilator thoracic T1/T2 | Hypothalamo-spinal | Dilation of pupil | Pupil diameter, defense |
| Pineal gland | Hypothal, spinal | Retino-hypothalamic tract | Thoracic T1/T2 | SCN, PVN, spinal cord | Inhibition of melatonin synthesis | Circadian rhythms of hypothalamic functions |

[a](i) Only spinal segmental and propriospinal (and equivalent reflexes in the brain stem and hypothalamus [related to the iris or pineal gland and the retino-hypothalamic/tectal tract]) are listed. For references see [3]. (ii) No autonomic long-loop reflexes are listed (e.g., spino-bulbo-►spinal reflexes related to pelvic organs, resistance vessels, cutaneaous blood vessels, sweat glands etc; long-loop reflexes related to peripheral autonomic [parasympathetic] pathways the brain stem). (iii) No autonomic reflexes are listed related to excitation or inhibition of hypothalamic neurons by osmotic stimuli (autonomic reflexes related to electrolyte-fluid balance), warm stimuli (thermoregulatory reflexes) or nutritive signals (glucose, lipids in the blood) and hormonal signals to neurons of the arcuate nucleus that are important in regulation of food intake and metabolism (leptin from adipocytes, insulin from B-cells of the endocrine pancreas, ghrelin from endocrine mucosa cells of the stomach, peptide YY from endocrine mucosa cells of ileum and colon-rectum).

[b]Some reflexes are listed by their genuine names as reported in the literature.

[c]Most afferent neurons are visceral (spinal or vagal); some afferent inputs are somatic (indicated) or central.

[d]Reflexes related to vagal afferents from atria and ventricles of the heart have not been listed.

[e]There must exist other reflexes mediated by the dorsal vagal complex (NTS, DMNX) that are related to regulation of secretion and transmural transport by the mucosa and to regulation of the endocrine cells of the mucosa (secreting e.g., cholecystokinin, gastrin, secretin, ghrelin, glucagon-like peptide, peptide YY or other hormones) or of the endocrine pancreas (secreting insulin, glucagon or pancreatic polypeptide). However, these reflex pathways have so far not been investigated (see [3] and Travagli RA, Hermann GE, Browning KN, Rogers RC (2006) Brainstem circuits regulating gastric function. *Annu Rev Physiol 68:279–305)*.

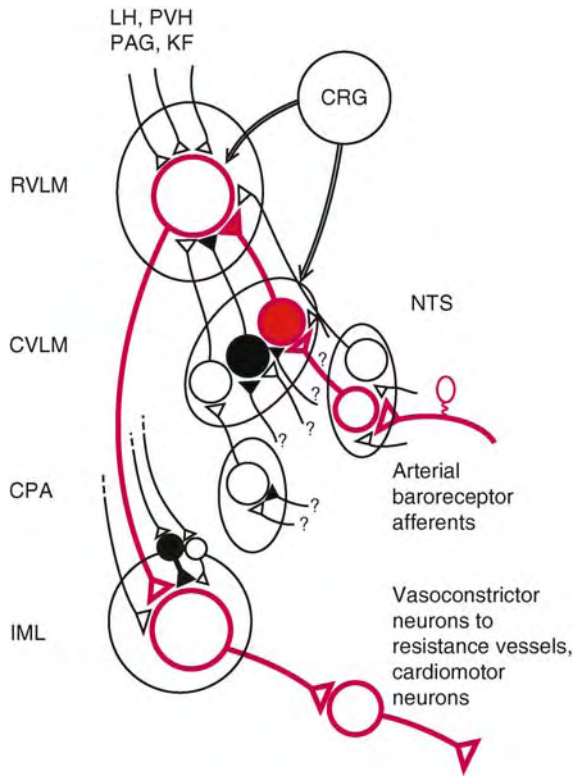
**Autonomic Reflexes. Figure 1** The spinal autonomic reflex pathway as building block between supraspinal centers and final autonomic pathways. There is usually at least one (excitatory or inhibitory [filled in]) interneuron (green) between (visceral or somatic) primary afferent neurons (blue) and preganglionic neurons (red). Supraspinal centers in brain stem and forebrain (hypothalamus and cerebral hemispheres) project mainly through the dorsolateral funiculus (DLF, brown) of the spinal cord and connect synaptically to the autonomic interneurons and the preganglionic neurons. DC, dorsal column. DH, dorsal horn. IML, intermediolateral nucleus. VH, ventral horn. Modified from [6].

segmental, in which afferent input and efferent output are located in the same spinal segment or neighboring spinal segments, or proprio-spinal in which afferent input and efferent output are located in different (separate) spinal segments (e.g., sacro-lumbar reflexes related to pelvic organs (see Fig. 4); muscle vasoconstrictor reflexes, cutaneous vasoconstrictor reflexes or sudomotor reflexes mediated by neurons innervating the hindlimb and elicited by stimulation of cutaneous afferents from the hindlimb).

The corresponding situation exists for autonomic reflexes mediated by the brain stem. Basic reflexes associated with the gastrointestinal tract (including salivary glands and mucosa of the oropharyngeal cavity), airways and eye mediated by the lower brain stem (nucleus tractus solitarii [NTS], trigeminal nuclei, nucleus ambiguus, dorsal motor nucleus of the vagus [DMNX], salivary nuclei) or the mesencephalon (nucleus Edinger-Westphal) correspond to segmental spinal reflexes, whereas other reflexes including the bulbo-spinal pathways (e.g., ►baroreceptor (see Fig. 2), chemoreceptor, diving reflexes) involving afferent inputs to the NTS [10] or trigeminal nuclei and sympathetic pathways to resistance blood vessels (in skeletal muscle and viscera, including kidney), to the heart, to cutaneous blood vessels (in particular arterio-venous anastomoses) or to other targets correspond to propriospinal reflexes.

## Function of Interneurons in Autonomic Reflex Pathways

It is generally assumed that reflexes are hard-wired components of the nervous system that can be inhibited or enhanced by higher centers. However, this ►concept may be misleading and too narrow. In analogy to the reflex pathways in the somato-motor system, the important components of the autonomic reflexes mediated by the spinal cord or the brain stem are the excitatory glutaminergic interneurons or GABA-ergic and/or glycinergic inhibitory interneurons interposed between afferent input and efferent output. These interneurons outnumber the preganglionic output neurons probably by an order of magnitude. With a few exceptions, notably baroreceptor reflexes (Fig. 2), reflexes represented in the dorsal vagal complex (Fig. 3) and reflexes related to the urinary bladder (Fig. 4), most autonomic interneurons have not been identified physiologically and anatomically. However, many functionally distinct types of interneurons are needed to explain the many distinct types of autonomic reflexes demonstrated in neurophysiological and other experimental investigations (Table 1). These pools of interneurons represent neural autonomic subroutines or "neural autonomic motor programs." Command signals from higher autonomic centers may target the neural autonomic subroutines via the interneurons leading in this way to a spatially and temporally coordinated smooth regulation of autonomic target



**Autonomic Reflexes. Figure 2** The baroreceptor reflex pathway to sympathetic cardiovascular neurons is modulated at all synapses in the brain stem and spinal cord. The neurons of the baroreceptor reflex pathway are outlined in red. Excitatory neurons/synapses, open symbols. Inhibitory neurons/synapses, closed symbols. CVLM, caudal ventrolateral medulla. CPA, caudal pressure area. CRG, central respiratory generator. IML, intermediolateral cell column. LH, lateral hypothalamus. KF, Kölliker-Fuse nucleus. NTS, nucleus tractus solitarii. PAG, periaqueductal gray. PVH, paraventricular nucleus of the hypothalamus. RVLM, rostral ventrolateral medulla. From [6].

organs. This principle of organization is probably responsible for the adaptability and flexibility of all autonomic regulations operating during behavioral changes of the organism. It applies to all levels of the central organization of the autonomic nervous system:

1. At the most basic level in spinal cord and lower brain stem the interneuron pools are responsible for the coordination and integration of different but functionally related autonomic systems (e.g., cutaneous vasoconstrictor and sudomotor systems; autonomic systems involved in regulation of pelvic organs) and of somatic and autonomic systems (e.g., sphincters and autonomic components of urinary tract (Fig. 4) or hindgut; cardiovascular and respiratory systems; cardiovascular, thermoregulatory and somatomotor systems during muscular efforts; see Chap. 10 in [6]).
2. Sympathetic premotor neurons (e.g., in the rostral ventrolateral medulla, in the raphe nuclei of the medulla and in the hypothalamus) may not primarily target preganglionic sympathetic neurons but rather, spinal autonomic circuits via their interneurons. The same may apply to parasympathetic premotor neurons targeting the autonomic reflex circuits in the sacral and sacro-lumbar spinal cord, the dorsal vagal complex related to the GIT (Fig. 3) or the circuits in the nucleus ambiguus related to heart and airways.
3. Signals from the cerebral hemispheres (e.g., the anterior cingulate cortex and the medial and lateral prefrontal cortex) may equally target, for example by way of the hypothalamus or the periaqueductal grey, these autonomic reflex circuits via their interneurons. This would lead to a smooth adaptation of the body during exercise, defense, diving, digestion and food intake, thermoregulation, reproduction etc.; Chap. 11 in [6]).

## Examples of Autonomic Reflexes and Their Integration in Autonomic Regulations

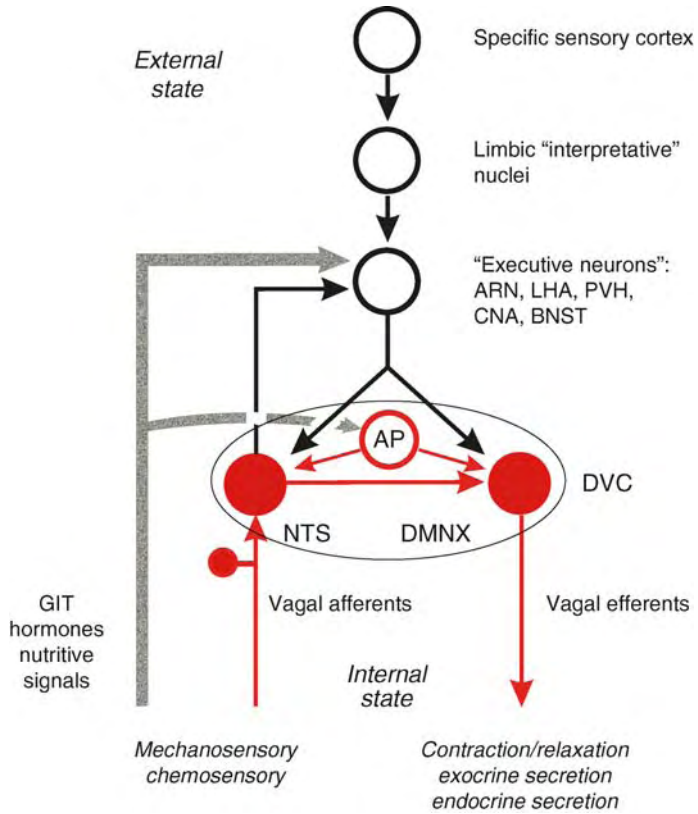
The concept of the functioning of autonomic reflexes during regulation of autonomic target organs as outlined above is exemplified by three examples.

### *Arterial Baroreceptor Reflexes Mediated by Sympathetic Cardiomotor Neurons*

The main components of the baroreceptor reflex pathways mediated by sympathetic cardiovascular neurons and parasympathetic cardiomotor neurons have been worked out in the last 20 years (Fig. 2; [6]). Every relay of this reflex pathway (red in Fig. 2 for the sympathetic cardiovascular neurons) in the lower brain stem (NTS, CVLM, RVLM) and spinal cord (IML) is under multiple synaptic excitatory and inhibitory controls from other centers in spinal cord, brain stem and forebrain. This (together with the structure of the baroreceptor pathway to the parasympathetic cardiomotor neurons) is one basis for the acute and chronic adaptation and plastic changes of the regulation of cardiovascular targets (heart, resistance blood vessels) under various behavioral conditions.

### *Vago-vagal Reflexes of the Gastrointestinal Tract in the Dorsal Vagal Complex (DVC)*

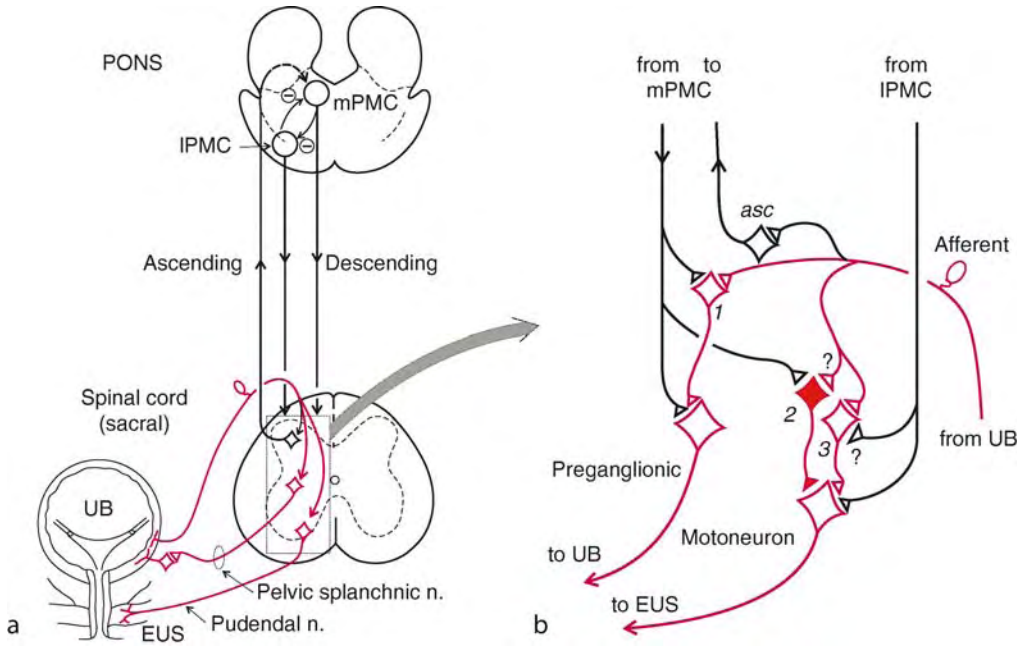
The functionally distinct reflex circuits formed in the DVC between the afferents from the GIT [10] and the preganglionic neurons to the GIT are the *basic building blocks* used by the brain to control GI functions (Fig. 3). Anatomical studies have shown that several nuclei in



**Autonomic Reflexes. Figure 3** Gastrointestinal vago-vagal reflex pathways in the dorsal vagal complex (DVC) and their modulation by centers in the hypothalamus and cerebral hemispheres. Several functionally specific vago-vagal reflex pathways organized in the dorsal vagal complex (nucleus tractus solitarii [NTS], dorsal motor nucleus of the vagus [DMNX], area postrema [AP]) of the medulla oblongata are the *basic neuronal building blocks* of the control of the gastrointestinal tract (GIT) by the brain. Vagal afferents measure mechanical, chemical and other sensory events and project to the NTS [10]; vagal preganglionic neurons are located in the DMNX and are involved in regulation of motility, exocrine secretion and endocrine secretion of the GIT. Second-order neurons in the NTS project to the preganglionic neurons in the DMNX, the synaptic connection being either inhibitory (transmitter noradrenaline or gamma-amino-butyric acid) or excitatory (transmitter glutamate). Multiple hormonal afferent inputs from the GIT and nutritive inputs (glucose, lipids) occur to the DVC (via the area postrema [AP]) and to the hypothalamus (mostly via the arcuate nucleus [ARN]). Neurons of the "executive" centers (e.g., ARN, lateral hypothalamic and parafornical area [LHA], paraventricular nucleus of the hypothalamus [PVN], central nucleus of the amygdala [CNA], bed nucleus of the stria terminalis [BNST]) evaluate the state of the internal milieu (by way of inputs from visceral afferents, hormonal inputs and nutritive signals) as well as the current or anticipated behavioral state (via input from limbic nuclei that evaluate the significance of exteroceptive signals). These executive centers adapt the internal state (e.g., the functions of the GIT) to the behavioral state of the organism. Modified from Rogers RC and Hermann G (1992) Central regulation of brainstem gastric vago-vagal control circuits. In *Neuroanatomy and Physiology of Abdominal Vagal Afferents* (Ritter S, Ritter RC & Barnes CD eds), pp 99–134 and Travagli RA, Hermann GE, Browning KN, Rogers RC (2006) Brainstem circuits regulating gastric function. Annu Rev Physiol 68:279–305.

the brain stem, hypothalamus and telencephalon have *reciprocal connections* with the circuits of the DVC. The functions of most of these neural connections are poorly understood. Thus, the reflex pathways of the DVC are under modulatory control of neurons in the medulla oblongata and supramedullary brain centers, including the insula, the anterior cingulate cortex and medial prefrontal cortex (so-called "executive" neurons) which also receive detailed afferent information from the GIT (via the NTS), from other visceral organs and from somatic body domains. Executive neurons and basic autonomic circuits in the DVC associated with the GIT represent the *internal state of the organism* as far as the GIT is concerned (Fig. 3).

An essential component of this internal state of the organism is the feedback by hormonal and nutritive signals from the GIT to the DVC via the area postrema and to the hypothalamus (mainly via the arcuate



**Autonomic Reflexes. Figure 4** The spinal micturition reflexes and their supraspinal control. (a) Sacral visceral afferents from the urinary bladder (UB) project to interneurons involved in micturition and continence and to ascending tract neurons (ascending) which project (probably via the periaqueductal gray) to the pontine micturition center (PMC) consisting of the lateral PMC (lPMC) and the medial PMC (mPMC). Activation of mPMC Barringtons nucleus enhances/initiates micturition and activation of lPMC continence; both inhibit each other reciprocally. Neurons in the PMC project to the sacral spinal cord (descending). Sacral preganglionic neurons project to the bladder body inducing contraction of the urinary bladder. Other sacral preganglionic neurons project to urethra and bladder neck inducing relaxation (not shown). Motoneurons project to the external urethral sphincter (EUS) that is activated during continence and inhibited during micturition. (b) Afferents from the urinary bladder form reflex circuits to preganglionic neurons and motoneurons in the sacral spinal cord via interneurons *1*, *2* and *3* (red). Neurons in the mPMC project to sacral preganglionic parasympathetic neurons and interneurons; they activate the preganglionic neurons to the UB (directly and via interneuron *1*) and inhibit motoneurons to the EUS (via interneuron *2*). Neurons in the lateral pontine micturition center (lPMC) activate motoneurons during continence (directly and possibly also via interneuron *3*). It is a matter of debate whether the micturition center acts mainly at the interneurons or at the preganglionic neurons and somatomotor neurons in the adult. Modified from [6] (see [8,9]).

nucleus: ARN). This hormonal feedback consists of several components and is integrated into the homeostatic regulation of metabolism (nutrition), body temperature, electrolyte balance, reproduction and protection of the body by the brain involving lower brain stem and hypothalamus. These homeostatic regulations are adapted to the behavior of the organism by cortical and limbic system structures that monitor and represent the *external state of the organism* (Fig. 3), e.g., during strong exercise, large environmental temperature changes, food and fluid deprivation, invasion of toxic compounds or bacteria (sepsis, toxemia). This concept shows that there is a close integration between the homeostatic regulation of GIT functions and higher nervous system functions related to body perception, emotions and adaptation of behavior. The highly specific autonomic reflex pathways in the DVC are at the basis of this integration.

### *Micturition Reflexes in the Sacral Spinal Cord*

In the adult under physiological conditions, the urinary bladder slowly fills and accommodates to the increasing intravesical volume. Depending on the degree of filling of the urinary bladder and the central (cortical) command signals, micturition is initiated. The detrusor muscle contracts and bladder neck, urethra and external urethral sphincter relax, resulting in the voiding of urine. These coordinated actions are initiated by activation of sacral afferents from the bladder dome and generated by (i) reflex activation of parasympathetic neurons to the detrusor muscle, (ii) reflex activation of inhibitory parasympathetic neurons to the urethra and bladder neck (leading to active relaxation of the outlet of the urinary bladder (not shown in Fig. 4) and (iii) inhibition of pudendal motoneurons.

Figure 4 outlines schematically the central reflex circuits involved in micturition:

1. Activity in sacral vesical afferents activates via an ascending pathway (*ascending* in Fig. 4b) neurons in the medial pontine micturition center (mPMC; Barrington's nucleus). The output neurons of Barrington's nucleus project to the sacral spinal cord and activate the preganglionic neurons mediating bladder contraction both directly and indirectly via interneurons (interneuron *1* Figure 4B) and at the same time, inhibit the motoneurons projecting to the external urethral sphincter via inhibitory interneurons (interneuron *2*). The lateral pontine micturition center (lPMC) is inhibited by the mPMC.
2. It is a matter of debate whether the spinal circuits represented by the interneurons *1, 2* and *3* are important during normal micturition when the spinal cord is intact. De Groat and his coworkers believe that the spinobulbospinal reflex pathway involving the mPMC mediates micturition in the adult and that the spinal reflex pathways are unimportant during normal micturition [8]. Others favor the idea that these spinal reflex pathways are involved in the normal micturition reflexes [6,9]. It is suggested for example that the signals from the pontine micturition center are gated by spinal interneurons activated by afferents from the urinary bladder.
3. Motoneurons to the external urethral sphincter are activated by neurons in the lateral pontine micturition center (lPMC) projecting to the sacral spinal cord during continence. This activation occurs by direct synaptic activation of the motoneurons or by synaptic activation of excitatory interneurons antecedent to the motoneurons (interneuron *3* in Fig. 4b). The neurons in the lPMC are inhibited during micturition, probably from the mPMC.

## Autonomic Regulation

### Definition

Altering visceral processes including those associated with the cardiovascular system, digestion, respiration, metabolism and thermoregulation through the nervous system, mainly via innervation of smooth and cardiac muscle.

## Autonomic Regulation of the Endocrine System

### Definition

Both sympathetic and parasympathetic nerves regulate secretion of some hormones. Hormones secreted in response to stimulation by sympathetic nerves include catecholamines from the adrenal medulla, glucagon from the pancreas and renin from the kidney. Stimulation by sympathetic nerves inhibits insulin secretion from the pancreas. Hormones secreted in response to stimulation by parasympathetic nerves include gastrins from the stomach and insulin from the pancreas.

Secretion of these various hormones can be elicited by either direct stimulation of the central nervous system, or by visceral and somatic afferent stimulation whereby autonomic nerves serve as the efferent limbs of the respective reflex arcs.

# Autonomic Testing: The Clinical Laboratory

Phillip A. Low, Mayo Clinic
Department of Neurology, Mayo Foundation, Rochester, MN, USA

## Advantages and Disadvantages

The autonomic nervous system (ANS) regulates such important functions as blood pressure (BP), heart rate (HR), respiration, and bowel, bladder, sexual, thermoregulatory and pupillary functions. Autonomic disorders affecting the brain, spinal cord, or peripheral nerves could cause damage to autonomic pathways and result in autonomic dysfunction. Testing can be done to evaluate the integrity of autonomic pathways and structures, and to detect deviations from normal. Such testing can be done as part of clinical laboratory evaluation or as research into ANS function and dysfunction. Autonomic tests can be divided into two broad categories, "Routine Tests" and "Research Studies."

## Routine Laboratory Tests of Autonomic Function

The goal in clinical autonomic testing is to detect the presence of autonomic failure in patients with suspected autonomic disorders, using a panel of tests that meet certain criteria. Thus, since these tests are to be widely used on many patients, they need to be straightforward to perform, comprehensive, reliable, and based on sound autonomic physiology. One set of routine tests comprises a study of the integrity of autonomic nerves that regulate sudomotor, cardiovagal, and adrenergic function. The aims are to detect the presence of autonomic failure, to quantify the severity, to apportion the type (sudomotor, adrenergic, cardiovagal) and distribution of deficits, and to determine the site (preganglionic versus postganglionic) of the lesion [1].

Postganglionic sudomotor function is evaluated using the quantitative sudomotor axon reflex test (QSART). QSART utilizes an axon-reflex pathway and tests the integrity of the postganglionic sympathetic sudomotor axon [2]. The stimulus is iontophoresed acetylcholine and the evoked sweat response is recorded in a different site. Typically, recording sites are the forearm, proximal leg, distal leg, and foot. In normal subjects, sweat volumes for all sites are similar and women have volumes that are approximately one-half those of males. The distribution of abnormalities is particularly useful in monitoring a length-dependent neuropathy; sweat volumes undergo a progressive decrease from proximal to distal sites. The test is also useful in monitoring the course of a neurologic disorder over time since the test is highly reproducible. Volumes from the same subjects on two different days correlate well ($R = 0.9$) with a coefficient of variation of 14.7%. QSART can be supplemented by the thermoregulatory sweat test (TST). Sweating in TST, in response to raising core temperature using ambient heat, is detected by an indicator powder. This test provides information on the distribution of sweat loss. The percent of anterior body surface anhidrosis can be quantified [3]. Taken with QSART, the site of the lesion can be defined. For instance, if a patient were anhidrotic at a site but had normal QSART, the lesion would likely be preganglionic.

Cardiovagal function is relatively straightforward to evaluate. Both cardiac afferent and efferent nerve fibers that are activated by maneuvers such as deep breathing, standing up, or the Valsalva maneuver are carried in the vagus nerve. Hence, tests in the time domain, such as those measuring heart rate response to deep breathing or to the Valsalva maneuver, evaluate vagal pathways to the heart. An alternative approach is to evaluate cardiovagal function in the frequency domain. Tests of cardiovagal function, especially the response to deep breathing, are reliable and reproducible, provided that the end organ is healthy [4].

Adrenergic function controls blood pressure (and heart rate) by regulating tone to the microvessels (mainly arterioles) and cardiac contractility. The major reflex is the baroreflex, which responds instantaneously to changes in blood pressure and volume by an increase or decrease in sympathetic nerve traffic [5]. We evaluate adrenergic function by measuring beat-to-beat BP responses to maneuvers that change BP in a standardized way. Two useful maneuvers are the Valsalva maneuver and head-up tilt (HUT) [1]. The Valsalva maneuver is performed by maintaining expiratory pressure at 40 mm Hg for 15 seconds, and results in changes in venous return to the heart resulting in a transient reduction in stroke volume and BP. This, in turn, results in unloading of baroreflexes. The ensuing vasoconstriction and resultant pressor response provide an index of baroreflex function. The phases of the Valsalva maneuver are under adrenergic control [6]. In HUT, orthostatic stress results in volume shift to the dependent parts of the body, and whether BP is maintained or falls depends on the integrity of baroreflexes. An angle of tilt of 60 or 70° is recommended.

Plasma catecholamines measured with the patient supine and then upright provide a profile of the humoral (mainly noradrenergic) response to standing. In a normal subject standing values are approximately double those with the subject supine. The results of this test correlate well with muscle sympathetic nerve activity [7]. When widespread postganglionic adrenergic failure is present, as in pure autonomic failure,

supine norepinephrine is markedly reduced (70 pg/ml) and fails to increase on standing. With a preganglionic lesion, as in multiple system atrophy, supine values are normal but on standing norepinephrine fails to increase.

The effects of age and gender have significant effects on these autonomic responses, so that an autonomic laboratory must generate a large normative data set in order that percentiles and normal variations for age and gender can be determined.

Laboratory evaluation is useful in a number of circumstances. It is useful in detecting the severity and distribution of autonomic failure. It is valuable in monitoring the course of autonomic failure and evaluating the response to therapy. It is also helpful in differentiating benign disorders (such as syncope) from more serious disorders (such as neurogenic orthostatic hypotension).

## Autonomic Testing: Research Studies

There are numerous tests of autonomic function for use in the research laboratory. The selection of tests depends on the research question at hand. Below is a selection of some tests that are in relatively wide use. This description is by necessity selective. For instance, we will not describe the extensive molecular studies of a whole range of autonomic receptors.

### *Microneurography*

Muscle sympathetic neural discharges from unmyelinated axons can be recorded in awake human subjects via tungsten microelectrodes inserted percutaneously into an accessible peripheral nerve [8]. This technique has provided important insights into normal autonomic physiology and aging. Recently, the technique is increasingly applied to gain insights into the pathophysiology of sympathetic dysfunction in the autonomic neuropathies, and pre- and post-ganglionic autonomic disorders.

### *Baroreflex Analysis*

A fall in BP leads to unloading of baroreceptors located in the carotid sinus and aortic arch. This results in activation of sympathetic outflow and inhibition of cardiovagal neurons, and so an increase in heart rate. The converse occurs with a rise in BP. The most reliable method to estimate baroreflex sensitivity is to relate changes in heart period to changes in SBP induced first by intravenous sodium nitroprusside. This is followed by a bolus injection of phenylephrine hydrochloride, thus inducing first a fall and then a subsequent rise in arterial blood pressure – a modification of the Oxford method [9]. Noninvasive approaches that omit vasoactive drugs have been adapted using BP and heart rate alterations that occur in response to autonomic maneuvers or even spontaneously. The sequence technique [10] is a time-domain method that relates spontaneous sequences of BP fluctuations to the associated heart rate fluctuations. The spectral technique is a frequency domain method, and the cross-spectral technique estimates the gain of the transfer function between changes in blood pressure and heart period [10]. lnduced BP changes secondary to neck suction or the Valsalva maneuver can also be used.

### *Cerebral Vasoregulation*

Cerebral autoregulation refers to the maintenance of constant cerebral blood flow in spite of changes in cerebral perfusion pressure [11]. Patients with autonomic baroreflex failure develop both orthostatic hypotension and supine hypertension. Cerebral autoregulation is especially important in these patients and indeed compensation is apparently sometimes augmented by an expansion of the range of autoregulation. The availability of transcranial Doppler methodology to measure blood flow velocity in the middle cerebral artery provides ready access to these measurements. Autoregulation can be studied by changing the steady-state BP (static method) or by rapidly altering BP (dynamic method). Both methods have yielded similar estimates of autoregulation in normal human subjects [12]. One concern with these methods is that the induced BP alterations cause rapid changes in critical closing pressure, rendering estimates of autoregulation inaccurate. Thus, a transfer function method has been proposed, and this is unaffected by changes in critical closing pressure. Cerebral autoregulation has been studied in orthostatic hypotension and intolerance [13].

### *Splanchnic-Mesenteric Vasoregulation*

The splanchnic-mesenteric vascular bed is unique in that it is a baroreflex-responsive capacitance bed. It is of large volume containing up to 20–25% of blood volume. The blood volume increases by 200–300% after a meal. Not surprisingly orthostatic hypotension develops or is aggravated post-prandially. Recent advances in duplex ultrasound technology have allowed reliable noninvasive evaluation of the mesenteric circulation. Superior mesenteric artery (SMA) blood flow can be measured by a real-time Doppler ultrasound transducer [14]. The cross-sectional area of the SMA (SMA-area) and time-average velocity (SMA-TAV) are measured using dedicated software, and blood flow and vascular resistance are calculated. The post-prandial fall in BP is linearly related to the increase in SMA flow. It is possible to define the effects of tilt and vasoconstrictors.

### Cardiac Innervation

Cardiac postganglionic sympathetic adrenergic innervation can be studied using isotopes and SPECT, or positron-emission tomography (PET) scanning. Cardiac uptake of [123 I]iodine-123 meta-iodobenzylguanidine, an analogue of norepinephrine which traces the functioning of postganglionic sympathetic adrenergic neurons [15], can be imaged using SPECT. PET scanning and 6-[18 F]fluorodopamine provide better resolution [16]. This test has been useful in differentiating MSA (normal uptake) and Parkinson's disease (reduced uptake when autonomic failure is present [17]). Uptake is also reduced in diabetic autonomic neuropathy. Interestingly, PET scanning has been reported to show hyperinnervated adrenergic islands in rostral segments in these patients, raising the possibility that these might be conducive to arrhythmias.

# Autonomic/Enteric Dysreflexia

## Definition

Autonomic dysreflexia is a clinical syndrome occurring in patients with severe cervical or upper thoracic spinal cord lesions. It normally appears several months following injury and manifests as exuberant reflex autonomic discharges in response to what might otherwise be relatively trivial stimuli. A classical presentation is paroxysmal hypertension, mediated via excessive splanchnic sympathetic output, triggered by bowel or bladder distension.

►Autonomic/Enteric Reflexes
►Autonomic Insufficiency

# Autonomic/Enteric Reflexes

Jackie D. Wood
Department of Physiology and Cell Biology and Internal Medicine, College of Medicine, The Ohio State University, Columbus, OH, USA

## Definition

Enteric reflexes are fundamental mechanisms in the autonomic neural control of motility up and down the digestive tract, starting with swallowing at the oral end and terminating with defecation at the anal end. With the exception of the control of the striated musculature in the pharynx during swallowing and control of the skeletal musculature of the pelvic floor during maintenance of fecal continence and defecation, most

enteric reflexes are mediated by the autonomic nervous system. The three divisions of the autonomic nervous system (i.e. the parasympathetic, sympathetic and enteric divisions) interact with each another in mediating involuntary control of motor behavior of the smooth musculature of the digestive tract, secretory behavior of the glands and gastrointestinal blood flow.

Reflex circuits were also called "reflex arcs" in earlier literature. A reflex circuit consists of a minimum of a sensory neuron that synapses with and excites a motor neuron, which in turn innervates an effector (e.g. muscle or gland). Reflex behavior evoked by a circuit consisting only of a sensory and motor neuron is a monosynaptic reflex. Reflex circuits in which interneurons are synaptically interposed between the sensory and motor neuronal components are polysynaptic reflex circuits. Enteric reflexes are generally polysynaptic with internuncial circuitry located in the brainstem, the spinal cord and within the ►enteric nervous system (ENS) positioned inside the walls of the digestive tract.

## Characteristics

### Brain-Stem Reflexes and ENS Reflexes

#### *Reflex Control of the Stomach*

Internuncial circuitry in both the brainstem and the gastric ENS is involved in reflex control of secretory and motor functions of the stomach. Motor functions in the stomach are more complex than in the intestines, and require the more sophisticated circuitry of the brainstem to achieve full moment-to-moment control during filling, grinding movements and emptying. Motor functions of the small and large intestines are less complex and are mainly organized by the ENS independent of the central nervous system (CNS).

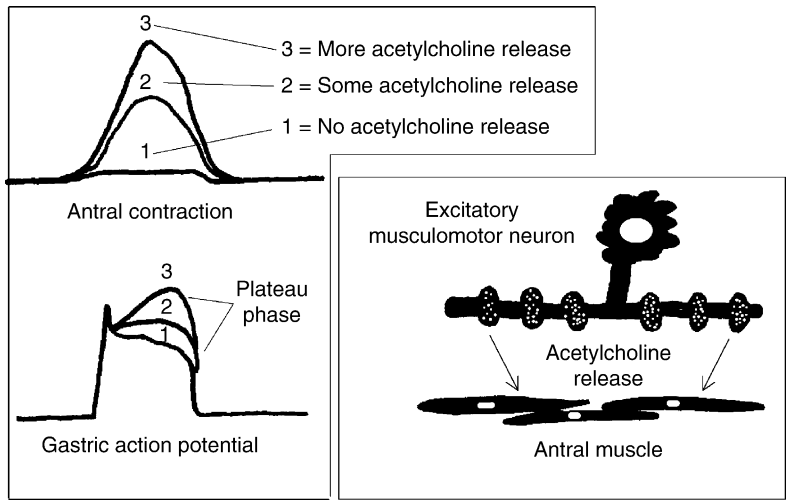
Functionally, the stomach is divided into a proximal reservoir and distal antral pump on the basis of distinct differences in motility between the two regions. The differences in motility between the reservoir and antral pump reflect adaptations for different functions [8]. The muscles of the proximal stomach are adapted for maintaining continuous contractile tone (tonic contraction) and do not contract phasically. In contrast, the muscles of the antral pump contract phasically. The spread of strong phasic contractions in the region of the antral pump propels the gastric contents toward the gastroduodenal junction. Strong propulsive waves of this nature do not occur in the proximal stomach.

#### *Antral Pump*

Gastric action potentials determine the duration, strength and aboral direction of travel of the phasic contractions in the antral pump. Gastric action potentials are initiated by a dominant pacemaker located approximately in the mid-region of the stomach. After starting at the pacemaker site, an action potential propagates rapidly around the gastric circumference and triggers a ring-like contraction. The action potential and associated ring-like contraction then travel more slowly until they reach the gastroduodenal junction where they stop [8]. ►Electrical syncytial properties of the myogenic gastric musculature (►myogenic musculature) account for the propagation of the action potentials from muscle fiber to muscle fiber away from the pacemaker site toward the gastroduodenal junction. Gastric action potentials are generated at 3 $min^{-1}$ in humans, have durations of about 5 s and have a rising depolarization phase, a plateau phase, and a repolarization falling phase (Fig. 1).

The action potentials trigger propulsive contractions when the plateau phase is above a threshold voltage and the strength of the contraction increases in direct relation to increases in the amplitude of the plateau potential beyond threshold.

The action potentials in the gastric reservoir are myogenic (i.e. an inherent property of the muscle) and occur in the absence of any neurotransmitters or other chemical messengers. The myogenic characteristics of the action potential are modulated by musculomotor neurons in the gastric ENS. Neurotransmitters released by enteric musculomotor neurons determine the amplitude of the plateau phase of the action potential, and thereby control the strength of the contractile event triggered by the plateau phase. Neurotransmitters (e.g. acetylcholine) released from excitatory motor neurons in the ENS increase the amplitude of the plateau phase and of the contraction initiated by the plateau (Fig. 1). Inhibitory neurotransmitters including norepinephrine, vasoactive intestinal peptide and nitric oxide decrease the amplitude of the plateau and the strength of the associated contraction. Postganglionic neurons projecting to the stomach from prevertebral ganglia of the sympathetic nervous system are the source of norepinephrine. The sources of vasoactive intestinal peptide and nitric oxide are inhibitory musculomotor neurons (►enteric inhibitory musculomotor neurons) in the ENS. The magnitude of the excitatory or inhibitory actions of neurotransmitters is related directly to the concentration of the transmitter substance at receptors on the gastric musculature. Progressively higher frequencies of impulse discharge by ►enteric excitatory musculomotor neurons progressively release greater amounts of neurotransmitter. In this way, motor neurons determine, through the actions of their neurotransmitters on the plateau phase, whether or not a propagating contraction occurs in the antral pump. With sufficient release of transmitter, the plateau exceeds the threshold and a contraction occurs. Beyond threshold, the strength of contraction is determined by the amount of neurotransmitter released and present at excitatory receptors on the musculature.



**Autonomic/Enteric Reflexes. Figure 1** Firing frequency and therefore the amount of acetylcholine released from excitatory musculomotor neurons in the myenteric plexus of the gastric antrum determine the amplitude of the plateau phase of the gastric action potential. The amplitude of the plateau phase determines the amplitude of antral contractions.

### *Gastric Reservoir*

The gastric reservoir functions in two ways. One is to accommodate the arrival of a meal without a significant increase in intragastric pressure and intramural tension. Failure of accommodation leads to the uncomfortable sensations of bloating, epigastric pain, and nausea in humans. The second function sustains a constant compressive force on the contents of the reservoir that "pushes" the contents into the 3-cycles $min^{-1}$ motor activity of the antral pump. Drug-induced relaxation of the musculature of the gastric reservoir (e.g. by insulin or glucagon) neutralizes this function and suppresses gastric emptying.

The musculature of the gastric reservoir is innervated by enteric excitatory and inhibitory musculomotor neurons. Vagal efferent nerves and neural networks in the gastric ENS control the firing frequencies of the musculomotor neurons. Changes in the firing frequencies of the musculomotor neurons, and coordination of the activity in excitatory and inhibitory enteric musculomotor neuronal populations, function to adjust the volume and pressure of the reservoir to the amount of solid and/or liquid present, while maintaining constant compressive forces on the contents. Neural control mechanisms continuously readjust the volume and pressure within the reservoir as required during both ingestion and emptying of a meal.

Increased activity of excitatory musculomotor neurons coordinated with decreased activity of inhibitory musculomotor neurons, results in increased contractile tone in the reservoir, a decrease in its volume, and an increase in intraluminal pressure. Increased firing of inhibitory musculomotor neurons, coordinated with decreased activity of excitatory musculomotor neurons, results in decreased contractile tone in the reservoir, expansion of its volume, and a decrease in intraluminal pressure.

Neurally mediated decreases in tonic contracture of the musculature are responsible for relaxation in the gastric reservoir (i.e. increased volume). Three kinds of relaxation are recognized: (i) Receptive relaxation is initiated by the act of swallowing. It is a reflex triggered by stimulation of mechanoreceptors in the oropharynx, followed by transmission over spinal and cranial afferents to the ►dorsal vagal complex in the medulla oblongata of the brainstem and activation of efferent vagal fibers to inhibitory musculomotor neurons in the gastric ENS. (ii) Adaptive relaxation is triggered by distension of the gastric reservoir. It is a ►vago-vagal reflex consisting of activation of stretch receptors in the gastric wall, transmission over vagal afferents to the brainstem, central processing of the afferent information and return transmission in efferent vagal fibers to stimulate inhibitory musculomotor neurons in the gastric ENS. (iii) Feedback relaxation is triggered by the presence of nutrients in the small intestine. This form of reservoir relaxation can involve both local reflex connections between receptors in the small intestine and the gastric ENS, or hormones (e.g. cholecystokinin) that are released from endocrine cells in the small intestine and transported by the blood to signal the gastric ENS.

### Pathology

Adaptive relaxation is impaired in patients who have suffered injury to the vagus nerves during laparoscopic fundoplication surgery or have undergone gastric vagotomy for treatment of an acid-related disorder.

Following a vagotomy, increased tone in the musculature of the reservoir decreases the wall compliance, which in turn affects the responses of gastric stretch receptors to distension of the reservoir. The loss of adaptive relaxation following vagotomy is associated with a lowered threshold for sensations of fullness and pain during a meal and filling of the gastric reservoir. Increased sensitivity to gastric distension in these cases is explained by excessive stimulation of the gastric mechanoreceptors that sense distension of the gastric wall. These effects of vagotomy underscore the importance of sensory detection in the gastric wall and processing of the sensory information in the dorsal vagal complex (see next section), and help to understand disordered gastric sensations in diseases that have a component of vagal nerve pathology (e.g. autonomic neuropathy in diabetes mellitus).

## Vago-Vagal Reflexes

Sensory nerve fibers in the afferent arm of ▶vago-vagal reflexes involved in control of gastric functions enter the brainstem and form synaptic connections with cell bodies of efferent vagal neurons that project efferent information back to the stomach. The cell bodies of efferent vagal neurons to the stomach are located in the dorsal motor nucleus of the vagus (DMNV). The vagal afferents also form synapses with second order neurons in the brainstem that distribute visceral information throughout the CNS. Fifty thousand vagal afferent fibers are estimated to supply the gastrointestinal tract. The number of vagal afferent fibers exceeds the number of efferent vagal fibers by about 10:1. Vagal afferent fibers are unmyelinated C-fibers that transmit different modalities of sensory information at low conduction velocity. Vagal afferents generally transmit physiological information on the nature and composition of the luminal contents, on shearing forces occurring at the mucosal surface and on contractile tension in the gastric musculature.

Some vagal afferents connect monosynaptically with vagal efferent neurons and thus become the sensory arm of monosynaptic vago-vagal reflex arcs. Nevertheless, the majority of gastrointestinal vagal afferents project to second order neurons in the nucleus tractus solitarius, and much of the afferent information from the upper gut is therefore processed in polysynaptic pathways through the brainstem. The nucleus tractus solitarius and DMNV combine to form the dorsal vagal complex. Various subnuclei form the nucleus tractus solitarius. Of these, the subnucleus gelatinosus and the medial and commissural nuclei are the principal targets for sensory information in gastric afferents. Gastric afferents also project to the area postrema in the medulla oblongata and transmit input that triggers nausea and emesis. Projections of neurons in the nucleus tractus solitarius to the DMVN complete the vago-vagal reflex arcs involved in regulation of gastric function. Additional sensory pathways ascend through the mid-brain and reticular nuclei to innervate higher brain centers, and in particular to hypothalamic nuclei involved in mechanisms of satiety and regulation of food intake.

Vagal efferent neurons form the cephalic component of the parasympathetic division of the autonomic nervous system. The cell bodies of the vagal efferents are centered in the DMVN, which is a spindle-shaped nucleus running rostro-caudally through the medulla oblongata on either side of the central canal as it emerges into the fourth ventricle. The DMVN is organized anatomically into longitudinal columns of neurons that ultimately give rise to the branches of the vagal nerves that supply the various abdominal organs.

Vagal efferent nerve fibers transmit CNS input to the ENS. A relatively small number of efferent vagal fibers supply synaptic input to a much larger number of neurons in the ENS. Vagal efferent fibers branch extensively within the gastric ENS where they make synaptic contact with the excitatory and inhibitory musculomotor neurons that innervate the gastric musculature. Most of the vagal efferents release acetylcholine to stimulate nicotinic excitatory receptors on the postsynaptic neurons.

Experimental electrical stimulation of efferent fibers in the vagus nerves evokes a mixture of muscular contraction and relaxation as a consequence of activating parallel pathways to excitatory and inhibitory musculomotor neurons. Contractile responses to vagal stimulation are largely cholinergic and are suppressed by drugs that block nicotinic receptors on enteric neurons or muscarinic receptors on the musculature. Vagally-evoked relaxation is mediated by release of nitric oxide, ATP and vasoactive intestinal peptide from the inhibitory motor innervation of the musculature. Vagally-mediated excitatory or inhibitory gastric reflexes therefore arise from selective activation or suppression of populations of efferent vagal neurons in the DMNV, which project either to inhibitory or excitatory musculomotor neurons in the gastric ENS.

Spontaneously discharged impulses, which reflect ongoing generation of neural activity in the DVMN, can be detected by electrodes on vagal efferent fibers. The spontaneous activity may be generated by DVMN neurons themselves or result from activity in circuitry elsewhere in the brainstem or in higher brain centers that supply excitatory synaptic input to the DVMN neurons. A diverse array of neurotransmitters, including glutamate, serotonin and gamma aminobutyric acid, is expressed in the synaptic neuropil surrounding the DVMN neurons. Brain regions with a prominent input to the DVMN include the medullary raphe nuclei, the paraventricular nucleus of the hypothalamus and the central nucleus of the amygdala. These connections underlie emotional and behavioral influences on vagal

outflow to the gut, and in particular, the effects of physical and psychological stress on gastrointestinal function.

As vagal efferents connect to both excitatory and inhibitory motor neurons in the ENS, these pathways are suggested to be reciprocally controlled in the brainstem such that contraction of the gastric musculature arises from activation of cholinergic pathways and simultaneous inhibition of inhibitory pathways [4]. Accordingly, vagally-evoked relaxation of the musculature in the gastric reservoir would involve simultaneous activation of inhibitory pathways and suppression of excitatory pathways. The reflex circuits in the brainstem may therefore be "hardwired" for reciprocal control.

## Lower Level Components

### *Reflexes Mediated by the ENS*

The ENS division of the autonomic nervous system is embedded inside the walls of the digestive tract (Fig. 2).

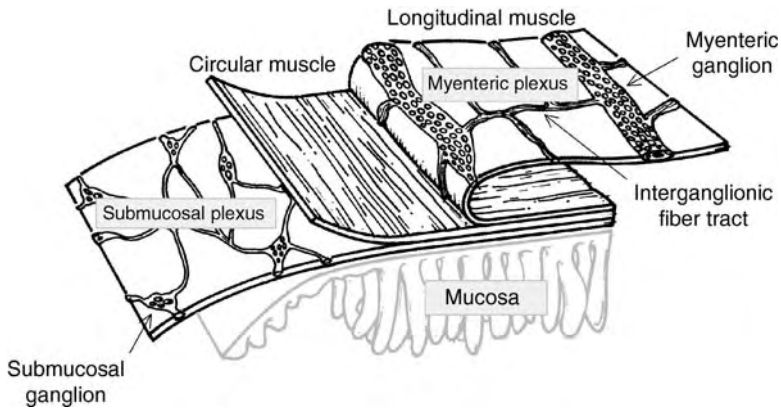
It consists of ganglia, primary interganglionic fiber tracts and secondary and tertiary fiber projections to the musculature, glands and blood vessels. Two ganglionated plexuses are the most obvious gross morphological feature of the ENS. The ►myenteric plexus, also called Auerbach's plexus, is located between the longitudinal and circular muscle layers of most of the digestive tract. The ►submucosal plexus consists of Meissner's and Schabadasch's plexuses and is situated in the submucosal region between the circular muscle and mucosa. The submucosal plexus is most prominent as a ganglionated network in the small and large intestine. It does not exist as a ganglionated plexus in the esophagus and is sparse in the submucosal space of the stomach. Neurons in submucosal ganglia project fibers to the myenteric plexus and also receive synaptic input from axons projecting from the myenteric plexus. The interconnections link the two networks into a functionally integrated nervous system.

The heuristic model for the ENS is the same as for the brain and spinal cord. Like the brain and spinal cord, the ENS develops with the neural elements and integrated circuitry necessary for independent processing of sensory information and programming of organized behavior of effector systems. The ENS controls the intestinal effector systems (i.e. musculature, secretory glands and blood vasculature) in the minute-to-minute regulation of the intraluminal environment of the gut. The population of neurons in the ENS, like the neurons in the brain and spinal cord, is divided into a subpopulation of sensory neurons, a subpopulation of interneurons and a subpopulation of motor neurons. The sensory neurons, interneurons and motor neurons are synaptically interconnected into integrated circuits that process sensory information, and program the variety of digestive functions found in the specialized compartments of the digestive tract during ever changing demands of the ingestive/digestive states of the functioning bowel.

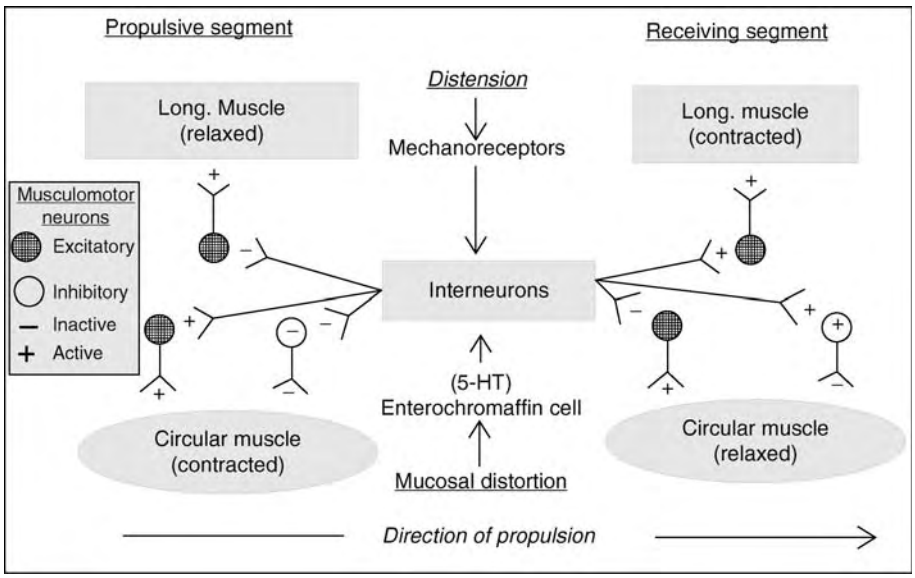
Integrated circuits of the ENS determine the distinctive patterns of motility that characterize the digestive and interdigestive states of the small and large intestine. The ENS microcircuits include a polysynaptic peristaltic reflex circuit (Fig. 3) that underlies all forms of propulsive intestinal motility.

The programs for physiological ileus (i.e. absence of motility), digestive and interdigestive motor and secretory behavior and small intestinal retropulsion during emesis are all stored in the integrated circuits of the ENS.

Microcircuits in the myenteric division of the intestinal ENS contain the musculomotor neurons to the musculature (Fig. 3). Like in the stomach, one subpopulation of musculomotor neurons excites the intestinal musculature to contract; another subpopulation inhibits muscle contraction. Acetylcholine and substance P are primary neurotransmitters released by the subpopulation of excitatory musculomotor neurons.



**Autonomic/Enteric Reflexes. Figure 2** Morphology of the enteric nervous system.



**Autonomic/Enteric Reflexes. Figure 3** A polysynaptic reflex circuit in the ENS evokes the peristaltic reflex. Two kinds of sensory input activate the reflex. One is distension of the intestinal wall and activation of stretch receptors that synapse with interneurons. Second is stimulation of release of 5-hydroxytryptamine from enterochromaffin cells by shearing forces on the mucosa. Output from the interneuronal reflex circuit activates excitatory musculomotor neurons to the longitudinal muscle and inhibitory musculomotor neurons to the circular muscle to form a receiving segment (see fig. 4) below the point of sensory stimulation. At the same time, the circuit inactivates excitatory musculomotor neurons to the longitudinal muscle, activates excitatory musculomotor neurons to the circular muscle, and inactivates inhibitory musculomotor neurons to the circular muscle in the propulsive segment above the point of stimulation (see fig. 4).

Nitric oxide, vasoactive intestinal peptide and ATP are implicated as inhibitory neurotransmitters.

Microcircuits in the submucosal division of the ENS contain ►secretomotor neurons that innervate the intestinal secretory glands (i.e. Brunner's glands and crypts of Lieberkühn). The secretomotor neurons are the efferent arm of secretory reflex arcs that release vasoactive intestinal peptide and/or acetylcholine at the neuroepithelial junctions to evoke secretion of $H_2O$, electrolytes and mucus. Collaterals of secretomotor neurons innervate submucosal blood vessels and stimulate vasodilation to increase blood flow in concert with elevated glandular secretion.

Chemical synapses connect ENS interneurons into integrated microcircuits that determine the timing and strength of neural outflow in the motor neuronal pathways to the musculature, secretory glands and vasculature. In addition to control of each of these individual effector systems, interneuronal synaptic circuits coordinate the activity of each of the systems to achieve homeostatic behavior at the level of the integrated organ system.

The ENS is envisioned as a "mini-brain" placed close to the effector systems it controls and this led to coining of the term "brain-in-the-gut" [6]. The brain-in-the-gut contains as many neurons as the spinal cord. Rather than packing the $2 \times 10^8$ neurons required for control of gut functions into the skull as part of the brain, and relying on signal transmission over long-unreliable pathways to the gut, natural selection during biological evolution distributed the integrative neural networks in locations next to the effectors along the 7 m of human small intestine and 1.5 m of large intestine.

### The Peristaltic Reflex

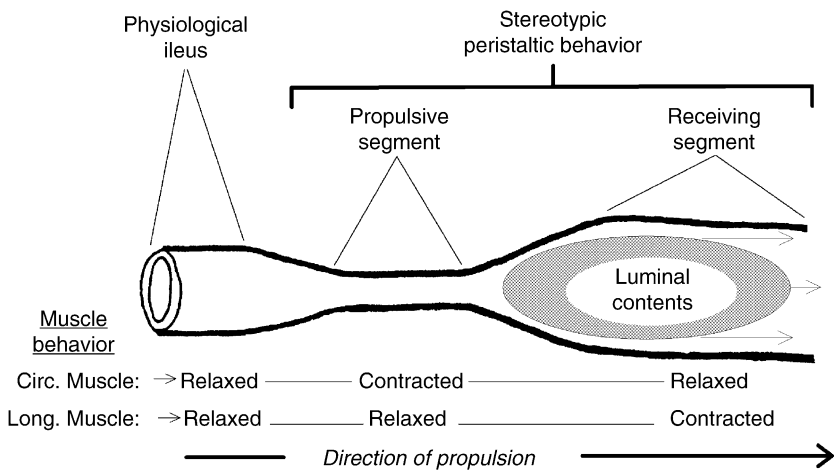
Peristalsis is a stereotyped propulsive motor reflex that underlies all propulsive motility patterns found in the small and large intestine. The peristaltic reflex is the ENS analog of spinal motor reflexes (e.g. monosynaptic patellar and Achilles tendon reflexes and polysynaptic withdrawal reflexes). Monosynaptic spinal reflexes are investigator-evoked artifacts arising from connections of stretch receptors in the muscle to alpha spinal motor neurons that innervate the same muscle. They reflect the effects of abrupt activation of stretch receptors (i.e. muscle spindles) in the muscle and have little relevance for fully understanding the complexity of fine neural control of movement. Polysynaptic spinal withdrawal reflexes occur in stereotypic fashion in response to noxious stimulation, such as touching the hand to a hot object. The peristaltic reflex is much the same as spinal reflexes in that it is a fixed response

evoked by investigational stretching of the intestinal wall or stroking of the mucosa in isolated intestinal preparations. It is like a polysynaptic spinal reflex in that it is a motor response to sensory stimulation that is repeated the same way each time the "hardwired" reflex circuit is activated. The peristaltic reflex circuit is "wired" such that it evokes relaxation of the circumferentially oriented muscle layer, contraction of the longitudinal muscle below the point of stimulation and contraction of the circumferentially oriented muscle layer above the point of stimulation.

Like spinal reflexes, the peristaltic reflex is positioned at the lowest level of the hierarchical organization of neural control of intestinal motility, and undoubtedly underlies each of the various patterns of propulsive motility that impart functionality to the intestine during daily life. As with a spinal motor reflex, the sequencing of the pattern of behavior of the intestinal longitudinal and circular muscles is hardwired into the circuitry, while the strength of each motor component of the pattern, and the repetition rate of the pattern, are adjusted by sensory feedback or other commands to automatically compensate for local loads and higher functional demands on the intestine as a whole. Distance and direction in which propulsion occurs in the specific patterns of motility that characterize the various digestive states are additional factors requiring a higher order of neural control. Short distance propulsion in the postprandial digestive state, propulsion over intermediate distances during interdigestive motility (i.e. the migrating motor complex) and long distance power propulsion, all in the orthograde direction, and retropulsion during emesis are neural control requirements that are met by the ENS. Better understanding of the neural basis for intestinal motility will require moving forward from the "over-worked" concept of the peristaltic reflex, on to investigation of microcircuits in positions at levels of organization beyond the reflex "hardwiring" that faithfully reproduces the muscle behavior each time the investigator stretches the intestinal wall or strokes the mucosa.

The muscle layers of the intestine contract and relax in a stereotyped pattern during peristaltic propulsion (Fig. 4).

This pattern is determined by the sequence in which the peristaltic polysynaptic reflex circuit activates excitatory and inhibitory musculomotor neurons to the longitudinal and circular muscle layers. During propulsion, the longitudinal muscle layer in the segment ahead of the advancing intraluminal contents contracts in response to activation of its excitatory motor innervation, while at the same time, the circular muscle layer relaxes in response to activation of its inhibitory motor innervation. The intestinal tube always behaves geometrically like a cylinder with constant surface area [10]. Shortening of the longitudinal axis of the cylinder during contraction of the longitudinal muscle is accompanied by a widening of the cross-sectional diameter. The simultaneous shortening of the longitudinal axis and relaxation of the circular muscle results



**Autonomic/Enteric Reflexes. Figure 4** The circular and longitudinal muscle layers of the intestine behave in a stereotypical pattern during peristaltic propulsion. A polysynaptic reflex circuit in the ENS determines the pattern of behavior of the two muscle layers. During peristaltic propulsion, the longitudinal muscle layer in the segment ahead of the advancing intraluminal contents contracts while the circular muscle layer relaxes. Simultaneous shortening of the longitudinal intestinal axis and relaxation in the circumferential axis in the same segment results in expansion of the lumen, which becomes a receiving segment for the forward-moving contents. The second component of the reflex is contraction of the circular muscle in the segment behind the advancing intraluminal contents. The longitudinal muscle layer in the same segment relaxes simultaneously with contraction of the circular muscle, which results in conversion of this region to a propulsive segment that propels the luminal contents ahead into the receiving segment.

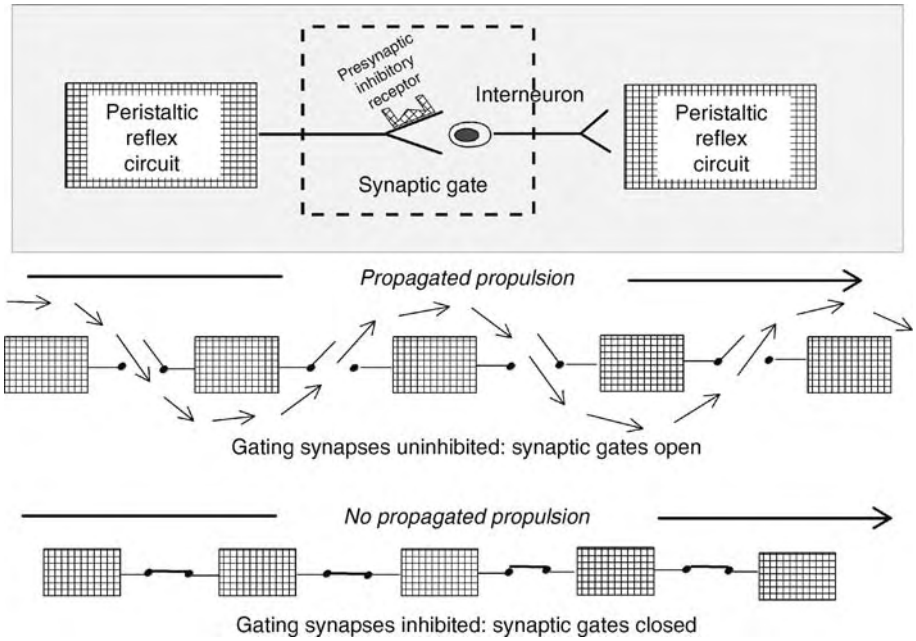
in expansion of the lumen, which prepares a receiving segment for the forward-moving intraluminal contents during peristaltic propulsion.

Organization of a receiving segment constitutes one-half of propulsive peristaltic reflex behavior. The second-half is contraction of the circular muscle in the segment behind the advancing intraluminal contents. The longitudinal muscle layer in this segment relaxes at the same time that the circular muscle contracts, resulting in the conversion of this region to a propulsive segment that propels the luminal contents ahead, into the receiving segment. The propulsive segment is formed when neural connections in the reflex circuit inactivate both the excitatory innervation to the longitudinal muscle and the inhibitory innervation to the circular muscle. Omnipresent myogenic pacemakers, which are also called intestinal electrical slow waves, evoke contraction of the circular muscle in the propulsive segment while the inhibitory innervation to the segment is silenced [2,8].

The heuristic model for peristaltic propulsion has blocks of the basic polysynaptic reflex circuit connected "in series" along the length of small intestine and large intestine (Fig. 5). A block of the basic polysynaptic circuit is formed by synaptic connections between sensory neurons, interneurons, and motor neurons (Fig. 3). Propulsion occurs over extended lengths of intestine, as blocks of the basic circuit are recruited to activity in consecutive segments. In this respect, the intestine is like the spinal cord where connections for polysynaptic reflexes remain irrespective of the destruction of adjacent regions of the spinal cord. Resection of an intestinal segment does not alter the reflex circuitry in the two segments remaining on either side of the resection. Consequently, organized propulsion is not impaired after surgical resection of various lengths of bowel.

Synaptic "gates" connect the blocks of basic circuitry in the heuristic model and contribute to a mechanism for controlling the distance over which the complex of propulsive and receiving segments travels (Fig. 5). When the gates are opened, neural signals pass between successive blocks of the basic circuit resulting in propagation of the peristaltic event over extended distances. Long-distance propulsion is prevented when all gates are closed.

Well understood presynaptic facilitatory and inhibitory mechanisms in the microcircuitry of the ENS [7,9]



**Autonomic/Enteric Reflexes. Figure 5** Synaptic gates determine distance of propagation of intestinal propulsive motility. Presynaptic mechanisms gate the transfer of signals between sequentially positioned blocks of peristaltic reflex circuitry. Synapses between the neurons that carry excitatory signals to the next block of circuitry function as gating points for control of the distance over which peristaltic propulsion travels. Messenger substances that act presynaptically to inhibit the release of transmitter at the excitatory synapses close the gates for transfer of information, and thereby determine the distance of propagation. Drugs that facilitate the release of neurotransmitters at the excitatory synapses (e.g. cisapride and 5-$HT_4$ partial agonists) have therapeutic application by increasing the probability of information transfer at the synaptic gates, thereby enhancing propulsive motility.

are presumed to be involved in gating the transfer of signals between sequentially positioned blocks of reflex circuitry in the heuristic model. Synapses formed by the interneurons that transmit excitatory signals to the next downstream block of circuitry are gating points for controlling the distance over which peristaltic propulsion travels (Fig. 5).

Messenger substances that act presynaptically to inhibit the release of transmitter at the excitatory synapses stop transmission and close the entrance gates to the next downstream block of circuitry, thereby determining the distance of propagation. So-called "prokinetic drugs" that facilitate the release of neurotransmitters at the excitatory synapses (e.g. cisapride and tegaserod) [3,9] have therapeutic application by increasing the probability of information transfer at the synaptic gates, and thereby enhancing propulsive motility.

### *Peristaltic Retropulsion*

The enteric neural circuits can be programmed to control for peristaltic propulsion in either direction along the intestine. For example, if forward passage of the intraluminal contents is impeded in the large intestine of a mouse model for Hirschsprung's disease, reverse peristalsis propels the bolus over a variable distance away from the obstructed segment. Retroperistalsis then stops, and forward peristalsis propel the bolus again in the direction of the obstruction [1]. During the act of vomiting, reverse peristalsis occurs in the small intestine and rapidly transports the luminal contents toward the open gastro-intestinal junction [5]. In this case, as well as in the obstructed intestine, the coordinated muscle behavior required for effective propulsion is the same except that it is organized by the ENS to travel in the oral direction.

# Autonomous System

## Definition

In systems theory, the term indicates a dynamical system that does not have an external input, so that next state, or its rate of change, only depends on the actual state. In the context of robotics, the term refers to a robot that behaves without intervention of an external supervisor. These artefacts (also referred to as autonomous robots) are equipped with sensors and actuators. Their actions are determined by the available sensory information and by their internal logic.

►Computer-Neural Hybrids

# Autopsychic Neurosis

►Personality Disorder

# Auto-regressive Model

## Definition

A model of a system as a differential equation where the output at a given time instant is a linear combination of

the outputs at previous time instances and the current input, usually taken to be a white noise input.

►Signals and Systems

## Auto-regressive Moving Average Model [ARMA]

### Definition

A model of a system as a differential equation, where the output at a given time instant is a linear combination of the outputs at previous time instances and the inputs at previous time instances.

►Signals and Systems

## Auto-spectrum

### Definition

The estimation of the frequency content of a stochastic signal. While cross-spectrum is the linear relationship between two different variables, expressed in the frequency domain, the auto-spectrum is computed as the cross-spectrum of a signal and itself.

►Signals and Systems

## Aversion, Aversive Behavior

### Definition

A repugnance for something with a desire of avoidance; Scientifically aversion or aversive behavior means the avoidance of certain stimuli, environments or situations.

## Aversive Conditioning

►Aversive Learning

## Aversive Learning

### Synonyms

Aversive conditioning

### Definition

In aversive learning an aversion is created toward a targeted behavior by pairing it with an unpleasant stimulus, such as a painful electric shock.

### Characteristics

Traditional analyses of learning posited two general classes of conditioning (i) classical or Pavlovian conditioning and (ii) operant or instrumental conditioning. In these analyses, the former involved stimulus–stimulus associations, whereas the latter reflected associations between responses and reinforcers. These paradigms were applied to both appetitive and aversive conditioning situations, and involved reinforcement or ►punishment, respectively.

In traditional models of aversive classical conditioning, the paradigm further emphasized that the unconditioned stimulus (US; usually some type of rapid onset pain such as footshock) elicits an unconditioned response, the UR. As associative conditioning develops, a conditioned response (CR) emerges in response to the conditioned stimulus (CS). The CR was regarded as basically the same response as the UR, with conditioning demonstrated by its elicitation by the formerly neutral CS.

Operant or instrumental learning involving aversive stimuli typically used the same types of US as in classical conditioning, but the learning component was evaluated by changes in responses that were either designed by the experimenter (e.g., bar pressing) or that enabled the animal to directly escape from a present US (►active avoidance learning) or to avoid the onset of a signaled US by inhibiting a previously punished response (►passive avoidance learning). In the ►learned helplessness model, animals undergo classic aversive conditioning to a shock US in an inescapable shock box, and are then tested in a two-way shuttle for ►active avoidance [1]. The effect depends on the degree of

controllability over the shock to which the animals are initially exposed.

These paradigms were less involved in analysis of responses to the US itself, except insofar as they might interfere with the operant response required to successfully escape from, avoid, or terminate the US. This interference could be substantial, particularly when elaborate operants such as bar pressing or wheel turning were required. In fact, higher levels of shock as a US often increased the time or trials required to learn an artificial, experimenter-imposed task, even though the higher shock should have produced an enhanced motivation to learn the response.

Although studies of classical and operant conditioning were about equally common several decades ago, with the rise of research on neural, neurochemical, and molecular mechanisms of learning, emphasis shifted from complex operant conditioning tasks (with the important exception of those analyzing behaviors related to addiction, most of which involve appetitive rather than aversive paradigms) to tasks providing simple, fast, and robust measures of conditioning. In terms of aversive learning, the shift has been dramatic, with the number of classical conditioning studies an order of magnitude higher than for operant conditioning, since the beginning of the millennium. This shift was associated with a number of developments in the analysis of aversive conditioning.

Two-factor theories of avoidance conditioning [1] long ago noted that the paradigm for classical conditioning is typically embedded in the operant paradigm: the CS that signals the opportunity to avoid necessarily has some temporal association with the US. In two-factor theory, the CS is regarded as eliciting an internal motivational state such as fear or anxiety that is reduced when the avoidance response was made. The operant behavior, avoidance, is reinforced by reduction of this aversive internal state, not by termination or omission of the US, per se. This formulation was useful in explaining difficulties in extinguishing avoidance learning with US omission.

Nonetheless, aversive conditioning studies were plagued by a number of poorly replicable or hard to explain results, many of which appeared to involve the intrusion of behaviors that did not reflect either the UR (in classical conditioning tasks) or to be related to the required CR in operant tasks. In analyzing these intrusive behaviors, R.C. Bolles coined the term "species-typical defensive responses" or "►SSDRs" [2], later commenting that "I have often regarded defensive behaviors as a great nuisance in the study of learning" [3]. Bolles argued that stimuli associated with danger elicit innate defensive reactions at the expense of any other behaviors, whether extensively reinforced or not. If a prominent SSDR is similar to a designated avoidance response rats quickly learn to perform well in that situation. For example, animals rapidly learn to jump onto a ledge of the apparatus or run to an adjacent compartment [1]. However, animals perform poorly when there is a conflict between an elicited SSDR and the designated measure; for example when required to shuttle back and forth between two compartments of a shuttle box [1] or to learn an extraneous behavior such as lever pressing.

## Freezing

Such SSDRs (more correctly called "species-typical defense reactions" or just "defensive behaviors" as they are highly conserved across mammalian species rather than specific to one group) have been extensively investigated in regards to both unconditioned threat and conditioning situations [3]. The first of these to be analyzed was an immobile "crouching" or "freezing" response following footshock. This behavior was strongly conditioned to the context in which shock occurred, sometimes after a single shock [4]. It was also elicited by exposure to nonpainful aversive stimuli such as noncontact encounters with predators or even partial predator stimulus such as odors [5]. Several features of this conditioning presented problems. Because the CR is quite different than the response to shock – generally limb twitching, running or jumping, depending on intensity – it is difficult to conceptualize freezing as a classical conditioned response, in terms of the classic model [6]. Similarly, a single aversive experience provides little scope for operant conditioning: The response to the shock is the only behavior that is consistently emitted just prior to shock termination, and thus positioned to be reinforced by termination of the aversive stimulus. As immobility, rather than the twitch/run/jump response, is the major behavior seen on replacement of animals into the shock situation, it is very difficult to view this as a conditioned operant response.

However, such immobility (for which the term "freezing" is most often employed) is so rapidly and robustly conditioned to contextual cues as to be virtually ubiquitous in a threat context, making it a particularly important modulator of other behaviors that might be used as measures in these tasks: The obvious solution has been to use freezing itself, rather than behaviors disrupted or facilitated by freezing, to evaluate classical aversive, or fear, conditioning. It has come to be one of the most common measures in aversive learning studies in a neuroscience context, with strong representation of both ►contextual fear conditioning ([7] for review) and cue conditioning, e.g., auditory fear conditioning ([8] for review).

## The Startle Response

The other most common measure of classical aversive conditioning in a neurosciences context is the startle response. Startle is the response to a highly salient,

rapid-onset stimulus such as a loud noise or an air puff. In wild rats, which are generally more defensive than lab rats, rapid movement of a potential predator can elicit robust startle jumps. The intensity of the startle response can be enhanced by stimuli associated with shock or by a number of unconditioned factors that are aversive or associated with threat. Fear potentiated startle, in which a cue associated with shock potentiates startle to an auditory stimulus, has a long history in psychology [9]. Recent work with unconditioned potentiation of the startle response, for example by light or isolation has provided information on brain systems involved in such potentiation, enabling comparisons with those underlying fear potentiated startle and pointing out a number of differences between the two [9].

## Analyses of the Biology of These Models

The neuroanatomical, chemical and molecular mechanisms involved in these classical conditioning models have been extensively investigated. There is a general consensus that aversive cue conditioning is mediated by information about the CS and US from sensory inputs that generally include the thalamus and sometimes sensory cortices as well [8] to the lateral and basolateral nuclei of the amygdala, with output projections from the central amygdala to behavioral, autonomic, and endocrine response control systems located in the midbrain and brainstem regions [8]. Many of these same sites are involved in ►context conditioning, but the hippocampus is conceptualized as playing a particularly important role when contextual memories are an important component of a learning paradigm [7]. The amygdala also appears to be involved in operant conditioning situations, but this involvement is seen as more variable and less essential than that of the amygdala in classical aversive conditioning.

## Conditioning of Other Defensive Behaviors

Although freezing and startle are the most often utilized behaviors in classical aversive conditioning, a number of other defensive behaviors elicited by threat stimuli have been analyzed [3], and are coming to be used more extensively in classical conditioning situations. A single confrontation with a cat, or with the odor of a cat, is sufficient to produce conditioning to the exposure context or to specific cues associated with cat odor [10]. While freezing is often the focal measure in these studies, risk assessment, including orientation to the threat stimulus, and approach and investigation of it, is a particularly common defensive behavior to ambiguous or partial stimuli such as cat odor, and may be seen as a conditioned response to cues associated with threat.

A number of studies have mapped brain sites showing fos activation to cat-related stimuli [5]. Effects of lesions in many of these sites on unconditioned and conditioned responses to cat or cat odor, and to footshock, suggest important differences in the brain systems serving shock-based versus predator-based unconditioned responses as well as conditioning to the two types of threat stimuli.

With regard to conditioning of defensive behaviors to partial predator stimuli, a current controversy may shed light on some possible evolutionary mechanisms involved in aversive conditioning. The odor of cat fur and skin supports one trial conditioning of responses such as freezing and risk assessment, whereas a number of additional predator-associated odors such as trimethylthiazoline (TMT), a component of fox feces, do not. However, given a number of trials, TMT does produce a conditioned aversive response in a two chamber "place preference" apparatus that enables avoidance of the situation where the odor was encountered. These data suggest two possibilities; First that TMT is effective in operant rather than classical conditioning tasks, or, second, that there is an important difference between conditioning based on aversive stimuli such as unpleasant odors, and those involving cues of potential danger, such as pain, confrontation with a predator, or the (rapidly dissipating and thus highly associated with cat presence) odor of cat fur/skin. According to the later view, rapid, i.e., 1-trial, learning of danger stimuli is particularly adaptive, whereas stimuli that are unpleasant or disgusting, but not dangerous can be conditioned in a more leisurely fashion. As responses to danger, rather than aversion of unpleasant stimuli, seem more likely to be involved in human emotional psychopathologies, this distinction may be an important one for understanding the role of aversive learning in emotional disorders.

## Aversive Conditioning and Human Emotional Psychopathology

The potential relationship between aversive conditioning and human psychopathology has served as the spur for a number of particular approaches to aversive learning. One such approach studies neurochemical and molecular processes that control the inhibition of fear signaled by previously conditioned stimuli (otherwise known as "fear extinction"). The fear extinction procedure involves reexposure to a CS in the absence of the aversive US, thereby successive extinction trials cause a decline in fearful reactions. Fear extinction is cue specific in that it shows negligible generalization across different sensory modalities. Extinction is not permanent, as shown in studies of reinstatement, renewal, and spontaneous recovery. Similar to fear acquisition processes, extinction has been shown to be dependant on NMDA receptors within the basolateral amygdala [9]. Extinction of aversive memories is of obvious relevance to disorders such as post traumatic stress disorder, that involve intrusive and debilitating

memories of trauma [9]. Extinction is procedurally comparable to several types of exposure-based psychotherapeutic treatments. Similar to fear extinction training, exposure therapy includes exposure to the feared cue or context in the absence of danger, with simultaneous psychotherapy aimed to reduce anxiety levels.

However, another traditional use of aversive conditioning tasks, to evaluate anxiety-like behaviors for preclinical psychopharmacology research, has (comparatively) declined in recent years, giving way to measures based on unconditioned responses in tasks such as the elevated plus maze (EPM) and the Open Field (OF). The exceptions are those tasks described above: Fear conditioning (to context or cue) or potentiated startle, which have increased in use over time; albeit not so rapidly as have the EPM and OF. In contrast, tests of anxiety-like behaviors evaluating punishment effects in operant tasks have all but dropped out of the anxiety researchers' armamentarium. While the need for "high throughput" tasks undoubtedly constitutes one reason for this change in use of classical versus operant conditioning models, it also reflects a view that the learning components of human emotional psychopathology more robustly reflect the former than the latter. However, a variety of aversive conditioning techniques and situations are currently being used in an attempt to identify brain areas and events associated with emotion-linked processes in people, and it is predictable that these processes will prove to involve both classical and operant conditioning, as well as individual differences in unconditioned responsivity to evolutionarily significant danger stimuli and cues.

# Aversive Stimulus

## Definition

An aversive stimulus is a signal or a cue that is repellent and leads the receiver away from the source of stimulation. The same stimulus can be attractive or aversive depending on physical features such as its intensity (for instance, concentration of an odor) or the behavioral context in which it is perceived.

►Attractive Stimulus
►Odor Coding

# Aversive Taste Memory

Milagros Gallo
Department of Experimental Psychology and Physiology of Behavior, Institute of Neurosciences, University of Granada, Granada, Spain

## Synonyms

Aversive taste memory; Bait shyness; Garcia's effect; Learned taste aversion; Learned toxiphobia; Taste aversion learning

## Definition

Conditioned taste aversion (CTA) is a robust type of learning relevant for predicting negative visceral consequences of oral intake. It relies on selective associations between taste and visceral cues. The association between a taste cue and a delayed visceral malaise can be readily formed in one trial. As a consequence the taste becomes disliked and it will be avoided in later presentations. This behavioral defensive mechanism, which favors survival by avoiding repeated poisoning, can be traced through the

phylogeny from invertebrates to humans and along the ontogenetic development from prenatal life to aging. Research on this type of learning has played a major role not only for modern learning theories but also for investigating the neurobiological basis of learning. It may also contribute to understand the learning mechanisms involved in human food selection, drug addiction, and cancer anorexia [1].

## Characteristics

CTA is widely considered as a form of classical conditioning since an associative link is formed between taste (conditioned stimulus) and visceral (unconditioned stimulus) cues. The learned response consists in a shift of the ►taste hedonic value, thus becoming unpalatable and being avoided in later encounters. Shifts of the taste hedonic value can be assessed in rats using the ►taste reactivity test. However, the acquisition of CTAs exhibits several peculiar features that can not be found together in other classical conditioning preparations [2]. First, CTA can readily be acquired in a single conditioning trial. Second, robust taste aversions are induced in spite of long delays, lasting conventionally 15–30 min, between the taste presentation and the outcome of visceral malaise. Moreover, the delay may be extended to several hours if visceral distress takes place under an unconscious state. Learning in unconscious states is also a fact not found in other types of classical conditioning. Third, the peculiar features of CTA rely on selective association between chemical sensory modalities. Robust one-trial and long-delay learning takes place only if gustatory cues, but not somatosensory, auditory, or visual cues, are followed by visceral malaise. However, similar aversions to olfactory cues may be formed provided that a flavor (odor and taste) was previously conditioned, a phenomenon termed ►taste-potentiated odor aversion [2]. The potential relationship between other food attributes such as color, texture, or temperature and CTA is not fully understood.

The adaptive role of CTA resides on its value for survival, since it is an efficient behavioral defensive mechanism to avoid repeated poisoning. Accordingly, it is extensively found from invertebrates to humans. Although it shows specializations throughout the phylogeny, such as resting on visual cues instead of taste cues in birds, it always enables to establish predictive associations among the sensory modality that identifies edibles and the aversive consequences of ingestion. Furthermore, CTA is one of the earliest types of learning demonstrated along the ontogenetic development. Even if it may not show all the characteristics of adult learning, prenatal chemosensory learning has been demonstrated from insects to mammals, including amphibians, fish, and birds. Prenatal CTA in mammals depends on the composition of the amniotic fluid that the foetus swallows. While the potential protective role in utero of prenatal learned aversions requires further research, these aversions can be retained after birth and they can be expressed during the postnatal life. Thereafter, the early development of the chemical senses allows mammals to learn in advance about the chemical environment to be encountered after birth, thus favoring survival. Moreover, CTA seems to be very resistant to aging. Far from being impaired, the acquisition of learned taste aversions is even enhanced in old rats as longer delays can be introduced between the taste cue and visceral malaise. This CTA facilitation by aging, which can not be attributed to an enhanced gustatory or visceral sensitivity, may represent an advantage for survival since to recover from poisoning may represent a stronger challenge during aging because physical deterioration [1].

## Related Phenomena

The acquisition of learned taste aversions is influenced by several phenomena, which depend on the way that taste cues are presented and on the previous experience with the conditioned taste [3]. Taste novelty is a potent modulator of CTA. A novel taste induces an unconditioned neophobic response, leading to a reduced intake. Subsequent taste presentations lead to habituation of the neophobic response as the taste becomes familiar. Thus, ►taste neophobia may be evident either by a reduced intake compared with the baseline intake or by a reduced intake during the first presentation compared with a later presentation. In fact, the habituation of neophobia (►Habituation of taste neophobia) may take place in the absence of a reduced intake during the first presentation as it is the case of highly palatable tastes. Taste neophobia facilitates CTA. Robust learned aversions are developed to novel tastes. On the contrary, the repeated exposure to the taste without consequences before the conditioning session retards CTA acquisition, a phenomenon called latent inhibition. However, under other training circumstances taste preexposure may facilitate learning. When using complex compound tastes or discrimination tasks, the preexposure to the taste may reduce generalization and facilitate learning, as perceptual learning takes place.

The novelty of the visceral malaise experience is also an important modulator of CTA acquisition. CTA acquisition is retarded if the visceral malaise has been experienced before conditioning, a phenomenon called the effect of the US preexposure. Moreover, random preexposures of both taste and visceral malaise induce a greater impairment of later conditioning than preexposing either taste or visceral malaise separately. This phenomenon is called learned irrelevance. In addition to the preexposure effects mentioned, CTA shows a variety of complex learning phenomena, similar to those appearing in other learning tasks [3]. A schematic account of the behavioral procedures used to study complex learning phenomena is presented in Table 1.

**Aversive Taste Memory. Table 1** Schematic account of the conditioned taste aversion procedures showing complex learning effects

| | Phase I | Phase II | Test | Outcome |
|---|---|---|---|---|
| First-order CTA | | A+ | A | Aversion |
| Preexposure effects | | | | |
| Attenuation of neophobia | | A | A | Increased intake |
| Latent inhibition | A | A+ | A | Reduced aversion |
| Effect of the US exposure | + | A+ | A | Reduced aversion |

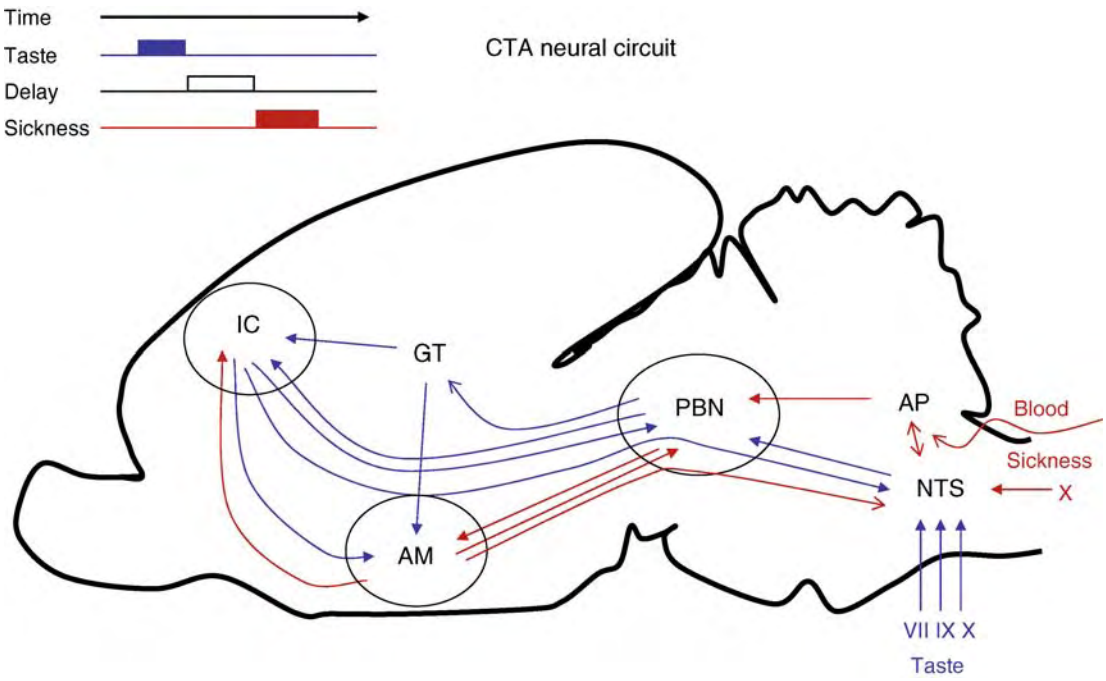
Most of them require two behavioral phases before testing. Note that control groups are not included. A and B represent tastes, (X) and (Y) indicate contexts and + means the aversive agent, such as LiCl. A/B refers to unrelated stimuli; AB refers to compound; "," separates different trials and "…" indicates that the first taste precedes the second in the same conditioning trial.

## Neural Circuit

In spite of being considered a primitive form of learning, the acquisition of CTA depends on a widely distributed neural circuit that engages multiple taste–visceral integration brain regions located at different levels from the brainstem to the forebrain [2,4–6]. Fig. 1 shows the rodent basic neural circuit involved in CTA acquisition.

On the one hand, facial, glossopharyngeal and vagus nerves convey taste afferents to the ►nucleus of the tractus solitarius (NTS), which in turn projects to the ►parabrachial area (PBN) in rodents and to the gustatory nucleus of thalamus directly in monkeys. Taste information reaches the gustatory area in the insular cortex (IC) either through thalamic or direct PBN projections. On the other hand, visceral information conveyed by the vagus nerve and the ►area postrema (AP) project to these brain regions in parallel with the gustatory projections and also reaches the amygdala (AM). Thus, the gustatory and visceral afferent pathways converge in the same brainstem areas from the first relay nucleus in the brainstem. Electrophysiological and immunohistochemical studies have shown that CTA modifies the neural response to the conditioned taste in brainstem areas, such as the nucleus of the solitary tract and the parabrachial area. CTA induces a shift in the response of gustatory neurons processing the hedonic value but not the quality of the taste. Additional data provided by permanent and reversible lesion studies in rodents have pointed out to the PBN, second relay station both for taste and visceral sensory pathways, as a crucial site for the taste–visceral integration involved in CTA acquisition [7]. The proposal of a brainstem integration site relevant for CTA acquisition is consistent with the primitive nature of this type of learning. However, the acquisition of CTA requires also the taste and visceral information to reach forebrain areas, because chronic decerebrate rats do not show CTA. The location of the forebrain integration site or sites remains elusive, although both IC and AM seem to play relevant roles related with higher taste and visceral processing and integration [2,4,5,8]. It has been proposed that interactions among multiple brain regions may be required for CTA acquisition. A critical role of the gustatory insular cortex in long-term maintenance of CTA memories in



**Aversive Taste Memory. Figure 1** Schematic drawing of the known rodent brain regions involved in conditioned taste aversion acquisition. AM, amygdala (central and basolateral nuclei); AP, area postrema; GT, gustatory thalamus (parvocellular part of the ventralis posteromedial thalamic nucleus); IC, insular cortex; NTS, nucleus of the tractus solitarius; PBN, parabrachial nuclei; VII, facial nerve; IX, glossopharyngeal nerve; X, vagus nerve.

rodents has been proposed [11]. The contribution of other brain regions associated with memory and central feeding control systems, such as the bed nucleus of stria terminalis, hypothalamus, the accumbens nucleus, the ventral tegmental area and prefrontal cortex to the acquisition, retention, and expression of CTA is not fully understood. As in other types of learning tasks, the hippocampal system may modulate CTA acquisition when complex learning phenomena are involved.

## Predictivity

The high reliability, robustness, and easiness to obtain CTA in the laboratory using a variety of strain and species, in addition to the fact that it allows to study a wide range of learning phenomena, have made CTA a sensitive tool for the behavioral and neurobiological study of learning. In addition, CTA has proven to be a useful tool for the determination of taste psychophysics and characterization of drug toxicity. However, the results strongly depend on the behavioral procedure applied.

CTA was first studied in the laboratory by John Garcia and coworkers. Since their pioneering study published in 1955 [9], the rat has become the choice animal model in CTA research. Taste solutions are typically used to induce CTA in the laboratory, because they are easily handled and they allow a precise assessment of the amount ingested. The procedure requires subjecting the animals to a water deprivation procedure. The standard behavioral procedure usually applies palatable taste solutions that will be avoided as a consequence of learning. After stabilizing the water consumption during the daily drinking sessions along several days, during the conditioning trial a novel taste solution is presented either for spontaneous drinking or intra oral administration. Several agents, such as radiation, body rotation, and a variety of drugs, being lithium chloride (LiCl) the most widely used, may induce CTA. All of them have in common the induction of behavioral and autonomic indexes of gastrointestinal illness, including emetic responses and also vomiting in those species with emetic ability. Testing consists either in a one-bottle session, with only the conditioned taste solution available or in a choice test in which the animals can choose between the conditioned taste solution and other (two-bottle test) or others (multiple-bottle test) nonconditioned taste solutions. One-bottle tests allow within-subjects comparison between the amount of taste solution drunk during the conditioning and testing sessions, and also between-groups comparisons with nonconditioned groups receiving a sham saline injection. The results of the choice tests are usually shown as a preference rate, which can be compared with that of the control nonconditioned groups. Choice tests are very sensitive for detecting weak

aversions, but they may not differentiate between groups showing different strength aversions. On the contrary, when using one-bottle tests weak aversions may be unnoticed, since the thirsty animal has no other choice to drink, but they are very sensitive for distinguishing among different strength aversions.

In addition, taste reactivity tests for recording orofacial and somatic responses may be required to assess the change of the hedonic response induced by CTA. CTA acquisition induces a change of the taste reactivity behavioral pattern from appetitive to aversive. Besides fluid rejection, the aversive pattern of responses to the conditioned taste include gaping, chin rubbing, forelimb flailing, increased locomotion, and aversive posturing.

Thereafter, when using basic CTA procedures, critical issues should be considered, such as unlearned palatability and novelty of the taste solution applied, form of taste solution presentation (spontaneous drinking versus intra oral administration) and testing protocol. If complex CTA learning procedures are applied, careful behavioral control groups for identifying potential alternative phenomena explaining the outcome should be designed.

## Relevance to Humans

Learned aversions play an important role in the human everyday life food selection. It reduces not only the repeated intake of potentially noxious substances but it also may lead to the avoidance of nutritious foods [4]. Understanding the mechanisms of CTA is crucial for studying and treating daily likes and dislikes, which contribute to diet-induced diseases. However, this issue remains relatively unexplored due to the difficulty of assessing food aversions by conscious verbal reports, a commonly used procedure [4,10]. Studies applying taste reactivity tests in humans may help to understand and modify naturally occurring learned food aversions, such as those involved in the rejection of certain foods by children and the elderly.

CTAs have also important clinical applications related with cancer anorexia and drug abuse. Besides food aversions induced by certain kinds of cancer associated with abdominal discomfort, nausea, and vomiting, controlled clinical studies have indicated that learned food aversions develop in patients receiving chemotherapy and radiation, being gastrointestinal toxicity and nausea the inducing agents. Of interest for the later situation, a behavioral intervention method to reduce the likelihood of forming aversions to the familiar foods consists in providing a novel tasting food before the treatment. The novel taste has proven to act as a scapegoat and to prevent the decrease in familiar food consumption and preference, both in children and adults. A similar treatment using a novel flavor may be also applied to prevent or reduce the anticipatory nausea described in cancer patients associated to the chemotherapy context [4].

Since the 1930s, chemical aversion induction by paired ethanol ingestion with emetically induced nausea was applied as a component of multimodal treatments for certain alcoholic populations [10]. At present, CTA have clinical applications to the aetiology and control of alcohol use and abuse, the receptor characterization of the motivational effects of drugs, the occurrence of drug interactions, and the characterization of drug withdrawal [1].

# Avian Auditory System

Frédéric E. Theunissen
UC Berkeley, Department of Psychology and Neurosciences Institute, Berkeley, CA, USA

## Synonyms

Auditory System of Birds; Hearing in Birds

## Definition

The avian auditory system is composed of multiple brain regions whose principal function is to process acoustical signals and to mediate sound source detection, localization and recognition.

## Characteristics

### Quantitative Description

The avian auditory system begins at the bird's ears and ends in what is referred to as higher or secondary auditory areas in the forebrain. These two end points are connected by a series of auditory processing stages that follow a gross anatomical plan very similar to the mammalian auditory system (see higher level structures). Birds rely heavily on the auditory sense (see function) and therefore have a well developed auditory system. Among the large number of avian species (~9,000), some auditory specialists have emerged. Barn owls hunt in total darkness and excel at localizing the sounds made by their prey. Songbirds use complex acoustic signals, including song and other calls, for social communication and use auditory feedback of their own vocalizations to guide vocal learning. In contrast with the mammalian system, the auditory hair cells, the sensory epithelium of the hearing system, in the bird's inner ear can regenerate after damage. For all the above reasons, the avian auditory system has become a powerful model system to study the neural basis of sound localization, as well as to investigate how the brain memorizes and processes vocalizations in order to mediate behavioral discrimination and recognition. The avian model has also been used to study neural plasticity in the auditory system and its potential in treating deafness.

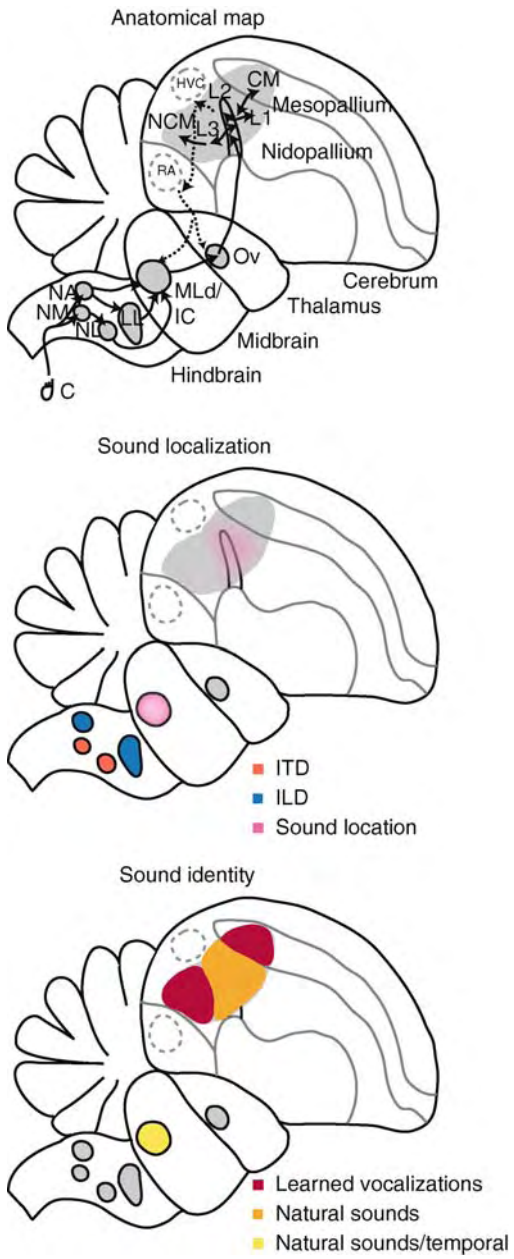
### Higher-Level Structures

The auditory system of vertebrates is an evolutionarily conserved structure. Therefore the avian system shares gross features across all avian groups and resembles other vertebrates, including mammals (►The Evolution of the Avian Auditory System). The most noticeable similarity rests in the number of auditory nuclei (or neural processing stages) and the pattern of feed-forward connections from the cochlear nucleus to the auditory forebrain. As shown in Fig. 1, afferents from the hair cells in the ear project to two cochlear nuclei in the medulla, called nucleus magnocellularis (NM) and nucleus angularis (NA), which are analogous to the anterior ventral and dorsal subdivisions, respectively, of the mammalian cochlear nucleus. As in mammals, the connections between the cochlear nuclei and the auditory midbrain have both a direct and an indirect route. In birds, the indirect route is via the nucleus laminaris (NL) and the nuclei in the lateral lemniscus. These pathways converge in the midbrain, in the dorsal lateral nucleus of the mesencephalon (MLd), which is analogous to the inferior colliculus (IC) in mammals [1]. Both Mld and IC are used in the avian literature. The auditory midbrain projects to a relay nucleus in the thalamus, Ovoidalis (Ov), just as the IC projects to the medial geniculate body (MGB) in mammals. Ov, in turn, sends projections to the primary auditory area in the pallium, field L. Field L has been further divided into subregions (L1, L2a, L2b/L, and L3) based on differences in cyto-architecture and connectivity [2,3]. Input from the auditory thalamus goes to subregions L2a and L2b, which in turn project to L1 and L3. Subregions L1 and L3 make bi-directional connections with two secondary auditory areas in the pallium: the nidopallium caudal medial (NCM) and the caudal mesopallium (CM).

Noticeable differences between the mammalian and the avian auditory system are observed in the feedback and inter-hemispheric connectivity patterns. In mammals, the primary auditory cortex shows strong feedback projections to the thalamus and more limited ones to the midbrain (►Mammalian Auditory Cortex). In birds this feedback circuitry exists, but it involves two additional processing stages in the forebrain, in the shell regions of song system structures HVC and the robust nucleus of the arcopallium (RA). Feedback circuitry in songbirds, is illustrated in the figure, and it lies in similar anatomical locations in non-songbirds. The direct inter-hemispheric connectivity between primary auditory cortex present in mammals is absent in birds.

### Lower-Level Components

The micro-circuitry of the lower auditory nuclei is relatively well known, particularly those involved in sound localization (►sound localization). In the medulla, excitatory neurons from NM converge bilaterally in NL providing temporal information for detecting interaural time differences (►ITD), whereas GABA-ergic neurons originating in the superior Olive provide a mechanism for gain control. Further morphological adaptations are observed on this pathway to enhance or to preserve temporal information. In the pathway involved in the computation of interaural level differences (►ILD), neurons in the lateral lemniscus receive excitatory input from the contralateral NA, and inhibitory input from the contralateral lateral lemniscus. At the next level of auditory processing, in MLd/IC, ILD and ITD information is combined by multiplication. This multiplication is performed by the local network and cellular mechanisms. The local network combines focused excitatory input from the concurrence of desired ILD and ITD responses with more diffuse inhibitory input from non-desired ILD and ITDs. The cellular properties provide a non-linear thresholding operation. This structure leads to neurons that are tuned for particular ILD and ITDs and correspondingly to a single location of a sound source [1].



**Avian Auditory System. Figure 1** Anatomical and functional cartoons of the avian auditory system shown in saggital section. *Top row: Anatomical map*. The figure shows the auditory nuclei and regions in gray as well as two of the song system nuclei that would be found in songbirds (HVC and RA). The feed-forward pathways are shown in solid and the feedback pathway is shown with a *dotted line*. Note that not all the pathways are shown: for example, the reciprocal pathway between NCN and CM has been omitted for clarity. The diagram is also only approximately anatomically correct: NCM would be found in a more medial region that the one drawn here. See text for the name of the areas. *Middle row: functional map for sound localization*. The figure shows the auditory areas specialized for extracting interaural time differences (ITD), interaural level differences (ILD) and the brain regions where neurons coding sound source location are found. The sound source location neurons in MLd/IC are found in the shell of the nucleus and make a topographical map of space. The sound source location neurons in the forebrain are found diffusively and are not organized in a mapped fashion. *Bottom row: functional map for sound identity.* The figure illustrates the hierarchical processing of complex sounds. Mld/IC is tuned for low-level statistics of natural sounds and its population response efficiently represents the temporal changes in the amplitude envelope of the sound. The primary auditory forebrain also efficiently represents sounds with natural statistics and, in addition, its neurons code complex temporal and temporal acoustical features. The secondary areas are sensitive to higher order acoustic features found in vocalizations. The neural response in these areas is also affected by the sounds that the animal learned and remembered. In both functional maps, the areas in gray indicate that the function of these nuclei has not been well characterized.

The micro-circuitry of the higher auditory areas, the morphology of neuron types and their cellular properties have not been examined in detail. Golgi stains suggest the presence of at least four types of neurons in the auditory forebrain [4]. The auditory telencephalon is also densely packed with inhibitory ►GABA-ergic neurons, most of which are very small and presumed to be ►interneurons.

## Structural Regulation

The development of the auditory system occurs either in the egg or soon after hatching. As in other sensory systems, both maturational and experience-dependant factors affect the neural structure. This interaction has been studied best in the sound localization system of the barn owl [5].

## Higher Level Process

As described above, a significant fraction of neural computations underlying sound localization are performed in the auditory medulla and midbrain, leading in the MLd/IC to an anatomically mapped representation of space based on sound source location. The relative contribution of these two areas for auditory scene analysis is currently being investigated [1].

The avian auditory system has also been used extensively to examine how complex acoustical communication signals – bird song and social calls – are processed by the nervous system for detection, recognition and memorization. Neurophysiologists have recorded responses to vocalizations and other complex sounds throughout most of the auditory system and have found a hierarchical processing that leads to specialized

selectivity for complex natural sounds, and ►conspecific vocalizations in particular [6].

Auditory neurons in MLd respond robustly to pure tones, complex tones, and songs, but show higher information rates for stimuli that contain the spectrotemporal features of natural sounds. The population neural response is able to track the temporal changes found in birdsong very accurately.

Neurons in the primary auditory forebrain area, field L, show an additional degree of selectivity in the sense that many of them respond poorly to simple synthetic sounds. Selectivity for conspecific sounds is present in field L but restricted to selection for the relatively low-level statistics of the spectrotemporal acoustical structure found in vocalizations and in other natural sounds. Neurons in MLd and field L can also be classified according to their joint spectrotemporal tuning. This classification shows specialization for detecting distinct acoustical features. Different groups of neurons specialize for detecting fast temporal changes in the sound envelope, the entire sound envelope, slow precise harmonic features or a coarse spectral shape. The efficient representation of these distinct acoustical features might underlie basic acoustical percepts such as rhythm, pitch, and timbre and constitute the building blocks for more selective representations in the secondary auditory regions [7].

Neurophysiological recordings with complex stimuli showed a higher number of selective units in CM than field L. Neurons in CM were also more sensitive than field L neurons to the natural phase of the temporal and spectral modulations found in song. Lesion experiments further support the role in CM for song discrimination.

Experiments using the degree of expression of the immediate early gene (►IEG), *zenk*, in NCM show selectivity for conspecfic song as opposed to ►heterospecific song, and show a lack of response to tone bursts. Neurophysiological studies in NCM also suggest selectivity for complex sounds, which might be absent in subarea L2a of field L. The degree of selectivity for vocalizations in the two secondary auditory areas NCM and CM, and their respective roles in processing and memorizing song in songbirds, is an active area of research.

Songbirds have evolved another specialized set of interconnected brain areas known as the song system, whose function is to produce, and to learn motor control of, ►song. The song system receives input from the auditory system from potentially multiple pathways, the most established one being via auditory area CM. The song system must receive information about what to sing (the tutor's song), about what the bird is actually singing (the bird's own song), and from acoustical signals that trigger singing (e.g., songs of other conspecific males and female calls). The pathway between the avian auditory system and the song system, and the nature of the acoustical information entering the song system, are other active areas of research.

## Lower Level Process

The cellular physiology of the auditory system has been investigated most in the lower-level auditory areas, as described above. There is a lack of neurophsyiological research at the cellular level in the higher levels of the auditory system. On the other hand, studies using histochemical techniques in the auditory telencephalon of songbirds have assessed the expression of receptors for particular neurotransmitters and neuromodulators, as well as ►sexual hormones. More recently, gene-array technology in combination with in situ hybridization has been used to make maps of gene expression in the auditory system [8].

## Process Regulation

Short-term and long-term plasticity have been well studied in the responses of neurons tuned to the spatial location of sound, in the external nucleus of the IC/MLd. These neurons change their tuning if there is a mismatch between the location specified by the auditory information and that obtained from visual feedback information. The plasticity is observed both in young barn owls and to a lesser extent in adult owls. In adults, greater neural plasticity is observed for owls that that have had experience with mismatched feedback as juveniles [5].

Short-term plasticity has also been measured in adult birds during the processing of complex sounds, in the tuning of neurons in the secondary auditory forebrain areas NCM and CM.

NCM exhibits stimulus specific adaptation (SSA). SSA manifests itself as a reduced neural response to repeated stimulation. However, unlike the ubiquitous neural adaptation which is a function of the output of the neuron, SSA is specific to the input of the neuron in the sense that the presentation of a novel (or unfamiliar) stimulus during SSA yields a normal response. SSA can last days and can therefore be considered a form of memory. SSA has been measured in NCM using both IEG studies and neurophysiological recordings. Recent neurophysiological experiments showed that the tutor song memorized by a young bird will later elicit an adapted response in the adult bird, even if that tutor song was not heard for an extended period of time. IEG and behavioral studies involving lesions similarly point to NCM as a potential auditory region where a memory trace for the tutor song resides [9].

Shorter-term plasticity has been measured in neurophysiological recordings in CM. After training birds to recognize individual conspecific songs either in a two-alternative forced choice (AFC) or a go/no-go paradigm, neurons in CM became selective as a population

for the songs. Interestingly, in the AFC experiment the two songs elicited similarly enhanced responses, whereas in the go/no-go experiment, the response to the go song was enhanced relative to the response to the no-go song. Therefore the learned selectivity cannot simply be explained by familiarity but must also involve top-down processing [10].

The avian auditory system also has great potential as a model to study the effect of sensory experience (beyond tutor song) on neural development. This line of research has just recently been initiated. The first study on this subject observed significant changes in the response of field L neurons of birds that were deprived of normal acoustical experience during early development; both the selectivity and the organization of frequency tuning properties were altered [6].

### Function

The acoustical sense is important in birds for detecting predators (of all species), for finding prey (e.g., in the barn owl), for echolocation (e.g., in the cave swiftlet) and, perhaps more remarkably, for complex communication. Listening to others allows birds to classify them as conspecific or heterospecific, neighbor or stranger, male or female, mate or non-mate, parent or non-parent, kin or non-kin. Birds are known to be particularly adept at recognizing individual conspecifics based solely on their vocalizations, often in unfavorable acoustical environments. How the auditory system performs such a difficult auditory scene analysis remains unknown. Furthermore, the communication signals are not just a signature of the sender but carry specific messages. Birds produce calls to maintain contact (contact call), to restore contact (separation call), to obtain food (begging call) or to advertise danger (alarm call). The complex song produced by birds of the suborder oscine (the songbirds) is used by males for territorial defense and mate attraction, and by male–female pairs for pair-bonding and cooperation. In songbirds, audition serves another important function: juvenile songbirds need to listen to adult conspecific song as well as their own vocalizations in order to learn to sing.

### Pathology and Therapy

The avian auditory system is also an experimental model system to study the effects of deafness, sensory deprivation or noise exposure, and hair cell regeneration on the central auditory circuitry.

# Avian Pineal Gland as "Third Eye"

### Definition

The pineal gland of birds is capable of photoreception and, therefore, light can directly regulate melatonin synthesis and release. The light perceived by the pineal gland can be used by the birds to entrain the entire circadian system. At least two functional photopigments.

Pinopsin and Melanopsin, are present in the pineal gland. One of these photopigments may mediate the acute suppression of melatonin synthesis while the other may mediate the entrainment of the circadian pacemaker that drives melatonin synthesis.

# Avoidance Behavior

### Definition

A response to elude negatively valenced events such as painful stimulation. One of the primary organizers of avoidance behaviors is the mid-cingulate cortex where predictions are generated about the outcomes of particular events and motor system responses are determined to minimize or avoid physical harm.

►Cingulate Gyrus

## Avoidance Learning

### Definition

Form of learning that leads to the recognition of dangerous or harmful situations and results in avoidance of such stimuli.

## Axon Degeneration and Regeneration of Peripheral Neurons

D. W. Zochodne
Department of Clinical Neurosciences, University of Calgary, Calgary, AB, Canada

### Definition

Axon degeneration and regeneration of ►peripheral neurons refers to a series of sequential events that occur following a peripheral nerve injury. Axon degeneration involves the breakdown of axons and myelin distal to an injury site, a requisite for subsequent regeneration, or regrowth of axons.

### Characteristics

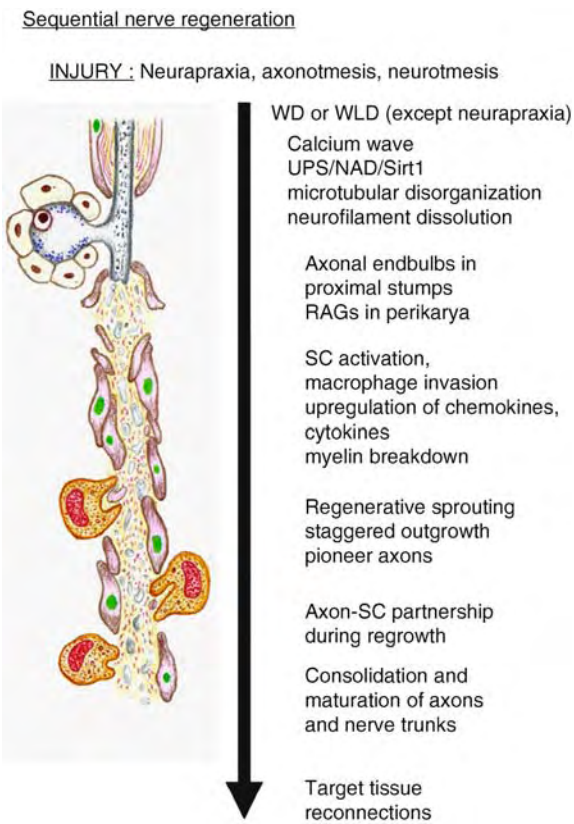
#### Introduction

Long term disability from neurological disease depends as much on loss of axons, or connections, as it does on loss of parent neurons. Sundered axons cannot simply reattach to restore function. Instead, axons must regrow, navigating their way to target tissues once again, as they did during development. Unfortunately this task is incomparably more difficult during adulthood. Cues once present and growth factors once plentiful may no longer exist.

This brief review will address some newer and older concepts concerning ►axonal regeneration of peripheral neurons. Contrary to assumptions otherwise, while peripheral axons regrow, they do so slowly and incompletely. They are also much more frequently injured by trauma or disease than axons of the spinal cord. In a patient with a brachial plexus lesion that disrupts axons supplying the upper limb, it is unlikely that regeneration of motor and sensory axons as far as the hand will occur. Hand movement and sensation are unlikely to be restored. The further axons must grow the less likely they are to find the correct target. Moreover, the pathway they follow becomes far less hospitable. Nerve trunks distal to an injury that have not been reinnervated for several months become much less supportive of regrowth [1]. The Schwann cell (SC), the essential partner of regrowing axons, changes its

phenotype, becomes atrophic and is unlikely to elaborate growth factors to support new axons.

The challenges of peripheral axon regeneration however, start immediately after the injury. These barriers require unique consideration of how axons interact with their microenvironment during the events of regeneration. Before axons re-enter a distal nerve following injury, it is essential that previous material from degenerating axons and myelin are cleared and that basement membrane pathways, or Bands of Bungner, are prepared for them. Injured axons must reseal, sprout, navigate the injury site they encounter, then move en masse towards their targets. Each step of this process can have a major bearing on the success of regeneration and I will briefly cover some aspects of each here (Fig. 1).



**Axon Degeneration and Regeneration of Peripheral Neurons. Figure 1** A simplified schema listing major sequential events involved in regrowth of peripheral nerves after injury. Wallerian degeneration and axon regrowth are involved in injuries that damage axons (axonotmesis and neurotmesis). Neurapraxic lesions are milder injuries involving segmental demyelination without axon interruption or ►axonal degeneration. The image on the *left* illustrates SC proliferation and macrophage entry into a zone of Wallerian degeneration distal to an injury site (illustration by Scott Rogers).

## Wallerian and Wallerian-Like Degeneration

In 1850 Augustus Waller described a series of morphological changes that developed in peripheral nerve axons following a transection injury. This series of events has subsequently been described as "►Wallerian degeneration" [2]. Strictly speaking, Wallerian degeneration (WD) refers to events that follow a nerve transection, also known as a neurotmesis or a Sunderland Type V injury of a nerve trunk. In this injury, the proximal and distal stumps of the nerve trunk are completely separated. "Wallerian-like degeneration" describes similar events and shared mechanisms that occur after many types of traumatic nerve injury where the injury may not be as catastrophic e.g. crush or blunt injures. It also occurs in diseases of nerves known as neuropathies. In the central nervous system, Wallerian-like degeneration (WLD) is also an essential prelude to axon regrowth but it operates at a much slower and less complete pace, a factor linked to very poor regrowth. Finally, axonal "pruning" in development or regeneration, a process that scales back supernumerary axons, shares in the machinery and mechanisms of WD.

WD involves the breakdown of axons and myelin distal to the injury site. Until recently, WD was thought to be a passive distal degeneration because of loss of protein axoplasmic transport from the cell body of the neuron. It is now recognized that WD is an active process with a unique set of signals triggered by an initial calcium transient [3]. The subsequent signals involve the ubiquitin-proteasome system (UPS) and inhibitors of the UPS can delay WD. Additional machinery involved in WD was identified through investigations of a spontaneous mouse mutant known as $Wld^S$. This mouse has axons that survive and persist for long periods after they have been transected: they appear to resist degeneration. The $Wld^S$ mutation is a triplication that forms a fusion protein involving UFD2/E4 (a protein involved in protein ubiquination), and nicotinamide mononucleotide adenylyltransferase (Nmnat, an enzyme involved in nicotinamide metabolism). As a result of this mutation and overexpression of the fusion protein, rises in Nmnat activity increase levels of nicotinamide adenine dinucleotide (NAD), an axonal protectant. NAD, in turn, operates through a protein deacetylase known as SIRT1 (a member of the Sir family of protein deacetylases). Discovery of these new mechanisms of WD offer opportunities to interrupt axon damage in some circumstances, such as axonal damage from peripheral neuropathies.

The next steps of WD involve axon microtubule dissolution, breakdown of the neurofilament axon lattice and, in the case of myelinated axons, a change in the phenotype of SCs associated with these fibers. "Activated" SCs upregulate a series of protein markers including GFAP(glial fibrillary acidic protein), N-CAM,

A5E3, Ran-2 and p75 [4], dissolve their own myelin and behave as phagocytes. To effectively break down axons and clear myelin debris, an inflammatory cascade is next required. This results from invasion of blood borne macrophages within the first 3–5 days after injury. In concert with inflammatory cell invasion, nerves undergoing WD express a series of cytokines and chemokines including IL-1β, IL-6, IFN-γ, TNF-α, MCP-1 (monocyte chemoattractant protein-1) and MIP-1α (macrophage inflammatory protein 1α). These molecules help coordinate inflammatory cell trafficking, axon and myelin digestion, or may operate as trophic factors for new axons. Interruption of their expression delays WD and subsequent regeneration.

Nitric oxide (NO) is an important participant in WD and it is generated by iNOS (inducible nitric oxide synthase) expressed in SCs and macrophages. Local NO dilates local blood vessels to promote clearance and to deliver trophic factors to the injured peripheral nerve trunk. Through lipid peroxidation, NO also promotes myelin breakdown, a task that removes inhibitory myelin products from areas of new axon ingrowth. Mice lacking iNOS have slowed WD and subsequent regeneration. Overexpression of iNOS and excess generation of NO however, may be detrimental to regeneration. NO released during intense inflammation or local infection can paradoxically shut down regeneration and collapse growth cones [5].

Thus, overall evolving concepts concerning WD emphasize its role as an active molecular cascade that later involves a directed inflammatory response. WD is an essential prelude to successful later regrowth.

## Early Regenerative Events

Once severed, axons quickly reseal then change the configuration of their microtubules, an alteration that may alter axoplasmic transport turnaround. Turnaround refers to the change in axoplasmic transport from anterograde to retrograde movement. Axonal endbulbs or boutons, originally described by Cajal as "sterile clubs" or necrotic profiles, next form at the proximal ends of transected axons. These structures, distinguished from growth cones, accumulate axoplasmic material that can include depolymerised neurofilaments, peptides, ion channels, enzymes and other molecules. As bulbs degenerate, some of their constituents can egress into the injury microenvironment and influence local glial cells, other axons or local microvessels. The neuropeptide CGRP (calcitonin gene-related peptide) released from endbulbs can dilate local microvessels and helps to render hyperemia, or rises in nerve blood flow, at injury sites. Endbulbs can also accumulate functional opioid receptors, sodium channels and nitric oxide synthases that generate NO within the injury milieu. These contents of axonal endbulbs may thereby influence the development of ectopic axon electrical discharges associated with neuropathic pain.

Axon sprouting develops at the ends of injured axons, or at nodes of Ranvier proximal to the injury zone in myelinated fibers. Sprouting is a local phenomenon that does not require a connection to the cell body and may normally be suppressed by nodal molecules. For an early sprout to form thereafter into a mature and growing new axon however, does require a connection to the perikaryon. In fact, an injury to an axon is associated with a cascade of changes in the parent cell body that shift its phenotype from a "stable" transmitting neuron to a robust regenerating one [6]. The genes that change in association with injury and regeneration are known as ►RAGs (regeneration associated genes). While the list of these changes is now extensive, key alterations include downregulation of neurofilament subunits, upregulation of tubulin that forms microtubules, upregulation of GAP43/B50 (growth associated protein 43) an actin assembly molecule, upregulation of nNOS (neuronal nitric oxide synthase) and upregulation of HSP27 (heat shock protein 27), a chaperone protein that helps refolding. Some RAGs develop from impaired retrograde transport of trophic factors and can be reversed with their replacement. Alternatively, in the CNS an attenuated RAG response may contribute to poor regeneration.

The overall progress of axon outgrowth and the behavior of growth cones therefore depends on coordinated activity between the cell body and local axons. For example, Perlson and colleagues have described a complex retrograde kinase signaling mechanism involving interactions between importins, dynein, depolymerized vimentin and pErk. Vimentin, an intermediate filament protein, and β importin, upregulated in sciatic axons after injury, complex with dynein and recruit phosphorylated activated Erk. Delivery of pErk to the cell body then allows it to influence nuclear gene transcription [7]. It is likely that more anterograde and retrograde signalling cascades like this will be identified. The interaction does illustrate how a nominal structural intermediate filament, vimentin, is upregulated in axons but subsumes a completely new role when depolymerised. Multiple tasking and interactions of neuronal molecules underlie regenerative events.

## Ras Superfamily GTPases

The list of molecular players influencing growth cones is also rapidly expanding. Their roles *in vivo* however, are less well defined during peripheral neuron regeneration. The Ras family GTPases (►Ras GTPases), specifically RHO GTPases, are molecular switches important in defining cell polarity and directed growth. In neurons, they appear critical to growth cone advance

or collapse. One member, RHOA, has emerged as a critical brake on regenerative activity within the injured spinal cord. Additional RHO GTPase members are CDC42 and RAC1 that promote filopodia and lamellipodial extension and facilitate growth cone advance. RAC1 influences actin filament behavior, stabilizes adherent contacts, and activates the kinase PAK (p21-activated kinase) to then activate NFkB and MAPK.

RHOA localizes to the leading edges of migrating cells, or growth cones in neurons where it can promote its actions [8]. It interacts with p75, formerly known as the "low affinity" nerve growth factor receptor, and other molecules that include LINGO-1, TAJ/TROY, and the epidermal growth factor receptor (EGFR). RHOA, operating through a kinase known as ROK (RHO kinase) and other pathways, collapses growth cones through increases in actin "arc" formation and central actin bundle contractility and stability. To accomplish this task, ROK enhances myosin II phosphorylation and subsequent actin mediated growth cone retraction. It may also accomplish retraction by inhibiting of myosin phosphatase and by activating LIM kinase. This latter pathway in turn phosphorylates and deactivates *cofilin* (also known as actin depolymerizing factor [ADF]) interrupting growth cone advance. There is a long list of additional players that influence actin dynamics and the fate of peripheral nerve regeneration. They include the Arp 2/3 complex, N-WASP, cortactin, Scar/WAVE, Ena/Mena/VASP proteins, Cap Z, actin monomer binding proteins, and profilin to name a few. Further protein cascades and interactions, not discussed here, but including RHO GTPases, are involved in microtubular plasticity, a second major determinant of growth cone behavior.

RHOA has garnered particular attention because its inhibition facilitates axon outgrowth. This has been demonstrated in several ways using central neurons or peripheral neurons growing on inhibitory central substrates such as myelin or myelin-associated glycoprotein (MAG). RHOA is activated by a number of molecules that include Nogo-66, MAG, semaphorins, ephrins, oligodendrocyte myelin glycoprotein and chondroitin sulphate proteoglycans. Wu and colleagues [9] have demonstrated that RHOA GTPase is actually synthesized in growth cones where it facilitates collapse in response to inhibitory cues. In peripheral neurons, an important role for RhoA in inhibiting in vivo regeneration across transection injuries also exists. Blocking ROK improves regeneration.

The role of RHOA in suppressing axon outgrowth is contrasted with that of PI3K-Akt (phosphatidylinositol 3-kinase-Akt; Akt is also called protein kinase B [PKB]), a growth factor activated pathway that promotes growth and differentiation. One of its actions is to phosphorylate and inactivate glycogen synthase kinase 3β (GSK3β), a multifunctional serine/threonine kinase at the leading edges of growth cones that suppresses growth cone extension and axon formation. When it is phosphorylated through the PI3K-Akt signaling pathway, GSK3β activity is shut down, allowing growth to occur.

Overall, while the impact of many of these proteins has been examined *in vitro* or in the CNS, their role specifically on peripheral nerve regeneration is less well known. Some are synthesized by the perikaryon and transported to growth cones to effect their actions. Some however, are also locally synthesized by axons, a novel mechanism for responding to regeneration cues including those from SCs [10]. The other important caveat is that optimal early growth cone behavior in complex injured nerve trunks does not necessarily translate into optimal functional reconnections. Each step of the regenerative process can enhance or inhibit the final outcome.

## Schwann Cell Plasticity

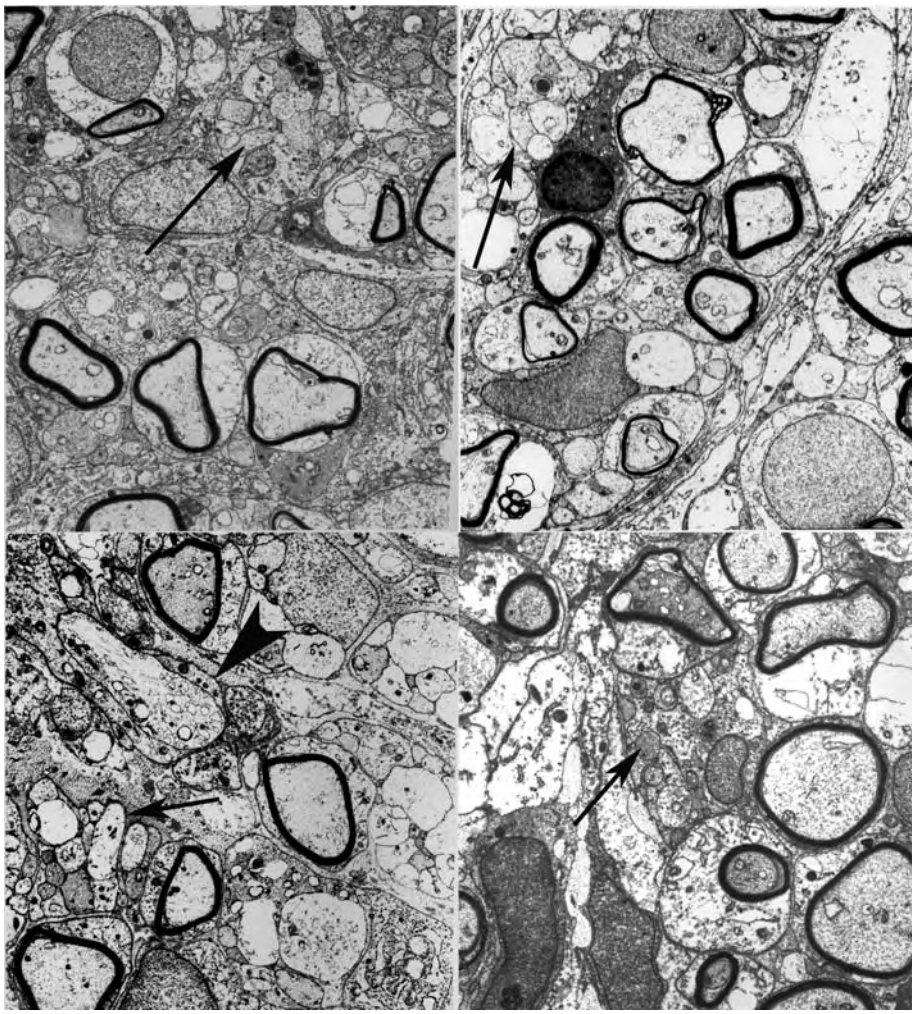
►Schwann cells (SCs) are essential partners for axon maintenance and outgrowth in the peripheral nervous system. Activated SCs lead axons, in part with long laminin trails, through three dimensional trajectories during regeneration. Long and delicate SC processes closely accompany outgrowing axons and participate in a bidirectional exchange of molecules. SCs lay down adhesive substrates of the extracellular matrix such as laminin and fibronectin, but they also provide gradients of growth factors. Axons, in turn, offer substantial signals of their own to SCs that lead, for example, to a change in the "stable" phenotype associated with an intact myelinated axon to a "reactive" SC. Reactive SCs recapitulate development in that they re-express markers such as GFAP and others listed above. Interestingly, many of these markers have ongoing expression in SCs of Remak bundles, the structures that ensheath unmyelinated axons in peripheral nerve trunks. Neuregulins (NRGs), a critical signal to SCs, are products of alternative-splicing of the NRG1gene and belong to a family of growth and differentiation factors. NRGs are released from axons to act on SC receptors erbB2 and erbB3 in order to activate an intracellular second messenger cascade. NRGs thus support new axon outgrowth but may also operate also during WD and myelination. SCs can coax NRG release from axons by offering a menu of growth factors to them first.

Overall, we have labelled these essential bidirectional exchanges the "axon-Schwann cell dance." The importance of this relationship is illustrated by experiments in which SC proliferation is deliberately inhibited by radiation or a mitosis inhibitor. Regeneration is severely limited. Alternatively, deliberately seeding gaps between proximal and distal nerve stumps after transection with SC precursors, substantially facilitates regeneration. Only rare axons advance "naked" for any

significant distances during regrowth. To support regeneration therefore, SCs must dedifferentiate, proliferate and migrate. In some injuries, such as nerve trunk crush, activated proliferating SCs form Bands of Bungner, guidance pathways for regrowth of axons into the distal denervated stump.

### Staggered and Preferential Regeneration

One of the interesting conundrums facing peripheral neurobiology revolves around why outgrowth of axons, for example from proximal nerve stumps, is not synchronized. Classical depictions of axon outgrowth envision simultaneous advance of growth cones and axons from all of their parents in the proximal nerve stump. This view, however, is incorrect and we now recognize that outgrowth is "staggered" such that some axons grow out early, and others lag far behind. After transection nerve injuries, for example, only a small proportion of axons from the proximal nerve stump may cross into the regenerative zone even within the first week. In regenerative bridges, instead of a uniform pattern of new axons of similar maturity, new axons exhibit a wide variation in their level of maturity (Fig. 2). "Staggered" axon regeneration has only recently been highlighted by Gordon and colleagues during regrowth of motor axons [1]. This interesting phenomenon was also linked to another, known as preferential motor reinnervation (PMR) described by Brushart [1]. PMR



**Axon Degeneration and Regeneration of Peripheral Neurons. Figure 2** An electron composite micrograph from a regenerative bridge connecting a transected peripheral nerve trunk forming a few days after injury. The bridge consists of regenerative clusters and axons of varying levels of maturity and myelination. The *arrows* point to small clusters of regenerating axons. The *arrowhead* shows a longitudinally directed axon process, probably a growth cone, accompanied by fine SC processes on either side of it. Although the nerve trunk underwent a single injury, the bridge illustrates "staggered" regeneration in which more mature elongated axons are closely associated with later appearing smaller and less mature axons (image taken by David McDonald, Zochodne lab).

refers to the tendency of motor axons to prefer to regrow along "motor" pathways when offered a choice.

Both "staggered" and preferential regeneration illustrate the less explored concept that local cues for guidance and outgrowth have major impacts on the success of peripheral nerve regeneration. PMR may be accounted for by specific basement membrane molecules expressed by "motor" SCs, but not others that prefer to interact with sensory axons. Axons may have staggered growth because they need these kinds of cues to begin their advance. "Pioneer" axons, following leading migrating SCs, may start the process, and they facilitate axons to follow by offering cues.

## Other Features of the Regenerative Cascade

We provide here only a brief overview of some selected topics and players in the early regenerative cascade of a peripheral neuron. There are many other parts to this story. These include the role of nerve microvessels, or vasa nervorum, during the support of nerve trunk regrowth. A major topic for consideration is the problem of target tissue innervation. Targets include the neuromuscular junction with its specialized complement of terminal SCs and the skin where both dermal and epidermal fiber innervation are required. Regrowing axons must reform the proper architecture of a nerve trunk, re-establish disrupted blood-nerve barriers and in many cases, acquire a stable mature myelin sheath. I have also not discussed the burgeoning topic of neuron growth factors and their downstream intracellular signals. The list has extended well beyond the classical neurotrophin family of nerve growth factor, first discovered by Levi-Montalcini almost 50 years ago. New neuron growth factors, sometimes originally described in other tissues, have emerged such as erythropoietin, GDNF family members and bone morphogenic proteins (BMPs), and vascular endothelial growth factors (VEGFs). Finally, the roles of adhesive molecules interacting with axon and SC integrin receptors are critical to the regenerative process. Not only do these interactions provide outgrowth and guidance cues, but they can generate intracellular signals of their own, interacting for example with growth factors.

## Summary

Peripheral nerve regeneration is a complex, coordinated cascade of events that involves multiple cellular players and an intensive series of molecular interactions. Central among these are the axon-SC partnership and their bidirectional exchange. There is a beauty to the sequential unfolding of all of these relationships, yet they remain largely unexploited for therapeutic purposes. While nerves regenerate, they have major barriers to do so and frequently fail to accomplish their tasks. The upsurge of interest and work on these barriers does promise to overcome them.

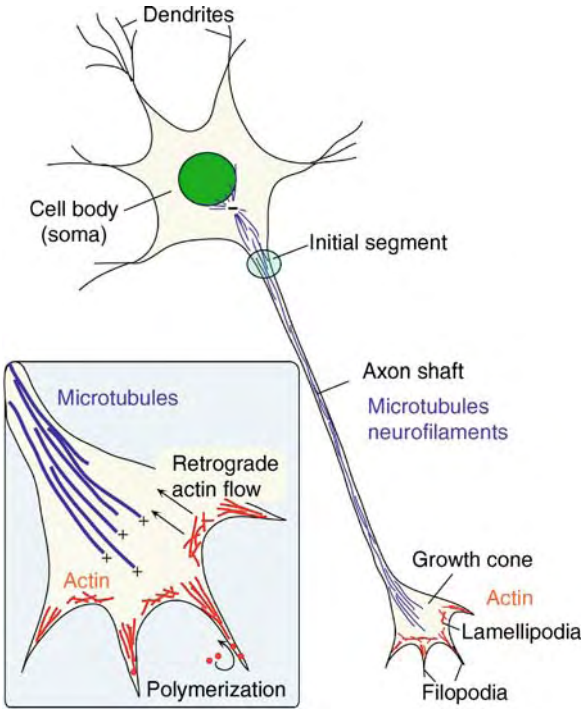
## Definition

The ►axon is the crucial output machinery of neurons. Along this cable, electrical signals, called ►action potentials, are propagated and transmitted to other cells via a ►synapse. Axon a outgrowth is an important developmental process, in which the axon is projected from the cell body (►soma) toward specific target cells. Both intrinsic and extrinsic factors precisely control this process to make sure that the nervous system builds up the correct wiring pattern of axons, because the neural network is fundamental to the complex functioning of the nervous system. The ►growth cone at the distal tip of axons plays a primary role in axon outgrowth, sensing extrinsic factors and determining the direction of the growth. Neurite is a special term referring to a fiber that has outgrown in culture, where the distinction between axons and ►dendrites is not necessarily clear.



**Axon Outgrowth. Figure 1** Structure of a neuron developing neurons can be divided into several parts such as the dendrite, cell body, axon shaft, initial segment and growth cone, each of which has a specific cytoskeletal composition. The *inset* is a close-up of the growth cone showing active cytoskeletal dynamics.

## Characteristics

### Quantitative Description

The lengths of axons vary enormously according to the type of neuron. For example, motor neurons in human have axons that sometimes reach one meter in length, while ►interneurons tend to have much shorter axons, such as tens of microns. The speed of axon outgrowth also depends on neuronal type. The typical speed of axonal outgrowth in culture is in the range of tens to hundreds of micrometers per hour [1]. It is difficult to measure the speed of axon outgrowth in vivo, but the speed has been estimated to be in this range in living animals such as *Xenopus* and *C. elegans* in which axon outgrowth is accessible [2]. The speed of ►axon regeneration in peripheral nerves is usually assumed to be 2–3 mm per day.

### Lower-Level Structures

The distal tip of the axon is called the growth cone and comprises finger-like protrusions, the ►filopodia and ruffling membrane called the ►lamellipodia (Fig. 1).

The ►actin cytoskeleton is the major structural component of the growth cone and the driving force for its movement. Bundled ►actin filaments control the extension and retraction of the filopodia and branched actin meshwork controls the ruffling movement of the lamellipodia. ►Microtubules, another major cytoskeletal component, are the backbone of the axon shaft and also partially populate the central part of the growth cone. ►Neurofilaments, which belong to a class of intermediate filaments, are also abundant in the axon shaft and seem to add stability to the axon cytoskeleton. The axon initial segment or the ►axon hillock, which is positioned at the boundary between the axon and the cell body (soma), usually develops a specialized structure in which various membrane scaffold proteins and ion channels are concentrated and serves as the ignition site for action potentials.

### Higher-Level Structure

The ultimate goal of axon outgrowth is making synapses onto specific targets. During the process, axon terminals turn into ►pre-synaptic structures, in which synaptic vesicles and the releasing machinery are properly installed. The pre-synaptic structure is usually perfectly matched with the ►post-synaptic structure on the target cell. This structural matching is achieved by accurate distribution of a variety of molecules such as cell-adhesion, cytoskeletal and scaffold proteins and ion

channels, through bi-directional signaling between the pre- and post-synaptic elements.

The ►myelin sheath is another important feature of the high level structure of axons. This intricate membrane is synthesized by ►oligodendrocytes and ►Schwann cells in the central and peripheral nervous systems respectively, wraps around many long axons in vertebrates and insulates electrical activity along the axons from leaking, so that the axons can propagate action potentials rapidly.

## Structural Regulation

The actin cytoskeleton and microtubules are dynamically controlled in axons [3]. Actin filaments are continuously transported in the proximal direction within the growth cone (retrograde actin flow in Fig. 1). To cope with this flow, actin filaments are polymerized by incorporating actin monomers at the distal end facing the leading edge of the growth cone. For axons to outgrow, the speed of actin polymerization has at least to keep up with that of the retrograde flow. If not, actin filaments will be withdrawn from the growth cone, stripping off the filopodia and lamellipodia altogether, leading to the reaction called growth cone collapse. Most repulsive ►guidance molecules induce growth cone collapse by affecting actin dynamics and inhibiting axon outgrowth. Microtubules also have a polarized structure and position the fast-polymerized plus-end to the distal direction of axons. When axons grow, microtubules selectively invade the distal part of the growth cone along actin filaments, converting the growth cone into the shaft and actually lengthening the axons. These cytoskeletal dynamics are regulated by a number of tubulin- and ►actin-binding proteins.

## Upstream Process

Generally, neuronal differentiation and migration precede axon outgrowth, although some types of neurons begin to grow axons while their cell bodies are still migrating. In culture, many neurons initially extend multiple immature processes that have the characteristics of neither axons nor dendrites. Subsequently, one of the processes, usually the longest one, is chosen and differentiates into the axon, whereas the others are committed to be dendrites [4]. Although we cannot see the exactly same phenomenon in vivo, a similar competitive interaction among initial processes is believed to take place in the establishment of the highly polarized structure of neurons that have a single axon and multiple dendrites.

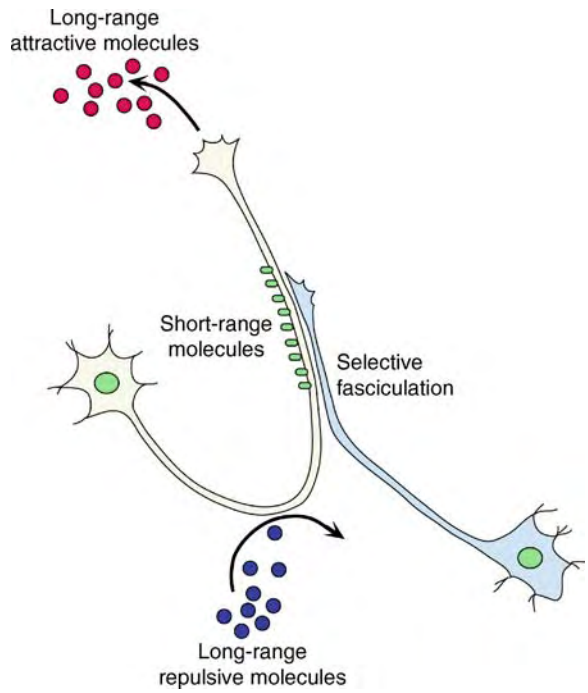
## Downstream Process

The axon is not always a simple single line structure but sometimes bifurcates and makes branches, which enable it to connect to multiple target cells and broaden the terminal field. There is also a naturally occurring degenerative process for axons, in which axons that have once projected are later eliminated. This ►axon pruning is widely used for the refinement of early rough neural networks and the establishment of more functional circuits during a later stage of development.

## Process Regulation

The route of axon outgrowth is stereotyped and barely differs among individuals, suggesting that it is mainly determined genetically. Indeed, the direction of axon outgrowth is controlled by a variety of extrinsic signals called guidance molecules, which are synthesized at a fixed time and place according to the developmental genetic program. The guidance molecules, which are basically proteins, can be categorized into several groups (Fig. 2).

One group is that of attractive molecules that pull the growth cone by changing the cytoskeletal status locally within the growth cone. ►Netrin is a famous example of this category. Another group is that of ►repulsive molecules, which repel the growth cone and create a domain inaccessible to axons. The repulsive molecules



**Axon Outgrowth. Figure 2** Guidance of axon outgrowth. Axon outgrowth is guided by attractive or repulsive guidance molecules. Either attractive or repulsive guidance molecules can act in the short- or long-range. In a later developmental stage, selective fasciculation can be a strong guidance force for the following axons.

destroy the actin cytoskeleton in the growth cone and induce collapse, thereby inhibiting axon outgrowth. Recent studies have identified many molecules that belong to this category including ►semaphorin, ►ephrin and ►slit. Another type of classification from a different standpoint is that of long-range versus short-range guidance molecules. The long-range molecules diffuse from their source and form a concentration gradient, which determines the pattern of axon outgrowth. The short-range molecules are somewhat immobilized in the place where they were synthesized and act only locally on axons. ►Extracellular matrix proteins and ►cell-adhesion molecules are often categorized in this group. Theoretically, either attractive or repulsive guidance molecules can have short- or long-range actions.

During outgrowth, axons are not always individual navigators but often travel together, bundling with each other in the same route. This is especially marked in later projecting axons, some of which simply follow earlier axons by adhering to them (Fig. 2). This selective ►fasciculation apparently eases the pathfinding task of followers; only the first ►pioneer neurons are assigned to the challenging job of pioneering the pathway.

### Function

Axon outgrowth is an important process that enables neurons to connect with distant targets. Therefore, this process underlies all the functions of the nervous system such as sense, movement, perception, memory, emotion and behavior.

### Pathology

Genetic engineering technology has generated many animals that have mutations in various types of genes involved in axon outgrowth and guidance. These animals show specific phenotypes and pathologies in the nervous system according to properties of the genes and could serve as animal models for various human diseases.

### Therapy

In mammals, axon outgrowth is only marked during development and the axons lose the capacity to grow with maturation of the central nervous system. Clinically, it remains extremely difficult to induce re-growth of central axons, although this field has been investigated extensively. Differences in the growing capabilities of developmental and adult axons can be partly attributed to the growth-inhibitory environment of the adult central nervous system. Especially, myelin in the adult central nervous system is assumed to be a component of the materials that prohibit axon regeneration.

## Axon Pathfinding

Nobuhiko Yamamoto
Dept Cellular and Molecular Neurobiology, Graduate School of Frontier Biosciences, Osaka University, Osaka, Japan

### Synonyms

Axon guidance; Axonal targeting

### Definition

During development, axons grow to appropriate directions and reach their target cells to form synaptic connections. In this developmental event, axons are guided by various molecular cues. Fundamentally, there are two types of axon guidance molecules, attractive and repulsive molecules. These molecules are further categorized into diffusible and contact-mediated cues, based on their chemical properties and/or actions.

### Characteristics

#### Quantitative Description

The volume of adult human brain is 1300–1500 $cm^3$ and composed of approximately 100 billion neurons. During development, neurons are produced by proliferation from neuronal stem cells, at a speed of 250,000 per min. After mitosis, a neuron extends an axon, a fine process with a small diameter (less than one micron in most cases). Axons grow at a speed of several ten microns per hour (~1mm/day). An axonal tip is called a growth cone, which is a swelling structure with various detectors to sense surrounding molecules. The size of a growth cone is varied among nervous systems and species, ranging from several to several ►tens of microns. One axon extends from a neuronal cell body, but forms branches and synaptic connections with numerous target cells.

## Higher Level Structures

The fundamental patterns of neural connections are surprisingly stereotyped. For instance, in the visual system (Fig. 1a), a million of the retinal axons originating from one eye run towards the midline of the brain.

Half of them further project to the opposite (contralateral) side of the brain to form connections with ►contralateral visual thalamus (lateral geniculate nucleus, LGN). The remaining half alters the direction at the midline (optic chiasm) and project to the LGN in the same (ipsilateral) side. Axons from the LGN, in turn, send axons to the ipsilateral visual cortex. In a microscopic view, LGN axons project to a particular layer of the visual cortex, which is composed of six cell layers. These connection patterns are completely the same among individuals and even common in higher mammals. Such stereotyped connections are found ►in many other systems. Thus, axons run in specific pathways and form connections with their target cells.

## Lower Level Components

Axons grow towards the location where diffusible attractive factors are concentrated, whereas axons turn away from the source of diffusible repulsive factors. The former and latter phenomena are called chemoattraction and chemorepulsion, respectively. Netrins and ►semaphorins (secreted type) are well-known protein families that have chemoattractive and chemorepulsive activities.

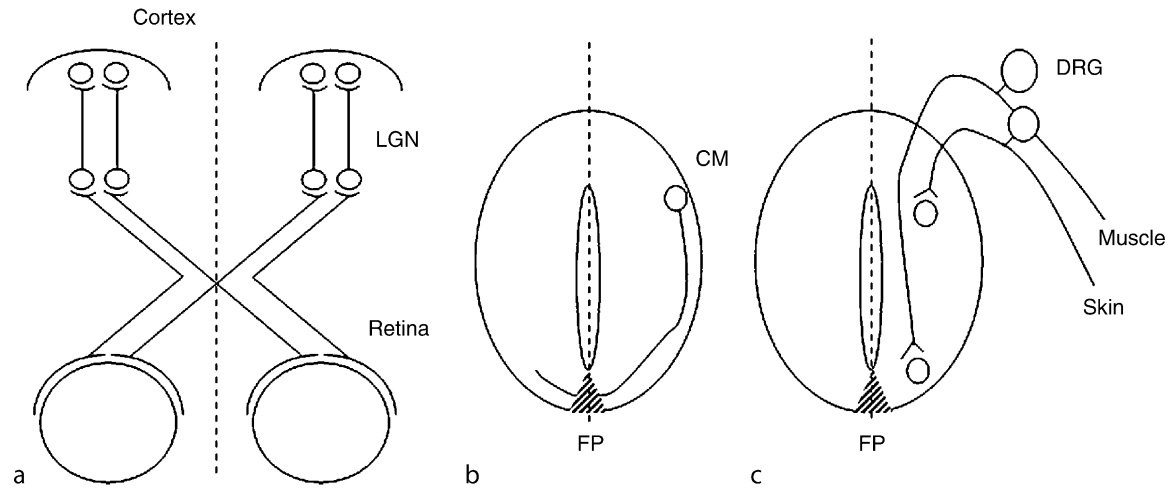
Cell surface and ►extracellular matrix (►ECM) molecules can also act as guidance molecules. Immunogloblin domain-containing proteins and cadherins (calcium-dependent cell adhesion proteins) are typical cell surface molecules which influence axon growth. Ephrins, ligands for a receptor tyrosine kinase family (Eph family), are also cell surface molecules, and are known to act as ►repulsive guidance molecules for axonal growth. Laminin and fibronectin are large glycoproteins in ECM, and promote axon growth of peripheral and central neurons. Proteoglycans, proteins with abundant sugar residues, are also ECM molecules and known to affect axon growth. The proteoglycans are categorized into several types such as heapransulfate proteoglycans and chondroitine sulfate proteoglycans based on kinds of sugar residues.

On the other hand, growth cones have various receptors that sense the above guidance molecules. Unc5 families and DCC (deleted in colorectal carcinoma) are receptor proteins for netrin family members; neuropilin and plexin are receptors for semaphorin family; Ephs are ephrin receptors; Integrin families are receptors for laminin and fibronectin. These receptors are membrane proteins with specific cytoplasmicm domains, which influence cytoskeleton components *via* second messenger systems and/or gene expression.

## Higher Level Processes

### *Chemotactic Behavior and Contact-Mediated Behavior*

The growth cone exhibits ►chemotaxis in *in vitro* experiments. When attractive factors are applied to a growth cone through a glass micropipette, it begins to extend towards the pipette [1]. When a repellent factor is applied, growth cones turn away from the source. Such turning behavior is thought to reflect a guidance property of chemoattractive and chemorepulsive factors *in vivo*: If target or intermediate target cells release attractive factors, growth cones could be directed



**Axon Pathfinding. Figure 1** Stereotyped neural connection patterns in the central and peripheral nervous systems. (a) Neural connections from the retina to the visual cortex. (b) Trajectory of commissural axons in the spinal cord. (c) Projection patterns of distinct sensory neurons. Dashed lines represent the midline. *LGN* lateral geniculate nucleus; *CM* commissural neurons; *FP* floor plate; *DRG* dorsal root ganglion.

toward them. Conversely, axons could avoid entering the brain region where chemorepulsive factors are released.

Growth cones exhibit not only chemotactic but also contact-mediated responses. When growth cones of retinal axons encounter (make a contact) axons from peripheral neurons *in vitro*, retinal growth cones are repelled by the peripheral axons [2]. By contrast, retinal growth cones do not exhibit retraction when meeting other retinal axons. Such contact-mediated cues also contribute to axon guidance.

### *Pathway Choice and Target Selection by Attraction and Repulsion*

Pathway choice and ►target selection are required for the formation of appropriate neural connections in the brain. In the spinal cord, commissural neurons, which interconnect both sides, are located in the dorsal part. During development, axons from these neurons extend ventrally, pass through the ventral midline and reach the contralateral side (Fig. 1b). *In vitro* experiments have shown that commissural axons from the dorsal spinal cord explant grow towards the cocultured floor plate (midline structure of the spinal cord), but do not grow towards explants dissected from the other parts of the spinal cord [3]. Commissural axons from the hindbrain also exhibit similar behavior [4]. These findings indicate that some factor released from floor plate cells, the intermediate target, acts as an attractive factor for commissural axons.

The dorsal root ganglion (DRG) neurons that are involved in pain or heat sensation (nociceptive DRG neurons) send axons to the interneurons that are located in the dorsal part of spinal cord, but do not project to motor neurons in the ventral part of spinal cord (Fig. 1c). In a culture experiment, the developing ventral spinal cord has been shown to secrete the factor that inhibits the growth of theses sensory axons [5]. The DRG neurons that sense muscular extension (proprioceptive DRG neurons) are not affected by the factor. Correspondingly, these sensory axons enter the ventral spinal cord to form synaptic connections with motor neurons. Thus, each type of DRG neurons can select their target cells (►target selection).

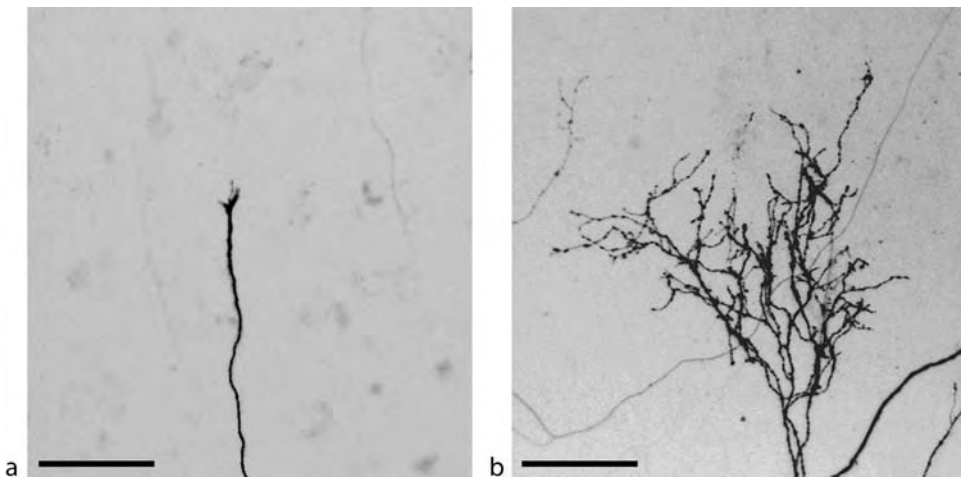
### *Fasciculation and Axonal Branching*

Axons often make a bundle in their pathways. The axon that first extends towards the target cells during development is called a pioneer fiber. The axons originating from the same origin follow the pioneer fiber, and form a bundle (fasciculation). Once these axons reach the target zone, they separate each other (defasciculation). Individual axons further grow to more specific locations and form branching to connect with a certain number of target neurons. In the retinogeniculate system, retinal axons form a bundle (optic tract), but defasciculate in the LGN and form arbors to make synaptic contacts with several LGN neurons. Moreover, LGN axons grow towards the visual cortex with fasciculation (optic radiation). Once arriving at the visual cortex, LGN axons defasciculate to innervate a lot of cortical neurons. Individual axons further form branching in their target layer (target selection) to form synaptic connections (Fig. 2) [6].

## Lower Level Processes

### *Molecular Mechanisms of Attraction and Repulsion*

Ligand-receptor interactions are critical for axon guidance. In the commissural axon guidance, netrin family members are released from the floor plate and



**Axon Pathfinding. Figure 2** Axon growth and branching. (a) Growth cone of a thalamocortical axon extends in the cortex *in vitro*. (b) Thalamocortical axon forms arbors in later developmental stages (*in vitro*). Scale bars in a and b represent 0.05 and 0.1 mm, respectively.

act as attractive factors for the commissural axons that express netrin receptors (Fig. 1b) [7].

Interactions between a member of the semaphorin family and its receptor, neuropilin are necessary for repulsive axon guidance of nociceptive DRG neurons. In this system, the semaphorin is expressed in the ventral half of the spinal cord and act as a repulsive guidance molecule for nociceptive DRG axons [5]. As a result, these axons do not enter the ventral spinal cord. By contrast, proprioceptive DRG axons can enter the ventral spinal cord as they do not express the receptor. However, these ligands do not necessarily produce the same effects in terms of attraction and repulsion. Netrins act as attractive factors in the commissural axon growth, but produce a repulsive action for axon guidance of a particular type of motor neurons. This is true for action of semaphorins.

Another molecular species also contribute to attractive and repulsive guidance mechanisms. Ephrin-Eph interaction produces growth-inhibitory action. Axons expressing Eph receptors are repelled by the brain region where ephrin ligands are expressed [8]. Moreover, chondroitine sulfate proteoglycans, an ECM molecule, also act as repulsive guidance molecules. On the other hand, laminin and fibronectin, ECM molecules, can promote axonal extension in a contact-mediated manner from most central and peripheral neurons that express intergrin receptors.

### *Molecular Mechanisms for Fasciculation and Branching*

Adhesion molecules are involved in axonal fasciculation primarily through their homophilic binding properties. If two axons express the same adhesion molecule, these two axons could run side by side, as high affinity is present between their extracellular domains. Immunoglobulin-superfamily proteins such as the neural cell adhesion molecule (NCAM) is crucial to form axon bundle. Axonal defasciculation is also ►regulated by adhesion molecules. In motor nerve projections, axons from motor neurons form a bundle on the way, but defasciculate around target muscle cells. A certain amount of sugar residues binding to NCAM promote the defasciculation by weakening homophilic binding of L1, the other adhesion molecule [9].

Axonal branching is also regulated by adhesion molecules, ECM and cell-surface molecules. In the cortex, thalamocortical axon branching is inhibited by the sugar residues, whereas it is promoted by ECM or cell surface molecules in the target layer [6]. Axonal branching is further regulated by neurotrophic factors secreted from target cells.

### *Process Regulation*

Expressions of guidance molecules and their receptors are regulated primarily by transcriptional factors. For instance, ephrin (ligand of receptor tyrosine kinase) expression is graded rostrocaudally in the visual center of amphibians as well as mammals. This expression pattern matches that for En (►Engrailed), which is a homeodomain-containing transcriptional factor. Similarly, the receptor expression in the retina is also regulated transcriptionally.

### Function

Brain functions are mostly attributable to its neural networks, that is, axon pathfinding mechanisms produce elaborate neural circuitries that enable us to sense everything and behave appropriately.

## Axon Reflex

### Definition

Generally, the term *axon reflex* denotes a neurally mediated effector response that is brought about by the passage of nerve impulses along axons without traversing a synapse, except that between the nerve ending and the effector tissue. Specifically, an axon reflex is elicited by a stimulus that excites afferent neurons which without transmission to efferent neurons modify the activity of effector tissues. The best known example is the cutaneous *flare* response of Thomas Lewis' triple response to irritation or injury. The reddening (flare due to vasodilatation) that spreads beyond a pin-point injury of the skin is explained as the result of axon reflexes between the arborizing collaterals of sensory nerve fibers. When some axon branches are activated by an irritant stimulus, nerve impulses travel centrally to the branching points where they pass antidromically to the other branches and thus back to the skin. Here, periarteriolar branches of sensory neurons can release vasoactive transmitters (e.g., calcitonin gene-related peptide and substance P) and thereby cause arteriolar dilatation.

### Synonyms

Growth cone guidance

### Definition

For correct functioning of the mature nervous system, precise synapse formation and network assembly during development is required. The neurons, which are the signaling units of the nervous system, possess specialized neurite processes known as dendrites and axons, which are responsible for receiving and sending signals. These neuritic processes, which grow out from the cell body of the neuron during development, must make accurate connections with appropriate targets. The axon in particular, may need to traverse great distances before reaching such targets and the process by which the axon navigates to its eventual destination is known as axonal pathfinding. The structure responsible for this pathfinding task is known as the neuronal ►growth cone [1].

### Characteristics

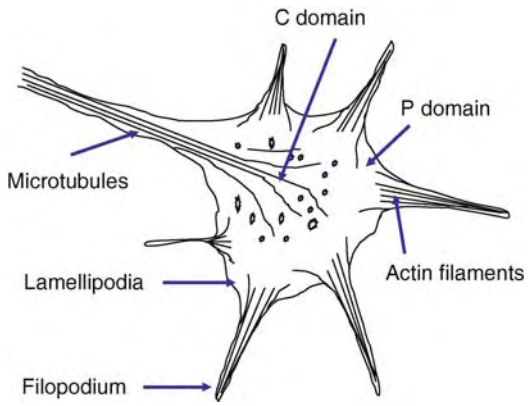
#### Early Development of the Nervous System – A Prelude to Axon Pathfinding and Network Assembly

The construction of an organ as complex as the human nervous system requires an integrated series of precise developmental steps that precede the formation of connections between maturing nerve cells. These

connections ultimately lead to the ability of these networks to process information and mediate complex behaviors. Uncommitted ectodermal cells in the future dorsal side of the embryo require factors provided by neighboring mesodermal and endodermal cells to become a columnar neuroepithelium, the neural plate, in a process called neural induction. Cellular shape changes and mitotic activity in this layer of cells leads to the folding up of this plate and formation of a dorsal ►neural tube. The neural tube contains an inner layer of cells called the germinative or ependymal layer consisting of the mitotically active progenitor cells for both neurons and glia of the brain and spinal cord. As these progenitor cells cease dividing, their fates as specific neuronal cell types or glial cells (►Radial glia) are determined by both intrinsic and extrinsic factors in the local environment of the early neural tube. Extrinsic factors include many diffusible molecules, cell surface glycoproteins and extracellular matrix factors (►Collagens). These factors influence the array of gene products produced in these now committed progenitors which influence neuronal shape, axonal pathway selection, connectivity and chemistry. Once determined, cells migrate away from the ependymal layer through the ever thickening neural tube, toward their final destinations. At the same time, within the dorsal outermost layer of the tube, a population of cells unique to vertebrates, the ►neural crest cells, are beginning to migrate along specific paths toward their ultimate destination in the periphery of the developing embryo. Once there, depending upon a mix of intrinsic factors and target-derived signals, they will differentiate into a wide variety of cell types, including autonomic and sensory ganglia as well as peripheral glia (Schwann cells).

## Structure of the Growth Cone

The growth cone is a small motile expansion of the cytoplasm at the ends of growing axons and dendrites and was first characterized in the late 1800s by the famous neuroanatomist Santiago Ramon y Cajal. The basic morphology of the growth cone is often described as resembling a hand, though growth cone appearance may vary depending upon its surrounding environment. *In vivo*, growth cones tend to acquire a compact shape, whereas *in vitro*, there is a tendency for the growth cone to splay out and enlarge, sometimes reaching diameters as great as 50 μm for large invertebrate neurons. Structurally, the growth cone is divided into two major domains, the central or C-domain and the peripheral, P-domain. Two characteristic features of the growth cone, the filopodia and lamellipodia, emanate from the P-domain. Filopodia are long, slender protrusions that extend from the growth cone and are important for sensing the external environment, whereas the lamellipodia are flattened veils between the adjacent filopodia. The thicker central (C) domain of the growth cone, unlike the filopodia and lamellipodia, contains organelles, vesicles and ►microtubules extending into the C-domain from the axonal shaft (Fig. 1).



**Axonal Pathfinding and Network Assembly.**
**Figure 1** Schematic of a neuronal growth cone.

## The Cytoskeleton

The growth cone is a highly motile structure, a feature which is dependent on the fact that the cytoskeleton of the growth cone is dynamic in nature [2]. Within the P-domain, extending filopodia contain bundled microfilaments made up of F-actin, the continuing polymerization of which pushes the ►filopodium outwards. The sheet-like lamellipodia contain a meshwork of short actin filaments, as well as longer, bundled filaments. Microtubules, which are long polymers of α- and β-►tubulin, extend down the axon shaft and enter the growth cone, radiating out distally in the C-domain, sometimes forming kinks and loop structures. Microtubules have also been seen entering the P-domain in such a way that they are aligned with a filopodium, even entering the most proximal portion of it. ►Microtubule growth has a polarity such that polymerization occurs at the "plus-end," which is directed into the growth cone. Microtubules are the key players in neurite extension, while the actin filaments are more important for filopodia and lamellipodia extension.

The ability of the growth cone to collapse the cytoskeleton in some regions, while constructing new cytoskeletal domains, underlies the motility of the growth cone. Due to the dynamic nature of the cytoskeleton, a host of specialized proteins are needed both to help stabilize, but also remodel the cytoskeleton. Microtubule-associated proteins (MAPs) known to be present in the growth cone include Tau and MAP1B (microtubule stabilizers), MAP2 (a microtubule bundling protein), SCG10 (a microtubule destabilizer) and Ezrin (a linking protein used to join microtubules and actin filaments). A different set of proteins contribute

to actin filament dynamics. These include ADF/cofilin (actin filament depolymerization), α-actinin and fascin (actin filament bundling), and GAP-43 (actin filament length control), among many others [1]. Ultimately, an environmental signal that affects elongation of the axon or growth cone behavior, will somehow regulate the actin and microtubule assemblies described above.

## Responses to Environmental Cues

A large number of guidance cues that direct the motile growth cone have now been identified [3,4]. These include cell surface molecules which generally act as short-range signals, or secreted and diffusible molecules that may act as long-range signals. These signals act in either a repulsive or attractive manner. Repulsive signals may cause a growth cone to turn away from the source, whereas attractive signals induce growth cone turning toward the source. An alternative behavior is growth cone collapse, which often results in the growth cone "shriveling up" (and sometimes retracting) in response to a contact-mediated or diffusible inhibitory signal.

The most well-known cell surface molecules that mediate attraction are the ►cell adhesion molecules (CAMs); for example, the cadherins and neural cell adhesion molecule (NCAM). EphrinAs are examples of repulsive cell surface signals that play an important role in retinotectal mapping [5]. Another repulsive surface signal is myelin associated glycoprotein, MAG, which is a component of myelin and can induce growth cone collapse *in vitro*. MAG may be one molecule that prevents neuroregeneration in some animals, (though it is necessary for both forming and maintaining the myelin sheath). Secreted or diffusible guidance signals are numerous and include the well studied netrins, slits, and semaphorins (class 3), but also include ►growth factors such as nerve growth factor (NGF) and brain-derived growth factor (BDNF), classical morphogens such as Wnts and bone morphogenetic proteins (BMPs), neurotransmitters, and extracellular matrix proteins such as the ►substrate adhesion molecules (SAMs), ►laminin and ►fibronectin.

## Transduction of Signals

A neuronal growth cone possesses a remarkable sensitivity to chemical gradients of guidance cues and has the capacity to detect a concentration difference of as little as one molecule across its surface [6]. The binding of a guidance cue (or ligand) to a surface receptor on the growth cone generates a signal that is ultimately transduced to the cytoskeleton, but exactly how this occurs is not clear. A number of second messengers have been identified as playing important roles in this process including calcium [7] and the cyclic nucleotides cAMP and cGMP [8]. The role of calcium has been known for many decades and it is generally proposed that global increases in growth cone calcium regulate the growth of the neurite (►Neurite outgrowth), whereas local asymmetric increases in the growth cone determine the turning response. Studies on the role of cyclic nucleotides have shown that the ratio of these messengers may be one determining factor for the growth cone's response. For example, studies in *Xenopus* spinal neurons have shown that the direction of growth cone turning in response to the cue netrin-1 is determined by the ratio of cAMP to cGMP, such that a high ratio supports chemo-attraction and a lower ratio, chemo-repulsion. Signaling involving cAMP generally involves the cAMP-dependent protein kinase (PKA) while cGMP involves cGMP-dependent protein kinase (PKG). Both of these kinases are able to affect changes in the cytoskeleton, which is important for the motility of growth cones.

Though most well known guidance factors act by binding to receptors on the surface of the growth cone there are others that may act at the cytoplasmic level and these include nitric oxide, retinoic acid and even a transcription factor, Engrailed-2 (which is internalized by the growth cone). Furthermore, the ability of electric fields to influence growth cone behavior, though not a recent observation, is gaining new attention [9]. Recent research suggests that electric fields may bring about changes in growth cone behavior *via* small GTPases which alter the cytoskeleton. In addition, electric fields may interact with trophic factors such as BDNF and the neurotrophins NT-3 and NT-4, thereby modulating growth cone responses. Table 1 provides some representative examples of guidance factors and their actions on specific cell types.

## Switching Responses

Growth cone responses to a particular guidance cue are not rigid or absolute, but can vary, depending on a number of conditions. The response to a guidance cue may be cell-type specific and even then, a single neuron may produce a differing response depending on the types of receptors present, the ratio of second messengers activated, the source of calcium, as well as the age of the cell. It is also very likely that most guidance signals do not act in isolation, but rather that the growth cone integrates many signals at any given moment in time. A growth cone's response will thus depend greatly on the context in which a specific guidance cue is encountered. A well-known example involves the retinal ganglion cell axons exiting the retina at the optic nerve head, to which netrin-1 serves as an attractive cue. If laminin is ectopically added at the optic nerve head however, netrin-1 is converted to a repulsive cue and the retinal ganglion cell axons fail to exit the eye. When the retinal ganglion cell axons travel from the retina to their targets in the brain, the repulsive guidance cue slit helps to define their pathway by constraining where these axons can grow. However, the

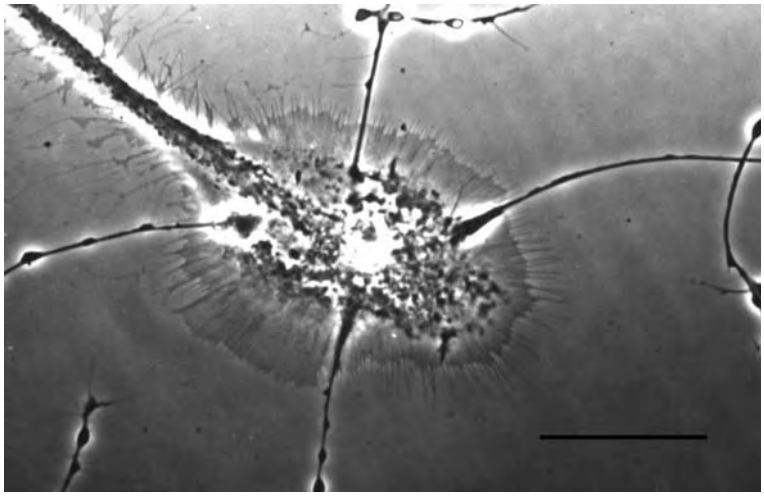
chemokine CXCL12 (SDF-1) is able to attenuate the repulsive effect of slit, thereby modulating the response of the growth cone. There may also be changes within a growth cone which lead to altered responses to a particular guidance cue. In *Xenopus* spinal neurons, BMP7 is initially attractive but later becomes repulsive. This change is mediated by the insertion of a calcium channel leading to the influx of calcium.

## Growth Cone Autonomy

It has become increasingly clear that growth cones are capable of local protein synthesis and that this is likely to contribute to rapid growth cone responses to environmental guidance cues [10]. One example is the requirement for local synthesis of the small GTPase Rho A in the collapsing response of *Xenopus* growth cones to the inhibitory factor Sema 3A. mRNAs that have been identified in developing axons include β-actin, β-tubulin, RhoA and cofilin, which likely play an important role in local regulation of the cytoskeleton. However, there is also evidence that membrane receptors may be synthesized locally at key developmental stages, such as the insertion of the ephrin receptor EphA2 following mid-line crossing in chick embryos. With local protein synthesis, comes the need for local control over mRNA expression. Localization signals may include "zip-code" sequences present on the mRNA, and control over local translation may involve microRNAs, short polynucleotide sequences that are incorporated into the RNA-induced silencing complex (RISC) and mediate repression of mRNA translation. In addition to local protein synthesis, local



**Axonal Pathfinding and Network Assembly. Figure 2** A *Lymnaea* growth cone in cell culture. Photomicrograph of regenerated neuritic processes from individually identifiable cultured neurons taken from the central nervous system of the pond snail, *Lymnaea stagnalis*. The large central growth cone is being contacted by 4 different target cell growth cones. Scale bar = 25 μm (Spencer and Syed, unpublished).

protein degradation plays an important role in producing some growth cone behaviors.

## Experimental Systems Used for Studying Axonal Pathfinding

Axonal pathfinding and growth cone behavior have been studied in many systems including vertebrate models such as chicks and frogs (*Xenopus laevis*) as well as invertebrate models such as worms (*C. elegans*), flies (*Drosophila*) and molluscs (*Aplysia californica* and *Lymnaea stagnalis* (Fig. 2)).

Perhaps some of the most well-studied systems to date include the role of netrins and their receptors (DCC/UNC5) at the midline in the vertebrate spinal cord, the role of slit and the roundabout (robo) receptor in crossing the midline, and the role of ephrinAs and ephrinBs and their receptors (EphAs and EphBs) in the establishment of topographic projections from the retina to the brain [3].

## Target Recognition Precedes Synapse Formation and Network Assembly

At the end of its journey, the neuronal growth cone is required to identify its appropriate target cells or synaptic partners, which include other neurons, glands or muscle cells. In order for correct formation of synapses and network assembly, this target cell selection must be an accurate process. It involves a number of processes that might include branching of the axon, growth cone stalling, increased morphological complexity of the growth cone, and eventual molecular recognition of the appropriate synaptic target, at which point, the axonal growth cone will eventually form the presynaptic terminal.

### Definition

►Axonal sprouting is a process where fine nerve processes – sprouts – grow out from the intact axons to reinnervate denervated muscle fibers. Thereby the sprouting sustains the nerve supply to muscles and, in turn, the ability to move.

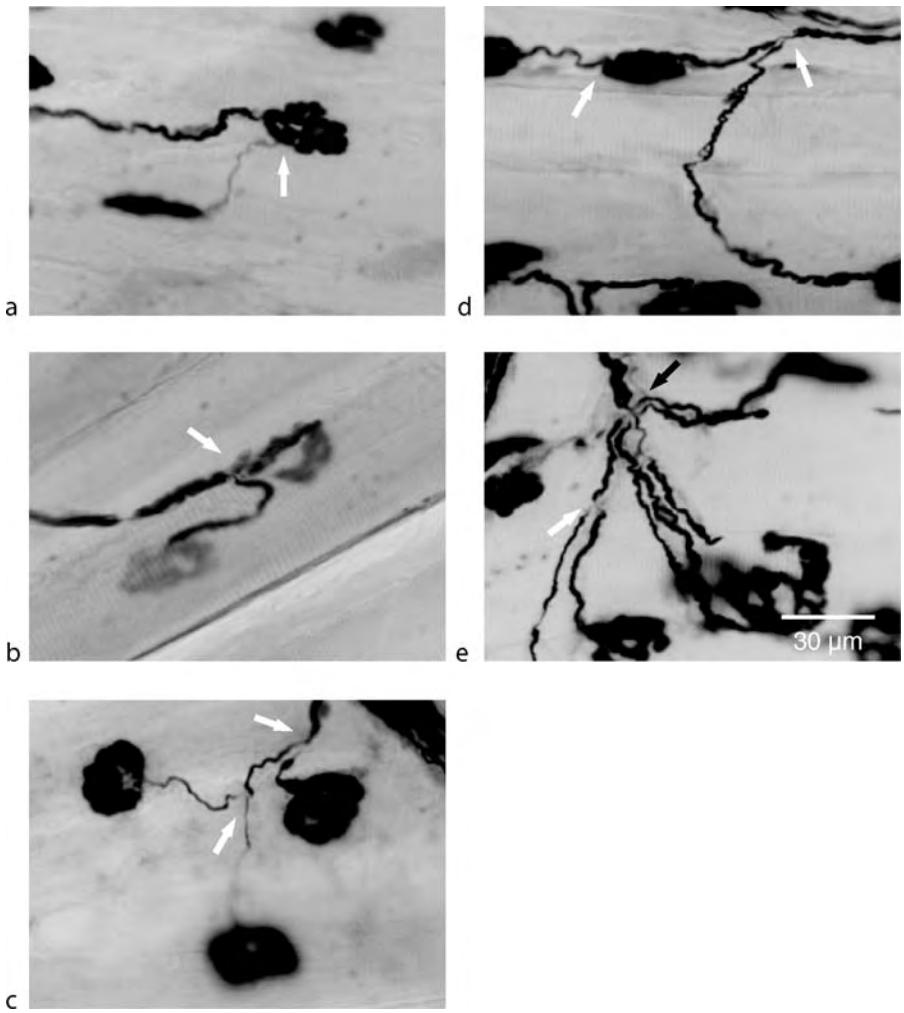
### Characteristics

Axon sprouting from intact ►motor units (a ►motoneuron and the muscle fibers that it supplies) commonly compensates for motoneuron loss in aging and/or in diseases such as poliomyelitis and amyotrophic lateral sclerosis, and/or partial nerve injuries due to the loss of axonal contact and/or death of many of the motoneurons [1]. The Schwann cells at the neuromuscular junction, the ►perisynaptic Schwann cells, play an essential role in leading the axon sprouts from intact axons to the denervated muscle fibers to reinnervate them at the neuromuscular junction. Excessive neuromuscular activity interferes with the normal role of the perisynaptic Schwann cells and thereby the enlargement of motor units (the inclusion of more muscle fibers) by sprouting. In ageing and in post-polio syndrome the number of functional motor units declines progressively. High levels of neuromuscular activity may be counter-indicated due to the inhibitory effects of the neuromuscular activity on the perisynaptic Schwann cells and in turn, on the enlargement of the surviving motor units.

#### Axonal Sprouting and Motor Unit Enlargement

Axonal sprouting is a process where fine nerve processes – sprouts – grow out from the intact axons including ultraterminal (Fig. 1a), preterminal (Fig. 1b), and nodal sprouts to reinnervate denervated muscle fibers (Fig. 1c). More complicated sprouting can occur (Fig. 1d, e).

Each motoneuron normally innervates as few as 10 muscle fibers and as many as thousands, the motoneuron and its muscle fibers being referred to as a motor unit (MU) [1] (Fig. 2). The muscle fibers that lose some of their nerve supply after nerve injuries and/or pathology, or motoneuron diseases, may be reinnervated by axonal sprouts such that the number of muscle



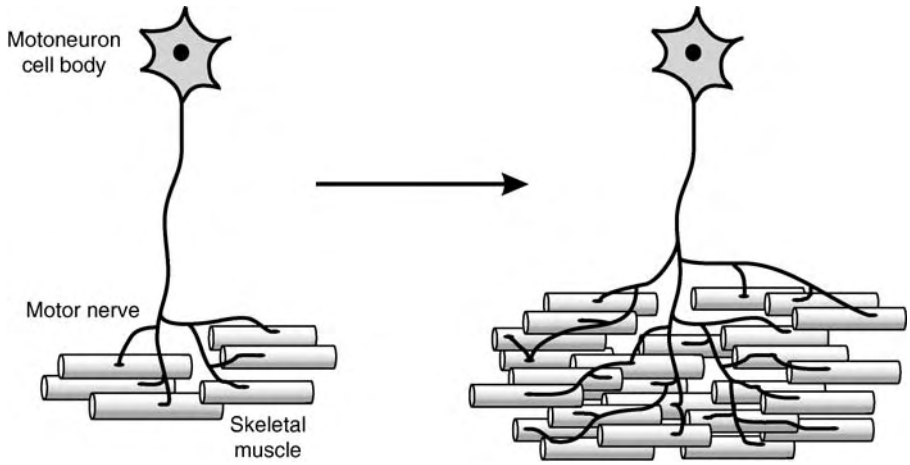
**Axonal Sprouting in Health and Disease. Figure 1** Types of axonal sprouts visualized with silver staining. Ultraterminal (a), preterminal (b) and nodal (c) sprouts. When more extensive sprouting is demanded a single axon can give rise to more than 1 sprout type (Fig. 1d: an ultraterminal and a nodal sprouts) or numerous sprouts of the same type (Fig. 1e: nodal sprouts). (Reproduced from Tam et al. 2001 with permission).

fibers innervated by each motoneuron increases up to a maximum of 8-fold [2]. Hence sprouting is able to compensate for loss of as many as 85% of the normal number of MUs. When less than 20% of functional MUs remain, the maximal capacity of axonal sprouting is exceeded, reinnervation of all denervated muscle fibers fails, and muscle weakness becomes evident [2].

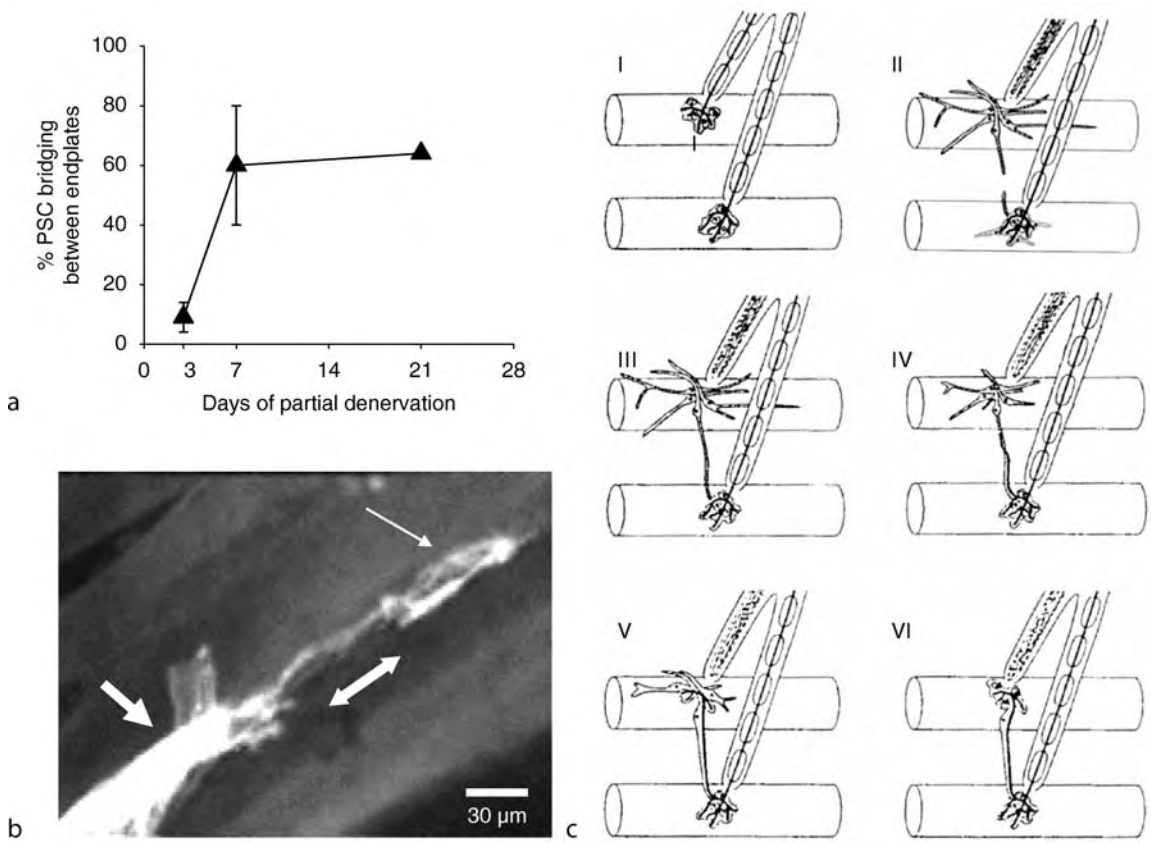
Axonal sprouting is commonly seen to compensate for motoneuron loss at least in part, in aging and/or in diseases such as poliomyelitis and amyotrophic lateral sclerosis (ALS), and/or partial nerve injuries due to the loss of axonal contact and/or death of many of the motoneurons [1]. Although the etiology of these neurodegenerative diseases is not well understood, it has been suggested that the severe debilitation suffered by the patients with these diseases, is a direct consequence of over-exhaustion and subsequent loss of the chronically enlarged MUs.

## The Role(s) of Perisynaptic Schwann Cells in Axonal Sprouting

►Perisynaptic Schwann cells (PSCs), which cover the intramuscular nerve terminals, play a critical role in supporting axonal sprouting in partially denervated muscles [3] (Fig. 3). PSCs at both innervated and denervated endplates form cellular processes which bridge between both types of endplates to the maximum level within about 1 week (Fig. 3a). These bridges behave like "tunnels" to guide the growing axonal sprouts to the denervated endplates (Figs. 3a, b). Muscarinic ►acetylcholine receptors on the PSCs at the endplate



**Axonal Sprouting in Health and Disease. Figure 2** The motor unit and its enlargement by sprouting. Each motoneuron innervates many muscle fibers. When some muscle fibers are denervated by nerve injury or motoneuron disease, axonal sprouts from intact motor units can expand the size of the motor unit (the number of muscle fibers per motoneuron) to a maximum of 3–8 times.

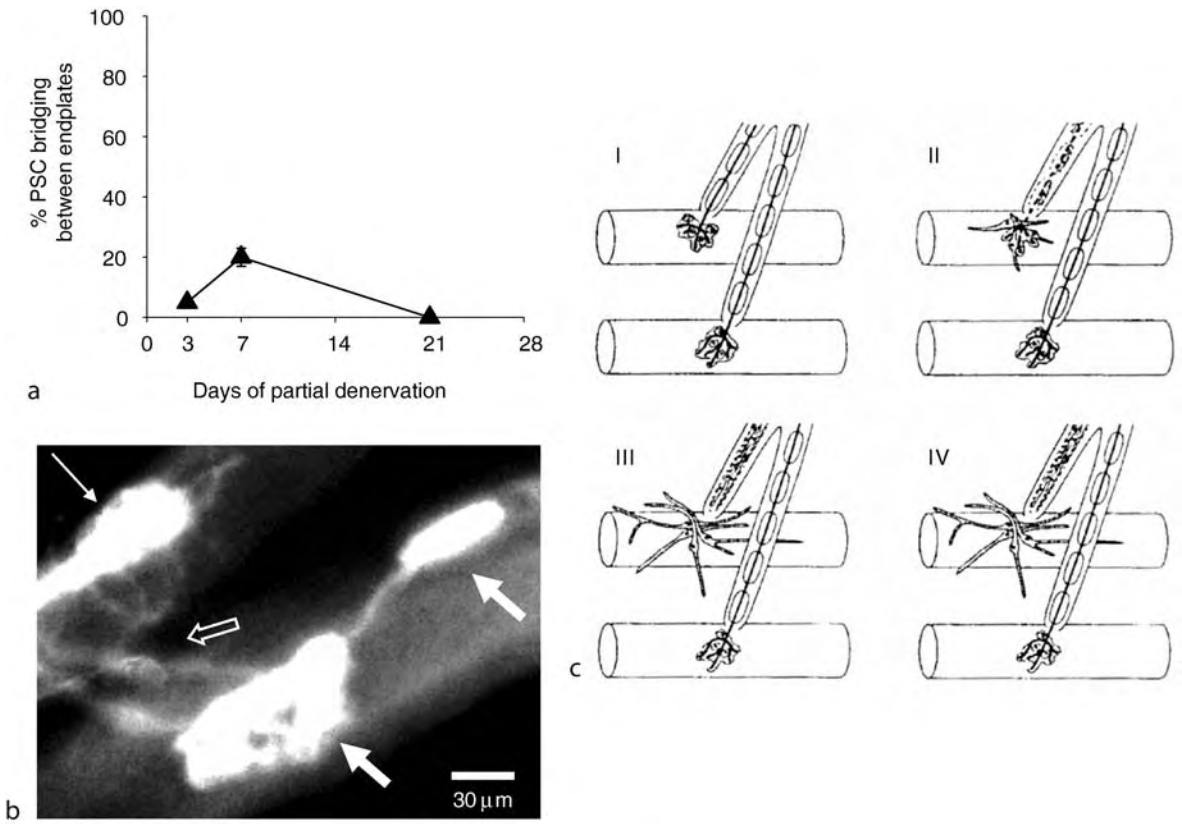


**Axonal Sprouting in Health and Disease. Figure 3** Guidance of axonal sprouting by the bridging of perisynaptic Schwann cells (PSCs) between ►muscle endplates. This bridging reaches a maximum within 1 week of partial muscle denervation (a). PSC processes formed at both innervated and denervated endplates form bridges to direct sprouts to reinnervate denervated endplates (b). Once a sprout reaches its target, the PSC processes withdraw (c). (Reproduced from Tam et al. 2001 with permission).

region of the neuromuscular junction normally respond to acetylcholine released from nerve terminals. The acetylcholine causes an influx of calcium which maintains low levels of glial fibrillar acidic protein (GFAP), in association with the absence of PSC processes (Fig. 3cI) [4]. Upon partial muscle ►denervation, the PSCs at the denervated endplates, which are no longer exposed to acetylcholine, upregulate GFAP and extend processes (Fig. 3cII). It has been postulated that the short-range diffusible, sprout-inducing stimuli generated from the denervated or inactive muscle fibers, have sufficient influence on the PSCs at the innervated endplates in the partially denervated muscles to trigger these PSCs to produce processes (Fig. 3cII) [1]. The PSC processes that form at both the innervated and the denervated endplates navigate out and bridge to support axonal sprouting (Fig. 3cIII). Once the sprouts make functional neuromuscular contact, the PSCs withdraw their processes in response to release of nerve acetylcholine (Fig. 3cIV–VI).

## Effects of Neuromuscular Activity on Axonal Sprouting

The effect of increased neuromuscular activity on axonal sprouting and MU enlargement was unclear and controversial for many years [3]. In attempt to clarify the controversy, we undertook a thorough evaluation to re-examine this issue. We analyzed MU enlargement in several functionally different rat hindlimb muscles whose extent of ►partial denervation was determined. This study clearly demonstrated that high daily neuromuscular activity imposed either by functional electrical stimulation (FES) or daily exercise constrained axonal sprouting and MU enlargement [5], by inhibiting PSC bridging (Fig. 4) [3]. The effect of neuromuscular inactivity on axonal sprouting was not inconsequential:



**Axonal Sprouting in Health and Disease. Figure 4** Increased neuromuscular activity inhibits bridging of perisynaptic Schwann cells. Daily exercise abolishes the PSC bridging right from the early stage (a). Immunofluorescent labeling with S-100 shows that high neuromuscular activity inhibits formation of PCS processes at innervated endplates (thick arrows) (b). Despite the formation of cellular processes of the PSCs at denervated endplates (thin arrow), the cellular processes entangle around the endplate regions and do not navigate out and in turn, do not bridge (open arrow) with the innervated endplates. A schematic representation details that daily exercise does not impair the formation of perisynaptic Schwann cell processes (CI,II) but effectively prevents the briding of the processes from innervated to denervated endplates and thereby, prevents sprouting of axons from innervated to denervated muscle endplates (C III-IV) (Adapted from Tam et al., 2003).

blockade of neuromuscular activity using either or ►tetrodotoxin or ►α-bungarotoxin, significantly reduced axonal sprouting and MU enlargement in partially denervated muscles [6,7].

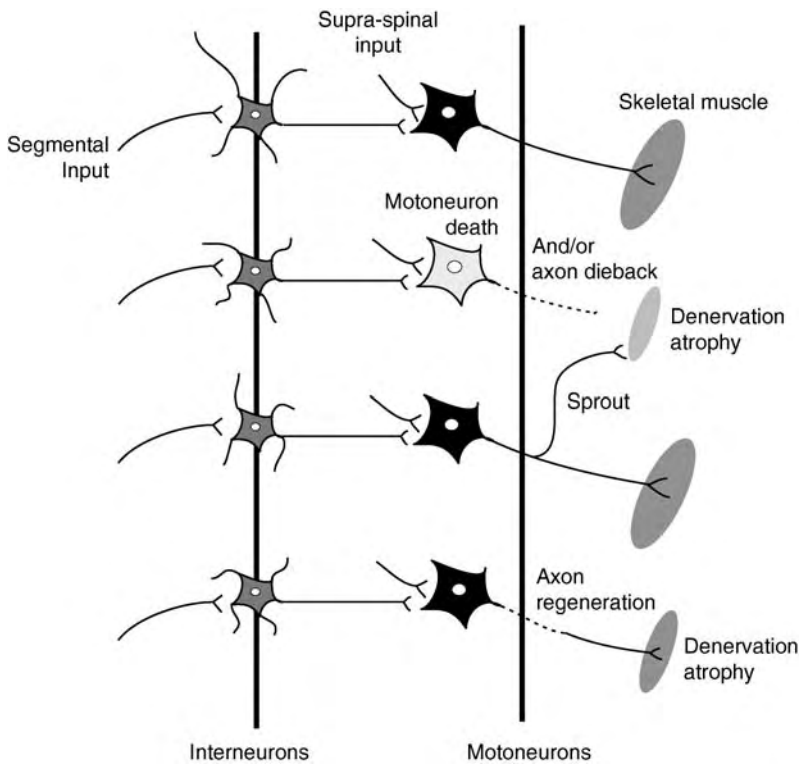
## Normal Aging: Progressive Loss of Functional MUs in the Context of Progressive Increase in Oxidative Stress and Neuromuscular Activity

With aging, there is a slow progressive decline in numbers of motoneurons and loss of ventral root axons that becomes more obvious from the sixth decade of life [8]. Oxidative stress progressively rises in the aging motoneurons, oxidative stress being generally defined as a condition where production of reactive oxygen species produced during normal aerobic metabolism overwhelms the endogenous antioxidant defence systems [1]. Ultimately the anti-oxidative enzymes, including copper/zinc superoxide dismutase (SOD1) in the cytoplasm and manganese superoxide dismutase (MnSOD) in the mitochondria, can no longer eliminate reactive oxygen species (superoxide and hydroxyl radicals) effectively. The oxidative stress progressively reduces neuromuscular efficacy. This is followed by loss of functional MUs, decline in axon transport rates, and transmitter storage and release that eventually reduces the capacity of MUs to sustain stable nerve-muscle connections, the endplate region undergoing progressive expansion and finally axonal die-back [1] (Fig. 5).

As the number of functional MUs declines with age, neuromuscular activity may be counter-indicated due to inhibitory effects of very high neuromuscular activity of progressively fewer intact MUs on the bridging of PSCs between denervated and innervated endplates [5]. Hence the sprouting and enlargement of the intact MUs becomes progressively compromised with age [9].

## ALS: Progressive Loss of MUs in Relation to Progressive Increase in Levels of Neuromuscular Activity and/or Oxidative Stress

ALS, unlike acute poliomyelitis, is strictly an adult onset disease, which usually presents in the fifth or sixth decade of life with a survival time of 3–5 years. Approximately 10% of all ALS cases are familial in origin, and of these 20% are linked to mutations in the SOD1 gene. The identified mutations to SOD1



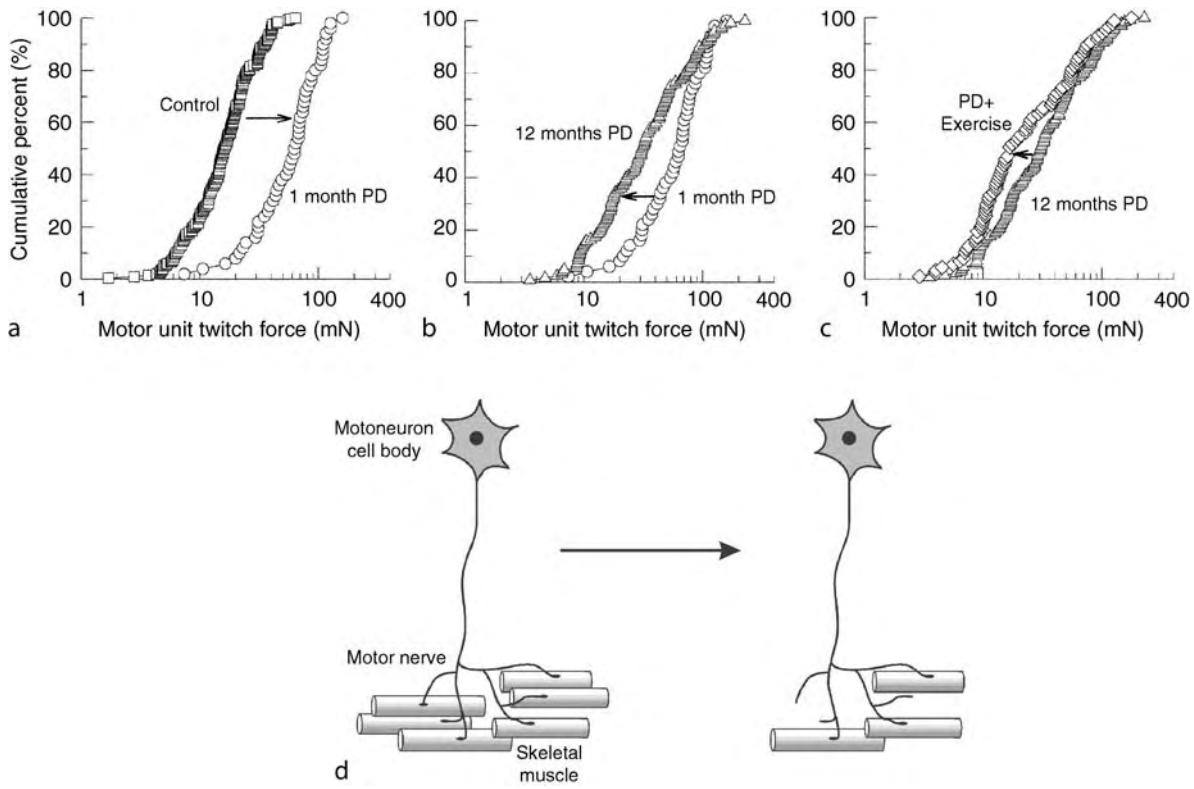
**Axonal Sprouting in Health and Disease. Figure 5** Loss of motor units as a result of aging and motoneuron diseases. At the initial stage of ageing and motoneuron disease, motor axons die back and the infected or susceptible motoneurons in the case of poliomyelitis or early stage of ALS, respectively, succumb to cell death. The remaining intact motoneurons enlarge their sizes by axonal sprouting to reinnervate the denervated muscle fibers which have lost their nerve terminals from axonal die-back and undergone denervation atrophy. The axons, which have died back and lost connections with affected muscles may regenerate their axons to reinnervate the denervated muscle.

confer a gain of cytotoxic function that increases the susceptibility of motoneurons to cell death, most likely linked to a direct involvement of misfolded SOD1 in the disease process, and through elevations in oxidative stress that can cause cellular damage, ►glutamate excitotoxicity, disruption of calcium homeostasis, motoneuron die-back and their subsequent neuronal death (Fig. 5).

Higher than normal levels of oxidative stress in association with genetic and/or environmental factors in familial and sporadic ALS, may be compounded by age-related accumulations of oxidative stress-induced cellular damage possibly contributing to a rapid decline in the safety factor of neuromuscular transmission and, in turn, the axonal die-back that initiates denervation of motor endplates [1]. The largest motoneurons with the lowest ►oxidative potential [8,10] are likely to be the most vulnerable to oxidative stress. Indeed, these motoneurons are the first ones whose axons die back and whose intact axons progressively fail to sprout effectively. It is only the motoneurons with higher oxidative capacity that supply the more oxidative muscle fibers that sustain their sprouting capacity [10]. In most muscles that contain relatively few oxidative muscle fibers, there is a rapid attrition of the motoneurons with progressive muscle weakness and paralysis [1].

## PPS: Progressive Loss of Enlarged MUs in Relation to Progressive Increase in Levels of Neuromuscular Activity and/or Oxidative Stress

Infection by the polio enterovirus results in extensive axonal die-back and death of many of the affected motoneurons [8] (Figs. 2, 3). while the surviving axotomized motoneurons may regenerate their axons, the remaining intact MUs undergo adaptive sprouting. Both the surviving intact and regenerating MUs enlarge their normal size to a maximum of 5–8-fold to reinnervate those muscle fibers that were denervated by death of their parent motoneurons [1]. The enlarged MUs are able to sustain muscle function for periods of time as long as 25 years or more until the chronically enlarged MUs progressively deteriorate in association



**Axonal Sprouting in Health and Disease. Figure 6** Regression in the size of motor units (MUs) in post-polio syndrome (PPS). In a rat PPS model, the maximum enlargement of MU force that is observed a month after partial (a) has receded after 12 months of partial denervation (b). There is a preferential decline of the size of the enlarged MUs at the lower end of the force spectrum, indicating that the least active motoneurons sustain more stable neuromuscular connections. High daily exercise imposed on chronically denervated nerve-muscle connections reduces the size of the enlarged MUs (c) by further destabilizing functional MUs. The destabelization and withdrawal of synaptic contacts by motoneurons in PPS is illustrated figuratively (D).

with the age-related loss of functional MUs. Because the reduced number of functional MUs are unable to enlarge beyond the normal limit of 5–8 fold, muscles become progressively denervated with the onset of muscle fatigue and weakness—post-polio syndrome (PPS) [8] (Fig. 2).

In PPS, the reduced numbers of enlarged MUs that survive the acute phase of the disease become progressively vulnerable to destabilization of nerve terminals and axon die-back, possibly concomitant with an increasing state of oxidative stress in the remaining motoneurons that had sprouted and sustained long-term innervation of large numbers of muscle fibers [1]. As the number of MUs declines, the high levels of neuromuscular activity will compromise the capacity of the surviving motoneurons to undergo sprouting to reinnervate denervated muscle fibers and, in turn, to compensate for the axonal die-back. This was shown in a study using an animal model of PPS in which rat muscles were partially denervated during adulthood and the remaining intact MUs enlarged maximally to compensate for the loss of motoneurons (Fig. 2). The MUs, showed a time-dependent regression of nerve terminals and a reduction in their size 1 year after partial denervation (Fig. 6a, b) [8]. The preferential decline of in the size of the enlarged MUs at the lower end of the force spectrum indicated that the most active MUs progressively failed to reform stable connections and hence the process of axonal sprouting became maladaptive. When these fewer MUs were subjected to high daily neuromuscular activity, significant reductions in MU size were detected (Fig. 6c).

In summary, motor axons can sprout to reinnervate denervated muscle fibers to enlarge MUs up to 8-fold. This compensatory mechanism is compromised by high levels of neuromuscular activity. The effects of this compromise are evident physiologically during the process of aging and, pathologically, in motoneuron diseases where sprouting may become maladaptive with instability and withdrawal of the axon sprouts.

# Axonal Transport

## Definition

Axonal transport is the transport of molecular cargo and organelles bidirectionally within the axon. Anterograde axonal transport carries cargo from the cell body to the periphery, whereas retrograde transport carries materials from the periphery towards the cell body. Neurons need to provide a constant supply of new material to the growth cone and mature synapse. The majority of proteins and all mRNA and membrane are synthesized in the cell body of a neuron, and need to be transported in an anterograde direction down the length of the axon.

Microtubules, oriented in axons with their plus ends distal to the cell body, are known to provide the support on which rapid axonal transport occurs. There are specific microtubule-based molecular motors called

dyneins and kinesins that move cargo towards the minus and plus ends of microtubules, respectively.

## Axotomy

### Definition

Transection or severing of an axon. This type of denervation is often used in experimental studies on neuronal physiology and neuronal death or survival, towards an understanding of nervous system disease.

## Ayurveda

### Definition

It is a traditional system of Indian Medicine dating back many centuries, and is still popular in India. The Charak Samhita and Sushruta Samhita form the basis of most of the Ayurvedic practices. Surgical procedures are believed to have their origin in Ayurveda, and Sushruta is said to be the Father of Surgery. Charaka has described many herbs for treating various ailments including disorders of the brain. Many modern and standardized herbal products manufactured in India are based on the Ayurvedic principles mentioned in the Charak Samhita.

## B1-B9 Cell Groups (Serotonergic Cell Groups)

### Definition

B1-B9 is the original designation of nine seratonin-containing cell groups visualized in the brainstem by the use of fluorescent histochemical methods. Some of these serotonergic groups project caudally to the spinal cord and others rostrally to different parts of the forebrain.

## Babinski Reflex (Babinski Response, Babinski Sign)

### Definition

Reflex response elicited preferably by a blunt rodlike instrument stroked along the lateral footsole from heel to toes. In neurologically normal adult persons, the stimulus elicits a flexor of foot and toes. In infants and adult patients with lesions of the ►pyramidal tract, the toes are spread apart, the big toe slowly extends and the other toes flex. Lesions limited to the pyramidal tract produce a Babinski sign and paresis (i.e., negative symptoms such as temporary weakness and loss of dexterity), but neither spastic ►dystonia nor permanent weakness.

►Pyramidal Tract

## Back Pain

### Definition

Pin perceived anywhere in a region bounded superiorly by an imaginary transverse line between the 12th thoracic and 1st lumbar vertebrae, inferiorly by an imaginary transverse line through the 4th sacral segment, and laterally by a line tangential to the lateral border of the erector spinae and a line between the posterior superior iliac spine and the inferolateral corner of the sacrum.

## Bacterial Artificial Chromosome (BAC)

### Definition

Bacterial artificial chromosome (BAC) is a DNA vector whose basis is a fertility plasmid (F-plasmid), which contains sites necessary for DNA to be handled and replicated as a bacterial chromosome. BACs are used for cloning in *E. coli*, and because their insert sizes can be large (100–300 kb), have proven useful in the identification of gene regulatory sequences that can involve huge pieces of DNA upstream of a gene. Human and yeast artificial chromosomes are also available.

## Balance Laws

Marcelo Epstein
Schulich School of Engineering, University of Calgary, Calgary, AB, Canada

### Definition

The statement of the causes of change of content of an extensive physical quantity (such as mass, energy, momentum, entropy and so on) over a certain domain. The quantitative aspects of balance laws are expressed in terms of balance equations.

### Description of the Theory

A *balance equation* in continuum physics is a rigorous accounting of the causes for the change in content, over a certain domain, of an extensive physical quantity. In continuum mechanics, in particular, physical content is attributed only to a material body or a part thereof (as opposed to a field theory such as electromagnetism, where a vacuum can be a carrier of fields). The time rate of change of the content of a physical quantity $\Psi$ in the body is postulated to be entirely due to only two causes, a *production* $\Pi$ within the body and a *flux* $\Phi$ through its boundary:

$$\frac{D\Psi}{Dt} = \Pi + \Phi. \tag{1}$$

To convert this general statement of balance into a more specific form can be done in either the referential ("Lagrangian") or spatial ("Eulerian") setting. The total content can be represented in terms of the referential volume element $d\Omega$ or its spatial counterpart $d\omega$ as follows:

$$\Psi = \int_{\Omega} \Psi_0 \, d\Omega = \int_{\omega} \Psi \, d\omega, \tag{2}$$

where $\Psi_0$ and $\Psi$ represent the content density per unit referential and spatial volume, respectively. These two densities are related by:

$$\Psi_0 = J\Psi, \tag{3}$$

where $J$ is the determinant of the deformation gradient $\mathbf{F}$, as defined in the kinematics of deformation (q.v.). Similarly, the production is assumed to be expressible as:

$$\Pi = \int_{\Omega} \pi_0 \, d\Omega = \int_{\omega} \pi \, d\omega, \tag{4}$$

with

$$\pi_0 = J\pi. \tag{5}$$

A flux is assumed to be defined not only through the external boundary of the body, but also through any internal boundary between sub-bodies. Moreover, the flux is assumed to be given by an integral (over the area of interest) of some density. But, unlike the case of the volume integrals, now it is not allowed to simply claim that this density is a mere function of position on the surface. A simple example will clarify this situation. If sun-tanning on the beach, it makes a difference whether one is lying horizontally or standing up. The heat energy flows at a maximum rate when the exposed surface is perpendicular to the rays. This is as true for the outer boundary as for an internal point. When considering an interior point of the endodermis, the flux at that point will vary depending on the orientation of the imagined surface element considered at the point. In other words, the flux density must depend not only on position but

also on some other characteristic of the boundary. The simplest assumption is that the flux depends on the boundary only through its (local) normal, namely through its orientation alone (as opposed to its curvature, for example). Having made these assumptions:

$$\Phi = \int_{\partial\Omega} \phi_0(\mathbf{X}, \mathbf{N}, t)\, dA = \int_{\partial\omega} \phi(\mathbf{x}, \mathbf{n}, t)\, da, \qquad (6)$$

where $\partial$ stands for "boundary of" and where the notation of kinematics of deformation (q.v.) is used. To obtain the relation between the referential and spatial flux densities ($\phi_0$ and $\phi$, respectively), (4) of kinematics of deformation (q.v.) might be invoked. However, in this equation the dependence on the normal is explicitly linear, whereas the assumed dependence of the flux densities on the normal is so far arbitrary. It would appear that the only way out of the impasse would be to *assume* such linearity (a logical thing to do, particularly considering the example of the sun rays, whose effect on the skin is governed by a simple projection on the normal). It is a rather remarkable fact, however, that such an assumption is superfluous, since it can be *derived* from the general statement of the balance law. This result is called *Cauchy's theorem*, since it was Cauchy who, in a series of papers published in the 1820's, first established its validity in the context of his theory of stress. The proof is based in the so-called *tetrahedron argument*. Assuming that the general balance law, (1), is valid, with the same densities for any sub-body (thereby essentially ruling out scale effects such as surface tension) and applying it to a tetrahedron with three faces aligned with the coordinate system and the fourth face with its vertices lying on the surface of interest, the mean value theorem is applied to each term of (1) and the far vertex of the tetrahedron is allowed to approach the surface. Observing that the two volume integrals approach zero with the cube of a typical line dimension of the tetrahedron, while the surface integral does so with the square, thereby being the only "survivor" in the limit, the theorem follows. Therefore:

$$\Phi = \int_{\partial\Omega} \mathbf{H}(\mathbf{X}, t) \cdot \mathbf{N}\, dA = \int_{\partial\omega} \mathbf{h}(\mathbf{x}, t) \cdot \mathbf{n}\, da, \qquad (7)$$

where $\mathbf{H}$ and $\mathbf{h}$ are the Lagrangian and Eulerian *flux vectors*, respectively. If the quantity to be balanced is vectorial in nature, these become *flux tensors*. Invoking now (4) of kinematics of deformation (q.v.), the following relation between the Lagrangian and Eulerian flux densities is obtained:

$$\mathbf{H} = J\,\mathbf{F}^{-1}\mathbf{h}. \qquad (8)$$

The integral statement of the generic law of balance in Lagrangian form is finally:

$$\frac{D}{Dt}\int_{\Omega} \Psi_0\, d\Omega = \int_{\Omega} \pi_0\, d\Omega + \int_{\partial\Omega} \mathbf{H} \cdot \mathbf{N}\, dA, \qquad (9)$$

and in Eulerian form:

$$\frac{D}{Dt}\int_{\omega} \Psi\, d\Omega = \int_{\omega} \pi\, d\Omega + \int_{\partial\omega} \mathbf{h} \cdot \mathbf{n}\, da. \qquad (10)$$

Although these statements may suffice for computational applications (such as the "finite-volume" method), under suitable assumptions of smoothness their local (differential) forms can be obtained by using the divergence theorem to convert the flux integral into a volume integral and invoking the fact that the resulting three integrals must be identically equal regardless of the domain of integration within the body. The results are, therefore,

$$\frac{\partial \Psi_0}{\partial t} = \pi_0 + Div\,\mathbf{H}, \qquad (11)$$

and

$$\frac{D\Psi}{Dt} + \Psi\, div\,\mathbf{v} = \pi + div\,\mathbf{h}, \qquad (12)$$

where the last equation necessitated the application of Reynolds' transport theorem. The operators *Div* and *div* stand for the referential and spatial divergence, respectively. Applying the general prescription just obtained to the five fundamental quantities to be balanced in a traditional continuum mechanics treatment gives the following.

## Conservation of Mass

A balance law is said to be a *conservation law* if the production and the flux vanish identically. This is the case for the mass of a classical continuum. (In modern theories of biological growth, however, or in theories of chemically reacting mixtures (when looking at each component of the mixture), conservation of mass does not hold, and specific mass production and/or flux terms are to be included). Denoting by $\rho_0$ and $\rho$ the referential and spatial mass densities, respectively, the Lagrangian and Eulerian differential balances are obtained as:

$$\frac{\partial \rho_0}{\partial t} = 0, \qquad (13)$$

and

$$\frac{D\rho}{Dt} + \rho\, div\,\mathbf{v} = 0. \qquad (14)$$

The latter (Eulerian) version is known in hydrodynamics as the *continuity equation*.

## Balance of Linear Momentum

This balance is a statement of Newton's second law as applied to a deformable continuum. It is, therefore,

important to recall that the frame of reference (which has been identified with a Cartesian coordinate system) must be assumed to be actually it inertial. The quantity to be balanced is the (vectorial) linear momentum, whose Lagrangian and Eulerian densities are, respectively, $\rho_0\mathbf{v}$ and $\rho\mathbf{v}$. Note that in both cases there is a *spatial* vector to balance, whether the statement of the law is referential or spatial. The production term is given by the (distributed) forces per unit volume, or *body forces*, with densities **B** and **b** respectively in the Lagrangian and Eulerian formulations. The flux terms are given by the *surface tractions* (namely forces **S** and **s** per unit referential or spatial area). It must be emphasized that these forces, even when measured per unit referential area, are *spatial* vectors. By Cauchy's theorem, it is known that these surface tractions are governed by a (tensorial) flux, which can be denoted by **T** and **t**, respectively for the Lagrangian and Eulerian settings: $\mathbf{S} = \mathbf{TN}$ and $\mathbf{s} = \mathbf{tn}$. To avoid any possible confusion, the final equations are expressed in components. Plugging the various terms into the corresponding forms of the generic law of balance, and invoking the already obtained conservation of mass, the following Lagrangian and Eulerian forms of the balance of linear momentum are obtained:

$$T^{iI}_{,I} + B^i = \rho_0 \frac{Dv^i}{Dt}, \tag{15}$$

and

$$t^{ij}_{,j} + b^i = \rho \frac{Dv^i}{Dt}. \tag{16}$$

The fluxes **T** and **t** are called, respectively, the *first Piola-Kirchhoff* and the *Cauchy* stress tensors. Note that, whereas the Cauchy stress is a purely spatial tensor, the first Piola-Kirchhoff stress is a mixed tensor. What these tensors do is to produce linearly out of vectors with components $N_I$ and $n_i$ respectively, the spatial forces acting on elements of area to which they are normal. The relation between these tensors follows directly from (8) as:

$$T^{iI} = J\,(F^{-1})^I_j\, t^{ij}. \tag{17}$$

Note that in the Lagrangian version (15), the material time-derivative of the velocity (appearing on the right hand side of the equation) boils down to a partial derivative. In the Eulerian version (16) on the other hand, the material time derivative includes a non-linear convective term.

## Balance of Angular Momentum

In the Newtonian mechanics (q.v.) of systems of particles, the law of balance of angular momentum follows from Newton's second law under the assumption that the particles of the system interact by means of forces abiding by Newton's third law ("action and reaction"). In the case of a continuum, the analog of such internal forces is the stress tensor, but this analogy is not easy to pursue rigorously. In fact, in continuum mechanics the postulation of a law of balance of momentum leads to a new result, without a clear analog in discrete systems. The balance of angular momentum states that the rate of change of the total angular momentum with respect to a fixed point (the origin, say) of an inertial frame is equal to the moment of all the external forces with respect to the same point. Using the general prescription of the Eulerian balance law, and invoking conservation of mass and balance of linear momentum, the somewhat surprising final result is

$$t^{ij} = t^{ji}, \tag{18}$$

namely, the Cauchy stress is symmetric. At this point it is appropriate to go back to the discrete analogy. There, it is assumed that the internal forces between the particles of the system abide by the principle of action and reaction. In the continuum case, what has been implicitly assumed is that the surface interactions are merely forces (stresses) and that there are no extra contributions of surface couples. A similar assumption was made regarding the external body forces. In other words, the only contribution to the moment equation is that arising from the moments of forces (no couple interactions). This assumption may have to be abandoned when dealing with electrically or magnetically polarizable materials. In those cases, the antisymmetric part of the stress may not vanish, but will be balanced by the external body-couple.

## Balance of Energy (the First Law of Thermodynamics)

In the case of a single particle or a rigid body, a direct application of Newton's laws yields the result that the rate of change in kinetic energy $K$ is exactly balanced by the mechanical power $W_{ext}$ of the external forces acting on the system. In other words, the application of an external force over time along a trajectory produces (or extracts) work, and this work is entirely expended in increasing (or decreasing) the kinetic energy of the system. In the case of a continuum, the kinetic energy is given by:

$$K = \int_\Omega \frac{1}{2}\rho_0 \mathbf{v}.\mathbf{v}\, d\Omega = \int_\omega \frac{1}{2}\rho\, \mathbf{v}.\mathbf{v}\, d\omega, \tag{19}$$

and the power of the external forces is:

$$\begin{aligned} W_{ext} &= \int_\Omega \mathbf{B}.\mathbf{v}\; d\Omega + \int_{\partial\Omega} (\mathbf{TN}).\mathbf{v}\, dA \\ &= \int_\omega \mathbf{b}.\mathbf{v}\; d\omega + \int_{\partial\omega} (\mathbf{t}.\mathbf{n}).\mathbf{v}\, da. \end{aligned} \tag{20}$$

It is a matter of daily experience that continuous media deform under applied heat and conversely deformation

may lead to the emission of heat (bending a metal paperclip repeatedly until it breaks is a good experiment to reveal this common effect, but more relevant examples abound in muscle mechanics). There are other occurrences of "non-mechanical" energy sources (chemical reactions, electromagnetic fields, etcetera). The non-mechanical power input ("heating") is lumped as might be expected into two terms, one corresponding to distributed volumetric sources ("radiation") and the other to an input across the boundaries ("conduction"):

$$W_{heat} = \int_{\Omega} R \, d\Omega + \int_{\partial\Omega} Q \, dA = \int_{\omega} r \, d\omega + \int_{\partial\omega} q \, da. \tag{21}$$

The law of balance of energy (first law of thermodynamics) asserts that, in addition to the kinetic energy $K$, there exists another kind of energy content $U$, called *internal energy*, such that the rate of change of the total energy content $K + U$ exactly balances the combined external mechanical and heating powers, namely:

$$\frac{D(K+U)}{Dt} = W_{ext} + W_{heat}. \tag{22}$$

To obtain the local versions of this balance law, the internal energy is assumed to be given by an integral of a density $u$, which is usually assumed to be given per unit mass (rather than unit volume). Using the tetrahedron argument, it can be shown that the flux terms in the heating input in (21) are given by referential and spatial flux vectors as: $Q = -\mathbf{Q}.\mathbf{N}$ and $q = -\mathbf{q}.\mathbf{n}$, the minus signs being chosen so that the flux vectors point in the direction of the flux (if the normals are the external normals to the boundary of the domain of interest). The standard procedure now yields the following Lagrangian and Eulerian forms of the local equations of energy balance:

$$\rho_0 \dot{u} = R - Q^I_{,I} + T^{iI} v_{i,I} \tag{23}$$

and

$$\rho \dot{u} = r - q^i_{,i} + t^{ij} v_{i,j} = r - div\,\mathbf{q} + trace\,(\mathbf{tD}). \tag{24}$$

Naturally, in this last (Eulerian) version, the material time-derivative of $u$ must include the convective term.

## Entropy Inequality (the Second Law of Thermodynamics)

An important conceptual element in continuum mechanics is the presence of an arrow of time, that is the natural irrevocable direction of phenomena prescribed by the second law of thermodynamics. There are different ways to deal with this delicate issue, but here only the formulation based on the Clausius-Duhem inequality is presented. There are two new ingredients that need to be added to the picture. The first one is a new extensive quantity, the *entropy* $S$, whose content will be measured in terms of the integral of a density $s$ per unit mass. The second element to be introduced is a new field, $\theta$, called the *absolute temperature*. It is assumed that $\theta$ is strictly positive and measurable instantaneously and locally by appropriate instruments (such as thermo-couples). This temperature scale is consistent with the temperature appearing naturally in the theory of ideal gases. It is moreover assumed that there are two universal sources of entropy production, one volumetric and the other through the boundary. These sources are obtained, respectively, by dividing the corresponding (volume or surface) heating source by the local value of the absolute temperature. The Clausius-Duhem inequality asserts that the rate of entropy production is never less than what can be accounted by these universal sources, namely:

$$\frac{D}{Dt}\int_{\Omega} \rho_0 \, s \, d\Omega \geq \int_{\Omega} \frac{R}{\theta} \, d\Omega - \int_{\partial\Omega} \frac{\mathbf{Q}\cdot\mathbf{N}}{\theta} \, dA \tag{25}$$

or, in the Eulerian version,

$$\frac{D}{Dt}\int_{\omega} \rho \, s \, d\Omega \geq \int_{\omega} \frac{r}{\theta} \, d\Omega + \int_{\partial\omega} \frac{\mathbf{q}\cdot\mathbf{n}}{\theta} \, da. \tag{26}$$

The equality corresponds to *reversibility* of a physical process, while all other processes (for which the strict inequality holds) are *irreversible*. The local forms of the inequality are obtained by the standard procedure as:

$$\rho_0 \, \dot{s} \geq \frac{R}{\theta} - Div\,\frac{\mathbf{Q}}{\theta}, \tag{27}$$

and

$$\rho \, \dot{s} \geq \frac{r}{\theta} - div\,\frac{\mathbf{q}}{\theta}. \tag{28}$$

It is often convenient to replace the Clausius-Duhem inequality by a linear combination with the balance of energy. In particular, subtracting from the (Lagrangian) equation of energy balance, (23), the (Lagrangian) entropy inequality, (27), multiplied by the absolute temperature, and defining the (Helmholtz) free *energy* density per unit mass as:

$$\psi = u - \theta \, s, \tag{29}$$

Equation (27) can be written in the form:

$$\rho_0 \dot{\psi} + \rho_0 \dot{\theta} \, s - T^{iI} v_{i,I} + \frac{1}{\theta} Q^I \theta_{,I} \leq 0, \tag{30}$$

with a similar expression for the Eulerian version.

In closing, it must be emphasized that the laws of balance presented in this article are limited by the

assumptions made in their derivation. In particular, it should be mentioned that in theories of continuous growth and remodeling (q.v.) important modifications take place. Essential modifications of the laws of balance and of the kinematics of deformation (q.v.) are also to be considered for theories of mixtures, particularly when the components of the mixture may react with each other chemically. Particular cases of mixture theories are routinely used in biomechanics (for example, the bi-phasic theory of cartilage). These topics are beyond the scope of the present article.

## Balo's Concentric Sclerosis

### Definition

An aggressive form of multiple sclerosis (MS), Balo's concentric sclerosis is usually characterized by an abrupt clinical onset with steady progression to major disability and death within months. Symptoms can include altered mental status, aphasia, headache and seizures. Demyelinating lesions are typically large, characterized by alternating layers of myelinated and demyelinated tissue. These alternating layers of myelin loss are seen as hypointense and hyperintense rings on T2-weighted MRI.

## Baroreceptor

### Definition

A receptor located on sensory nerve endings in the wall of arteries, which responds to an increase in arterial blood pressure. The actual stimulus to the receptor is stretch of the wall of the artery, which results from an increase in blood pressure. The baroreceptor nerve endings are located mainly in the outer layer (adventitia) of arteries, predominantly in the carotid sinus and aortic arch, but also in other arterial regions including the brachiocephalic artery and pulmonary artery. The baroreceptor sensory nerves in the carotid sinus are part of the glossopharyngeal nerve (IX cranial nerve), while the other baroreceptor sensory nerves are all part of the vagus nerve (X cranial nerve). The carotid sinus and aortic arch baroreceptors are tonically active at normal levels of arterial pressure, and increase (or decrease) their rate of firing in response to an increase (or decrease) of both the mean level as well as the pulsatile component of arterial pressure.

►Blood Volume Regulation
►Homeostasis

## Baroreceptor Reflex

### Definition

The baroreceptor reflex (baroreflex) is a cardiovascular reflex devoted to the control of blood pressure. An increase in baroreceptor activity resulting from an increase in arterial blood pressure normally results in a reflex inhibition of the activity of sympathetic nerves innervating blood vessels (especially arterioles) and the heart, and a reflex excitation of vagal nerves innervating the heart. The effects of these reflex changes in sympathetic and vagal activity are to dilate blood vessels and reduce the rate and contractility of the heart, thus reducing the arterial blood pressure. Similarly, a decrease in baroreceptor activity leads to a reflex increase in sympathetic activity and a reflex decrease in cardiac vagal activity that tend to increase arterial pressure. Thus, the main effect of the baroreceptor reflex is to minimize changes in arterial blood pressure that would normally result from disturbances, e.g. a change in posture.

## Barrel Cortex

Ford Ebner, Maria Popescu
Department of Psychology, Vanderbilt University, Nashville, TN, USA

### Synonyms

Barrel field cortex; Posteromedial barrel subfield; PMBSF

## Definition

The entire layer IV of mouse and rat S-I cortex is parsed into zones that, when viewed in sections cut parallel to the cortical surface and stained with the cytochrome oxidase (CO) stain, appear as oval dense zones: one for each of the digits and pads on the feet, and one for each of the large and many of the small whiskers on the face around the nose and mouth. The largest barrels are representations of the large facial whiskers (a.k.a. mystacial vibrissae or facial sinus hairs), and these barrels were given the specific name of the posteromedial barrel subfield or PMBSF [9].

## Characteristics

### Whisker Somatosensory Pathway

Different species have evolved different sensory capabilities to survive in their particular ecological niche. Rodents, in particular mice and rats, have specialized the whiskers on their face into exquisitely sensitive tactile organs with which they explore their environment, especially under low light conditions, by moving the whiskers back and forth (whisking). Each whisker in these species is a complex sensorimotor organ that can move the whiskers precisely to gather the most salient information. In mice and rats, but not all rodents, the facial muscles have been specialized such that they form a sling around the whisker follicle, and when the muscle contracts the whisker is levered (protracted) so far forward that they extend well in front of the nose.

Each whisker follicle is innervated by over 200 sensory fibers that render it extremely sensitive to the direction, magnitude, duration, frequency and velocity of any stimulus that can perturb the whiskers. The motor fibers that innervate these intrinsic, individual, facial muscles travel in the seventh cranial nerve and arise in the brainstem from motor neurons in the facial nerve nucleus. The sensory fibers that innervate the follicle travel with the fifth cranial or trigeminal nerve and terminate in the brainstem trigeminal nuclei.

In the rat's vibrissa (whisker) system, neurons representing whiskers at each level in the pathway are topographically organized into functional "whisker maps." These maps correlate well with the anatomically discrete cell aggregates at each level: "barrelettes" in the brainstem [Ma PM 1991], "barreloids" in thalamus [Van der Loos 1976] and "barrels" in layer IV of the primary somatosensory cortex (SI) [9]. Each map replicates the spatial arrangement of whiskers on the contralateral face (Fig. 1).

The mechanosensory axons bifurcate as they enter the brainstem: some collaterals end in the Principal Trigeminal Nucleus (PrV) and others end in a descending cascade of axon terminals along the length of the the Spinal Trigeminal Nucleus (SpV). SpV is subdivided into three sub-nuclei, oralis, interpolaris, and caudalis, with the interpolaris division (SPVi) providing the main projection to the thalamus. The receptive field of PrV cells includes one, sometimes two, whiskers, while the receptive field of SpVi cells is much larger and includes 6–8 whiskers on average. Since nearly all of the primary mechanosensory axons bifurcate on entry, this difference in receptive field size can be accounted for by the degree of axon divergence and convergence in the two nuclei. PrV is the beginning of the lemniscal sensory pathway to thalamus and then to barrel cortex, and SpV is the beginning of the paralemniscal pathway. As each of these pathways ascends to the thalamus they decussate to the opposite side of the brain. This crossing is what causes the whiskers on the right side of the face to be represented in the left cortex, and vice versa.

In the thalamus, the PrV fibers terminate primarily in the ventral posterior nucleus of the thalamus (VPM), while the SpV fibers terminate primarily in an adjacent thalamic nucleus, the medial division of the posterior nucleus (POm). New findings in the last few years have identified two subdivisions of the VPM nucleus into a dorsal lateral portion (VPMdl) that receives mainly lemniscal inputs, and a ventral medial portion (VPMvm) that receives mainly paralemniscal inputs [7]. This has led to the notion that there are in fact three parallel pathways to cortex: lemniscal (PrV to VPMdl), paralemniscal (SpV to POm), and what has been called extralemniscal (SpV to VPMvm) pathway [10]. Physiological evidence supports the idea that the lemniscal pathways convey information mainly about object perception, the paralemniscal pathway mainly about whisker position, and the extralemniscal pathway mainly about a combination of the two. The lemniscal VPMdl nucleus projects to primary somatosensory cortex (S-I) after giving off collaterals just outside the thalamus to cells in an inhibitory thalamic feedback nucleus called the thalamic reticular nucleus (RTN). In cortex the VPMdl fibers give rise to a substantial number of axon collaterals that spread out and end in the deep layers, between layer V and VI, and then proceed to terminate profusely in one of the discrete cell aggregates of layer IV (a barrel): these layer IV cell clusters are the basis for calling this "barrel cortex."

In layer IV of the rat barrel cortex there is a clear distinction between cell dense barrels that receive a VPMdl input, and the region around the barrels called the septa that receive input from another nucleus in the thalamus, the POm nucleus. The barrel/septum feature of barrel cortex is very species specific, and hence, has caused considerable confusion in the literature. Clear evidence suggests that the septa are well developed in rat cortex, but almost non-existent in mouse cortex (<20 μm wide). In the rat POm fibers terminate in layer Va, $IV^{septa}$, and layer III. The extralemniscal projections from the VPMvm cells in the rat go mainly to the second somatosensory cortex (S-II), with a smaller contingent

Only the major projections are indicated.

that terminates in the septal zones of S-I cortex similar to the POm terminal field (Fig. 1). Neurons in layer IV project mostly to layer III: barrels project to above the barrels and septa project to above the septa.

## Cortical Organization

The general organization of barrel cortex is similar to other mammalian sensory cortices. Granular layer IV where the barrels are located is the primary input layer, the supragranular layers II, III project to other areas of cortex both ipsilateral and contralateral, and the infragranular layers V and VI project widely to cortex and to subcortical structures, such as striatum, thalamus, midbrain, medulla and spinal cord. A major feature of barrel cortex that is now receiving deserved attention is the massive layer V and VI projections back to the thalamus and trigeminal nuclei in the sensory pathway that project to cortex. These massive projections allow cortex to influence the directional preference and enhance the contrast of multiwhisker responses in the subcortical relay nuclei. Layer V gives rise to a driving input to POm, while layer VIa provides a precise modulatory input to the RTN and VPM, and layer VIb projects more diffusely to VPM.

Two cortical domains have been anatomically and physiologically described in the barrel cortex: the barrel columns and the septal columns. They are considered to be involved in distinct intrinsic and corticocortical

circuitries and to relay information about different sensorimotor processes. The intrinsic projections of barrel column neurons are generally short-ranged and terminate for the most part within the most immediate neighboring barrel columns. In contrast, the septal cells send projections as far as three barrel diameters along the same whisker row, preferring the septal columns. Moreover, the corticocortical projections of the barrel columns reach the second somatosensory cortex, S II, in a loosely topographic manner. The septal columns preferentially connect to dysgranular cortex anterior to the E-row, S II, and to the posteromedial parietal cortex [6]. Recent physiological data also points to the barrel columns as conveying information related to whisking-touch signals as part of the lemniscal pathway, while the septal columns are implicated in processing and transmitting information related to the rat's whisking behavior [10].

## Physiology

The receptive fields of barrel field cortical neurons are organized into center and surround subdivisions of the whiskers that activate a given cortical cell. The whisker generating the maximum response at the shortest latency forms the center receptive field, and is called the principal or best whisker. The principal whisker is almost always the whisker that is anatomically connected to a single barrel. The whiskers constituting the excitatory surround receptive field are classically defined as all other surround whiskers that elicit suprathreshold responses. However intracellular recordings have shown that all whiskers on the contralateral side of the face can generate postsynaptic potentials in any barrel field neurons.

Principal whisker angular tuning or directional preference maps have also been described. Thus, each barrel can be divided in minicolumns of cells exhibiting the same preferred stimulus direction.

The transmission of principal whisker responses through its respective barrel column is relayed from layer IV and then to layers III and II. Barrels and septa transmit separately until the activity is integrated in layer III [8]. Layer V receptive fields are then usually quite large and integrate inputs over a larger area [3].

Guic-Robles et al. showed that rat whiskers can be used to perform a texture discrimination task, and this is dependent upon a functional barrel cortex. Newer studies by [1] showed that barrel cortex neurons use stimulus frequency and amplitude to represent texture at the cortical level.

## Plasticity

While each barrel column is the primary representation of a distinct whisker, much of the barrel cortex research has focused on uncovering cortical plasticity mechanisms. Thus, peripheral activity has been manipulated mostly by trimming or plucking whiskers, but also by using different patterns of stimulation to certain vibrissae, resulting in both firing pattern and anatomical changes.

Barrel cortex remains modifiable by selective activation of sensory inputs throughout life [2], even though there is a critical period just after birth, when cortical plasticity can be elicited by sensory experience in ways that are diminished later in life [5]. if sensory inputs are abnormally reduced in barrel cortex during an early postnatal period of roughly 1 month, then synaptic modification is impoverished in ways that persist throughout life. The behavioral effect of sensory deprivation is to decrease the ability of the rats to make tactual discriminations. The physiological correlate of similar deprivation is to reduce the magnitude of sensory response and to significantly slow the rate of plasticity that is usually induced by trimming all but two whiskers (called "whisker pairing plasticity"). A major current thrust of research on barrel cortex is to understand the coding of tactual information by ensembles of whiskers and cortical neurons that leads to perception and higher order processes [1].

Corticothalamic projections have also been shown to be important for cortical and thalamic plasticity. Corticothalamic projections are highly reciprocal, and studies in auditory, somatosensory and visual systems in bats, cats, rats and monkeys have demonstrated that corticofugal projections are responsible for altering the transmission mode and the receptive field properties of thalamic relay neurons as well as firing synchrony during the animal's sleep/wake cycle. Such studies make it clear that barrel cortex influences the thalamus through top-down processes which may modulate the sensory information processing. Recent results have shown that the cortex modulates the responsiveness of thalamic relay neurons by sharpening the tuning properties of thalamic neurons recorded and modifying their directional preference.

# Basal Forebrain

## Definition

The term basal forebrain refers to a heterogeneous set of telencephalic and diencephalic structures that are located on the ventral aspect of the brain underneath or at the level of the anterior commissure. Despite the lack of a precise definition, the main brain regions included are the preoptic-anterior hypothalamic continuum, septal nuclei, bed nucleus of the stria terminalis, diagonal band nuclei, substantia innominata including the basal nucleus of Meynert, nucleus accumbens, olfactory tubercle, olfactory cortex, and the amygdaloid nuclei.

A more common definition refers to the cholinergic neurons related to these systems that occupy the sublenticular areas of the brain (i.e. the areas below the lenticular nuclei which are comprised of the "lens shaped" putamen and globus pallidus).

►Olfactory Tubercle

# Basal Ganglia

Suzanne N. Haber
Department of Pharmacology and Physiology, University of Rochester School of Medicine, Rochester, NY, USA

## Definition

The basal ganglia (BG), a collection of interconnected subcortical structures, have captured the interest of scientists and clinicians for well over a century due to the remarkable range of dysfunctions associated with BG disorders. Historically, the BG have been associated with the control of movement. Motor control problems are prominent in several BG disorders including the tremor and rigidity in Parkinson's disease (PD), graceful writhing movements, in Huntington's chorea (HD), and motor tics in Gilles de la Tourette's syndrome. However, in addition to motor deficits, these BG diseases also impair the intellect and emotions, and dementia and depression are prominent in both HD and PD. Recent advances in understanding the connections and physiology of these structures as well as a more thorough understanding of clinical manifestations associated with their dysfunction have expanded our appreciation of the functions of the BG to include a critical role in cognitive, emotional and motivational functions as well as motor control. Indeed, parts of each BG structure are linked to cognition, emotion and motivation. It is now well accepted that pathology in these structures, plays an important role in drug addiction and psychiatric disease, including schizophrenia and obsessive-compulsive disorder.

Despite the continued interest and clinical relevance of the BG, this collection of subcortical nuclei remains among the least understood of all brain structures. Still, neurobiologists and clinicians have advanced the field extensively in the past decade and continue to move it forward with new imaging tools and molecular biology techniques. For example, using a combination of PET and MRI imaging techniques, we know which specific regions of the BG are affected by drugs of abuse such as cocaine and amphetamine and involved in cognitive dysfunction and impulse control.

## Characteristics

### Components and Anatomy of the BG

Key to understanding the anatomy and function of the BG is that these structures are intimately associated with the cerebral cortex, which provides the main input to the BG. There are two main outputs of the BG. One descends to brainstem motor effector systems in the mesopontine tegmentum. The other is directed toward the thalamus, which in turn projects back to cortex. Thus the basic cortical BG loop is: cortex-BG-thalamus-cortex. The BG do not have direct input or output connections with the spinal cord. The BG are composed of four nuclei: the striatum (the caudate nucleus, putamen, and nucleus accumbens), globus pallidus (comprising internal segment and external segments, and the ventral pallidum), substantia nigra, (pars compacta and pars reticulata), and subthalamic nucleus. The putamen and globus pallidus are referred to as the lenticular nucleus. For a review of the anatomy and connections of the BG, see reference [1].

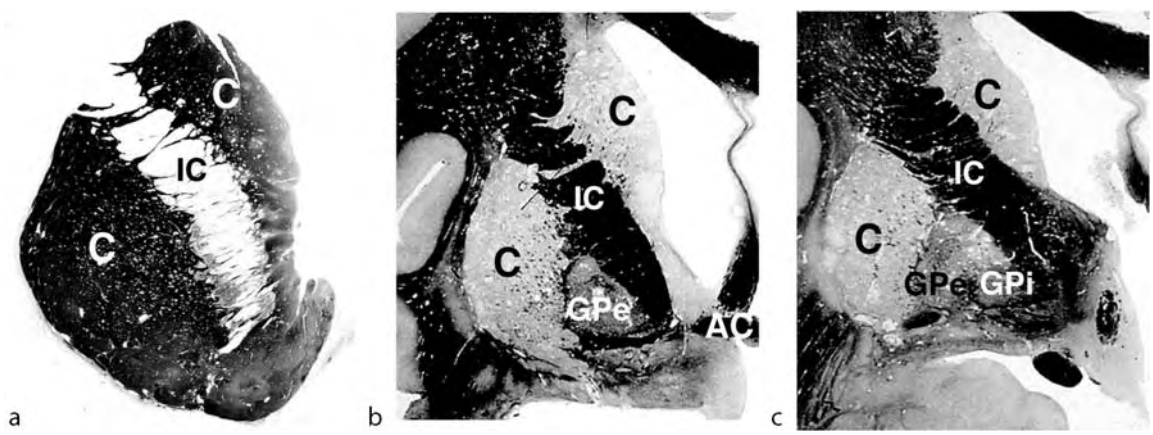
### Striatum

The striatum is the main afferent component of the BG, receiving input from the entire cerebral cortex. Three nuclei, which are similar with respect to their cells types, general projections, transmitters and receptors, comprise the striatum: the caudate nucleus, putamen and nucleus accumbens (Fig. 1a–c).

The internal capsule divides the caudate nucleus and the putamen. Although the caudate nucleus is one structure, it has three parts: the head, body, and tail. The nucleus accumbens is located in the ventral region of the rostral striatum. At this rostral level, the caudate nucleus, the putamen, and the nucleus accumbens are joined. Recently the nucleus accumbens has been incorporated into the concept of the ventral striatum, a term used to refer to the part of the striatal complex associated with reward and motivation.

The striatum is the receiving end of the BG. Inputs are derived from the cortex, thalamus, and the brain stem. These project to the striatum in a generally topographic manner. Areas associated with reward and motivation (orbital prefrontal cortex and cingulate cortex) along with the amygdala and temporal pole of the cortex, project to the ventral striatum. Cortical areas associated with cognition (the dorsolateral prefrontal cortex) project to the dorsal and medial caudate nucleus Finally, cortical regions involved in motor control, including motor cortex and premotor areas, project to the dorsolateral striatum. Thalamic inputs associated with these various functions project onto the same striatal region as does the comparable functional area of cortex. The midbrain dopamine cells project in an inverse dorsal/ventral manner, such that the dorsal midbrain projects to the ventral striatum and the ventrally placed cells project dorsally.

There are two general neuronal cell types in the striatum: (i) projection neurons and (ii) interneurons. The projection neurons make up 95% of the striatal neurons. They are called medium spiny neurons because they are medium sized neurons and have many spines on their dendrites. These cells receive an excitatory glutamatergic input from the cortex and thalamus and a dopaminergic input from the SNc. They also receive input from the striatal interneurons. Medium spiny neurons are GABAergic and thus are inhibitory and project to the globus pallidus and substantia nigra. They also contain one of two pharmacologically distinct types of dopamine receptors, the D1 and D2 receptors. Thus, there are two types of medium spiny neurons: (i) Cells in which GABA is colocalized with the neuropeptide, enkephalin. These enkephalin-positive cells also contain D2 receptors, which inhibit cAMP. The dopamine signal to these cells is therefore inhibitory. These cells project primarily to the external segment of the globus pallidus (GPe); and (ii) Cells in which GABA is colocalized with the neuropeptide, substance P. These substance P-positive cells also contain D1 receptors, which stimulate cAMP, such that the dopamine signal to these cells is excitatory. The substance P-positive cells project primarily to internal segment of the globus pallidus (GPi) and to the substantia nigra, pars reticulata (SNr). There are four types of striatal interneurons, each of which has different physiological and chemical characteristics. Three are aspiny-type I interneurons, each of which co-contains



**Basal Ganglia. Figure 1** Photomicrographs at coronal levels to illustrate specific BG structures: (a) the rostral striatum (stained for acetylcholinesterase); (b) at the level of the anterior commissure (stained for Nissl); (c) at the level of both the internal and external segments of the globus pallidus (stained for Nissl). *AC* anterior commissure; *C* caudate nucleus; *GPe* globus pallidus external segment; *GPi* globus pallidus internal segment; *IC* internal capsule; *P* putamen.

GABA as a transmitter and either calretinin, parvalbumin, or somatostatin and neuropeptide Y. The other main interneuron type is the large cholinergic cell. These cells fire spontaneously and are referred to as "tonically active neurons" or TANS.

The striatum projects primarily to the pallidal complex, (GPe, GPi and ventral pallidum), substantia nigra (both the SNr and SNc) and ventral tegmental area in a generally topographic manner. Projections to the pallidal complex are arranged in a dorsal/ventral, medial/lateral topography. However, those to the midbrain are organized in an inverse dorsal/ventral manner, such that the ventral striatum projects dorsally, and the dorsal striatum projects ventrally. We will return to the striatal-midbrain-striatal projection system and its functional significance below.

### The pallidum

Pallidal cells are large, with long dendrites that extend throughout a broad medial/lateral region. They use GABA as a transmitter and are inhibitory. Unlike the components of the striatum, the GPi, GPe and ventral pallidum do differ with respect to projections. The GPi receives a GABAergic (colocalized primarily with substance P) input from the striatum and a glutamatergic input from the subthalamic nucleus. It projects primarily to the ventral lateral and ventral anterior nuclei of the thalamus, which, in turn, project to specific regions of frontal cortex, completing the basic cortico-BG-thalamocortical loop (see Fig. 2).

The GPe receives a GABAergic (colocalized primarily with enkephalin) input from the striatum and a glutamatergic input from the subthalamic nucleus However, unlike the GPi, the GPe projects to the subthalamic nucleus and to the SNr, but not directly to the thalamus.

The ventral pallidum receives input from the ventral striatum. It contains intermixed elements of both the internal and external segments. That is, both enkephalin and substance P containing GABA striatal neurons project here. The ventral pallidal output is to both the thalamus (primarily to the medial dorsal nucleus and lateral habenular nucleus) and to the subthalamic nucleus. It also projects to the VTA in the midbrain.

### The Subthalamic Nucleus

The subthalamic nucleus is located at junction of diencephalon and mesencephalon and receives an excitatory glutamatergic input from cortex, an inhibitory GABAergic input from the GPe and also input from the SNc. It contains glutamate and is therefore excitatory. As mentioned above, the subthalamic nucleus projects to both the internal and external segments of the globus pallidus, to the ventral pallidum, and to the SNr. The subthalamic nucleus receives a fast glutamatergic input directly from cortex. This input triggers activity in the subthalamic nucleus that, in turn, activates the pallidal segments. Because this cortical input reaches the subthalamic nucleus before the pallidal input, it is referred to as the "hyper direct" pathway.

**Basal Ganglia. ### The Substantia Nigra

The SNc receives inhibitory input from the striatum and GPe, and excitatory input from brainstem nuclei. It is made up of dopamine containing cells and can be either excitatory or inhibitory, depending on the postsynaptic receptor subtype. Dopaminergic SNc neurons project primarily to the striatum, but also to the globus pallidus, subthalamic nucleus and cortex, and are the cells that degenerate in PD. The SNr also receives input a GABAergic from the striatum, a glutamatergic input from the subthalamic n and other brainstem inputs including, e.g. from the dorsal raphe nucleus (serotonergic). SNr neurons are similar to pallidal cells and are GABAergic and inhibitory. They project to the ventral anterior nucleus of the thalamus and superior colliculus. The ventral tegmental area is located medial to the substantia nigra and contains components of both the SNc, in that there are dopamine cells that project to the striatum (the nucleus accumbens, or the ventral striatum), and SNr, in that they receive input from the ventral striatum. The VTA is associated with reward functions of the BG.

## Overview of the Circuits

There are two cortico-BG-thalamocortical circuits: (i) The direct pathway; and (ii) The indirect pathway (Fig. 2).

The circuit through the direct pathway is: cortex-striatum-GPi/SNr-thalamus-cortex. Information carried through this pathway has a net effect of excitation. The cortex sends an excitatory input to the striatum. This increases firing in the striato-GPi/SNr pathway. Remember, this pathway is inhibitory. Thus, cortical excitation inhibits the GPi/SNr. Since these nuclei are also inhibitory, this striatal inhibition removes the inhibitory influence of the GPi/SNr on the thalamus. The thalamus is excitatory, and the removal of the GPi/SNr inhibition to the thalamus increases the thalamocortical firing. Thus, the direct pathway has a positive feedback effect on cortex.

The indirect pathway involves the intrinsic nuclei, i.e. the GPe and the subthalamic nucleus This circuit is: cortex-striatum-GPe-subthalamic nucleus-GPi/SNr-thalamus-cortex. Note, the indirect pathway involves a side loop through the GPi and subthalamic nucleus before projecting to the output nuclei. Information carried through this pathway has a net effect of inhibition. The cortex sends an excitatory input to the striatum. The increases firing in the striato GPe pathway. Remember, this pathway is inhibitory. Thus cortical excitation inhibits the GPe. Since this nucleus is also inhibitory, the striatal inhibition removes the inhibitory influence of the GPe on the subthalamic nucleus The subthalamic nucleus is excitatory, and the removal of the GPe inhibition to the subthalamus increases the subthalamo-GPi firing. The increase in excitation of GPi results in an increase of the inhibitory GPi projection to the thalamus. Inhibition of the thalamic firing results in decreased cortical activity.

Thus, the direct and indirect pathways affect the cortex (via the thalamic neurons) in opposite ways. This model of circuits has been used extensively to model how the BG may function in motor behavior. There are at least such two functional models: (i) Signals associated with a particular voluntary movement are directed over both pathways to the same population of neurons in the GPi. Inputs from the direct pathway facilitate the movement while inputs from the indirect pathway simultaneously brake or smooth the movement. (ii) Signals associated with a particular voluntary movement are directed to different sets of neurons in the GPi. The selected pattern of voluntary movement is reinforced by the direct pathway and conflicting patterns are suppressed via the indirect pathway, thus focusing on the desired movement. Insofar as loss of striatal dopamine inhibits the facilitatory direct pathway and disinhibits the inhibitory indirect pathway, with both effects theoretically depressing BG-thalamocortical activity, these models have been used to explain the pathophysiology underlying Parkinson's disease.

## Functional Cortico-BG-Thalamocortical Pathways

The striatum receives input from all of cortex and projects, via the thalamus, primarily back to frontal cortex. Cortico-BG-thalamocortical projections are topographically organized. This topography renders a remarkable functional specificity within each structure. The frontal cortex can be divided into general functional regions: motor (involved in sensorimotor processing), including motor and premotor cortex; association (involved in cognition, working memory, strategic planning), including the dorsolateral prefrontal cortex; and limbic (involved in reward processing and motivation), including the anterior cingulate cortex and orbital cortex. Each of these cortical regions projects to specific parts of the striatum. In general, the motor regions project to a large area of the putamen, caudal to the anterior commissure; the association areas project to a large part of the caudate nucleus and putamen rostral to the anterior commissure; and the limbic regions project to the ventral striatum including the nucleus accumbens. Each of these parts of the striatum project to specific parts of the pallidum and SNr, which, in turn project to specific parts of the thalamus. These thalamic regions extend the functional specificity in their projections back to the cortex of origin. This organization has been referred to as parallel processing of information via separate and segregated circuits.

The topography of cortico-BG projections has led to a model of BG function based on parallel and segregated pathways operating through discrete functional channels (limbic, associative, and sensorimotor), which are represented in specific regions in each BG structure. However, mechanisms by which information flows through functional circuits are now being explored. At least two networks have been identified, one through the striato-dopamine-striatal pathway, and one through the cortico-thalamic cortical pathway. Within each of these sets of connected structures, there exist both reciprocal connections linking up regions associated with similar functions and, in addition, non-reciprocal connections linking up regions that are associated with different cortical BG circuits. For example, the midbrain dopamine neurons play a unique role in BG and cortical circuits modulating a broad range of behaviors from learning and "working memory" to motor control. This is achieved by the interface between the efferent and afferent projections of the striatum to the dopamine cells. Projections from the limbic regions of the striatum terminate in the region of dopamine neurons that project not only back to the

limbic striatal domain, but also to the cognitive portions of the striatum. Striatal cells in the cognitive domain project, not only to midbrain regions that have a reciprocal connection, but also terminate in motor control areas. In this way information from the ventral striatum reaches more dorsal striatal parts to influence cognitive and motor control striatal areas. Of particular interest is the fact that dopamine neurons do not respond to movement, but rather signal unpredicted reward, thus focusing attention on significant and rewarding stimuli, a requirement for the acquisition of new learned behaviors [2]. The dopamine pathways that signal salience, are in a position, through their input from the striatum and projections back to the striatum, to provide an interface between cognitive, motor, and limbic functional domains of the forebrain, through complex forebrain neuronal networks [3]. The BG are a key element in the development of goal-directed behaviors and the action plans that them carry out. Goal-directed behaviors require processing a complex chain of events beginning with motivation, proceeding through cognitive processing that shapes final motor outcomes. This sequence is reflected in the feedforward organization of both the striato-nigral connections and the thalamo-cortical connections. Information is channeled from limbic, to cognitive, to motor circuits. Decision-making processes are thus influenced by motivation and cognitive inputs, allowing the animal to respond appropriate to environmental cues.

## The BG in Neurological and Psychiatric Disorders

The substantia nigra was first identified in eighteenth century, but it wasn't until the twentieth century that it was linked to the motor system, primarily due to the connection of nigral cell loss in Parkinson's disease. The involvement midbrain dopamine in the pathogenesis of major psychoses evolved in the 1950's when it was discovered that the phenothiazines were an effective treatment for psychosis. Since that time the midbrain dopamine system has been linked to psychosis and behavioral disorders including, Gilles de la Tourette's disease, and drug abuse. Because of the early distinction between limbic and motor components of the BG circuitry, including anatomical and behavioral studies, the dopamine cells have been divided into a motor group (the SNc), and a limbic group (the ventral tegmental area). However, our concept of BG function has dramatically changed in the last 30 years, to a recognition that this division is too simplistic and the realization through new imaging techniques, among other new methodologies, that the BG mediate the full range of goal-directed behaviors, including, the elements that drive actions, emotions, motivation, and cognition. As indicated above, regions within each of the BG nuclei have been identified as serving not only a sensory-motor function, but also different aspects of reward processing and cognitive planning. Ventral regions of the BG play a key role in reward and reinforcement [4] and are important in the development of addictive behaviors and habit formation [5]. More central BG areas are involved in cognitive functions such as procedural learning and working memory tasks [6]. Diseases affecting mental health, including schizophrenia, drug addiction, and obsessive-compulsive disorder, are linked to pathology in both the dorsal and ventral striatum [7,8]. This is in contrast to diseases that interfere with motor control and primarily affect the dorsal BG. Thus, the role of the BG in cognitive and emotional behaviors is now as well accepted as is the role in motor control. Although several new theories of general function have emerged from the enormous progress in understanding the anatomy, physiology, and behaviors associated with the BG [9], the actual role of the BG in executing goal-directed behaviors remains elusive. What is clear from the recent progress is that this set of subcortical nuclei work in tandem with cortex (particularly frontal cortex) via a complex cortico-BG network to develop and carry out complex behaviors.

In summary, the concept of what the function of the BG do is changing from sole involvement in motor control to mediation of learning and the development of goal directed behaviors. Cortico-BG networks work together, allowing coordinated behaviors to be maintained and focused, but also to be modified and changed according the appropriate external and internal stimuli. Indeed, loss of both the ability to execute specific behaviors and to adapt appropriately to external and internal cues, are key deficits in BG diseases which thus affect motor control, cognition and motivation.

### Definition

The basal ganglia consist of four prominent nuclei, which are interposed between the cerebral cortex and the lower centers of the brain stem and spinal cord. These nuclei include the:

1. Striatum (caudate, putamen, ventral striatum including nucleus accumbens)
2. Globus pallidus internal (GPi) and external (GPe) segments
3. Substantia nigra pars compacta (SNpc) and pars reticulata (SNpr)
4. Subthalamic nucleus (STN)

Most of the inputs and outputs of the basal ganglia arise from or go to the cortex either directly or indirectly through the thalamus. Thus, the basal ganglia form something of a side loop or detour in the relation of the brain to behavior. As a result, determining the function of the basal ganglia has been more difficult than for brain areas that more directly respond to impinging sensory stimuli (See ►Sensory Cortex) or elicit distinct motor outputs (See ►Motor Cortex).

While the basal ganglia mediate many nonmotor functions including cognition, emotion, and sensory processing, they have long been regarded as primarily involved with movement. Lesions of the basal ganglia cause motor deficits. The disorders most associated with the basal ganglia – such as Parkinson's disease (PD), dystonia, and Huntington's disease (HD) – are considered movement disorders, even though other functions can be disrupted in these patients (e.g. sleep in PD, mood in HD, cognition in both PD and HD).

Within the basal ganglia, the putamen is most directly associated with movement and receives abundant cortical input. From the putamen, impulses flow through the GPi/GPe, STN, and SNpr to the thalamus. The SNpc sends a large dopaminergic projection to the striatum (See ►Dopamine). The SNpc is the nucleus most degenerated in PD.

### Characteristics

1. The basal ganglia is a source of motor disorders

   The close connection between the basal ganglia and movement goes back to classical clinical neurological findings showing basal ganglia damage in many patients with movement difficulties. Indeed, the whole field of *movement disorders* has focused primarily on conditions that involve the basal ganglia. More recent explorations using cellular recordings and neuroimaging (see below) have confirmed this finding by establishing abnormal activities within these nuclei in motor disorders [1].
2. Methods of elucidating the motor functions of the basal ganglia

   Several different techniques have contributed to our understanding of the organization and function of the basal ganglia. These techniques include neuroanatomical studies of animals and human autopsy tissue, cellular recordings from animals and humans undergoing invasive brain surgery, radiotracer and functional imaging studies (►functional neuroimaging methods), and behavioral studies of patients with motor disorders, particularly PD.

   a. Anatomical organization

   Earlier studies confirmed the general scheme of input and output relations of the basal ganglia. More recent studies have identified several more distinctive and specialized pathways. The following discussion is a simplified view of these results and omits much of the emerging complexity of the basal ganglia pathways.

   i. The direct and indirect pathways

These two pathways are thought to work as a push-pull system that can finely control the level of basal ganglia output. A correct balance is necessary for normal motor function. All basal ganglia output is thought to be inhibitory and to suppress thalamic activity, which in turn reduces stimulation of interconnecting cortical regions. The direct pathway runs from the striatum to the GPi and suppresses GPi output, thus releasing the thalamus to provide excitation to the cortex. The indirect pathway from the striatum to the GPe and STN, excites the GPi, thereby suppressing the thalamus and withdrawing excitation from the cortex. Selective activation of different elements of these pathways can create a "center-surround" input to the cortex that selects specific motor activities for expression while inhibiting others [2]. In PD, a hypokinetic disorder, relative hyperactivity of the indirect pathway leads to excessive inhibitory GPi output and poverty of movement; this may be due to thalamic inhibition, but it could also be due to a breakdown in the specificity and segregation of GPi output [3]. In dystonia, a hyperkinetic disorder, relative hyperactivity of the direct pathway leads to reduced GPi output and excessive, involuntary motor activity.

More recent studies indicate that a third, "hyperdirect" pathway exists, with cortical input going directly to the STN. This pathway would also tend to increase GPi inhibitory output and reduce cortical excitation.

ii. The nigrostriatal pathway

This dopamine projection is the most degenerated in PD and has abundant projections to the striatum, whereas other dopaminergic systems project widely from the cortex to the spinal cord. Its basic effect is to increase basal ganglia output by acting on ►D1 dopamine receptors in striatal neurons that stimulate the direct pathway and on ►D2 dopamine receptors that stimulate the indirect pathway. Much of SNpc activity tends to be tonic or sustained rather than phasic or transient, which has led to some difficulty in establishing the pathway's explicit contribution to motor control (►motor control Hierarchy).

iii. Basal ganglia loops

A major advance in understanding the circuitry of the basal ganglia was the recognition that its neurons were organized within a series of parallel loops. Each loop began in the cortex with excitation of the striatum followed by input to the GPi, which then variably inhibited the thalamus whose projections sent excitation back onto the original cortical source. Although this architecture continues to be studied, more than five separate loops and several divergent connections have been identified. The "motor loop" has been most studied and is best understood [1]. This form of organization is especially suited for feedback or feed-forward effects, while cross-talk between loops may be crucial for correlated activities in different cortical regions.

b. Single cell and local potential recording

Single cell recording was pioneered in animal models where implanted electrodes could be used to monitor cellular activity during a variety of behaviors. Such studies include normal primate models and disease models such as the MPTP monkey, which has been rendered Parkinsonian by the targeted administration of MPTP, a selective neurotoxin for dopaminergic cells. More recently, cellular studies have been extended to patients, especially those with PD, who have been recorded during ablative procedures or the installation of stimulators in the GPi, thalamus, or STN.

These studies have shown that like thalamic and cortical somatotopy, some degree of somatotopy exists throughout the nuclei of the basal ganglia, with activity in the skeletomotor loop segregated between arm, leg, and orofacial movements. While the general background activity of cells is one of frequent discharge, it can be modulated by the behavioral context both during preparatory periods prior to the onset of a goal-directed movement and during movement. Because most cells directly related to movement fire during, rather than before, a movement, basal ganglia activity does not appear to directly produce movement. Altogether, these observations are consistent with a role for the basal ganglia in planning movements and in motor learning [4]. The physiological changes in firing rate observed in normal animals have led to the suggestion that altered rate might underlie basal-ganglia dysfunction in PD. Indeed, GPi firing is excessive in PD, consistent with an overall inhibitory effect of this output on movement. However, this hypothesis is inconsistent with a similar increase of GPi firing in HD, a hyperkinetic disorder. Moreover, changes in firing frequency are modest. As a result, more attention has focused in recent years on the patterning of GPi output, especially the modulation of firing in an oscillatory manner within different frequency bands. It has been suggested that low frequency oscillatory activity – in the theta to beta range (4–30 Hz) – may be associated with inhibition of motor activity and bradykinesia, while higher frequency activity in the gamma range (>40 Hz) may facilitate movement. In both the MPTP monkey and humans with PD, slower oscillations are more prominent [5]. Treatment of PD with dopaminergic agents or deep brain stimulation (DBS) can enhance higher frequency oscillatory power.

c. Neuroimaging

►Radiotracer imaging, which measures nigrostriatal neuronal loss during a "resting state," has been

widely used in PD to study disease progression and the effects of pharmacotherapy. In contrast, functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), typically measure brain activity while a person actively performs a task to assess how neural systems function in different behavioral contexts. One standard method to study normal brain functioning is to compare brain activity at rest with activity during movement or motor learning in neurologically intact individuals. In general, basal ganglia and cortical activity are increased for self-generated movements. Similar to cellular recordings in animals, basal ganglia activity during task-activated fMRI is modulated by the behavioral context such that it increases with the complexity of movement in planning stages, but not during motor execution [6]. During motor learning, however, both increases and decreases in basal-ganglia and cortical activity have been reported, depending in large part on the degree of uncertainty about what movements are required and the amount of practice given [4]. Another approach has been to compare patients with normal individuals to identify abnormal patterns of brain activity in the patients. Some PET studies of resting-state brain activity have revealed a disease-related pattern of activity in PD characterized by elevated pallidal, thalamus, pontine and cerebellar activation and reduced premotor and parietal-occipital activity relative to normal individuals [7]. Even more interesting are PET and fMRI studies that have investigated brain functioning during movement and motor learning. In PD, dysfunction of the basal ganglia and interconnecting cortical regions can be studied by temporarily stopping pharmacotherapy so that dopamine levels are reduced to a practical "off state" or by turning off DBS devices. In areas specifically related to planning movements, such as the supplementary motor area, PD "off" patients typically show decreased activity. In other areas, such as the premotor, prefrontal and parietal cortices, PD patients can show hyperactivity together with a failure to show normal reductions in activation as motor behaviors become learned or "automatized" [8]. This abnormal functional pattern can be reduced by reinstatement of dopaminergic or DBS treatment.

3. Presumed functions of the basal ganglia

Progress has been made in understanding how the basal ganglia modulate different aspects of movements. In this section, we discuss the contribution of the basal ganglia to regulating intensive aspects of movement, motor planning, motor coordination, and motor learning. Although these facets of movement are not entirely independent, their relative importance can be emphasized by certain task conditions. Emerging research suggests that some treatments for PD can better remediate certain aspects of motor function, while having little or no effect on others, which lends support to their distinctiveness.

a. Intensive dimensions of movement

Peak force, velocity, and scaling are all aspects of movement that show a single major dimension of intensity. Clinically, PD patients are hypokinetic, so that they are slower, take longer to complete certain tasks, and generate less force. PD patients are also hypometric (e.g., ►micrographia) and tend to fall short of a target when reaching for it. With farther targets their output increases, but continues to be hypometric, even when it far exceeds the output needed to reach a closer target. Yet when permitted feedback of their position, PD patients can acquire targets as accurately as normal individuals. This may indicate a reliance on compensatory pathways that are relatively intact. Treatments of PD rather effectively remediate deficits in the intensity aspect of movements; with medication or surgical treatments, PD patients become faster and reach further. This suggests that the basal ganglia play a more trophic role with regard to movement intensity, which is mediated by the balance between direct and indirect pathways that inhibit undesired movements while facilitating chosen ones [2].

b. Feed-forward versus feedback control

In general, the basal ganglia are more important for self-generated movements that require feed-forward control than for sensory-guided movements under feedback control, suggesting that they play a key role in prediction or planning. This agrees with cellular and fMRI studies reporting that the basal ganglia exhibit dynamic modulation largely during response preparation [6]. These findings contrast with reports that PD patients can be faster than normal individuals in making saccadic eye movements to targets. This is likely due to relatively intact pathways involving the cerebellum, parietal cortex, and frontal eye fields, which process and modulate responses to external stimuli. Without adequate ability to prepare responses, feedback dominates predictive control.

c. Sensorimotor processing and integration

PD patients are also impaired in processing and utilizing proprioceptive information, a task analog of the postural deficit that is among the key clinical features of the disorder. As a general rule, PD patients have difficulty with integrating different forms of sensory input with sensorimotor (►sensorimotor integration) transforms that guide behavior, and with the integration of different

components of targeted movements (e.g. integration of reach and grasp components when moving to a target object) [9]. Such coordinative aspects of basal ganglia function are less readily normalized by pharmacologic or DBS treatment of PD. This suggests that current treatment approaches may restore more trophic or intensive functions of the basal ganglia, but may not restore the more precise, highly localized integrative functions related to specific brain regions or behaviors. Like most basal ganglia functions, we cannot indicate with great specificity how this occurs. One possible function is the ability of the BG to facilitate the binding of different cortical regions as they act in a coordinated fashion to shape motor behavior. Different sensory and motor coordinates resident in separate brain regions are required to effectively shape motor output, and the evidence from PD indicates that the basal ganglia are needed to facilitate their coordination.

Coordinative abilities are also important for sequencing motor behaviors and for dual task performance, both of which are impaired in PD. The basal ganglia may be most critically important in the preparation of motor sequences [6], which involves assembling a series of movements into a coordinated action. When preparation fails, actions may be decomposed into a series of movement segments rather than a smoothly structured sequence. Similarly, performance of even well-learned behavioral sequences may break down when a dual task is imposed [8].

d. Role in motor learning

The basal ganglia are important for learning new motor acts, which partially depend on preparative processes. A recent fMRI study reported that basal ganglia plasticity during both motor-sequence learning and when switching to new motor sequences correlated with reaction time, a measure of preparation [4]. No other structures, except the thalamus, showed this relationship, which agrees with its key role in preparation. This finding is consistent with slowed and incomplete visuomotor learning in PD, especially when there is a need to change from one behavioral context to another, a deficit in set shifting [10]. The distinction between preparation and learning may be one of degree; even well-learned behaviors need to be calibrated and prepared when called upon. Thus preparation and learning form a continuum in which overlapping abilities are needed to predict and model behavior.

## Conclusions

New conceptualizations are emerging about corticostriatal circuitry, cellular properties of basal ganglia nuclei, and brain-behavior-treatment (e.g., pharmacotherapy, surgical) relationships, which have considerably advanced our knowledge about facets of motor function and their physiological underpinnings. One dominant theme is the central role of the basal ganglia in modulating intensive aspects of movement and feed-forward control, the latter of which may support to some extent other functions including integrative processing and learning. Especially fruitful have been studies demonstrating that these aspects of movement are differentially responsive to pharmacotherapy in PD. Exciting developments are also now taking place in neuroimaging studies of PD, which are beginning to delineate abnormal neural patterns associated with motor dysfunction, and assess their response to therapeutic interventions. Continued progress in these areas holds promise for further illuminating the workings of the basal ganglia nuclei and their modulation of motor, but also nonmotor functions represented more directly by the cerebral cortex.

# Basal Ganglia: Role in Eye Movements

Okihide Hikosaka
Laboratory of Sensorimotor Research, National Eye Institute, National Institute of Health, Bethesda, MD, USA

## Definition

A major function of the basal ganglia is the control of body movements. This is illustrated by a variety of movement disorders caused by dysfunction of the basal ganglia, such as Parkinson's disease and Huntington's disease. Symptoms include the inability to initiate a movement and the inability to suppress involuntary movements. Eye movement is not an exception [1]. A fixed, vacant facial expression of patients with Parkinson's disease, which is often called the "Parkinson's mask," is due to the paucity of movements in the face, including the paucity of eye movements. Most affected among various kinds of eye movements are smooth pursuit and saccade, which require more voluntary control. Parkinsonian patients are often impaired in smoothly pursuing a moving object (deficit in smooth pursuit). They are also often impaired in shifting their gaze from one position in space to another (deficit in saccade).

## Characteristics

### Higher Level Processes

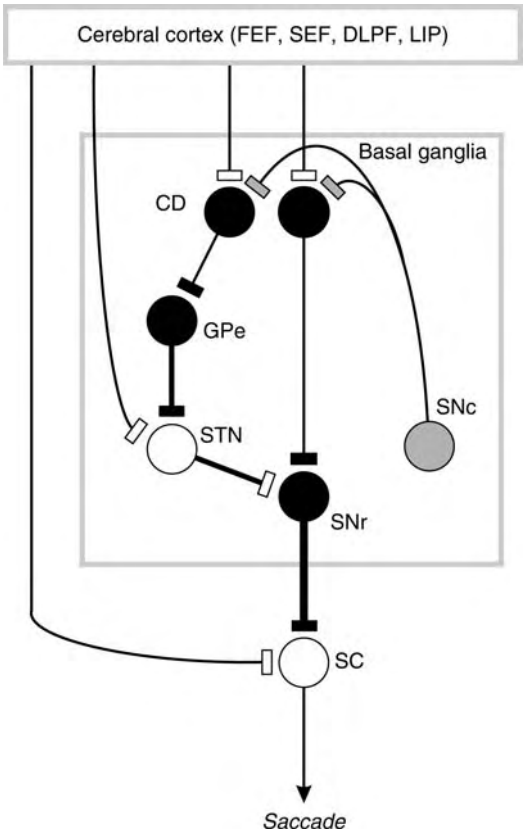
The impairment in ►saccadic eye movement in patients with basal ganglia disorders has been repeatedly demonstrated using more rigorous tests with accurate measurement of eye position [1]. Typically, the subjects are required to fixate their gaze on a spot of light (target) on the screen and, if the target steps, follow it by quickly shifting their gaze. This is called a "visually guided saccade task." Compared with age-matched control subjects, saccades (►Spontaneous Saccades) of parkinsonian patients tend to be small in amplitude (i.e., hypometric), slow, and delayed (i.e., long latency). Curiously, the deficit in saccade is often more severe if there is no visible object and the saccade must rely on memory. In a "memory-guided saccade task" a target appears briefly while the subject is fixating at the central spot and the subject has to make a saccade after a delay to the position where the target was presented. Parkinsonian patients are more impaired or selectively impaired in ►memory-guided saccades than in ►visually guided saccades. This phenomenon may illustrate the context-dependent movement deficits in Parkinson's disease, which are widely recognized among neurologists. Selective deficits in memory–guided saccades are observed in other basal ganglia disorders, including Huntington's disease. The similarity between Parkinson's and Huntington's diseases is noteworthy because they are caused by different mechanisms, the former by a loss of neurons in the substantia nigra (SN) and the latter by a loss of neurons in the caudate nucleus (CD). This suggests that the SN and the CD work together for the control of saccadic eye movement (see the sections ►caudate – role in eye movements and ►substantia nigra – role in eye movements).

How the basal ganglia might control eye movements has been studied by single unit studies using trained animals [1]. The animals were trained on the visually guided and ►saccade – memory-guided tasks. Electrical activity of single neurons was recorded with microelectrodes and was correlated with saccadic eye movements. Saccade-related activity has been found in various nuclei in the basal ganglia, including the substantia nigra, CD, ►subthalamic nucleus (STN), and ►globus pallidus (GP) [1]. Such saccade-related neurons are clustered in a sub-region of each nucleus: dorsolateral part of the pars reticulata of the substantia nigra (SNr), central-ventral part of the CD, ventral part of the STN, and dorsal part of the external segment of the globus pallidus (GPe). Anatomical studies have shown that these saccade-related parts are connected within the basal ganglia and with saccade-related regions outside the basal ganglia. For example, the saccade-related part of the CD receives inputs from the ►frontal eye field and the ►supplementary eye field in the frontal cerebral cortex [2], while the saccade-related part of the SNr projects their axons to the ►superior colliculus (SC) [3]. Note that neurons related to skeletal movements are found in different sub-regions in the basal ganglia, such as the putamen (equivalent to the CD) and the internal segment of the globus pallidus (GPi) (equivalent to the SNr). These facts are consistent with the idea that there are functional sub-divisions within the basal ganglia as well as in larger networks including the cerebral cortex and the cerebellum, each of which may form a closed-loop functional unit [4]. Recent studies, however, indicate that such functional segregation is not perfect.

### Lower Level Processes

An interesting feature of the basal ganglia circuits is that they use inhibitory connections as a primary means

to convey signals [5] (Fig. 1). Each area contains projection neurons and interneurons. While cortical inputs to the CD are excitatory and use glutamate as a transmitter, projection neurons in all areas in the basal ganglia, except the STN, are thought to be GABAergic and inhibitory. This means that the polarity of a signal is reversed each time it passes through projection neurons in one area. There are at least three parallel pathways in which saccade-related signals can be processed in the basal ganglia [6]: (i) direct pathway from the CD to the SNr; (ii) indirect pathway from the CD to the SNr through the GPe and/or the STN; (iii) hyper-direct pathway from the STN to the SNr. Since the direct pathway consists of a series of two inhibitory connections (CD and SNr), the net effect is facilitatory. Since the indirect pathway and the hyper-direct pathways consist of three and one inhibitory connection, respectively, the net effect is inhibitory. The basal ganglia thus could facilitate or inhibit motor processes by selectively using these pathways. Another determinant of the basal ganglia mechanisms is background activity of neurons: very high in the output areas (i.e., SNr and GPi) and very low in the input areas (i.e., CD and putamen). Neurons in the target areas of the basal ganglia are thus inhibited most of the time (due to the rapid firing of SNr or GPi neurons), but are released from the inhibition (if the direct pathway is deployed) or are further inhibited (if the indirect or hyper-direct pathway is deployed). The target area for saccadic eye movement is the SC.



**Basal Ganglia: Role in Eye Movements.**
**Figure 1** Basal ganglia neural network involved in the control of saccadic eye movement. *CD*, caudate nucleus; *SNr*, substantia nigra pars reticulata; *SC*, superior colliculus; *SNc*, substantia nigra pars compacta; *GPe*, globus pallidus external segment; *STN*, subthalamic nucleus; *FEF*, frontal eye field; *SEF*, supplementary eye field; *DLPF*, ▶dorsolateral prefrontal cortex; *LIP*, area LIP in parietal cortex. Excitatory and inhibitory neurons and synapses are indicated by open and filled symbols, respectively. *Gray symbol* indicates dopaminergic neuron which exerts modulatory effects on CD neurons. The thickness of the line (axon) roughly indicates the level of spontaneous activity. The direct excitation of SC neurons by inputs from the cerebral cortex is gated by the inhibitory input from the SNr.

## Process Regulation

The throughput of these GABAergic and glutamatergic pathways is thought to be modified by various groups of neurons [7]. Probably the most important among them is a group of dopaminergic neurons located in the substantia nigra pars compacta (SNc) and surrounding regions. They modulate saccadic and other motor signals in the CD or putamen by projecting their axons to these nuclei. The power of the dopaminergic modulatory action is evident by the deficits in saccadic eye movement and other movements in patients with Parkinson's disease. The role of cholinergic interneurons in saccades is less clear.

With respect to saccadic motor control in general, the basal ganglia system is situated as a side path that has been added to the direct effect of the cerebral cortex on the SC (Fig. 1). Probably the most important question is: How unique is the function of the basal ganglia, compared with the direct cortico-SC effect? The answer to this question should be found in two other sections: "caudate – role in eye movements" and "substantia nigra – role in eye movements".

## Synonyms

Basement membrane

## Definition

The ►basal lamina is a thin layer of extracellular matrix covering the connective tissue surface of Schwann cells, muscle fibers and epithelial cells in general. The main structural component of basal lamina is type IV collagen, with which heparan sulfate proteoglycans and laminin, a major adhesion molecule, are associated. Regenerating axons grow through basal lamina tubes derived from Schwann cells, skeletal muscle fibers and other tissues. This means that extracellular matrices such as basal laminae can serve as an effective scaffold for the growth of regenerating axons.

## Characteristics

### Axonal Growth Through the Nerve Segments of Wallerian Degeneration

The peripheral nerve fiber consists of axons and Schwann cells. Schwann cells cover axons along their entire length except at the ►node of Ranvier, where a gap is formed between the neighboring Schwann cells. In addition, Schwann cells are covered on their outer surfaces by basal laminae that are continuous, even at the node of Ranvier. Therefore, the peripheral nerve fiber resides within a basal lamina tube.

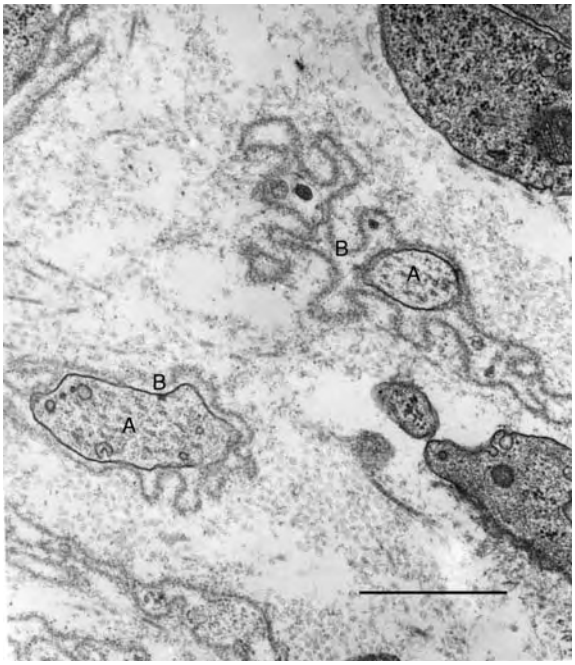
Following Wallerian degeneration, degraded myelin sheaths are removed by macrophages that have invaded the basal lamina tube. These macrophages are derived from blood monocytes. Schwann cells that lose their myelin sheaths during Wallerian degeneration form cell strands called Schwann cell columns. Regenerating axons extend along such Schwann cell columns to the target.

### Nerve Regeneration Through the Extracellular Matrix

If a nerve fiber is freeze-treated, the Schwann cells die, and the myelin sheaths disintegrate. Macrophages invade the basal lamina tubes and phagocytose the degraded myelin sheaths. However, the basal laminae remain intact in the form of the original tube. If a freeze-treated nerve segment is grafted to the proximal stump of the transected nerve, regenerating axons extend through the basal lamina tube [1,2] (Fig. 1). Growing axons are always in contact with the inner surface of the basal laminae. Laminin is the main adhesion molecule in the basal lamina. In mice in which the γ1 laminin chain was disrupted, nerve regeneration was impaired [3]. On the other hand, integrin α7β1, a receptor for laminin, is essential for the neurite outgrowth of sensory neurons, as demonstrated in the α7–integrin null mice [4] and an *in vitro* experiment [5]. In addition, α4 ingerin is also an important receptor of fibronectin in neurite outgrowth [6].

In regeneration, de-differentiated Schwann cells migrate from the proximal stump along regenerating axons. At first, these immature Schwann cells surround all axons as a bundle within a basal lamina tube, and then gradually separate thick-diameter axons into individual ones, with Schwann cells vs. axons at a ratio of 1:1. Finally, myelin sheaths are formed on axons. Thus, complete nerve regeneration occurs in basal lamina tubes in the absence of living Schwann cells. This indicates that the basal lamina tube provides an appropriate scaffold for axonal regeneration in the peripheral nervous system [7].

The fact that the extracellular matrix, like the basal laminae, can efficiently support the growth of regenerating axons is the theoretical basis for the artificial nerve in the peripheral nervous system. Basal laminae form a three-dimensional matrix of all tissues including nerve fibers. Therefore, the three-dimensional architecture of the basal laminae provides an essential scaffold for the repair of tissues and organs in general.



**Basal Lamina in Nerve Regeneration.**
**Figure 1** A nerve segment excised from the sciatic nerve of mice was freeze-treated to kill Schwann cells, and sutured again to the original site, allowing the growth of regenerating axons from the proximal stump into the segment. Within several days, degraded myelin sheaths had been removed by macrophages, and the original basal laminae of Schwann cells remained in the form of a tube. Regenerating axons (A) extend through such basal lamina tubes (B) of Schwann cells. Scale bar: 1 μm.

Basal laminae derived from non-neural tissues are also effective conduits for regenerating axons. By freezing- or detergent-treatment, skeletal muscle fibers die and the basal laminae remain in the form of original tubes, as in the case of freeze-treated Schwann cells. When such basal lamina preparations are grafted onto the proximal stump of the transected peripheral nerve, regenerating axons enter and extend through the basal lamina tube [8], indicating that the basal laminae of non-neural tissues can also serve as a scaffold for regenerating axons.

It has been proposed that basal lamina tubes can be used for clinical application as a substitute for fresh nerve grafting. At present, ►autografting is generally used for clinical treatment. On the other hand, ►allografting has a limited application for clinical use. Our study shows that allogeneic basal laminae cause almost no immunological rejection, indicating that the allografting of Schwann cell basal laminae might be of clinical use. In fact, the grafting of a long segment of freeze-treated peripheral nerve facilitates good nerve regeneration in dogs [9].

## Sprouting and Growth

Regenerating sprouts usually emanate from the node of Ranvier at the proximal stump near the site of injury. Sprouts from the node extend without exception through the space between the basal laminae and myelin sheath, i.e., the Schwann cell plasma membrane [10]. Sprouts contain many vesicles at an early stage, and extend along the inner surface of the basal laminae of Wallerian-degraded nerve fibers as growth cones containing many mitochondria and vesicles. Regenerating sprouts never extend through the space surrounded by old myelin sheaths, in which the original axon resided. All myelin sheaths of nerve fibers disintegrate, and are removed by phagocytosis carried out by macrophages in Wallerian degeneration. Axons that were regenerated or merely demyelinated remain for a long time with thin and irregular-lamellated myelin sheaths in the spinal cord.

## Basal Nucleus of Meynert (Ch.4)

### Synonyms

►Basal nucleus of basal substance

### Definition

In the basal forebrain, between the septum verum and amygdaloid body directly in the middle of the substantia innominata, are situated four groups (Ch.1–Ch.4) comprised of large cholinergic cells, of which Ch.4 are the most pronounced in humans. Afferents come primarily from the limbic system, the projections pass, on to all parts of the cerebral cortex. The nuclear region plays a role in the coupling of complex behavioral modes to basic emotional state (motivation).

In the presence of presenile or senile demence, especially in the case of Alzheimer's disease, there is marked degeneration of the cells of the basal nucleus Meynert (Ch.4), with concomitant impairment of memory, disorientation, motor unrest and impaired speech.

►Telencephalon

## Basal Optic Neuropil (BON)

### Definition

A small number of retinal axons separates forming quickly a distinct fascicle, the basal optic tract. It consists of a lateral and a medial fascicle, which innervate different parts of the teminal field of the BON.

Afferents originate mainly from the entire contralateral retina. Neurons are sensitive to temporo-nasal direction of stimulus movement; cells that respond preferentially to vertical movement are also present. Together with the pretectum, the BON is involved in the guidance of compensatory optomotor movements.

►Evolution of the Visual System: Amphibians

## Basal Plate

### Definition

The ventral half of the neural tube. In the spinal cord and rhombencephlon, it contains most of the motor neurons.

►Evolution of the Posterior Tuberculum and Preglomerular Nuclear Complex

## Base of Support (BOS)

### Definition

The area of the body that contacts the environment and thereby allows generation of supporting "environment reaction" forces (i.e. ground reaction forces at the feet, and analogous forces occurring at the hand if it is in contact with a stable object or surface). In the absence of hand support, the horizontal location of the center of mass of the body must remain within the limits of the base of support defined by the feet (i.e. the area circumscribed by the outer margins of the feet) in order to maintain a state of static postural equilibrium.

## Basilar Membrane

### Definition

The acellular membrane of the cochlea upon which rests the organ of Corti. Due to its graded stiffness, it

sustains traveling waves that propagate from the cochlear base toward its apex. Traveling waves peak at cochlear sites with tonotopically-arranged characteristic frequencies, so that sites near the base and apex, respectively, vibrate maximally when stimulated by high- and low-frequency stimuli.

►Cochlea

## Basis Pedunculi

### Definition

The basis pedunculi (L. foot or stalk) is a large collection of descending fibers located at the base of the midbrain. All arise from cell bodies in the cerebral cortex. They end in the pons, medulla and spinal cord. This bundle is more commonly called the cerebral peduncle or crus cerebri.

## Basolateral Amygdala

### Definition

Brain region in the medial temporal lobe involved in regulating emotional arousal influences on memory.

►Emotional Learning/Memory

## Bat

### Definition

Mammalian family (Chiroptera). Two subfamilies are distinguished (Macro- and Microchiropterans). While Macrochiroterans (fruit eating bats) are herbivores and do not possess a biosonar system, Microchiropterans hunt prey by using biosonar. The echolocation behavior and the neural basis of this behavior have been a neuroethological model system (see essay on "Neuroethology of biosonar in bats").

## Bauplan

### Definition

The anatomical organization of a body or structure that is characteristic of a taxonomic group. In essence, the "bauplan" defines the basic organizational plan that typifies a particular group of organisms and sets them apart from other groups. For the vertebrate nervous system, the bauplan would include the fundamental embryological divisions of the brain as well as basic features of the connections defining sensory and motor systems.

## Bayesian Statistics (with Particular Focus on the Motor System)

Konrad Körding
Institute of Neurology, London, UK

### Synonyms

Probabilistic inference; Statistical inference; Bayesian inference; Antonym: Frequentist statistics

### Definition

As our sensors are not perfect and do not provide information about all the properties of the world, we are faced with sensory *uncertainty*. Moreover, our muscles also produce noisy outputs and so we are also faced with motor uncertainty. *Bayesian statistics* is the

systematic way of dealing with uncertainty by expressing its many forms in terms of probability.

## Description of the Theory

Bayesian statistics can be used to infer the states of variables that are not directly measured, a process called *Bayesian inference*. "For example, when we see a tennis ball (observed variable) and we know from experience how they usually fly (prior knowledge) then Bayesian statistics allows us to calculate how likely the ball will land at any given position on the field (unobserved variable)." The way inference is done is the following:

(i) The *prior knowledge* about the system is specified. The structure of the problem is defined, specifying which variables depend on which other variables in which way. (ii) Bayesian methods are used to infer how probable each state of the unobserved variables is given the values of the observed variables. There are numerous methods available towards this goal. Some methods deliver an approximate answer efficiently while some other methods deliver exact solutions to simpler problems.

Numerous articles summarize the mathematical [1] and philosophical [2] ideas that are behind Bayesian statistics and how to use them. The main focus of this article is on the concepts behind Bayesian methods that are used to understand the human behavior.

## Notation

Upper case letters denote random variables (e.g., the position of my hand); lower case letters denote a particular value that a random variable can take (e.g. 10 cm).

$p(A = a)$ is the probability that a random variable $A$ takes on a specific value a, given that there is no additional knowledge about other related variables.

$p(A = a|B = b)$is the probability of observing A = a given that the statistician has the knowledge that the variable B has the value of b (*conditional probability*).

$p(A = a, B = b)$is the probability that $A = a$ and $B = b$. It can be rewritten to be:

$$p(A = a, B = b) = p(A = a)p(B = b|A = a)$$

## Conditional Independence and Graphical Bayesian Models

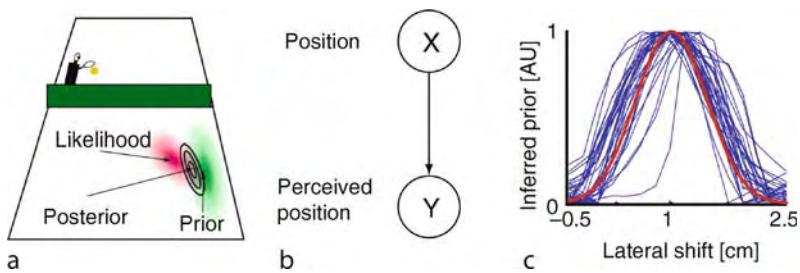
Statistical problems become a lot easier once we understand their structure. If we have three variables, $A$, $B$ and $C$ we could, for example, know that $A$ causes $B$ and $C$ and that $B$ and $C$ do not interact. As an example, $A$ could be the size of an object, $B$ is the size as reported by our sense of touch alone and $C$ is the size reported by our visual system alone. B and C thus show *conditional independence* on A. As many problems have such a structure, graphs are often drawn to depict how variables depend on one another. There is a range of variants of such graphs, but for the problems considered here *graphical Bayesian networks* (directed acyclic graphs) are used. If no direct link exists between two variables $B$ and $C$ then they are independent, conditional on the other variables that are "in-between":

$$p(B = b|C = c, Others = o) = p(B = b|Others = o).$$

## Using Bayes Rule: Ball Positions in Tennis

If we are playing tennis we want to estimate where the ball will hit the ground (see Fig. 1a). As vision does not provide perfect information about the ball's speed, there is uncertainty about where the ball will land. If we, however, have played a lot of tennis before, we can have knowledge about where our partner is likely to play to. We want to combine this knowledge with what we see to obtain an optimal estimate of where the ball will hit the ground.

This example can be abstracted the following way (Fig. 1b): The physical properties of the ball define the



**Bayesian Statistics (with Particular Focus on the Motor System). Figure 1** a) Example: The other player is hitting the ball. Seeing the ball we can estimate that it will land in the red region (with a likelihood proportional to the saturation). We have prior knowledge that the ball is likely to land in the green region (with a probability proportional to the saturation). The black ellipses denote the posterior, the region where the Bayesian estimate would predict the ball to land. b) Structure: The position influences the perceived position. c) Human subjects had to estimate a position. From these measurements their priors were inferred (blue lines). The real distribution is shown in red. Data replotted from citation 3.

position $X = x$ where the ball will hit the ground. The visual system, however, does not perceive where the ball will really hit the ground but rather some noisy version thereof, $Y = y$. Knowing the uncertainties in the visual system we know how likely it is to perceive the ball being at $Y = y$ if it is really at $X = x'$. This is called *likelihood* ($p(Y = y|X = x')$) and is sketched in red in Fig. 1a. Just based on this knowledge we could ignore any other knowledge we might have and our best estimate would be in the middle of the red cloud, at $y$. This procedure, however, ignores that we could have prior knowledge about the way our partner plays. In particular, over the course of many matches the positions where the ball hits the ground will not be uniformly distributed but highly concentrated within the confounds of the court, and if our enemy is a good player highly peaked near the boundary lines where it is most difficult to intercept them. This distribution of positions where the ball hits the ground, $p(X = x)$, is what is called a *prior* and which could be learnt using methods of *Bayesian learning*. We can apply *Bayes Rule* to compute the *posterior* ($p(X = x|Y = y)$), the probability of the ball landing taking into account the prior and the new evidence:

$$p(X = x|Y = y) = p(Y = y|X = x)\frac{p(X=x)}{p(Y=y)}.$$

Our uncertainty about its position is thus set in terms of probability. We know where we can expect the ball to land with which probability, given everything we know about it.

If we can assume that the prior distribution is a symmetric two-dimensional Gaussian with variance $\sigma_p^2$ and mean $\hat{\mu}$, and the likelihood $p(Y = y|X = x)$is also a symmetric two-dimensional Gaussian with variance $\sigma_v^2$ and mean $y$, it is possible to compute the optimal estimate $\hat{x}$, as:

$\hat{x} = \alpha y + (1-\alpha)\hat{\mu}$ where $\alpha = \frac{\sigma_p^2}{\sigma_p^2+\sigma_V^2}$. It is thus possible to define the optimal estimate given, seen and prior knowledge. Not only is it possible to calculate what the optimal strategy is, it is also possible to calculate how much better the estimate is compared to a strategy ignoring prior knowledge: The variance of the estimate if only the visual feedback is used is $\sigma_V^2$ if, however, the prior is used to the variance is $\frac{\sigma_p^2}{\sigma_p^2+\sigma_V^2}\sigma_V^2$ which is always less than the variance of the non-Bayesian estimate. If the prior has the same variance as the likelihood then the variance of the Bayesian estimate is half the variance of the non-Bayesian estimate.

In a recent experiment [3] it was tested if such a Bayesian strategy was used by human volunters. Subjects had to estimate the value of a one-dimensional variable, the displacement of a cursor relative to the hand, in close analogy of estimating the position where the ball will land. This variable was drawn randomly in each trial out of a Gaussian distribution defining a *prior* distribution, and subjects received extensive training so that they would know the *prior*. In addition, they saw the position, thus receiving the *likelihood*. The experiment allowed the measurement of the subject's estimate of the displacement. Out of this data, it is possible to infer the prior that human volunters are using. If they ignore the prior information the prior should be flat. The data shown in Fig. 1c (blue) shows that human volunters used a prior that was very close to the optimal one (shown in red). This experiment thus showed that human volunters can use Bayes rule to estimate the state of an important variable.

It is possible to use the same method used here for combining prior knowledge with new evidence to combine information obtained from two different sensors. A large number of cue combination experiments have since been modeled successfully using these techniques. A recent experiment also showed that human volunters use Bayesian methods to combine visual and haptic information [4] [5].

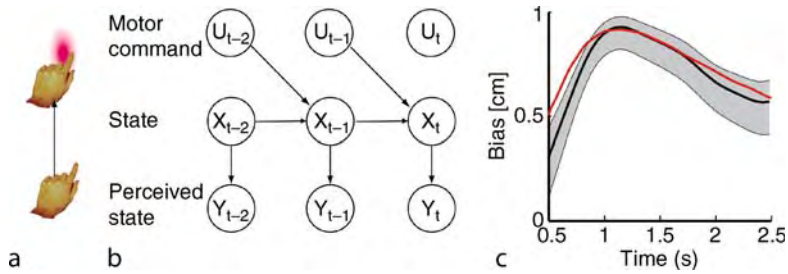
## Kalman Controllers: Hand Position in the Dark

If we move our hand in the dark we have uncertainty about its exact position or velocity because our proprioceptive sensors are not perfect (Fig. 2a). We are thus faced with the problem of estimating the state $\mathbf{X}$ of the hand, which is characterized by the position and velocity. From experience, people know how the state of the hand changes over time. In particular they know that the position changes proportional to its velocity and that the velocity changes proportional to the force applied, although there might be noise in this process. The subjects thus have *prior* knowledge that they can combine with the *likelihood* provided by their sensors. In this case, however, they constantly have to update their estimate, thus effectively using Bayes rule at every time-step.

The model for the hand is shown in Fig. 2b. Assuming that the real state X of our hand is X = x, then the perceived state Y will be some noisy version thereof and U = $u$ is the motor command we are sending to our muscles. We know something about the structure of the problem: The state of the hand at time t only depends on the state of the hand at time t-1 and the applied force, this is the *Markov property*. The state of the hand does not explicitly depend on the state of the hand at any but the preceding time. Using Bayes rule twice it is possible to obtain:

$$p(X_t = x_t|X_{t-1} = x_{t-1}, Y_t = y_t, U_t = u_t)$$
$$\approx p(X_t = x_t|X_{t-1} = x_{t-1}, U_t = u_t)p(Y_t = y_t|X = x_t)$$

Where $p(X_t = x_t|X_{t-1} = x_{t-1}, M = m_t)$is the probability of finding oneself in state $x_t$ at time t after having been in state $x_{t-1}$ at $t$-1. People can be expected to have a model for their hand in terms of these variables (called *forward model*) that they acquired from past experience.



**Bayesian Statistics (with Particular Focus on the Motor System). Figure 2** a) Example: The hand is moving in the dark, we want to estimate where it is. The uncertainty about the state of the hand is sketched in red. b) Structure: The state at time t is influenced only by the previous state and the motor command. The perceived state is the state with added noise. c) The error of the human estimates of travelled distance is shown as a function of the duration of the movement. The optimal (assuming overestimated force) Kalman controller predicts the red curve. Data replotted from citation 5.

Figure 2b shows the graph with the relations between the variables.

Assuming that random variables have n-dimensional Gaussian distributions, the equations obtained describe the optimal *Kalman controller* and it is possible to derive the optimal strategy [5] for predicting the state of the hand:

$$\dot{\hat{x}}(t) = \hat{A}\hat{x}(t) + \hat{B}u(t) + K(t)[y(t) - \hat{x}(t)]$$

where $\hat{x}$ is the current optimal estimate, $\dot{\hat{x}}$is the change of the optimal estimate, $\hat{A}$is a matrix that characterizes how the hand moves without perturbation, $\hat{B}$a matrix that characterizes how forces change the state of the hand, and $K(t)$ is the *Kalman gain* that is a function of the other matrices. The Kalman controller is a generalization of the *Kalman filter* [7] that does not allow a motor signal.

In an experiment, human volunteer subjects [6] moved their hands in the dark. After each movement they had to estimate where their hand was. Movements of varying temporal duration were done between 500 ms and 2500 ms. Subjects systematically estimated that their hand had moved further than it actually had moved (Fig. 2c gray). An optimal Kalman controller (Fig. 2c, red) produced very similar results if it was assumed that people systematically overestimate their forces. For small times, the overestimation of distance increased with time. This was due to the overestimated forces. As times increased, however, the likelihood became more important compared to the prior. That is why the controller becomes better if the movement lasts a long period of time. The optimal controller thus shows very similar errors to those made by human subjects. It seems, therefore, that people are able to continuously update their estimates based on information coming in from the sensors.

## Dealing with Rewards

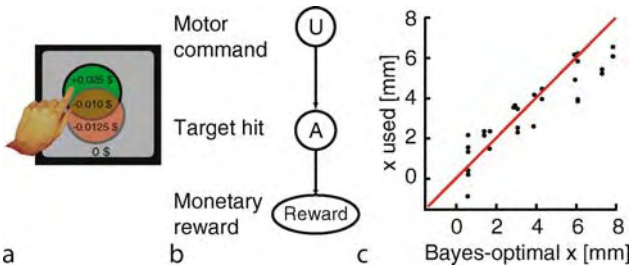
In many situations there are not only probabilities involved but also costs or rewards. Consider for example throwing darts. While the 20 gives us a large number of points the neighbours only give a low number of points (1 and 5). The 19 however has neighbours that give more points (3 and 7). An expert thrower will therefore usually try to hit the triple 20 as she is unlikely to miss it. An intermediate player will try and go for the triple 19 while a novice is best off targeting the middle of the board. Such problems thus ask for a combination between statistical theory and information about rewards, called *Bayesian Decision Theory*.

Figure 3a shows a simple abstraction of such a task. People have to move their hand very fast towards a target, just like in darts, so that uncertainty cannot be avoided. There are two circles that people can touch. Touching one leads to a monetary gain, touching the other leads to a monetary loss. Depending on the motor command $U$ there will be a probability distribution of hitting each target $p(A = a|U = u)$. Fig. 3b shows the structure of the problem. Optimal behaviour for such tasks can be derived calculating the expected value of the reward:

$$\text{Expected Reward} = \int p(A = a|\text{knowledge})\text{Reward}(a)\,da$$

where Reward(a) is the number of points scored that way. The optimal behaviour is then defined as the one that leads to a maximal expected gain. Bayesian decision theory thus emerges naturally as probabilities are combined with rewards.

A recent experiment tested if human subjects are able to use Bayesian decision theory to move optimally [8]. Subjects had to touch a touchscreen monitor very fast that displayed two spheres, one defining a monetary loss, the other one a monetary gain. They then measured where on average subjects touched the screen. Fig. 3c shows the position where the screen was touched against the optimal position according to the theory. Subjects are very close to the optimal solution. This deaconstrates that people can move in a fashion that is close to the optimal predictions of Bayesian decision theory.



**Bayesian Statistics (with Particular Focus on the Motor System). Figure 3** a) Example: People rapidly move their hand to a computer screen to touch circles and gain rewards. The circles are quite small and they have to move so fast that they cannot be certain about their final finger position. b) Structure. Depending on the motor commands there is a probability distribution about which circles are hit. Depending on which circles are hit there are monetary rewards. c) The positions towards which people moved are shown against the positions they should have pointed to assuming the use of Bayesian decision theory. Data replotted from citation 7.

### Outlook

Bayesian statistics is a large field [9]. Some researchers develop novel algorithms for Bayesian inference. They developed fast algorithms that lead to exact solutions. There are a large number of novel uses of this algorithm for complicated problems where the graph has loops called loopy belief propagation, which often results in good approximations. As an example, the technologically important issue of efficient data transmission through noisy information channels is best solved using this method [9]. Bayesian methods are a systematic way of thinking about function approximations and thus supersede the neural networks literature. Bayesian methods are also the best known methods for speech recognition using *hidden Markov models*, which are a discrete version of the Kalman filter.

"Bayesian methods as they are applied to the study of the movement system are a special case of normative models [5]. Normative models assume, that the nervous system needs to solve a specific problem. They also assume that the nervous system is likely to solve these problems in a fashion that is close to optimal. Many of the problems, that the nervous system needs to solve involve uncertainty. Whenever we want to derive how the nervous system could optimally solve a problem that involves uncertainty, we will need to use Bayesian statistics. Recent work has allowed those techniques to move well beyond simple Gaussian problems [10]. The main challenge for the field at the moment is extending the methods that work so well for simple prolems, such as the combination of two cues in a dark room to more realistic problems encountered in the real world."

## BBB Score

### Definition

This score was proposed by Basso, DM, Beattie, MS, and Bresnahan, JC in 1995 (J. Neurotrauma 12:1–21).

This indicates the open field locomotor scale to assess recovery after contusion injuries to the spinal cord in the rat. The score has a range from 0 to 21, showing a totally paralyzed condition at 0, and the normal state at 21.

Score 9 is critical, because this score means that the rat can walk with the weight support on the hind limbs.

### Definition
Beaconing is the use of a single distal cue as a goal.

There are numerous forms of beaconing, from simple to sophisticated. Taxis, and its subform chemotaxis, is the process of moving up or down an environmental gradient to reach a goal. Chemotaxis is a common form of navigation in one-celled organisms. In the visual system the offset of the beacon image from the foveaserves as a signal to turn the head towards the beacon and move forward. In sound localization (mammals), echolocation (bats), electrolocation (fish) and infrared detection (snakes) the receptors are paired; comparison of the two inputs serves as an orienting cue. Bees follow chemical trails by bees flying in a zigzag pattern along the edge of an odor plume. In dogs odor tracking is accomplished by a similar zig-zag sampling of the trail on the substrate. Snakes follow prey-odor trails in a manner similar to dogs, but rely on their vomeronasal organs rather than the main olfactory apparatus. Finally, a variety of insects use "snap shot memory" to reach a goal. This is accomplished by comparing current visual input with goal memory and moving to decrease the difference.

## Becker Muscular Dystrophy

### Definition
Milder form of ►Duchenne muscular dystrophy, such that dystrophin is present, but at lower amounts or with reduced length.

►Duchenne Muscular Dystrophy

## Bed Nucleus of the Stria Terminalis

### Definition
Group of neurons near the tip of the lateral ventricle that is connected to the amygdala and involved in sexual behavior, anxiety, the stress response and autonomic regulation.

►Neuroendocrinology of Psychiatric Disorders

## Bedwetting

### Definition
The voiding of urine while asleep. Bedwetting is common in childhood. Most children stop wetting the bed at five years of age, but in some cases bedwetting may still occur in adolescence and adulthood. If bedwetting continues past the age of five, it may be referred to as nocturnal enuresis. There is a strong genetic component to bedwetting and bedwetting is two to three times more common in males than in females.

Various mechanisms that may contribute to bedwetting include a small bladder, inability to react to a full bladder, inadequate release of the hormone vasopressin, developmental delays, urinary tract infections, urinary tract abnormalities, stress, sleep apnea or other primary sleep disorders, seizures, type-I diabetes, spinal cord trauma, and drug and medication use. Behavioral and pharmacological treatments for bedwetting are available.

## Definition

The biological discipline to study behavior is ethology. The biology of behavior may be discussed in relation to 3 key issues: evolution, ontogeny and mechanism. Behavior has been shaped by evolution. The main function of evolution lies in optimizing fitness. Innate behavioral programs may be modified during ontogeny by learning. The mechanisms underlying behavior are based on physiology. However, behavior is more than physiology: for example, some animals have physiological mechanisms to control body temperature. If an animal such as a lizard is sunbathing, a behavioral component is included in addition to the physiological control mechanism. This synopsis deals mainly with the proximate, physiological mechanisms of behavior and not the ultimate, socio-biological causes underlying a certain behavior. Thus, the term behavior as it is used here refers to the actions or reactions of animals and man to internal and external stimuli. Since neural activity plays such an important role in behavior, the discipline of neuroethology developed. Neuroethology integrates behavioral studies with neurobiology. This synopsis shall mainly deal with neuroethological approaches to behavior.

- ►Neural correlates of imprinting
- ►Neuroethology of biosonar in bats
- ►Neuroethology of the behavior in caenorhabditis
- ►Neuroethology of visual orientation in flies
- ►Song learning in songbirds
- ►Sound localization in the barn owl

## Characteristics

### History

People have long been interested in animal behavior (review in [1]. Explanations of the underlying causes and mechanisms have changed through the centuries. The vitalists of the 19th century claimed internal, subjective causes as the source of behavior: for example, that the cause underlying singing in the ►songbird was the joy the birds experienced or that curiosity would drive moths to approach a light source. Such claims could not be validated on a scientific basis. As a reaction, the behaviorists developed a theory strongly opposing every internal cause of behavior. Behavior was regarded as occurring in reaction to external stimuli. In a similar way, Sherrington's reflex theory did not require internal sources for generating behavior. It was realized by the ethologists that both the reflex theory as well as the concepts of the behaviorist fell short of explaining all observations on behavior. The ethologists filled the gap by recognizing that internal causes indeed played important roles in behavior – but in a different way as envisioned by the vitalists.

The precise observations and field experiments of ethologists such as von Frisch, Lorenz and Tinbergen built a solid fundament for the study of behavior [2,3]. Lorenz, for example, working with jackdaws and goslings observed that behavioral patterns had a stereotyped part that he called ►fixed action pattern. He also saw that there were flexible components that he called ►taxis. Animals would display a behavior if certain ►key or sign stimuli were there, acting like a trigger by having a so-called ►releasing value. However, action might also occur without any external stimuli (►vacuum activity), pointing towards internal causes of behavior.

Working with newly hatched gulls, Tinbergen observed that some stimuli had higher ►releasing values than the natural stimulus. Such stimuli were called ►supernormal stimuli. Also, some behavioral patterns were innate (►innate (instinctive) behavior), and some were learned (learned behavior). In some cases, ►learning was life long, in others there were ►sensitive and ►critical periods during which a learned pattern was imprinted and could not be changed afterwards. The neural basis of ►imprinting is investigated in ►animal models these days. ([4]; Essay on "Neural correlates of imprinting.") All behaviors of an animal were summarized in an ►ethogram.

From their observations the ethologist drew general conclusions about the organization of behavior. Some of the claims, especially of Lorenz, as, for example, that ►aggression is an innate behavior of man, have received much criticism, and can no longer be held up. Scientifically, a much bigger problem was that most of the elements in the models of behavior could not be (easily) found in neurophysiological studies and could not be implemented in computer models of behavior (►computational approach). Therefore, in most modern work on behavior the terminology developed by the ethologists plays only a marginal role.

### Levels of Analysis

According to [5], function may be studied at three different levels: the phenomenological level, the theoretical level and the level of implementation. In the most general sense, ethology refers to the phenomenological description of behavior. However, the development of models of behavior has always played a key

role in the study of behavior. The level of implementation in brain and motor circuits is investigated by ►neuroethology. This level may be split into several sublevels: the molecular, the cellular and the systems levels. Each of these levels has its own methods of description and explanation. One may even add another level: the level of application. At this level modeling and implementation are combined in building neurons, neural circuits, or robots that mimic certain neural action, sometimes even behavior (►neuromimes). Seen on a broad perspective, behavioral studies encompass all levels of function.

Physiologist, often being close to physics, have favored ►bottom-up approaches, using simple, well-described stimuli. Such work has been very useful, but often, peripheral mechanisms turned out to be so difficult that physiological research has neglected central processes for a long time. In addition, in a bottom-up approach, it was often not clear what had to be explained. A typical example is auditory physiology. Neuroethologists, on the other hand, have used ►top-down approaches. This allowed to define the behaviorally relevant situation, derive the behaviorally relevant stimuli and find neural structures where a giving behavior was implemented. The integration of both approaches turned out to be very fruitful as in the study of sound ►localization in the barn ►owl (Essay on Sound localization in the barn owl) and of biosonar in ►bats (Essay on Neuroethology of biosonar in bats).

Scientific analysis of behavior may take place in the field, in a more restricted environment such as a zoo or in the laboratory. To study behavior, one always has to consider the range of action needed by an animal to display a certain behavior. This range has at least to be available to obtain meaningful data. Ethology is a science that developed mainly from field studies. The strength of field studies lies in the possibility to investigate behavior in natural settings. On the other hand, laboratory studies in general allow for a better stimulus as well as (re-) active control. They allow for a controlled manipulation of behavior to dissect the often complex whole into simpler sequences. Modern research has mainly turned towards laboratory studies, but it remains a challenge to study brain function in the field, because this is where the brain and the behaviors it controls evolved.

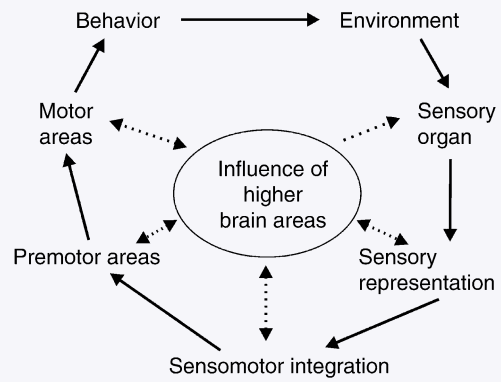
## What has to be Explained?

Take a singing robin. The male is singing. He shows that he is present, that he is a robin, that he has a territory and is willing to mate and produce offspring. But through singing the male also exposes itself to predators. The female has to detect the song, discriminate it from songs of other species, decide which singing male to approach, then approach the male thereby localize its position, start to fly, land, and show willingness to mate by herself…

The questions underlying this example may be sorted into 3 categories:

- Ultimate questions: Why did this behavior evolve? What is its survival value?
- Developmental questions: How does the behavior maturate? Is it innate or learned? What kind of learning is involved?
- Proximate issues: How does the bird generate the song? How does the syrinx work? How does the female recognize the male and how does it approach it? In other words, we have to deal with issues of ►detection, ►recognition, ►discrimination, ►localization, decision making, motor control, ►orientation, ►cognition, and ►attention.

How can these questions be put into basic terms? In the most general sense, behavior needs effectors, sensors and nervous activity (Fig. 1). Effectors, muscles, etc., translate the neural programs into movement (motor control). The motor system is organized in a hierarchical way (►hierarchy), including a level that makes a decision about the purpose of the movement, a level that is concerned with the formation of a motor plan, a level that coordinates spatial-temporal details and a level that executes the movements. The motoneurons often act as a ►final common pathway by integrating different aspects into one command to a muscle or set of muscles. Sensors measure the behavioral consequences of effector action. There is also subdivision of work: reflexes are stereotyped reactions as are rhythmic movements, while voluntary movements are goal-directed. The sensory pathways are also organized in a parallel and hierarchical way and often have feedback loops. The activity of nerve cells and brain circuits governs behavior and may initiate behavior even without external stimuli. Internal, self-generated action may, in turn, be influenced by ►endocrinal or (spontaneous, i.e. unexplained) neural activity. Internal factors often



**Behavior. Figure 1** Thye Sensory-motor 100P.

influence ►motivation or ►emotion. Hormonal action may be influenced by a ►biological clock and then induce a circadian, circalunar or circannual ►rhythm.

Behavior is not a one-way process from the brain to muscular action; it is also not only a reflex-like reaction to external stimuli. Instead, behavior influences the environment, and thus the sensory input. Thus, behavior may be seen to be embedded in a closed-loop situation (►closed-loop behavior). Of course, in the lab the loop may be opened (►open-loop behavior) thus separating the actions from their consequences on the sensory input. The brain has evolved mechanisms to deal with the consequences of actions, and signals are sent out to cope with expected as well as unexpected sensory input (►corollary discharge, ►efference copy, saccadic suppression).

## Function of Behavior

Behavior certainly has an adaptive value. It helps the animal in the "struggle for life". Behavior improves ►fitness. Thus, in an ultimate sense, behavior helps the "selfish" genes of its carrier to spread. The selfishness leaves limited space for ►altruistic behavior. Indeed, most claims of ►altruistic behavior have in many cases been explained by fitness models or game-theory models.

As was already indicated in the example of the singing robin, behavior may help an animal to find a conspecific, to orient, to navigate, to mate, to reproduce, but also to find a resting place, to find food, and so on.

Many behaviors require ►communication. In a communication situation, a ►sender emits an en ►coded signal that is transmitted through a ►transmission channel to a ►receiver. The receiver decodes the signal and reacts accordingly. Signals may be directed to a conspecific, as in courtship behavior, or to a predator, as in mimicry, or to both, as in ►defensive, escape, ►aversive or avoidance behavior. On the other hand internal ►drives may initiate behaviors to serve an animal's own needs, like in ►appetitive behavior (drinking, feeding) and sleep.

To achieve these functions, genetic determinants constitute an important basis, but ontogenetic and sometimes life-long shaping by learning is required in addition to fine tune behavior. There has been a long debate about "nature and nurture" in the behavioral community. However, it is clear now that both play a role. In some behaviors such as the courtship behavior of crickets, involving ►phonotaxis, innate mechanisms are more important, while in others such as hunting in wolves acquired factors play a dominant role. The function of learning may be seen as a means to increase behavioral variability as well as a means to adapt to unpredictable situations. Learning occurs as a reaction to evolutionary pressure and is observed in both invertebrates and vertebrates. Paradigms of ►associative learning such as ►classical and ►operant conditioning have become very important instruments to study behavior. Studies on learning also encompass simpler forms of learning (habituation, sensitization) as well as more complex forms of learning (►context learning, ►spatial learning, ►avoidance learning). Where learning occurs, memory is necessary. Indeed many concepts of memory observed in humans underlie animal behavior as well (►working memory, ►spatial memory, ►eidetic and ►photographic memory). In the last decade it has been realized that ►cognitive functions (►attention, ►recognition) are part of animal behavior as well, sometimes even in invertebrates. For example, bees have developed a language to direct conspecifics to a food source.

The recent advances in genetic techniques allow for studying behavioral mutants. In fact, many Drosophila mutants were detected by behavioral screens. Such screens have been used in fish as well as in tadpoles to study phenomena like ►optomotor responses [6]. While careful analysis of heredity has already revealed the genetic basis of some complex human behaviors and diseases, the near future will certainly bring more refinement of techniques to allow for a better dissection and study of complex behaviors in both animals and humans. In the animal kingdom it has, for example been found that the mongoose that is preying on the poisonous cobra, has as a protection from the venom in form of a mutation in the acetylcholine receptor [7].

## Neural Basis of Behavior

Most behavior is controlled by brain circuits [8]. These may be simple, automate like in optomotor behavior or more complex as in face recognition. Real simple behaviors don't exist. Even the behavior of a seemingly simple animal like the nematode ►Caenorhabditis has turned out to contain complex elements [9]; Essay on Neuroethology of the behavior in Caenorhabditis). Similar arguments hold for the model system for animal learning, the snail ►Aplysia. The gill ►withdrawal reflex of this animal has proven to be complex enough to study many phenomena of learning, from the behavioral via the neural to the molecular level [10]. Studies in ►honey bees have detected a neuron that represents the conditioned stimulus [11]. The stomatogastric ganglion and the ►gastric mill of ►lobsters has served to understand the control of a simple behavior by networks made up of a small number of neurons [12].

In their attempt to understand behavior, neuroethologists have typically taken a top-down approach. Based on the belief that evolution has shaped brains to meet specific behavioral needs, bee behavior and bee brains have been used to study orientation and learning. Electric fishes have served as a model system for

dealing with a communication situation [13], Essay on communication in electric fish). Studies on barn owls have contributed much to understand the neural basis of sound localization [14], Essay on sound localization in the barn owl). The biosonar in bats has served to understand the specific adaptations underlying the occupation of specific ecological niches in the different species, the parallel and hierarchical processing of the different stimulus attributes and has been compared with speech-processing in humans [15,16], Essay on Neuroethology of biosonar in bats). Studies on song-learning in songbirds have also strongly influenced our thinking about motor learning [17], Essay on song learning in songbirds). The finding of ►place cells in hippocampus has changed our view on how this structure is involved in orientation [18].

One important issue in studying behavior has been the question of whether neural action reflects perception and whether we can influence behavior by ►electrical stimulation. Indeed early experiments by [19] indicated that this was possible. Recent experiments with awake, behaving monkey on binocular rivalry demonstrated that in certain brain areas the activity changes of a reasonable number of cells corresponded to changes in perception reported by the monkey [20]. Furthermore, in motion-detection and stereo-vision tasks, it was demonstrated that electrical stimulation changed the monkeys behavior in specific, predictable ways [21]. This paved the ground for the possible use of neural responses to control the movement of external robot arms [22], which in turn gave hope for the use of neural prostheses in paralyzed patients. Neural stimulators are already successfully used in Parkinson patients to help them initiate movements [23]. We do not know yet how our perception is changed by stimulation. An answer could only be obtained by experiments with humans. Such experiments are ethically questionable and have not been done.

## Models of Behavior

Models of behavior attempt explanation at different levels. First, there is the general communication model as outlined above that underlies the description of many behaviors. Second there are the phenomenological models developed by the ethologists. A good example is the so-called psychohydraulic model of Lorenz [24]. In this model, a large reservoir of water provided an internal force to drive behavior. This reservoir was connected to a valve. The valve might be opened to initiate behavior by a releasing stimulus or, if this was missing, by the build-up of action-specific energy (internal ►drive), symbolized by a continuous influx through an open water-tap.

The most detailed models describe a behavior in terms of its processing stages, sometimes symbolized by black boxes containing equations, but sometimes also realized through exact neural circuits. Models at this last level include concepts developed in control theory and have the goal to reveal the neural basis of behavior in general and specific mechanisms underlying neural ►coding (e.g. [25]. As indicated in Fig. 1, one basic insight was that behavior may best be described as a loop, thus requiring feedback control. It has long been recognized that sensory circuits, ►sensorimotor transformation, and motor loops are organized in a parallel and hierarchical way. Neurons functions as filters (►neural filters), thus, selecting specific stimulus attributes. However, there has been a long debate on how specific these filters are. Theoretical arguments speak against the representation of one attribute by one neuron as was implied by the ►grandmother-neuron concept and favor distributed processing (►ensemble code) [26]. On the other hand, the observation of specific neurons, such as face neurons have made it clear, that the brain uses both distributed processing and specific processing to represent stimuli. As this became clear, the terms ►detector neurons, ►decision neurons, ►deviation-detecting neurons, command neurons, and ►central pattern generators that were popular in the 70ies and 80ies lost attraction. Neural ►network theory, suggested that most of the detection and decision processes are part of the underlying networks, leading to ►ensemble coding, and not of single neurons. Nevertheless, in some examples, such as the escape response of cockroaches, it seems that the fast, stereotyped response is driven by a command-like neural signal. However, even there parallel pathways exists, and the slower pathway is plastic, while the faster pathway is not. In a similar sense, the ideas of ►gating, developed amongst others to explain locomotor activity in ►locusts [27]. A similar situation occurs in ►fly orientation in which widefield optomotor stimuli interact in specific ways with smallfield, object-defining stimuli [28], Essay on Neuroethology of visual orientation in flies).

Thus, behavior is an integral part of neuroscience. It should be the ultimate goal to explain behavior from molecular action. We just appear to come close of having all the experimental tools to achieve this task.

## Behavior, Innate

### Definition

A behavior is supposed to be innate, if an animal can display it without learning from conspecifics. Usually behaviors shown by animals reared in isolation are thought to be innate. There is some debate on how much experience changes "innate" behaviors.

## Behavior, Simple, Complex

### Definition

In general actions or reactions of animals to internal and external stimuli. There is not a well defined distinction between simple and complex behavior, but a graded transition.

## Behavioral Dimension

### Definition

The way an individual behaves or acts in response to a particular setting, process, characteristic, attitude, or sensation. A full description of a particular item would usually include the behavioral dimension of the item, along with its cognitive and affective dimensions (plus sometimes the sensory dimension).

## Behavioral Methods in Olfactory Research

Gilles Gheusi
Pasteur Institut, Laboratory of Perception and Memory, Paris, France

### Synonyms

Experimental approaches to the study of olfactory control of behavior; Behavioral measurement of olfactory processing; Olfactory-guided behavior studies

## Definition

A variety of behavioral paradigms have been developed to assess the ability of a subject to process olfactory information. Here, I will examine how the behavioral methods in olfactory research, mostly coming from research on laboratory animals and especially the rodent, aim to give insight and generate hypotheses in the way animals detect, discriminate and memorize olfactory information. These methods range from simple recording of spontaneous olfactory investigation of odorant stimuli to psychophysical measures providing detailed sensory analyses. These extremes reflect two main approaches: one which relies on ethologically relevant procedures that take advantage of some species' tendency to use the sense of smell for gathering information of their world and one which relies on classical and ►operant conditioning (instrumental learning) procedures used to train animals to perform tasks designed to probe their olfactory capabilities. The formers generally involve paradigms, which are based on the spontaneous responses of subjects to odorants whereas the latter used differential ►reinforcement of odorants. These different behavioral methods used in olfactory research differ widely in their experimental settings, in the control of generating and delivery of odor stimuli, and in the control of quantifying sensory and performance variables. Behavioral paradigms in olfactory research can be classified in three main sections: those, which are based on measurements of spontaneous responses to odors, classical conditioning (►classical conditioning (Pavlovian conditioning)) and operant conditioning (operant conditioning (instrumental learning)). However, all represent a critical tool to examine the predictions based on coding mechanisms such as spatial map and temporal patterns of neural ensembles, which emerge during olfactory processes.

## Characteristics

In light of the significant advances in the field of molecular and neurobiology of olfaction during the past years, understanding how chemosensory information is encoded and processed into the brain is a central goal of olfactory research and behavioral methods constitute a critical step to complete our knowledge of the functional organization of the sense of smell. Unlike vision and hearing, olfaction's stimulus space is highly multidimensional and it still remains difficult to specify which aspects of an odorant space are connected with which aspect of our perceptual experience. Many experimental animals, like rodents and insects, exhibit a very keen sense of smell and the ability to detect, discriminate and memorize odor stimuli. Furthermore, there exist very striking similarities between the synaptic organization of the antennal lobe and the olfactory bulb, respectively in insects and mammals [1] suggesting that several mechanisms for olfactory processing may be very well conserved. Behavioral experiments represent a unique opportunity to provide information about the functional aspects between neural processes sustaining olfactory perception, discrimination and memory and behavioral outcomes of these neural processes. The importance of considering behavioral approaches in studying neuronal dynamics in the olfactory system is definitively supported by the evidence that the activity in the olfactory bulb greatly differs between anesthetized and awake animals [2]. A variety of behavioral methods have been developed to assess olfaction in animals [3]. They differ in many aspects such as the control over the purity, concentration, timing and delivery of odor vapors. Whatever the limits associated with the use of each method, they all represent a unique tool to understand how the brain generates representations of odors, achieves precise odor identification, defines broad odor categories, extract invariant features and stores the representations for efficient memorization and recognition. I will now concentrate my analysis on the main behavioral methods used in olfactory research with laboratory animals, especially the rodent, to assess the functional properties of the olfactory system.

### Spontaneous Responses to Odors

Measurements of spontaneous responses of subjects to odors represent a simple way to investigate olfactory performance in animals. It consists in presenting odor stimuli and measuring their ability to detect, discriminate, prefer or avoid odorants. The *food localization test* has been first introduced by Alberts and Galef [4] to explore olfactory sensitivity in the rat. Hungry animals are introduced in a random location into a clean cage with a 3–5 cm thick layer of bedding underneath, which a food pellet was buried. Subjects are run for one to several trials with one scented pellet available per trial. The latency to locate the food pellet is defined as the time required for the animal to dig up and grasp the pellet following introduction into the cage. As expected, olfactory bulbectomy induces a failure to find the target pellet in rats. This procedure has been used to assess impaired olfactory sensitivity in animals with damage to the olfactory system as well as in transgenic mice deficient in the expression of proteins involved in olfactory transduction processes. The procedure is simple and requires no special apparatus. However, it provides no control of odor delivery. Furthermore, according to the technique used to induce olfactory deficits, some manipulations may produce secondary effects, which alter the motivation, the physiology and the behavior of the animal studied, thus increasing their latency to find the food pellet.

Recording the sniffing duration, as the measure of behavioral responses to odors, represents also a very simple way to examine and compare the spontaneous

degree of interest of subjects for different odorants. Sniffing attraction tasks consist of recording the time spent by an animal investigating a single odorant whereas preference tasks involve the simultaneous exposure of the subjects to two or more odorants. Tests are generally carried out in the home cage of the subjects or in neutral arenas (open field, maze), although testing in neutral arenas has been reported to provide more sensitive measures [5]. In forced-choice preference tasks, which always test the relative attractiveness of each odor, the interpretation may be problematic since it may not be clear whether the subject is attracted to one stimulus or repelled by others. Preference tests are also used to assess the acquired properties of odors that had previously been paired with reinforcement. Acquisition of a conditioned odor preference (or aversion) has been widely studied in young rat and mouse pups using a variety of ►reinforcers. These include intraoral milk infusion, tactile stimulation, warmth, shock, tail-pinch.

Across many mammalian and non-mammalian species, recognition of a stimulus can be easily assessed by a decline in spontaneous investigation measured in repeated encounters of this same stimulus. Indeed, the successive presentations of the same odorant lead to a decreased interest to that odor, a form of learning known as ►habituation. Habituation and habituation-derived paradigms have become useful tools with which to investigate odor memory and odor discrimination processes in animals. Habituation tests are categorized into two types: *habituation-dishabituation* tests and *habituation-discrimination* tests, each type involving a two-phase process. During the first phase, habituation is conducted over repeated presentations of the same odorant separated by inter-trial intervals of varying lengths. The use of various lengths between two brief exposures of a same odor stimulus can provide information about the duration of memory for that odor. Habituation–dishabituation tests involve a second phase (post-habituation phase) in which individuals encounter a novel odor. The presentation of a novel odor during this phase triggers an increase in sniffing showing that the subject is able to discriminate between the first and second odor. The renewed responsiveness to a novel odor argues against sensory or effector fatigue during the first phase. The habituation-discrimination tests represent a variation of the habituation-dishabituation tests. Here, following repeated exposures to a first odor, the subjects are given a choice between the previously encountered odor and a novel odorant. Comparing the difference in the time spent investigating the familiar and unfamiliar odor stimuli assesses discrimination between the two odors. Using habituation tests, amnesic and memory-enhancing properties of different drug treatments can be examined in tests scheduled at various time intervals after administration. The appeal of the habituation tests rests in their simplicity. Here again, the odor response occurs spontaneously without any prior training. One of the principal advantages of these tests is that they can be implemented rapidly with minimal instrumentation. One shortcoming of this type of test, however, is that it provides information about memory for familiar versus unfamiliar odor, but not about memory for a specific odor among equally known odors. Another shortcoming is that, using this type of paradigm, only short-lived memories for odors can be studied. Furthermore, a main drawback to habituation-dishabituation and habituation-discrimination tests is that a lack of differentiated responses in subjects towards familiar and novel stimuli does not necessarily imply that no discrimination occurred.

## Classical Conditioning

Classical conditioning has become a predominant paradigm in studying mammals and insect olfactory processes. Classical conditioning basically involves two stimuli: a neutral ►conditioned stimulus (CS) paired with a biologically significant ►unconditioned stimulus (UCS). The UCS reflexively elicits strong responding. As a result of CS-UCS pairings, the CS becomes associated with the UCS so that the previously neutral CS elicits the same reflexive response as the UCS. In conditioned aversion (or preference) learning, odorants are presented to animals and subsequently followed by a noxious (or pleasant) event. Such approach has provided compelling evidence for the formation of olfactory memory traces due to classical conditioning in the olfactory bulb of mammals as well as in the antennal lobe of insects. Measuring the rate of responding to the conditioned odor stimulus can easily assess learned odor preference/aversion. Conditioned odor aversion is a learned association that involves the avoidance of a tasteless solution (CS), which precedes illness (UCS). However, it has been reported that in contrast to the well-known conditioned taste aversion paradigm, conditioned odor aversion is obtained if the delay separating the presentation of the odor from the malaise is short. Despite mixed results, conditioned odor aversion has been shown to be a robust and long-lasting learned association and may be useful for assessing generalization among similar odors. Furthermore, the combined presentation of both an odor and a taste paired with visceral malaise leads to a strong aversion to the odor [6]. In this case, the taste might enhance the odor processing and subsequently might facilitate its association with illness. It has been proposed that the taste cue could gate the olfactory information and make it associated with the visceral illness. Such phenomenon has been referred as ►taste-potentiated odor aversion. Due to its particular features, such as rapid acquisition, possibility of long intervals between the CS and the UCS and its robustness, taste-potentiated odor aversion is a powerful model to study the neuronal and

behavioral mechanisms that subserve the acquisition, consolidation and retrieval of olfactory information in subjects.

## Operant Conditioning

Psychophysical studies of olfactory processes widely use operant conditioning to probe the subject's ability to detect, discriminate and memorize odors. Briefly, animals are first trained to discriminate between two odors. During training, they received trials in which one odor (CS+) is paired with a reward and another odor is paired with no reward. The go/no-go olfactory discrimination training paradigm illustrates this approach. Operant olfactory conditioning may be carried out using computer-controlled systems, such as olfactometers, which generate and deliver odors. Water-deprived animals are trained to introduce their snout into a combined odor/reward port. A nose poke triggers the opening of one of several odor valves and a stimulus odor is presented. During the presentation of the $S^+$ odor, the animal is required to keep its nose into the sampling port for a specific length of time and lick the water tube. This is followed by the delivery of a reward. If the $S^-$ odor stimulus is presented, no reward is given whatever the duration of the nose poke and the response on the water tube made by the animal. Subjects therefore learn to maintain nose pokes and lick the tube during the presentation of the $S^+$ odor stimulus and to withdraw rapidly from the odor/reward port during the presentation of the $S^-$ odor stimulus. Because animals are required to act (lick) and are rewarded only upon presentation of the $S^+$ odor, the go/no-go task is asymmetrical. Training animals to perform two-alternative choice odor discrimination can achieve symmetrical reinforcement. In this case, subjects initiate trials by a nose poke into an odor sampling port, which triggers the delivery of an odor for a specific length of time. After leaving the odor sampling port, the animal is rewarded for making a nose poke at the water port designated as correct between two spatially separated water choice ports.

Operant olfactory conditioning has also been developed by exploiting rodents' natural foraging strategies that employ olfactory cues [7]. Animals are trained with stimuli that consist of distinctive odors added to a mixture of ground rat chow and sand through which they dig to obtain buried cereal rewards. Training consists of presenting two stimulus cups, one scented with an odor stimulus ($S^+$) paired with the reward and the other scented with another odor stimulus ($S^-$) presented alone. A choice response is scored when the animal touches the sand in one of the stimulus cups with its paw. A correct response is recorded when the first dig occurs in the baited cup. Problems associated with the olfactory digging task are the weak control over odor dispersion from the cups and the difficulty to prevent mixing of the odors.

Mazes and runways represent also conventional systems to study associative olfactory learning processes. These designs have been used to demonstrate that mice are able to discriminate between various types of odors, although they vary among studies [8,9]. Basically, animals are trained in the maze to enter one arm scented with an odor stimulus in order to receive a reward. Another arm is scented with a different odor but contains no reward. The odors are randomly assigned to either arm after each trial. In some cases, fans are used to direct odor flows at the choice point and an exhaust fan is mounted above this choice point to pull the odors down the arms and out of the testing maze. However, the levels of odor control remain approximate compared to those offered by the computer-controlled olfactometers mentioned above.

In addition to the sensitive measures provided by combining operant conditioning with computer-controlled systems, a considerable body of literature from several laboratories demonstrates that rat olfactory learning has unique properties. Behavioral studies have revealed that odors provide particularly salient cues for rodents. Rats are able to show errorless learning of detection and discrimination tasks, ▶reversal learning, rapid interproblem transfer and acquisition of a learning set, learn matching and non-matching to sample tasks (▶delayed matching-to-sample task – delayed nonmatching-to-sample task) and demonstrate excellent memory for odors [10]. Thus the development of psychophysical methods has not only made olfaction amenable to specialists interested in the field of olfactory sensory processing but also to cognitive neuroscientists.

Undoubtedly, future works combining the accuracy of psychophysical approaches with the functional interest of ethologically relevant methods constitute a critical challenge in behavioral olfactory research.

### Synonyms

Behavioral pharmacology; Psychopharmacology; Neuropsychopharmacology

### Definition

Behavioral neuropharmacology is concerned with understanding the neural and pharmacological mechanisms of complex behavior, as well as the behavioral abnormalities that accompany neuropsychiatric disorders, using animal models. The use of these animal models can follow two approaches: first, behavior is used to answer questions where the primary interest is in pharmacology, and a behavioral measure is studied to evaluate drug effects in much the same way as in any other experimental preparation. Second, the study of behavior itself is the primary interest, and drugs are used to dissect and elucidate the underlying mechanisms of certain behavioral phenomena. The goal for both approaches is to observe and quantify behavior in animals (or humans) and to relate this behavior to specific brain processes. In order to do this, one can either study spontaneous behavior and correlate it with brain activity (measured in vivo by means of intracranial ►microdialysis, voltammetry, electrophysiological recording, brain imaging techniques, or measured ex vivo by means of histological, morphological or gene expression analysis), or one can manipulate the central nervous system by means of drugs, lesions, or electrical stimulation, and study how this affects behavior. As such, behavioral neuropharmacology stands at the threshold of a profound scientific challenge: to understand the neuroanatomical, neurochemical, cellular and molecular basis for the enormously complex and varied human behavior and the functions of the human brain. In this regard, the concept of "animal models" of human neuropsychiatric diseases rests on the assumption that one can appropriately infer, from observations of behavior or physiology, that the states experienced by animals are equivalent to the emotional states experienced by humans, expressing the same types of behavioral or physiological changes.

Note that because of space constraints, this essay will focus on behavioral neuropharmacology as it relates to animal (i.e., predominantly rodent and primate) models of human neuropsychiatric disorders. It should be noted, however, that there are other fields within this discipline that examine the neuropharmacological underpinnings of behavior, e.g., in insects or lower vertebrates – a line of research that is not related to issues mentioned above and that will therefore not be elaborated further.

### Characteristics

#### Principles of Behavior

When studying behavior for neuropharmacological purposes, it is important to be aware of some basic principles of behavior and of different categories of behavior, which in turn influence the way a particular behavior is analyzed. Over time, the various forms of behavior have been categorized differentially. Below, only one of these categorizations, which is particularly pertinent to the present topic, has been outlined. One basic type of behavior is ►reflexive (or respondent) ►behavior. It is elicited by specific stimuli and usually involves no specific training or conditioning; rather, the responses are typically part of the natural behavioral repertoire of the species and are expressed under suitable environmental conditions. In some cases, the behavior is elicited by the administration of a drug, and then the particular behavior is used to define or assess pharmacological activity of that drug. Examples of this type of behavior include the startle reflex and the phenomenon of ►prepulse inhibition (an animal model for testing antipsychotic drugs, or for studying mechanisms of schizophrenia), the avoidance of the open arms of an ►elevated plus maze or the production of ultrasonic vocalizations of pups upon maternal separation (animal models for testing anxiolytic drugs, or for studying mechanisms of anxiety), or the various

nocifensive responses to nociceptive stimuli, e.g., tail-withdrawal, paw-withdrawal, vocalizations, increase in blood pressure (animal models for testing analgesic drugs, or for studying mechanisms of pain) [1–3].

In contrast to ►reflexive behavior, ►operant behavior is controlled by its consequences, i.e., by positive ►reinforcement or negative reinforcement (=punishment) that is the consequence of a particular behavior and that shapes the future expression of that behavior. Examples of this type of behavior include: various forms of navigation in mazes (►water maze, T-maze, eight-arm maze) (animal models for testing cognition-disrupting or – enhancing drug effects, or for studying mechanisms of learning and memory); various forms of responding in ►operant chambers (►Skinner boxes) (animal models for assessing the abuse potential or the ►discriminative stimulus effects of drugs, or for studying mechanisms of drug addiction, regulation of food intake, etc.); or conditioned avoidance reactions to electric shocks (e.g., conflict procedures such as the ►Vogel conflict test) (animal models for testing anxiolytic drugs, or for studying mechanisms of anxiety) [1–3].

## Principles of Animal Models and the Issue of Validity

In the present context, a model is defined as an experimental preparation intended for studying a condition in a different species. Typically, models are animal preparations that attempt to mimic a human condition and that allow the study of that condition. Different animal models can have different intended purposes. At the one extreme, an animal model can attempt to reproduce a whole psychiatric disorder in a laboratory animal. Such an approach is fraught with difficulties, in part because it often relies on arguments of apparent similarities that are not well defined and can be subjective (see the issue of validity, below), and in part because often the human psychiatric disorder itself that is intended to be modeled is not well characterized in every aspect. The defining symptoms and the diagnostic categories for many psychiatric disorders have sometimes changed repeatedly over the decades.

At the other extreme, a more limited purpose for an animal model is to provide a way to systematically study the effects of potential new therapeutic drugs. In this case, the aim is not to model a disease but to find a preparation in which the therapeutic utility against a certain disease can be tested. Although this approach is usually less burdened with the conceptual problems mentioned above, there are other problems. Such models are usually developed and validated by reference to the effects of known therapeutic drugs. This can limit the ability of the model to identify drugs with new mechanisms of action, and it can fail to detect drugs that would be active against symptoms that are refractory to the known drugs [3,4].

The primary purpose of an animal model is to enhance understanding of a human condition or to predict the action of a drug in humans. Therefore, from a practical point of view, the single most important feature of a model is the model's ability to lead to accurate predictions, i.e., its ►predictive validity. There are a number of other categories of validity that can have great heuristic value from a scientific or theoretical point of view, such as ►construct validity (the accuracy of a model with which the model measures what it is intended to measure), ►etiological validity (the phenomenon in the model has the same etiology as the phenomenon in the human condition) or ►face validity (the phenomenological similarity between a behavior exhibited in an animal model and in the human condition) [3,5].

A problem related to the issue of validity is that some ethologically-based models work with healthy animals that are exposed to an artificial situation, and the effects of a drug are evaluated in that situation. There have been attempts to create better models by inducing particular "pathological" states in experimental animals against which a drug can then be tested. These states can be produced by molecular, pharmacological, neurodevelopmental or behavioral manipulations and are aimed at enhancing the construct or etiological validity of the models.

These issues can be exemplified with the available animal models of Parkinson's disease and anxiety. The symptomatology and pathology of Parkinson's disease is well described (progressive degeneration of dopaminergic neurons within the midbrain substantia nigra pars compacta, leading to progressive disturbance of motor functions), however, the etiology of the underlying pathophysiological mechanisms is not known yet. In other words, it is known what is happening in Parkinson's disease, but very little is known about why this is happening. The human syndrome is mainly characterized by the typical symptoms, akinesia, rigor, and tremor. In a very simple animal model, "neuroleptic-induced ►catalepsy", akinesia and rigor is induced by a dopamine antagonist, e.g., haloperidol. This drug mimics the hypodopaminergic state of Parkinsonism insofar as it blocks dopamine receptors. However, this pharmacologic manipulation does not produce tremor in rodents or primates. This catalepsy is alleviated by known anti-Parkinson drugs. Thus, this model has reasonable predictive validity (because it can show therapeutic effects of drugs), but only partial face validity (because it only mimics akinesia and rigor, but not tremor), and it does not have etiological validity (because the symptoms are produced by a manipulation that is completely unrelated to the underlying pathophysiology, i.e., dopamine receptor blockade versus degeneration of dopaminergic neurons).

Therefore, more elaborate animal models attempt to mimic the underlying pathophysiology more closely

by lesioning (i.e., destroying by means of a neurotoxin) the dopaminergic cells. Although this more closely mimics the real pathophysiology, it is still an artificial situation inasmuch as the neurotoxin produces an acute degeneration of the dopaminergic neurons within a few days, whereas in humans the degeneration is a very slow and chronic process. The model that is currently thought to best mimic the etiology and progression of Parkinson's disease is the "rotenone model" [6]. Rotenone is a mitochondrial complex I inhibitor which, when administered over many weeks, causes a slowly progressing degeneration of dopaminergic neurons that may even involve some of the pathophysiological mechanisms that are also active in the human situation.

Although these models of Parkinson's disease may lack etiological and face validity, they do have a good degree of predictive validity. This situation is rather different regarding animal models of anxiety. There are a number of models with a varying degree of face and etiological validity; the major problem, however, is that the models have little or unknown predictive validity. The most widely used model is the elevated plus maze. Rodents have an innate tendency to avoid wide, open space and to prefer enclosed areas; thus, naïve animals show a clear preference on the plus maze for the closed arms versus the open arms. Standard anxiolytic drugs such as benzodiazepines increase the time spent on the open arms, the interpretation being that the drug makes the animals less "afraid" of the open arms. The model is well suited to detect anxiolytic-like effects of drugs with a benzodiazepine-like mechanism of action. However, in modern psychiatry first line treatment for anxiety disorders has changed from benzodiazepines to antidepressant drugs with a serotonergic mechanism of action (selective serotonin reuptake inhibitors, SSRIs). Despite being clinically effective, these drugs do *not* increase the time spent on the open arms of an elevated plus maze; if anything, they even show an anxiogenic-like effect and decrease the time on the open arms. Thus, the elevated plus maze is well suited to detect the effects of one class of drugs, but entirely unsuited to detect the effects of another class of drugs that has demonstrated clinical efficacy. Thus, the model does not have general predictive validity, and it is not known whether drugs with new mechanisms of action would show anxiolytic-like effects in this model. This is a big dilemma for pharmaceutical drug development searching for compounds with new mechanisms of action, especially since other animal models of anxiety have the same principle problem.

## Methods for Monitoring Brain Mechanisms

As mentioned above, the aim of behavioral neuropharmacology is not only the pharmacological manipulation and analysis of behavior, but also to relate behavior to brain mechanisms. Methods for measuring and analysing brain function were developed concurrent with the methods for systematic manipulation and analysis of behavior. The earliest method for direct assessment of activity in the nervous system was electrophysiology. This method allows region- or even cell-specific measurement of the activity of nerve cells. In the 1980s, the method of intracranial microdialysis was developed. At the tip of a probe implanted into the brain, molecules diffuse across a semi-permeable membrane along a concentration gradient. This very valuable method allows the measurement of transmitter release in response to pharmacological or environmental manipulations. For example, with this method it has been shown convincingly that drugs of abuse, but also naturally rewarding stimuli such as sex or food, lead to an increase of dopamine release in the nucleus accumbens. This observation has become one of the central building blocks of the dopamine hypothesis of reward [7].

With the fast development of molecular methods, new tools for analysing brain function and activity have become available. The analysis of expression profiles of genes, RNA or proteins is now a valuable tool for assessing the effects of pharmacological or environmental manipulations. The newest addition to the methods available for the study of the interrelationship between brain function and behavior are neuro-imaging techniques such as functional magnetic resonance imaging (fMRI). Although first only available for use in humans, technology has now reached a stage where it can also be applied to experimental animals [8].

## Outlook

Molecular techniques like the creation of transgenic animals (e.g., knock-out or knock-in mice) are regarded by some as a panacea for a range of human diseases, and the advent of molecular biology was already considered by some as the end of behavioral neuropharmacology. However, it is becoming increasingly clear that the important genotypes that are created by molecular techniques can only be fully exploited for the benefit of human therapeutics when their phenotype, and in particular, their behavioral phenotype is thoroughly characterized [9]. On the other hand, behavioral neuropharmacology can profit from the generation of transgenic animals, in particular in cases where highly specific pharmacological tools for certain receptors are lacking. Deleting or overexpressing a particular receptor can offer valuable insights into the relevance of this receptor for a certain disease, and can facilitate the establishment of new animal models [4]. Furthermore, the discovery of new receptor subtypes or subunits provides an opportunity for improved pharmacological selectivity of drug tools. Thus, despite (or because of) the advances in molecular neurobiology, it is to be expected that behavioral neuropharmacology will remain an indispensable discipline of the neurosciences.

## Synonyms

Analytical behaviorism; Semantical behaviorism

## Definition

Logical Behaviorism is the view that every statement about mental phenomena can be translated without loss of meaning into a statement about behavioral dispositions [1]. Thereby it could be conceived as a version of ►Semantical physicalism which is the view that every statement containing mental terms can be translated without loss of meaning into a statement containing only non-mental (broadly physical) terms [2,3]. There also is a definition of Logical Behaviorism available in the material mode. Logical Behaviorism, then, is the view that beliefs, desires, thoughts, feelings and all other mental phenomena are basically behavioral dispositions. Logical Behaviorism is accurately called "behaviorism" because, according to it, mental phenomena are reducible to mere dispositions to behave. And it is correctly called "logical" because, according to it, this reduction is not an empirical matter, but results from the meanings (the "logic") of mental expressions alone.

## Description of the Theory

Behaviorism comes in many varieties, the most important of which are Methodological (or Psychological) Behaviorism, Eliminative Behaviorism, and Logical Behaviorism. In psychology, behaviorism became increasingly dominant in the 1930s by the influence of Watson [4] and Skinner [5]. Their approach, aptly called Methodological Behaviorism, can be characterized by two main claims. The first is the claim that psychology is at its core a discipline about the explanation, prediction and control of behavior. The second is the claim that the only scientifically acceptable data in psychology are behavioral data, i.e. data which concern patterns of observable responses to physical stimuli. Watson and Skinner, though, were less clear about the ►ontological status of mental

phenomena. Despite their view that inner states are not objects adequate for psychological explanations, they were not clear about whether inner mental states do exist but are irrelevant to psychology or simply do not exist at all. The latter thesis is known as Eliminative Behaviorism, a forerunner of Eliminative Materialism [6].

In philosophy, behaviorism became popular as Logical Behaviorism. This view is one of the classical materialist positions towards the mind-body problem and, as such, is an account of how mental phenomena fit into the natural order. Often it is said that Ryle [1] and Wittgenstein [7] are proponents of Logical Behaviorism. This may not be exactly true, but there can be no doubt that Ryle's and Wittgenstein's analyses of many mental concepts inspired philosophers to go forward in trying to understand mental phenomena as behavioral dispositions. Logical Behaviorism does not entail either Eliminative Behaviorism, nor Methodological Behaviorism: It does not eliminate mental phenomena, but says that they are nothing but certain behavioral dispositions; and it is a claim about the nature of mentality which is not tied to any particular scientific methodology.

The Semantical Physicalists (Carnap [2], Hempel [3]) were mainly concerned with the question of how psychology as a special science relates to physics. As part of their unity-of-science agenda, they aimed to show that "psychology is an integral part of physics" (Hempel [3]:18). And they tried to demonstrate this by trying to show that every bit of mentalistic discourse can be translated into synonymous bits of physicalistic discourse. If this were true, it would be obvious how every psychological explanation also would be a kind of physicalistic explanation. In their argument for this rather strong view, the so called ►Verification theory of meaning played an essential role. This theory of meaning, popular in the Vienna Circle, is basically the view that the meaning of every non-analytic statement "is established by the conditions of its verification" (Hempel [3]:17). Two empirical statements have the same meaning, according to this view, if and only if they can be verified under exactly the same conditions. The Semantical Physicalists used this theory in order to make plausible their reductive view on mentalistic statements. Hempel's example is the mentalistic sentence "Paul has a toothache." He claims that all circumstances which verify this sentence are expressed by a very long list of physical test sentences which includes "Paul weeps and makes gestures of such and such kinds"; "At the question "What is the matter?", Paul utters the words "I have a toothache"; but also "Such and such processes occur in Paul's central nervous system" (Hempel [3]:17). Therefore, Hempel argues, given the Verification theory of meaning, this mentalistic sentence is synonymous with the conjunction of all the relevant physical test sentences.

## Motives for Logical Behaviorism

Logical Behaviorism could be seen as a special version of Semantical physicalism, because it implies that every mental sentence is translatable into a synonymous sentence which does not include mental expressions. But it is important to note that the Logical Behaviorists neither shared the motives of Carnap and Hempel, nor are committed to their ideas of the ►unity of science thesis and the Verification theory of meaning in particular. Instead, one important motive behind Logical Behaviorism was to avoid Cartesian Dualism with its "dogma of the Ghost in the Machine" (Ryle [1]: 17). According to the view which Ryle attacks, an action is, e.g. intelligent (or clever, prudent, wise etc.) if and only if it is caused by a piece of intelligent reasoning, and an action is voluntary if and only if it is the effect of a volition or act of the will. What makes an action intelligent or voluntary, therefore, are certain "ghostly" inner processes which cannot be observed by people other than the actor itself. Ryle thinks that this picture of the mind is due to a deep misunderstanding of our mental concepts. These concepts, he argues, do not refer to private inner processes in the mind, but are correctly analyzed as dispositional concepts. Expressions like "intelligent," "critical," "logical," "witty" are, as Ryle tries to show, semantically closer to "fragile," water-soluble, or "inflammable" than to expressions which denote objects or processes. (Although, unlike "water-soluble," mental concepts are what Ryle calls "determinable concepts," i.e. refer to ►multi-track dispositions whose manifestations can widely vary.)

Another important motive is the Logical Behaviorist's elegant dissolution of the problem of mind-body interaction. How do mental and physical events interact? How can we understand that events in the physical world like Mary's walk to the office are the effects of mental events like Mary's thought that going to the office would be the best thing to do? According to the Logical Behaviorists, the assumption that there are such causal relations between the mental and the physical is just a misunderstanding. They think that mental concepts denote behavioral dispositions and these dispositions are not the causes of behavior, but rather a piece of behavior is a manifestation of a disposition.

But perhaps the most important motive behind Logical Behaviorism is its solution to an epistemological worry: How can we know what other people think, believe, desire, hope, intend, etc.? If these are essentially events in other people's minds, and we can not literally look into these minds, it seems that we are precluded in principle from knowing what other people think and feel or even whether they think and feel at all. Maybe they are like robots without an inner mental life. According to Logical Behaviorism, this is not a real problem because mental states are no mysterious

inner episodes in people's minds, but are behavioral dispositions whose manifestations are as observable as any other public manifestations are.

## Objections to Logical Behaviorism

Logical Behaviorism faces several strong objections. The first is that it raises a worry concerning ►first-person authority. Logical Behaviorism explains our knowledge of other people's mental states by viewing these as behavioral dispositions. But this third-person account of knowledge of minds leads to a related difficulty: How do we know our own mental states? If these were really behavioral dispositions, then we should know our own minds primarily by observing our own behavior. But this seems to be plainly false. Instead, there seems to be a kind of privileged access to our own mental states.

There is a second objection saying that Logical Behaviorism ignores the essential ►phenomenal character of many mental phenomena. Is it credible that mental phenomena like pains or sensations of warmth are mere dispositions to behave? Most laymen and many philosophers do not think so. Instead, there is a nagging intuition that there is definitely more to a pain than just being disposed to whine and groan, say that one is in pain, go to the doctor, and take some pills, etc. This objection naturally leads to a view (e.g. the Identity Theory as defended in [8]) that understands sensations as manifest inner states which cause things like my whining and groaning.

A third objection is perhaps the strongest one. It emphasizes the conceptual interdependence of many intentional expressions as a fundamental obstacle to analyzing mental states solely in terms of behavioral dispositions. Take beliefs. To believe that there is a bottle of Bordeaux in the basement, according to Logical Behaviorism, just means to be disposed to go down the stairs when certain circumstances occur. But, as Chisholm [9] demonstrated, a substantial reference to a desire is hidden here behind the phrase "when certain circumstances occur": Believing that there is a bottle of Bordeaux in the basement, I will go down the stairs for the bottle only if I desire to drink it. Unless I indeed have such a desire, the bottle will remain in the basement. The upshot is that you cannot understand what it is to believe something, unless you know what it is to desire something. And the converse is also true: You cannot understand what it is to desire something, unless you have the concept of belief. Desiring to drink a bottle of Bordeaux, I will go down the stairs for the bottle only if I believe that there is a bottle of Bordeaux in the basement. Unless I do believe this, the bottle, again, will remain in the basement. Such conceptual relations make it clear that belief sentences and desire sentences cannot be translated without loss of meaning into sentences about mere behavioral dispositions. And this kind of reasoning generalizes to many other ascriptions of mental states.

This last objection naturally leads to ►Analytical functionalism which is another classical materialist position concerning the mind-body problem. What seems to have gone wrong in analyzing mental phenomena as mere behavioral dispositions is the Logical Behaviorist's ignorance of conceptual relations between mental concepts themselves. They overlook that relations between individual mental states and actual or possible behavior are not the only ones relevant to our mental concepts. This is fixed in the Analytical Functionalist's picture (see [10]). Analytical functionalism is the theory that, by conceptual necessity, every mental state of an organism can be characterized by its causal relations to perceptual input, other internal states, and the behavioral output of the organism. Because according to Analytical functionalism, mental states are explicitly defined by reference to input and other internal states of the organism, they are not mere behavioral dispositions. But nevertheless mental states are conceptually tied to behavior, because they are defined by reference to behavioral output as well. Analytical functionalism therefore can preserve one important feature of Logical Behaviorism without being vulnerable to the objection that it ignores certain essential conceptual relations.

These objections are rather strong. As a reductive account of the mental Logical Behaviorism is an almost philosophically dead position. That does not mean that it is wrong about every mental phenomenon. Textbook wisdom nowadays has it that there are two features of the mind which are basic, namely intentionality and phenomenal content, and that every mental state has either one of these basic features or both in some combination. And although as it seems to many that Functionalism is a quite good account of the former, and the Identity Theory a quite good account of the latter basic feature, there are some non-basic kinds of mental states that Logical Behaviorism seems to be a quite good account of, e.g. talents or traits of character and personality like honesty, ambitiousness, and short-temperedness.

## Belief

### Definition

A belief is either a person's state of believing something or a propositional content that is believed. Belief states are long-term mental attitudes rather than mental events like thoughts.

They play a typical causal role : they are changed by perceptual input and influence our behavior. Beliefs come in different degrees. It is a controversial matter whether beliefs are representational states.

►Argument
►Logic

## Bell's Palsy

### Definition

Bell's palsy results from injury of the VIIth cranial nerve, commonly after viral infections, e.g. a herpes zoster infection of the ►geniculate ganglion, leading to blisters in the external ear canal, loss of ►taste sensation, distortion of the face (pull to the contralateral side because of ipsilateral weakness of facial muscles). Aberrant subsequent nerve regeneration may lead to ►synkinesias, such as jaw winking, in which movements of the lower face coincide with, e.g., eye closure.

## Bell-shaped Speed Profile

### Definition

The velocity profile for a movement between two points in space with velocity zero at the begin and end, as predicted by the minimum-jerk model, is symmetric in time relative to peak velocity. This profile is bell-shaped.

►Motor Control Models

## Benedikt Syndrome

### Definition

The Benedikt syndrome results from lesion (infarction) of the ►midbrain peduncle and ►tegmentum and characterized by oculomotor paresis, weakness and ataxia.

## Benign Essential Tremor

►Essential Tremor

## Benign Familial Tremor

►Essential Tremor

## Benign Paroxysmal Positional Vertigo (BPPV)

### Definition

Disorder of the labyrinth that occurs when otoconial crystals become dislodged from the otoconial membrane and pass into one or more semicircular canals.

The posterior semicircular canal is most commonly affected because it is in the most dependent position of the labyrinth. Head movements in the plane of the affected canal result in motion of the crystals, which leads to abnormal deflection of the cupula. Vertigo and nystagmus then follow. Repositioning maneuvers can be very effective in the treatment of BPPV.

►Disorders of the Vestibular Periphery

## Bergmann Glia

### Definition
Bergmann glia are specialized astrocyte glia cells in the cerebellar cortex. Their cell bodies are in the Purkinje cell layer and their processes extend upward through the molecular layer to the pial surface of the cerebellum.

## Bernstein Problem

### Definition
The problem of elimination of redundant degrees-offreedom during natural movements.

## Beta-motoneuron

### Definition
A motoneuron that innervates both extra- and intrafusal muscle fibers.

►Motor Units

## Betz Cells

### Definition
Betz cells, discovered by and named for a nineteenth century Russian anatomist, are large pyramidal-shaped neurons found in primary motor cortex. Some Betz cells have cell bodies of over 100 μm across.

## Bezold-Jarisch Reflex

### Definition
The Bezold-Jarisch reflex is a cardiovascular response consisting of a decrease in heart rate and arterial blood pressure automatically evoked as a direct consequence of chemical or pharmacological stimulation of receptors in the heart or lungs. The decrease in blood pressure is due both to the slowing of the heart and a vasodilation caused by inhibition of sympathetic vasomotor activity.

This reflex was first described by von Bezold and Hirt in 1867, who observed that intravenous injection of veratrum alkaloids caused a profound fall in blood pressure and heart rate. Other chemical agents, such as phenylbiguanide, also trigger the response. The receptors for the reflex are located on the terminals of sensory unmyelinated fibers in the vagus nerve (CN X). The functional significance of the Bezold-Jarisch reflex in circulatory regulation is not understood, although it has been suggested that the reflex may contribute to the severe hypotension associated with vasovagal syncope.

## B-FABP

### Definition

B-FABP is a member of the fatty acid binding protein family. It is highly related to the peripheral myelin protein P2. B-FABP is expressed by radial glial cells in the developing CNS, and also expressed by satellite cells in DRGs in embryonic and adult mice and by glial cells in embryonic nerve trunks but not by adult.

Schwann cells. B-FABP is not expressed by migrating crest cells or by developing neurons. Therefore, it likely labels cells that are common precursors of Schwann cells and satellite cells.

## Biased Competition Theory of Attention

### Definition

Biased competition theory was originally proposed by John Duncan and colleagues in order to explain two basic phenomena that occur while processing a crowded visual scene. First, not all objects in a scene can be processed at the same time, that is, there is limited processing capacity. Second, while processing a particular object, one is able to filter out the unwanted information in the scene, that is, there is selectivity.

Biased competition theory rests on three general principles that conceptualize these basic observations further. First, of the many brain systems that represent visual information (sensory and motor, cortical and subcortical), most are competitive. Within each system, a gain of representation for a visual object will be at the expense of other objects' representations. Competitive interactions among multiple objects (such as the faces in a crowd) occur automatically and operate in parallel across the visual field. Second, the competition between systems is integrated. As a visual object gains dominance in representation within one system (e.g. visual cortex), it will tend to gain similar dominance in other systems (e.g. higher-order frontal and parietal areas). And third, competition is controlled within and across brain systems. If one looks for a particular object (e.g. a friend's face), units matching the internal "template" of that object will be pre-activated and therefore gain an advantage by receiving an increased processing weight. Thus, such top-down attention mechanisms introduce bias signals that help resolve the ongoing competition. The competition among multiple objects can also be biased by bottom-up mechanisms that separate figures, or constitute objects, from their background by principles of perceptual organization (see Visual attention).

## Bickerstaff's Brainstem Encephalitis

Tomasz Berkowicz, Krzysztof Selmaj
Department of Neurology, Medical University of Lodz, Lodz, Poland

### Synonyms

Bickerstaff's encephalitis; Bickerstaff's syndrome

### Definition

►Bickerstaff's brainstem encephalitis (BBE) is an uncommon central nervous system (CNS) disease characterized by acute external opthtalmoplegia, cerebellar ataxia with disturbances of consciousness and pyramidal signs. Its etiology remains unknown but it is postulated that BBE has an autoimmune origin because of an antecedent illness and frequently the presence of anti-GQ1b antibodies. BBE is usually a monophasic disease with a generally good outcome.

### Characteristics

#### Clinical Presentation

The first cases of descending brainstem syndrome were described in 1951 by Bickerstaff and Cloake under the title "Mesencephalitis and rhombencephalitis" [1].

In 1957 Bickerstaff defined the disease as "brainstem encephalitis" [2]. The condition has been called Bickerstaff's brainstem encephalitis since 1978 when Bickerstaff wrote a review for the Handbook of Clinical Neurology under the title "Brain stem encephalitis (Bickerstaff's encephalitis)" [3]. The largest cohorts of BBE patients were published by Al-Din et al. (18 cases) in 1982 [4] and Odaka et al. (62 cases) in 2003 [5]. Most of the BBE patients described in the literature had signs of infection before the onset of neurological disease. They usually had upper respiratory infection symptoms, fever, headache or diarrhoea. In the antecedent infections many pathogenic microorganisms were identified. They include *Campylobacter jejuni*, herpes simplex virus, cytomegalovirus, Epstein-Barr virus, varicella zoster virus, *Salmonella typhi* and *Mycoplasma pneumoniae* [6]. Cases of BBE were also reported during pregnancy, after generalized trauma, head trauma and after otological operation (mastoidectomy for a cholesteatoma).

The most common initial symptoms are diplopia, gait disturbances and drowsiness. During the course of the illness almost all the patients develop external opthalmoplegia, ataxia and most of them have disturbances of consciousness (drowsiness, stupor, semicoma or coma). Opthalmoplegia has characteristic features, progressing frequently from symmetrical impairment of conjugate upward and lateral gaze to complete opthalmoplegia. Disturbances of consciousness tend to be a reflection of involvement of the rostral part of the reticular formation. Extensor plantar response (Babinki's sign), papillary abnormalities, nystagmus, facial weakness and bulbar palsy are also frequently found. The progression of cranial palsies is usually rostral-caudal. If ataxia is the primary demonstration of BBE, it involves gait instability, upper and lower extremities dysmetria, dysdiadochokinesis, past-pointing and truncal instability. Development of neurological symptoms of BBE is relatively fast, within 1–2 days. Deep tendon reflexes are usually brisk, but can be normal or decreased. There are cases of BBE with symmetric flaccid limb weakness and with dysesthesias occurring as typical initial symptoms. These cases are classified as BBE with overlapping/coexisting ►Guillain-Barré syndrome (GBS), an acute demyelinating neuropathy. Two atypical cases of BBE with severe muscle rigidity were observed. One of them was misdiagnosed in the beginning as tetanus. Some of the BBE patients develop respiratory failure in the period of maximal disability. They need intubation followed by mechanical ventilation in a critical care unit. When prolonged mechanical ventilation is necessary sometimes a tracheostomy is performed. BBE progresses from 1 to 8 weeks in a steady and unremitting way. The period of most severe neurological symptoms is variable, from 5 days to 4 weeks. The main signs typically improve within 2–3 weeks but full recovery can take as long as 3–18 months. BBE usually has a monophasic course but there are also reports of remitting cases. We observed two remitting cases, one of them with overlapping GBS. The final outcome is generally good but occasionally the disease can be fatal. From the largest group of 62 patients only three died. Some patients have residual symptoms: dysesthesias, limb weakness, diplopia, gait disturbances, dementia, dysfagia and psychotic changes (emotional liability, violent behavior). Bickerstaff also described a case of BBE with development of typical Parkinsonism during the recovery phase. For a diagnosis of BBE, it is necessary to exclude the following conditions: vascular lesions of the brainstem, Wernicke's encephalopathy, central pontine myelinolysis botulism, myasthenia gravis, neoplasm of the brainstem (glioma, lymphoma), pituitary apoplexy, acute disseminated encephalomyelitis, multiple sclerosis, neuro-Behcet disease, Lyme disease, neurosarcoidosis, Whipple's disease and toxic effects of alcohol and drugs, especially anticonvulsant drugs. In this regard it is worth remembering that sometimes cerebral tumors, for example brainstem glioma, may relapse and remit.

## Laboratory Findings

In BBE no abnormalities are usually discovered in routine blood investigations and urinary tests.

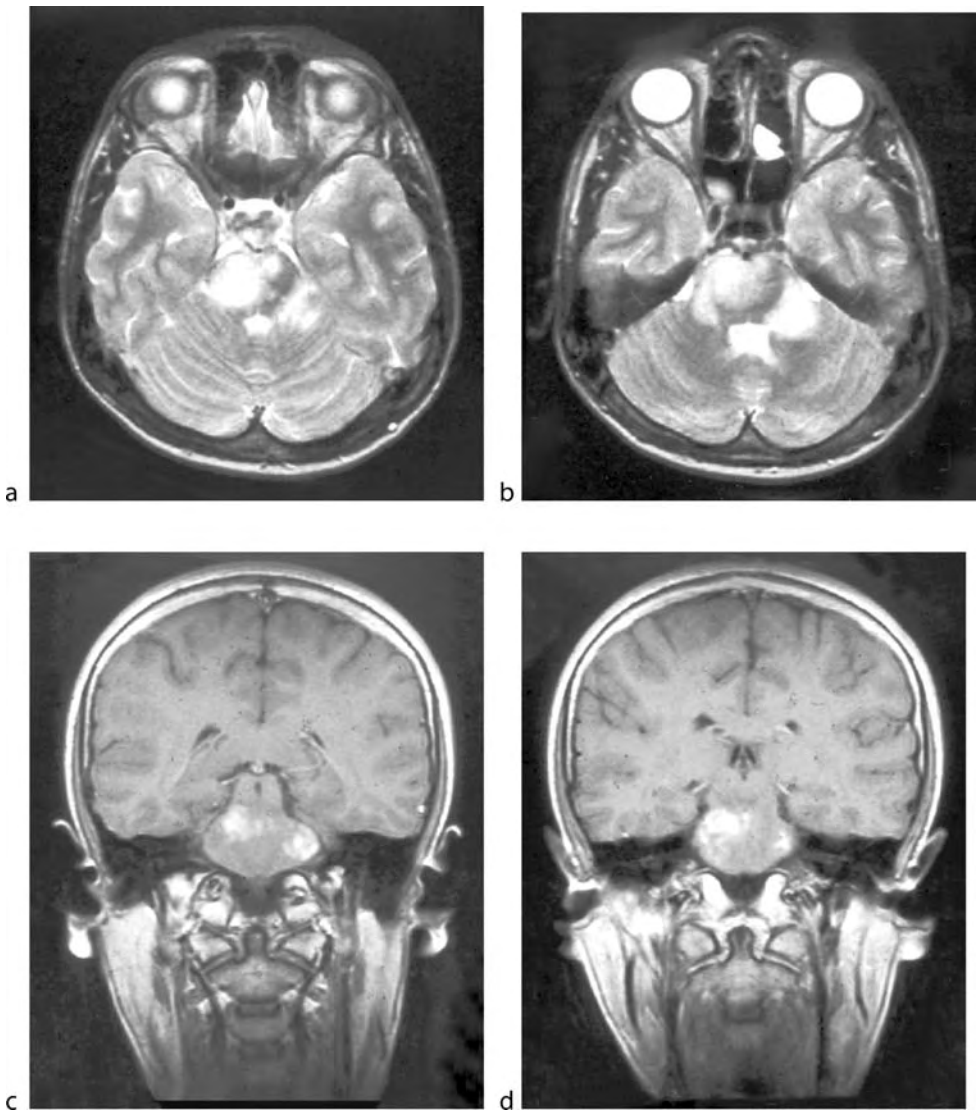
The cerebrospinal fluid (CSF) pressure is usually normal. CSF examination shows mild lymphocytic pleocytosis (usually not more than 100 cells/μl) with or without a moderate rise of protein. Albuminocytological dissociation (protein ≥45 mg/l, cellularity ≤5cells/μl) can also be observed.

About two-thirds of BBE patients have high titers of immunoglobulin G (IgG) antibodies against ganglioside NeuAcα2–8NeuAcα2–3Galβ1–3GalNacβ1–4(NeuAcα2–8NeuAcα2–3) Galβ1–4Glcβ1–1'Cer (GQ1b). ►Anti-GQ1b antibody titres decrease with clinical improvement of the disease. The potential role of this antibody in the pathogenesis of BBE supports the fact that the third, fourth and sixth cranial nerves contain GQ1b ganglioside. The paranodal regions of the extramedullary portion of human oculomotor, trochlear and abducens nerve can be strongly stained using mouse anti-GQ1b monoclonal antibody. It is also probable that anti-GQ1b antibody is closely associated with impairment of these cranial nerves involved in ocular movement. This antibody also weakly stains deep cerebellar nuclei, the gray matter in the brainstem, spinal cord, some cells of large dorsal root ganglion and muscle spindles. Anti-GQ1b antibodies cross react with lipopolysaccharide present in the bacterial coat of *Campylobacter jejuni* and in fact serological evidence of recent *Campylobacter jejuni* infection was found in many of the BBE patients. Additionally, an absorption done with anti-GQ1b antibody showed that human fibroblasts express the

GQ1b epitope after herpes simplex virus (HSV) infection was also detected in patients with BBE. In some patients, therefore, anti-GQ1b antibodies may be induced after *Campylobacter jejuni* or HSV infection. Antibody to GQ1b ganglioside can also be detected in the sera of patients with ►Miller Fisher's syndrome (MFS), GBS with opthalmoplegia and acute opthalmoparesis positive for anti-GQ1b antibodies. Due to the possibility of common autoimmune mechanisms of these four illnesses and the fact that they are similar clinically a term "Anti-GQ1b antibody syndrome" was created [7]. Anti-GM1b and anti-Ga1Nac-GD1a IgM antibodies were also detected in the sera of BBE patients. These antibodies are much less frequent than the antiGQ1b antibody, but they may, however, also be useful serological markers for identifying BBE patients.

Electroencephalography (EEG) in BBE shows widespread diffuse slow-wave activity in the teta and delta range. Features of sleep with K complexes and vertex sharp waves are also seen. Pathological activity is normalized with clinical improvement.

Electrophysiological examination shows that even in the BBE patients without overlapping GBS almost half of the patients have abnormal nerve conduction study findings. Predominantly BBE patients have features of axonal degeneration with reduced amplitudes of CMAPs and relatively normal motor conduction velocities in peripheral nerves. Findings characteristic for frank demyelination are much more frequent.



**Bickerstaff's Brainstem Encephalitis. Figure 1** MRI of the patient during the course of BBE – T2-weighted images (a, b), T1-weighted images enhanced with gadolinium (c, d).

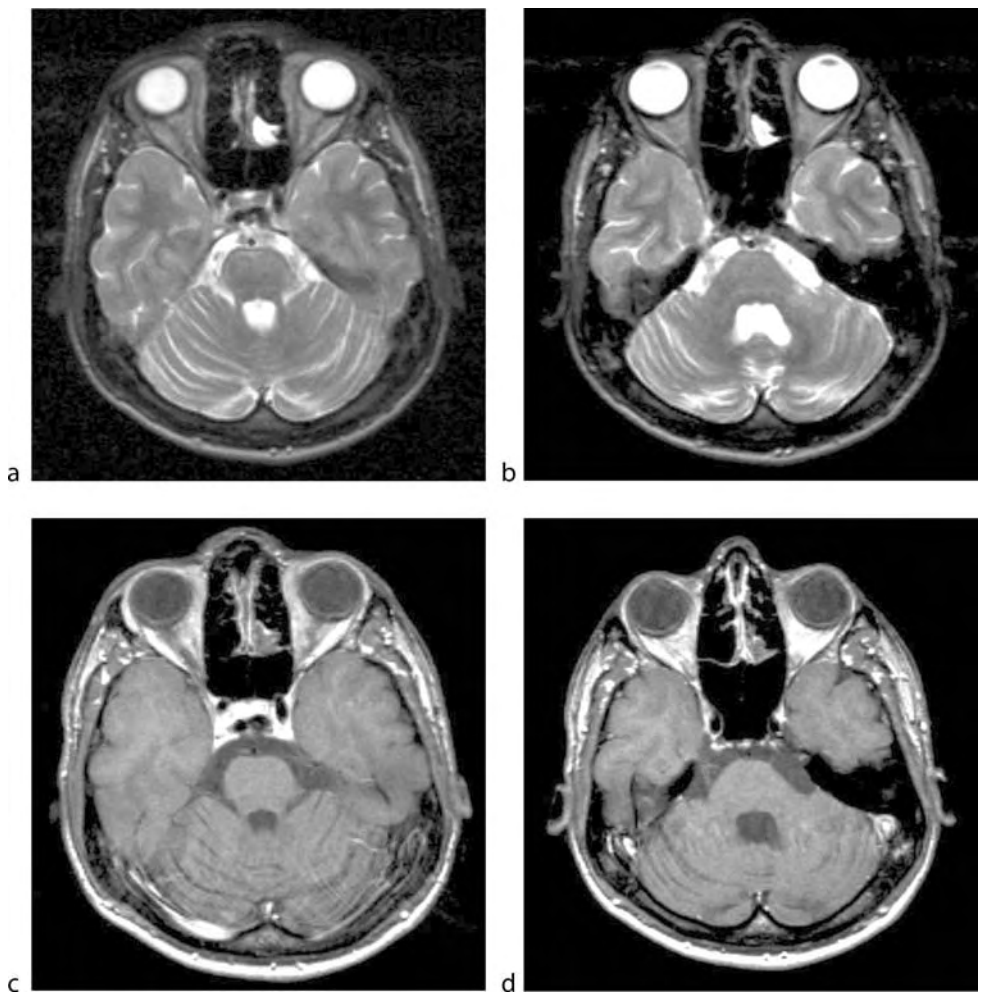
## Imaging

Computed tomography (CT) was used for the imaging of brains of patients suspected of suffering with BBE before the magnetic resonance imaging (►MRI) era. CT scans showed no abnormalities or low density areas with various degrees of enhancement localized in brainstem, particularly in the pons and sometimes in the thalamus.

MRI is the most helpful tool in establishing diagnosis of BBE. In the majority of BBE cases MRI shows typical changes localized within brainstem [8]. On T1-weighted images, brainstem swelling is usually seen as well as widespread hypointense lesions within the pons, medulla oblongata and sometimes in the upper midbrain These hypointense lesions showed various degree of gadolinium enhancement (Fig. 1) on most occasions. The enhancement lasts for several days. On T2-weighted sequences large lesions of hyperintesity can be easily spotted in the brainstem and sometimes outside it, within cerebellum, thalamus or even in white matter of the cerebrum. Frequently these lesions were nearly symmetrical and combined large portions of brainstem. These changes can migrate or regress with the clinical course of the disease. Caudal migration of these changes was described during the course of the disease. BBE lesions usually vanish after several months (Fig. 2). Occasionally MRI can be normal in BBE despite of typical clinical presentation. In the absence of any abnormality on brain MRI, involvement of brainstem and cerebellum can be visualized with (18) F-FDG positron emission tomography (PET).

## Pathology

Due to the good prognosis of BBE, neuropathological findings in this disease are relatively scarce but consistent with clinical signs. On the section of the brainstem numerous focal lesions with large areas of central necrosis were described. Perivascular lymphocytic infiltrations



**Bickerstaff's Brainstem Encephalitis. Figure 2** Control MRI of the same BBE patient after 4 years – T2-weighted images (a, b), T1-weighted images enhanced with gadolinium (c, d).

with perivascular oedema were also found, and sometimes with very large numbers of macrophages. There was astrocytic proliferation present, sometimes forming "glial stars". In the cerebellum, loss of Purkinje cells and degenerative changes in the dentate nucleus were found. Lymphocytic infiltration was also seen in the dorsal root ganglia. Chromatolytic changes of neuronal cytoplasm were described in the trigeminal motor nucleus and in the spinal anterior horn. Outside the central nervous system lymphocytic infiltrations were also described in bronchial mucosa of the lungs and peri-portal areas in the liver, which might indicate the appearance of systemic infective processes.

### Diagnosis

Early diagnosis of BBE could be difficult based on clinical findings, because characteristic symptoms do not always come together during the early phase of the disease. In our opinion the diagnosis of BBE should not only be based on symptomatology. Odaka et al. proposed very strict, purely clinical criteria. Based on them, "Progressive, relatively symmetric external ophtalmoplegia and ataxia by 4 weeks" and "disturbance of consciousness or hyperreflexia" are required for the diagnosis. We think that if clinical criteria are not complete, typical MRI pictures with a high signal lesion on T-2 weighted images localized in the brainstem confirms the diagnosis of BBE. The high titers of anti-GQ1b antibody may contribute to diagnosis of BBE. A good recovery from clinical symptoms helps to diagnose BBE.

### Therapy

There is no established therapy for BBE. Most patients are given immunotherapy such as steroids, plasmapheresis and intravenous immunoglobulins (IVIg). There are various types of plasmapheresis used, such as plasma exchange, double filtration plasmapheresis (DFPP) or immunoadsorption with a tryptophan-conjugated column, which highly absorbs anti-GQ1b IgG antibody [9]. In some BBE patients treatment with IVIg leads to rapid clinical recovery. IVIg may be an alternative treatment in BBE if plasma exchange is not available or contraindicated. Also, combination of these therapies was very often used, for example, steroids followed by plasmapheresis, steroids and plasmapheresis followed by IVIg etc. Some patients are treated additionally with antbiotics and antiviral drugs. We also observed BBE cases misdiagnosed as pontine glioma. Brainstem lesions were irradiated with good outcome, although this could not of course be considered as a potential therapy for BBE.

## Binaural

### Definition

Having, or relating to, two ears. Sensitivity to binaural localization cues, including differences in the time of arrival or intensity of the sound at the ears, enable humans and other animals to determine the direction of a sound source.

## Binaural Beats

### Definition

A stimulus paradigm in which tones of slightly differing frequencies are presented to each ear. At the site where the timing of sounds from the left and right ears are compared, such as the nucleus laminaris in birds or the medial superior olivary nucleus in mammals, the slight difference in frequency causes a slight difference in phase between the left and right ears inputs. This interaural phase difference varies as a function of time, leading to a sensation of motion.

►Neuroethology of Sound Localization in Barn Owls

## Binaural Cross-Correlation

### Definition

A process that approximates the computation of the delay between the signals in the two ears. In ordinary cross-correlation, a signal is multiplied by a delayed version of another signal in a point-by-point fashion, and the products are summed. The delay, called the "argument," is changed and the multiplication and addition are repeated. The sum of the products is plotted as a function of argument. The cross correlation r(J) is computed thus:

$$r(\vartheta) = \Gamma \mathrm{l(t)r(t+}\vartheta\mathrm{)}$$

where l(t) and r(t) are the two signals and J is the argument. The argument J is equivalent to the interaural time difference. Mathematically, the result is a graph of the sum of products as a function of J, with a major peak at the J that equals the delay between l(t) and r(t). In the brain, typically in the nucleus laminaris of birds or the medial superior olive of mammals, a neuron tuned to a particular ITD (J) is maximally activated.

## Binaural Interactions

### Definition

The neural process of combining the input from the two ears in some way.

# Binaural Pathways and Processing

David McAlpine
UCL Ear Institute and Department of Physiology, University College London, London, UK

## Synonyms

Auditory processing; Sound localisation pathways

## Definition

Binaural hearing refers to the ability to extract information about the acoustic environment using two ears, which would not be possible using one ear only. Most commonly, binaural hearing is considered in terms of sound localisation cues, interaural time and interaural intensity differences. Specialized brainstem pathways exist that converge input from each ear onto individual neurons, rendering them sensitive to one or other of the binaural cues. The means by which binaural information is processed in the brain has been of considerable interest for some time, in large part due to the exquisite temporal capabilities of neurons that process interaural time differences.

## Characteristics

### Spatial and Binaural Hearing

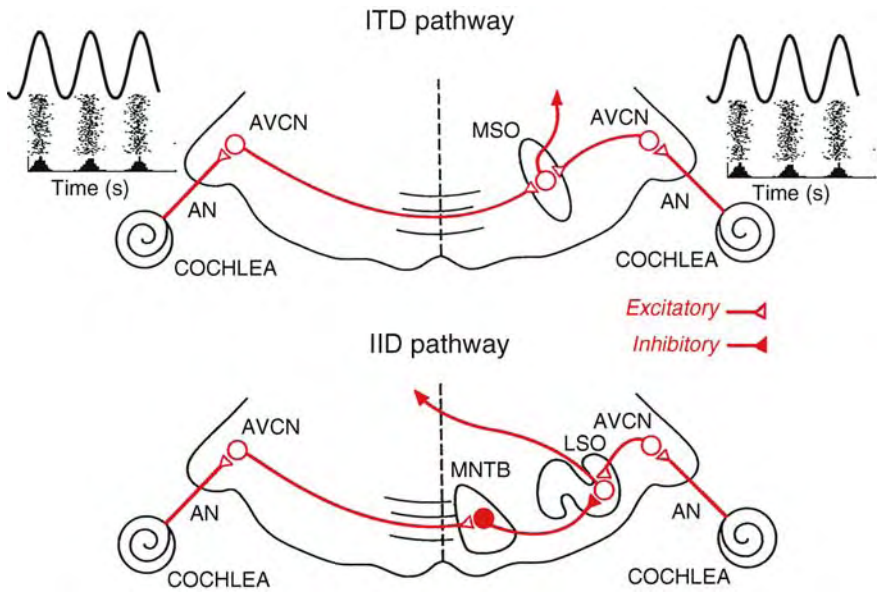
In the visual system a relatively complete understanding of spatial processing has been achieved, at least with respect to the two-dimensional representation of visual space projected on the back of the retina. In contrast, the study of neural coding of auditory space constitutes an altogether more complex problem – the primary representation of the ►cochlea, the sensory end organ in hearing, is sound frequency, rather than the location of the source. Nevertheless, the percept of a sound as originating from a distinct source is a fundamental property of normal hearing. Most ecologically-relevant sounds have a distinct quality that renders them spatially extant, and this attribute is provided for by a combination of the acoustic spatial cues, namely sensitivity to binaural cues for sounds in the horizontal plane, and sensitivity to spectral changes that occur as a sound source shifts in the vertical dimension.

According to Rayleigh's ►duplex theory [1], human ►binaural hearing is subserved by two mechanisms: at low frequencies (<1,500 Hz), sources of sounds are localized using ►interaural time differences (ITDs), whereas at high frequencies ►interaural intensity differences (IIDs, also called interaural level differences, ILDs) mediate localization. The dichotomy suggested by the duplex theory is, to a first approximation, reflected in the anatomy and physiology underlying sensitivity to ITDs and IIDs in the mammal brainstem. The medial superior olive (MSO) of the brainstem shows a relative over-representation of neurons tuned to low ►characteristic-frequencies (CFs) and, in many mammals, appears to be specialized for the processing of ITD information, whilst the lateral superior olive (LSO), with a relative overrepresentation of high (>2 kHz) CF neurons, processes IID information. The tonotopic (sound frequency) organization at subsequent centers in the auditory pathway maintains this separation.

### Functional Anatomy of Pathways Sub-serving Binaural Hearing

Brainstem pathways underpinning binaural hearing (Fig. 1) mainly those contributing to ITD sensitivity, are highly specialized, comprising the most temporally-precise neural elements in the brain. An absolute requirement for ITD sensitivity is the ability to generate and retain information concerning the fine-structure waveform of the sound arriving at each ear independently, at least until the primary stage of binaural integration in the brainstem. Primary ►auditory nerve fibers (ANFs) synapsing at the base of the inner hair cells (IHCs) of the cochlea respond to the cycle-by-cycle changes in the IHC membrane potential (itself reflecting the back-and-forth deflections of the stereocilia) with action potentials that are "phase-locked" to the stimulus waveform (see Fig. 1).

The ability of ANFs to phase-lock their action potentials degrades with increasing frequency, such that for frequencies above approximately 4-kHz, ►phase-locking is absent in mammals, providing an upper limit for which temporal information is accessible. This upper limit is reduced at each synaptic stage, so that by the level of binaural integration the upper limit lies around 2 kHz. Certainly most mammals are insensitive to ITDs in the fine-structure of a sound above this frequency. However, although the upper limit of phase-locking is reduced in the ascending auditory pathway, both the synchronization (quality of phase-locking) and entrainment (whether or not an action potential is generated during each stimulus cycle) improves between the ANFs and the first synaptic stage in the ►cochlear nucleus (CN). ANFs entering the CN bifurcate, innervating both the ventral and dorsal aspects of the CN (VCN and DCN, respectively). Neurons of the VCN, particular the ►spherical bushy cells (SBCs) of the anterior division (AVCN) and the ►globular bushy cells (GBCs), appear specialized for temporal processing, with large synaptic contacts and fast membrane kinetics. Recordings made from the axons of SBCs indicate improved synchrony entrainment of phase-locking relative to ANFs, particularly for frequencies up to 1 kHz. As well as projecting ipsilaterally to the MSO, SBCs innervate the MSO on the opposite side via the fibers of the trapezoid body. The MSO in most mammals with well-developed low-frequency hearing is a laminar structure several cells thick located medially to the more prominent LSO.



**Binaural Pathways and Processing. Figure 1** Traditional dichotomy of binaural brainstem pathways:- *Top:* Presumed pathway involved in processing ITDs. Phase-locked action potentials are transmitted from the auditory nerve fibers to the spherical bushy cells of each AVCN. Outputs of these neurons converge onto individual MSO neurons. *Bottom*: Projections from the cochlear nucleus innervate the principal cells of the MNTB on the opposite side. LSO neurons receive excitatory inputs from ipsilateral AVCN, and a glycinergic inhibitory projection from the MNTB. This pathway underpins sensitivity to IIDs. It is now know that the MNTB also provides the MSO with inhibitory input, and that this input is also important in the processing of ITDs (see text).

It is organized such that CFs are highest towards the ventrolateral pole of the nucleus, and lowest towards the dorso-medial. Individual MSO neurons typically show bipolar morphology, with two major dendrites emerging from the soma 180° to each other extending orthogonally with respect to the dorsoventral axis of the nucleus. Spherical bushy cells from the CN on each side of the brain converge onto single MSO neurons, with ipsilateral inputs synapsing on the lateral dendrites and contralateral inputs on the medial dendrites. MSO neurons also receive bilateral inhibitory inputs via some of the largest and most reliable synapses in brain, including the ►calyx of Held in the ►medial nucleus of the trapezoid body (MNTB). Recent studies indicate that for mammals such as gerbils with well-developed low-frequency hearing, these inhibitory inputs are largely restricted to the soma of MSO neurons following a period of developmental refinement [2]. Species in which low-frequency ITD processing is absent do not show this refinement. The major output of the MSO is primarily to the ipsilateral ►inferior colliculus (the major auditory nucleus of the midbrain).

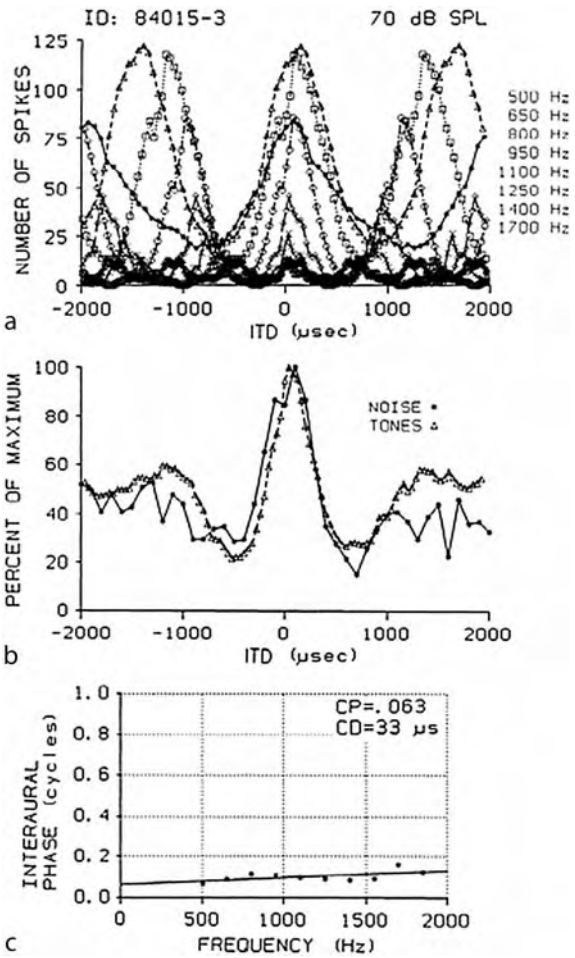
LSO neurons receive their major inputs from the SBCs of the ipsilateral AVCN and the principal neurons of the ipsilateral MNTB. In turn, the principal neurons of the MNTB receive their main input from the GBCs of the contralateral AVCN via the fibers of the ►trapezoid body. It is interesting to note that although the LSO is associated primarily with the processing of interaural intensity, rather than temporal, cues, its neurons are innervated by neurons possessing exquisite temporal capabilities. Several reasons can be posited for this. First, as in the MSO neurons, low-CF neurons in the lateral limb of the LSO show sensitivity to fine-structure ITDs. Second, sensitivity to ITDs in the envelope structure of high-frequency modulated sounds is widely-reported to exist in the LSO [3]. Third, the fast-temporal capabilities of SBCs and neurons of the MNTB likely also support extraction of temporal cues other than binaural temporal cues, albeit cues requiring lower temporal fidelity. The largest excitatory projection from the LSO is to the contralateral IC, although the low-frequency lateral limb projects largely ipsilaterally. This ipsilateral projection contains both excitatory and inhibitory (glycinergic) neurons.

## Binaural Coincidence Detection

It is well established that neural sensitivity to ITDs arises first in the MSO, although the reported difficulties in recording from the MSO mean that relatively few successful recordings of ITD-sensitive MSO neurons have been made compared with other auditory centers. From those studies that have been successful, the consensus is that MSO neurons act as ►binaural

coincidence detectors [4], responding maximally to sounds at favorable ITDs; i.e. when phase-locked input from each ear arrives in temporal coincidence, and submaximally at other ITDs (Fig. 2).

Neural discharge rates are highest (and modulation of those rates generally greatest) for tones near to the CF. Other frequencies elicit fewer spikes and lower depths of response modulation. Consistent with the Jeffress model of coincidence detection [4], neurons show a characteristic delay (CD) an ITD for which the relative discharge rate



**Binaural Pathways and Processing. Figure 2** [Fig. 10 from: Yin TC, Chan JC. (1990) Interaural time sensitivity in medial superior olive of cat. J Neurophysiol. 64 (2):465–488] Response of MSO neuron to interaurally-delayed sounds. (a) Response to tones of different frequencies. (b) Summed responses to tones compared with response to interaurally-delayed broadband noise. (c) Function plotting best interaural phase difference (*IPD*) as a function of stimulus frequency, to derive the characteristic delay (*CD*). The characteristic phase (*CP*), which is close to zero, indicates that the CD occurs close to the peak of the response function.

is identical for different stimulus frequencies. When a range of static ITDs is imposed on the stimulus waveform, a cyclic pattern of responses is evoked; response maxima occur at intervals separated by the period of the stimulus waveform (See Fig. 2a). This reflects the underlying binaural coincidence detection, presumably at the level of the MSO. Theoretically, for neurons with a fixed axonal conduction delay from one or either ear, the CD corresponds to the ITD at which response peaks are aligned for all stimulus frequencies to which the neuron is sensitive. The CD is often evident in responses to different tonal frequencies (or by presenting interaurally-delayed broad-band noise as a stimulus – Fig. 2b), and can be quantified by plotting the response phase (with respect to the period of a pure tone) as a function of the stimulating frequency (Fig. 2c). However, although MSO neurons satisfy the basic requirement of coincidence detectors, evidence for any systematic arrangement of preferred ITDs that would indicate an ordered arrangement of delay lines in mammals is, at best, equivocal (in contrast to the well-established anatomical arrangements reported for birds). Further, recent evidence indicates that the preference of individual MSO neurons to respond maximally to a particular ITD is mediated by the inhibitory neurotransmitter ▶glycine, most likely derived from MNTB and/or LNTB inputs. Blocking glycinergic inhibition *in vivo* shifts a neuron's preferred tuning for ITD towards zero [5], suggesting axonal conduction delays between the ears are essentially matched.

Despite the MSO being the site of primary binaural integration, the majority of studies examining ITD sensitivity in mammals have been investigated in the IC. Chief amongst these is the series of reports throughout the 1980s by Yin and Kuwada [6], documenting responses of IC neurons to a range of binaural stimuli containing ITDs, including interaurally-delayed tones, ▶binaural beats noise and clicks. To a first approximation, IC neurons were reported to respond to ITD cues in a similar manner to (the relatively few) MSO neurons previously recorded at that time, an observation confirmed by later, more extensive MSO recordings in several laboratories.

## The Neural Code for Interaural Time Difference

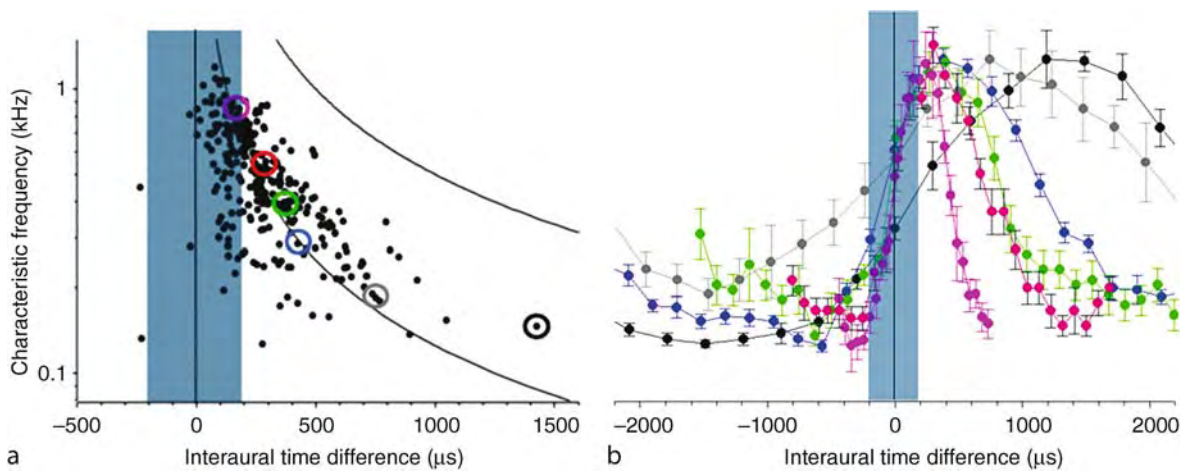
A common assumption of most models of ITD processing is that individual neurons signal the location of a sound source by virtue of their peak firing rate; neurons are selectively tuned to a specific ITD, and therefore to a unique spatial location in the horizontal plane. One consequence of such behavior would be the requirement that at some level of the brain, neurons be sufficiently sharply tuned for ITD to account for the observed behavioral sensitivity (a few tens in human listeners). Skottun and colleagues [7], argued that, as in many other neural systems, the slopes of ITD

functions are likely to be the most sensitive region in terms of neural discrimination of ITDs. Such an eventuality answers a long-standing puzzle concerning the distribution of preferred ITDs across populations of neurons, many of which lie outside the range of natural ITDs, defined by the head-size of most small mammals. Related to this is recent evidence indicating that the arrangement of preferred ITDs in the IC runs parallel with, rather than orthogonal to, the main frequency gradient [8]; Figure 3a plots the distribution of peak ITDs as a function of neuronal CF. Surprisingly, given that sound frequency is the primary feature represented in the cochlea, and that this mapping is maintained at least to the level of primary cortex in the form of tonotopically-organized auditory centers, the relationship between neural CF and preferred ITD has been overlooked. The demonstration that peak ITD tuning is CF dependent marked the beginning of a significant departure from the view that ITD is represented in the brain in form of a "local code." The outstanding question as to whether this relationship represents specific processing in the IC or reflects processing at the level of the MSO appears to have been answered by reports of a similar relationship in MSO of the gerbil [5]. The functional importance of this relationship appears indeed to be related to the need to position the slopes of ITD functions through the range of ecologically-relevant ITDs. In response to interaurally-delayed noise, neurons with the lowest CFs, and consequently the broadest ITD functions, show peak responses at relatively long ITDs – beyond the ecologically-relevant range – placing the sensitive slope of the function where greatest ITD discrimination is required. As CF increases, peak ITDs shift closer to zero, maintaining the position of a function's slope through the range of ecologically-relevant ITDs (Fig. 3b).

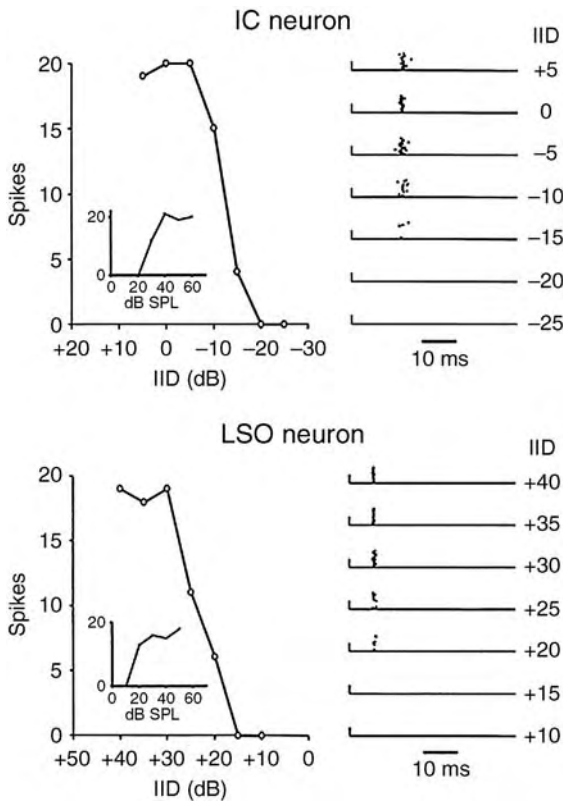
## Neural Sensitivity to Interaural Intensity Differences

In contrast to ITDs, the magnitude of IIDs depends on sound frequency as well as head-size (higher frequencies, with their shorter wavelengths, evoke a larger ►head-shadow). One way of overcoming the limitations in localisation performance this would bring is by exploiting ITDs at low-frequencies (e.g. gerbils, kangaroo rats), or by extending the hearing to the ultra-sound range (e.g. bats, mice). Species in which the latter strategy has been adopted have contributed to a significant number of studies of IID sensitivity, particularly echo-locating bats, in which spatial hearing extends beyond the assessment of interaural differences. Significantly more reports of LSO recordings exist than is the case for the MSO, and many LSO neurons, particularly those in the high-frequency limb, are excited by the ipsilateral ear and inhibited by the contralateral in a manner dependent on the relative intensity of the sound at each ear (see Fig. 4).

Nevertheless, despite the relative ease with which LSO responses can be recorded compared with the MSO, it is equally the case that the IC provides a substantial number of reported studies of IID sensitivity. As with ITD cues, the largest single factor determining the sensitivity of IC neurons to IIDs is presumed to be the synaptic input they receive from binaural brainstem neurons, almost certainly the LSO.



**Binaural Pathways and Processing. Figure 3** (a) Distribution of peak ITDs for inferior colliculus neurons as a function of neuronal CF. The shaded area indicates the ecologically-relevant range of ITDs for the guinea pig (±180 μs). Note the CF dependence of the distribution and that many neurons are tuned to ITDs beyond the ecologically-relevant range. (b) Representative ITD functions for six neurons (color-coded from part a). As CF increases, the peak ITD shifts closer to zero, maintaining the steep slope of the function through the ecologically-relevant range (*shaded area*).



**Binaural Pathways and Processing.**
**Figure 4** [Fig. 1 of [9]] Plots of discharge rate as a function of IID for a typical IID-sensitive in the inferior colliculus (*IC; top*) and a typical IID-sensitive neuron in the lateral superior olive (*LSO; bottom*). Raster plots are shown to the right of each function. Positive IIDs indicate a greater intensity at the excitatory ear (opposite ears for IID sensitive neurons in the LSO and IC). *Inset*: rate-level functions for each neuron.

The decussating projection pattern of the LSO renders IC neurons excited by contralateral, and inhibited by ipsilateral, stimulation. However, this sign reversal aside, a major difference between neural coding for ITDs and IIDs exists in the possibility that neural sensitivity to IIDs can be created *de novo* at multiple stages in the auditory pathway. Unlike the requirements of exquisite temporal sensitivity in ITD processing, which is supported by specialized anatomical structures in the auditory nuclei of the lower brainstem and imposes limitations on the ability of neurons higher in the auditory pathway to retain and/or extract timing information, IID sensitivity does not require the same degree of specialization. As such, there is no reason *a priori* why neurons in the IC, for example, or indeed any neurons in the auditory pathway at which inputs from the two ears could conceivably converge, should not constitute a site at which neural sensitivity to IIDs is generated. Consistent with this notion, several studies have demonstrated, by means of blocking the action of inhibitory neurotransmitters locally in the IC, the modification, or even complete abolition, of IID sensitivity in IC neurons [10]. A likely source of ►GABA-ergic inhibition to the IC is the cross projection from the ►dorsal nucleus of the lateral lemniscus (DNLL) and removing this connection, either by sectioning its projecting axons or by pharmacological inactivation of the DNLL itself, results in a release from binaural inhibition in IC neurons. Nevertheless, given the sufficiency of the LSO in producing neural sensitivity to IIDs, it seems likely that IID sensitivity in the majority of IC neurons reflects LSO input, with modifications provided by mechanisms local to the IC. Indeed, several studies have reported a transformation in the coding of IID cues between the LSO and the IC. In particularly, Park [9] reported that IID sensitivity (in Mexican free-tail bats) was relatively more biased toward the inhibitory ear in the IC than in the LSO, with neurons requiring a more intense signal at the inhibitory ear to achieve the same degree of suppression. Further, a greater proportion of IC than LSO neurons show IID functions that are stable with absolute sound intensity. Whereas IID sensitivity in LSO neurons was characterized by IID functions that shifted in a systematic manner with increasing intensity to the excitatory ear, those in IC were less affected by absolute intensity, suggesting that at one function of hierarchical processing of IIDs is to provide for a stable representation of IIDs across a wide range of absolute sound intensities.

# Binding Problem

Michael Herzog
Laboratory of Psychophysics, Brain Mind Institute, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

## Definition

Information processing in the human brain is highly parallel. This means that different features of an object are processed in different parts of the brain. For example, the color and the shape of a red square are coded by different neurons in the visual system (►visual field). However, we do not perceive "red" and "square shaped" separately but a "red square." The binding problem deals with the question of how features that are processed in parallel are bound to the one unique percept.

The term "binding problem" usually refers to the binding of features such as color and shape in contrast to, for example, binding the visual experience of one square to general concepts about squares such as equiangularity. Feature binding is often implicitly thought to occur in an epoch of 50–200 ms.

## Characteristics

### Information Processing

A picture is presented. Recognizing an object in this picture cannot simply be accomplished by comparing this object with some mental "images" stored in memory. Such a strategy would require an abundantly huge memory capacity. Think about a square. Even a slight rotation or translation of the square changes its projection on the retina dramatically. Moreover, views of an object from different perspectives would not be recognized as the same object if neural representations of these different views were not be related to each other.

For this and other reasons, information processing is thought to be parallel in higher animals. The brain contains many areas that analyze certain features of a visual picture separately. For example, there are different brain areas dedicated to different tasks such as analyzing motion, faces, or simple visual features. Moreover, different regions within one brain area analyze different features, e.g., the orientation of a line is coded by different neurons than its color in the ►primary visual cortex of macaque monkeys.

If a red square is presented, different neurons are active than if a green disc is displayed. In the first case, some neurons fire for vertical and horizontal contours while others for red, analogously for the green disc. A problem arises when the red square and the green disc are presented simultaneously (Fig. 1). How does the brain know that the square was red and not green? This problem was called the superposition catastrophe [1].

There are three major approaches to solve the binding problem.

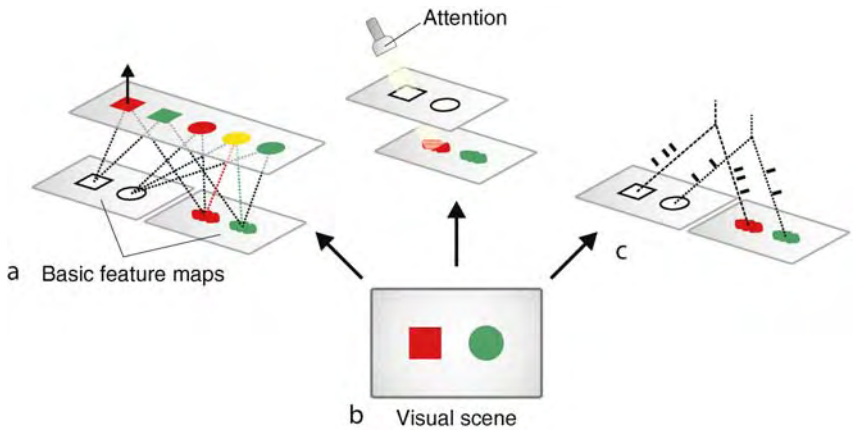
### Convergent Hierarchical Coding

It is assumed that information processing proceeds from the analysis of low level to high-level feature detectors in a feedforward manner (►Feedforward processing). For example, a visual image is first analyzed in terms of the orientations of the single elements in the image. In a second step, this information is combined. On further stages, more and more complex features are added (Fig. 1a). In convergent coding, recognition of an object occurs if one metaphorical "grandmother" neuron or a designated "sparse" population of neurons is activated by neurons converging to this neuron or the population of neurons (e.g., [2]). The activity of this population is thought to be sufficient for perception, i.e., no other aspects such as the temporal firing pattern of neurons are of interest.

Converging coding models may quickly run into abundant memory problems, since not only for each object but also for each view of an object neurons are required. Current architectures avoid this problem by assuming that, for example, not every color has to be coded but only a few basic ones [3]. Other colors can be represented by a combination of neuronal activities. For example, "red" and "green" may be coded by the full activity of one dedicated neuron, respectively, whereas half activity of these two neurons may represent "yellow" (Fig. 1a).

#### *Evidence*

In physiological experiments, it was shown that, indeed, some neurons were vigorously activated for a certain view of an object whereas other views seemed to be presented by combinations of such neurons. Moreover, neurons responding to highly specialized feature combinations were found (e.g., [4]). In accordance with feedforward object recognition, it was shown that animals in a visual scene could be ultrarapidly detected.



**Binding Problem. Figure 1** Three approaches to solve the binding problem. In all theories, basic feature detectors analyze a scene of the outer world, indicated by the red square and the green disc. In each basic feature map, there are detectors for all basic features at one retinotopic position. In the above figure, only the most active detectors are shown. (a) In *convergent coding*, basic feature detectors, makes neural connections to specialized feature indicating the presence or absence of combined features. On a higher stage, the activation of a "red square" neuron occurs when both the basic "red" and "square" neurons are active. Not all objects have to be coded by one neuron. A "yellow disc" neuron may be activated by the "disc" neuron and both the "red" and "green" coding neurons. (b) In *feature integration theory*, attention binds the information of basic-feature maps into a master map. (c) In *temporal coding*, the presence of combined features is indicated, for example, by a synchronous firing of basic feature detectors. In the figure, temporal patterns are indicated by the black strokes. In temporal coding, there is no explicit need for combined feature detectors.

#### *Discussion*

One question is whether convergent coding can account for the recognition of entire visual scenes. It is unlikely that for each novel object and scene a prewired representation exists. For this reason, learning plays an important role in recent approaches of convergent coding. However, many novel objects and scenes can be recognized without prior experience. Just think about a red square with bird wings. It remains to be shown whether convergent coding and learning are sufficient to account for novel real-world scene recognition.

### Feature Integration Theory

It is assumed that there are distinct maps coding for basic features such as the different colors and shapes (Fig. 1b). A red square elicits responses in the "color" and the "shape" map in a retinotopic manner (►Retinotopic organization), i.e., for each spatial location of the visual field, there is a bundle of basic feature detectors in each map. For example, at each spatial position, there are neurons coding for each basic color. A retinotopic *master* map determines to which location attention is paid. At this attended location, the various features in the different maps are integrated. The superposition catastrophe is avoided since attention focuses only on the features at one spatial position at one point of time. No memory capacity problem occurs since only basic, single features are coded and not conjunctions of features such as a "red square."

#### *Evidence*

Feature integration theory implies that binding errors occur if attention is not deployed to a certain location. Exactly this was found in illusory conjunctions [5]. For example, a red square might be perceived as green when also a green disc is in the display but less likely as a yellow square if no yellow element is in the display. Hence, illusory conjunctions do not result from "hallucinations." Patients with deficits in certain brain regions, related to attention, show such illusory conjunctions also if attention is not distracted. Moreover, it was shown that attention could change the responses of neurons and possibly the shape of their ►receptive fields. A narrowing of receptive fields may contribute to avoiding illusory conjunctions.

#### *Discussion*

Although there is strong evidence for the involvement of attention in many object recognition processes, it is an open question whether attention is necessary for the binding of features. For example, it may be that illusory conjunctions do not result from a faulty "perceptual" feature binding but are caused by a faulty combination of features during the recall when giving the response. Moreover, fast object recognition can also occur if attention is deployed in dual-task paradigms.

## Temporal Coding

To gain a higher flexibility of coding, it was proposed to add the timing of neuronal responses as an independent dimension to information processing (Fig. 1c). In this theory, basic feature detectors analyze the visual scene as described before [6,7]. The existence of a combination of features is indicated with a unique temporal pattern. For example, if a red square is presented "square neurons" fire in *synchrony* with "red neurons." If in addition, a green disc is contained in the scene, "disc" and "green" neurons fire synchronously with each other but in asynchrony with the "square" and "red" neurons. If a red disc and a green square are presented in the next scene, the same neurons will fire, only the synchrony of firing changes. Hence, no superposition catastrophe occurs. Temporal coding is very flexible without a need for combined feature detectors. If, for example, $m$ types, such as shape and color, have to be coded of which each compromises $n$ features, such as the particular colors, then, $m \times n$ neurons are required for temporal coding. If each conjunction of features has to be coded explicitly, $n^m$ neurons are required.

### *Evidence*

It could, indeed, be shown that two neurons fire in synchrony if they code for features belonging to the same object, but neural firing is out of synchrony if the features belong to different objects. In psychophysical experiments, if elements are flickered with the same frequency but with different phase, these elements appear as distinct objects even though the flicker itself is barely visible. Hence, it may be that presenting visual elements with different phases induces asynchronous firing rates. Amplitudes in the electroencephalogram (EEG) (►Electroencephalogram (EEG)) arise when many neurons fire synchronously. Changes in the recognition of objects usually change the EEG.

### *Discussion*

Athough there are no doubts about the existence of temporal patterns in neural firing, it remains unclear whether these patterns are causal for object recognition and are not epiphenomenal. For technical reasons, there are, up to date, almost no studies that investigated whether changing the temporal pattern of neural responses induces a change of binding states. Moreover, the biological plausibility of synchrony coding was doubted (e.g., [8]). Another question is how the synchronous firing is detected in the brain. Are special neurons needed that detect whether primary neurons fire in synchrony to indicate the binding of certain features?

## General Discussion

The binding problem is at the very heart of neuroscience because it addresses questions about how neurons code the stimuli of the external world, how these stimuli are represented in the brain, and how neurons communicate in general with each other. The binding problem touches also the problem of consciousness since it is about how distributed neural activity (a physiological concept) gives rise to the unity of conscious experience (a psychological concept).

A solution of the binding problem is, moreover, of primary interest for the experimentation itself. For example, if binding is mediated by temporal mechanisms data obtained by an averaging of neural responses in a certain time window may overlook some important aspects of neural coding and must be considered inadequate.

An important distinction has to be made between the mechanisms of binding and the representation of combined features (see also [4,8]). In Fig. 2, single

**Binding Problem. Figure 2** Perceptual grouping. (a, b) Dependent on the spatial layout of elements and following so-called Gestalt rules, elements are bound into different entities. Changes in the spatial layout of the elements can change perceptual grouping. For example, rotating the second and forth row from the top by 45° yields a clear grouping of all elements into lines (b). (c) The picture contains the image of a Dalmatian dog. To perceive the dog, some of the black dots have to be bound to the background whereas others to the Dalmatian dog.

elements are displayed. Depending on their spatial arrangement and so-called Gestalt laws, these elements are grouped differently together. This perceptual grouping can be regarded as evidence of binding of features within the spatial domain. It is not different from binding, for example, one color to one shape since in both cases different neurons at different positions in the brain are responding. In displays analogous to Fig. 2, it was shown that neurons fire synchronously when elements are grouped. Hence, a temporal pattern of neural firing may represent whether or not two features belong together. However, the temporal coding hypothesis does not specify *explicitly* when two dots in Fig. 2b belong to the Dalmatian dog and when not. However, this seems to be the first important step to solve the binding problem.

Interocular Rivalry; Dichoptic Rivalry

### Definition

In normal vision, the two eyes receive largely matching views of the world from slightly different perspectives,

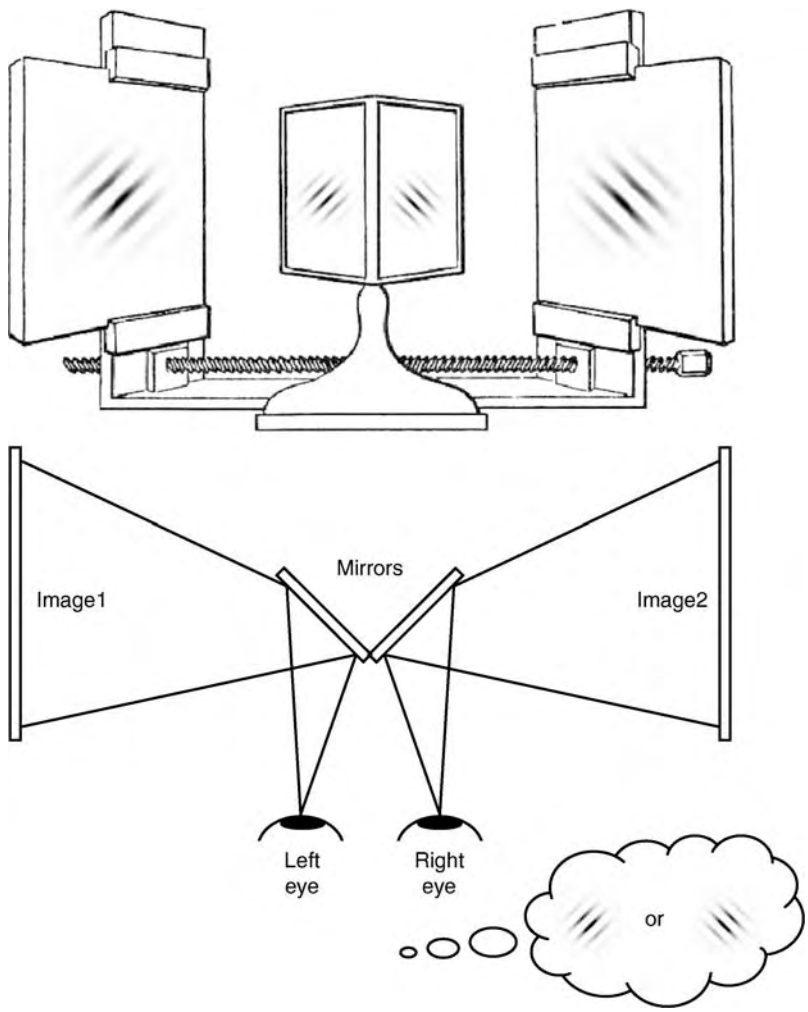
and perception is stable. Yet under certain circumstances, which are typically exploited in the laboratory by showing different images to each eye, the eyes may face irresolvable conflict.

The term binocular rivalry (BR) is commonly used to describe the perceptual phenomenon that occurs under these conditions. During BR, the brain proves incapable of arriving at a single, stable visual ▶percept for an extended period of time. The percept is not a transparent superposition of the dissimilar images as one might expect. An observer rather experiences an unstable and wavering series of perceptual snapshots, with one eye's view dominating for a few seconds before being replaced by its rival from the other eye. With continued viewing of such binocular conflict, one inevitably experiences a sequence of subjective perceptual reversals, separated by random time intervals, that proceeds as long as the sensory conflict is present.

The study of the geometry of binocular vision dates back to the classical world and it is very likely that BR was already known to the ancient Greeks. From the nineteenth century on, when Charles Wheatstone introduced an apparatus to show different images to each eye (the mirror stereoscope; see Fig. 1), to the present day, the very essence of BR has been a topic of debate, with modern neuroscientific theories of rivalry ranging from concrete hypothetical neuronal models to more abstract cognitive models.

## Characteristics

While the experience during BR is often described as a simple alternation process between the right- and left



**Binocular Rivalry. Figure 1** Depiction of a common way how binocular rivalry is brought about in the laboratory. The upper panel depicts a drawing by Sir Charles Wheatstone of his invention, the mirror stereoscope, accompanied by a set of stimuli with the potential to instigate binocular rivalry. The lower panel schematically demonstrates the optical geometry that allows to separately stimulate the two eyes. Note that a person using this setup would be unaware of either the leftward or the rightward titled stimulus at any point in time.

eye's views (not unlike opening and closing each eye successively), this is a considerable oversimplification of what subjects observe under most rivalry conditions. Particularly with larger stimuli, perception during BR can proceed as a much more complex sequence of ever-changing mosaics (so-called piecemeal percepts), each consisting of an interleaved patchwork of the two eyes' views. Several other features of rivalry further speak against the assumption of a simple alternation process between each eye's view. First, the perceived structure of this patchwork is influenced and sometimes even determined by ►Gestalt- or even semantically driven grouping principles (such as to complete geometric patterns or photographs that appear to be split between the two eyes). Second, perceptual switches often entail wave-like transitions between the left- and right- eye's view that may reflect the spatial spread of neuronal activity in the ►visual cortex. Third, competing rivalry patterns which are very low in their ►visual contrast and poor in detail can sometimes be seen in superposition. Finally, very short presentations of conflicting binocular stimuli are frequently perceived as stably fused, suggesting that the conflict must be present for several hundred milliseconds for the brain to lapse into a bistable perceptual state.

Nonetheless, for a circumscribed conflict of a few visual degrees or less, rivalry suppression is generally "complete," with the non-dominant pattern rendered wholly invisible. At the same time, and somewhat paradoxically, perceptual suppression is very superficial when measured psychophysically. The threshold for detecting test probes presented in the perceptually non-dominant eye is only minimally elevated during this period of time. In other words, even minimal changes to the suppressed stimulus will instantly return this eye to perceptual dominance. As information presented to the perceptually suppressed eye is not completely lost, neither is information about the unperceived stimulus, which continues to impact the brain. In fact, careful measurements show that the temporal dynamics of BR alternation processes is largely determined by the suppressed, rather than the dominant, stimulus. This counterintuitive finding is in agreement with neurophysiological studies demonstrating that most neurons in the ►primary visual cortex (V1) continue to respond to a suppressed stimulus during BR. Perceptual suppression, it appears, does not significantly affect the responses of most neurons in this major area of the visual cortex. As discussed below, however, neuroimaging results in humans have reached a nearly opposite conclusion, and this puzzle is presently a topic of active research.

Interocular rivalry can be considered, more generally, a form of *bistable perception*, owing to the temporal alternation between two mutually exclusive perceptual solutions. While BR may seem unrelated to ambiguous geometric patterns that give rise to two competing perceptual interpretations (e.g., the famous ►Necker cube and the ►Rubin's Face vs. Vase, Visual Illusions), the shared temporal dynamics of their reversals are nearly identical. In fact, virtually all bistable visual phenomena share the same temporal dynamics, often characterized as a memory-less process that results in a long-tailed probability distribution of reversal times. In other words, the perceptual alternations during BR are for the most part completely unpredictable and spontaneous (although some limited voluntary control can be achieved with training).

Interestingly, it has been shown that the temporal dynamics of BR and other bistable visual phenomena are linked to several cognitive variables that seem to be unrelated at first sight. Switching frequency can vary by an order of magnitude between observers while remaining consistent within an observer over multiple testing sessions that are separated by weeks or even months (the perceptual reversal rate does seem to decline slowly with age). A large number of studies have attempted to link IQ and personality type to alternation rate with bistable figures and binocular rivalry, albeit with limited success. Although observers can improve their ability to control perceptual reversals with practice, it seems impossible for normal observers to inhibit reversals altogether. Neurostimulants, mood disorders, and certain meditative states can all impact the rate of reversal. Brain damage to the right frontal cortex has been shown to slow the reversal rate down, and in some cases even abolish perceptual switching. The connection between the diverse variables affecting the temporal dynamics, and processing of sensory stimuli, is by no means clear, but the general influence of these variables may hint at the possibility that perceptual alternation is initiated outside the sensory domain. This hypothesis is strongly supported by neuroimaging data showing activation in the frontal and parietal cortex associated with spontaneous perceptual reversals.

The vanishing of salient patterns in BR is closely related to that in phenomena that do not require local conflict between the two eyes, such as the inappropriately termed *monocular rivalry* and other illusions (i.e., "Motion induced Blindness," "Generalized Flash Suppression" and "Induced Perceptual Fading"). All of these similarly involve complete perceptual suppression of an otherwise easily visible stimulus that is shown to both eyes or against a blank background in the other eye. While not yet fully understood, these illusions seem to rely on other, more global types of visual conflict and are generally limited to a very specific set of stimuli.

It is the fact that BR is the only paradigm that permits the suppression of virtually any visual pattern that has made it the centerpiece for the study of perceptual suppression. It is possible that this unique quality is related to its relevance in natural vision, as binocular

vision in a cluttered 3-D environment involves zones of interocular discrepancy, including a vast zone outside of so-called ►Panum's fusional area where there is no interocular correspondence at all. Under these conditions, the brain is often forced to choose one eye's view while completely suppressing the other's. However, remarkably little is known about the role of BR in natural vision, and this real-world account of the origins of binocular rivalry remains speculative.

The neural mechanism underlying both the alternation and maintenance of a perceptually dominant rivalry state have been explored using functional imaging and electroencephalography techniques in humans, as well as single neuron and local field potential recordings in laboratory animals and epileptic patients. The importance of these studies lies in the fact that understanding BR has direct implications for our understanding of how a percept gets established and supported in the brain. The only factor that is changing over time during rivalry is the perceptual experience itself. Thus, any neuronal mechanisms that co-fluctuates with the changing visual impressions are likely to be linked to the perceptual level rather than to sensory processing. It follows that by gaining insight into the neuronal mechanisms of BR, we will also learn about the brain processes underlying visual perception in general. All studies unanimously agree upon the fact that there are widespread activity changes throughout the brain at the moment of a spontaneous perceptual reversal. Disagreement exists, however, between imaging and single-unit data on the role of the earliest stages of cortical processing. In particular, it has been shown that single neurons in the first stages of visual processing such as the ►lateral geniculate nucleus (LGN) in the thalamus or the primary visual cortex (V1) show none or minimal correspondence with the perceptual state. This is at odds with several human neuroimaging studies that have reported hemodynamic responses in the LGN and V1, which are closely coupled to the visibility of a pattern during rivalry. Recent data hints at a resolution of this apparent conflict by demonstrating electrical signal changes in V1 that are likely to be caused by recurrent activity from other brain areas rather than being generated by a local population of neurons. This finding unifies theories about a limited role of V1 for binocular rivalry with other studies that suggested its involvement. Yet, much remains to be learned about the distributed networks that give rise to the alternating perceptions during binocular rivalry and vision in general.

The phenomenon of BR has always attracted students of diverse disciplines. It has been used as a tool to study the human unconscious, to assess cognitive abnormalities, and to learn more about binocular vision and perception in general. Its complex temporal dynamics have invited comparisons with earthquakes, stock prices and mammalian sleep patterns. It has served as an unlikely but important common ground for philosophers, biologists, psychologists and physicists, who all seem captivated by the implications for subjective experience. While a great deal is known about BR, it is, perhaps surprisingly, the big picture questions that are the most contentious. With technical advances in neurophysiology and imaging, passive-correlational approaches are slowly being complemented by causal manipulations (such as electrical or pharmacological brain stimulation). Binocular rivalry has been and continues to be a vital and fascinating paradigm for the study of sensory processing and visual awareness in the brain.

# Binocular Vision

Ralph D. Freeman
Vision Science, School of Optometry, Helen Wills Neuroscience Institute, University of California, Berkeley, CA, USA

## Synonyms

Coordinated visual processing through both eyes, coordinated dichoptic processing, neurophysiological mechanisms, binocular correspondence, far and near cells, position and phase disparity

## Definition

Binocular vision is a process by which signals from left and right eyes are combined to produce a fused image of visual space. This is a necessary condition for stereoscopic depth discrimination.

## Characteristics

### Overview

Evolution has created a variety of species with multiple eyes. But two eye species predominate. In order to achieve binocular vision, the visual fields of the two eyes must overlap extensively. There is a wide range of degrees of overlap. In general, animals such as rabbits have widely spaced eyes with minimum overlap

of left and right images. But their visual field range is very wide permitting early detection of a predator. The fusion of overlapping visual fields for animals with frontally positioned eyes provides a basis for ►stereopsis as illustrated in Fig. 1.

A subject views three vertical bars, two of which are in adjacent positions at the same distance from the observer. The third bar (red) is closer to the observer, as illustrated. A top view of the object to image condition shows the different image patterns on the ►retina of each eye. Since each eye has a slightly different view of the three vertical bars, the image patterns on left and right eyes are dissimilar. Specifically, the angle between the closer bar (red) and the central distant one (blue) is larger for the right compared to the left eye. This is depicted by the images on the lower right in which linear distances are represented by angular subtense. In this case, $\alpha_R$ and $\alpha_L$, are the angular distances between right and left eye images of two of the three bars. This difference is called retinal or ►binocular disparity [1]. It is the necessary and sufficient condition for stereoscopic vision, which has been studied in a wide range of theoretical, behavioral, and physiological investigations.

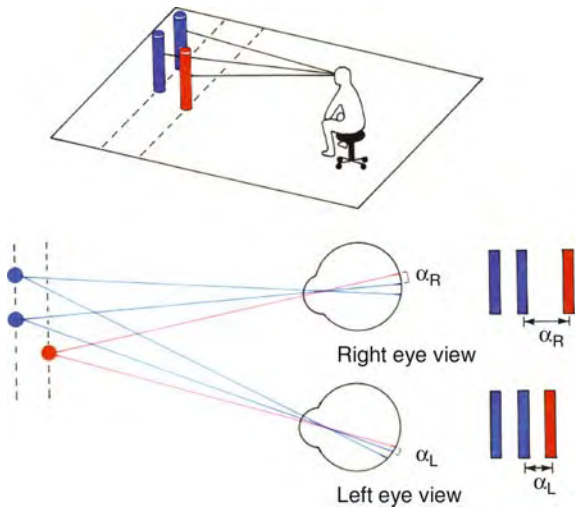
## Theoretical

The required condition for stereopsis, binocular disparity, is problematic because the process of fusion of left and right eye images is not straight-forward. The reason for this is that the visual system must eliminate false targets in order to obtain the correct depth plane for fusion. This problem is illustrated in Fig. 2.

There are six objects in visual space, depicted as squares numbered 1–6 in Fig. 2, which may be fused in different combinations that represent the depth planes illustrated by the dashed lines in the figure. However, only one depth plane, the solid line, is correct. This plane is defined when objects 1 and 4 (yellow) are fused by the visual system. Other combinations, 2 and 5, and 3 and 6, will also define the correct plane. But all other combinations will produce false target planes. A theoretical consideration of this problem was put forward to account for how this process may occur. It involves a trade-off between disparity range and resolution. The theoretical solution to the correct fusion problem is a four-step process. First there is a match in image coarseness for left and right eyes. Second, the coarse channels activate ►vergence eye movements, which guide fine channels to correspondent positions. Third, correspondence between left and right eye images in then fixed. Fourth, a depth map is then embedded in ►memory, which assists the fusion process. The entire process means that accurate stereopsis is a coarse-to-fine process [2]. Recent neurophysiological experiments provide data that are consistent with this hypothesis [3].

## Behavior

Stereoscopic vision is one of the finest facilities that the eye or any sense organ exhibits. The resolution of ►stereoscopic acuity is extraordinarily high. An example of this precise function is illustrated in Fig. 3, which shows the dimensions involved in the simple act of threading a needle.

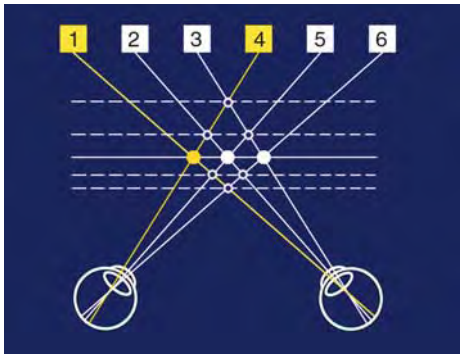


**Binocular Vision. Figure 1** Viewing condition for binocular disparity. A person views three vertical posts, two of which (*blue*) are in a single distance plane and the third (*red*) is closer to the viewer. Geometrical relationships from a top view are illustrated which shows the angular subtense for left and right eyes ($\alpha_R$ and $\alpha_L$) of the differences in images for the three vertical posts. The same angular distance differences are shown in vertical depictions of the images of the posts.

That process is depicted on the left of the figure. On the right side, the approximate dimensions are given. A working distance from the head of the needle to the eye is around 50 cm. The opening in the needle into which the thread fits may be as small as 0.2 mm. A standard distance between the two eyes is 6.5 cm. For these dimensions, the angular subtense of the opening of the needle head is 10 s of arc. This is an exceedingly small space but the standard human visual system is able to detect it successfully to enable threading of a needle.

## Neural System

A great deal of data have been collected on various behavioral aspects of binocular visual performance [4].

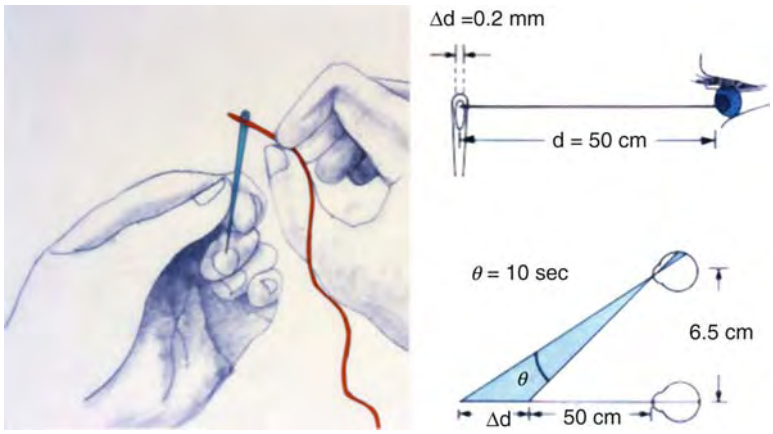


**Binocular Vision. Figure 2** Illustration of the ►binocular correspondence problem. Five depth planes are illustrated for binocular viewing. The correct plane is represented by a solid line and the dashed lines depict incorrect depth planes. The numbered squares (1–6), are points in object space for which different combinations yield different depth planes. In this case, the correct combination is squares 1 and 4.

The neural basis of that performance has also been investigated. The original study was conducted in the cat's visual cortex where it was determined that there were neurons apparently tuned specifically to different distances in visual space [5]. Later, awake behaving monkeys were trained to respond to specific distances. Simultaneously, neurons were studied in the ►primary visual cortex (striate cortex, area V1) in order to ascertain their response properties while monkeys viewed different distance planes [6]. The experimental arrangement is illustrated in Fig. 4.

A fixation point is viewed via a beam splitter such that it is superimposed on a stimulus display. The position of the receptive field (►Visual cortical receptive fields) for the cell under study, that is the territory within which a neuron is responsive to visual stimuli, is also shown on the display. The resulting populations of neurons studied provided categories of response properties as shown in Fig. 5.

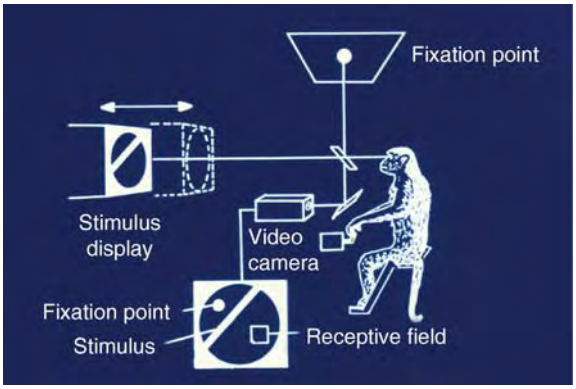
Four categories are shown. On the left side of the figure are two types of responses, tuned excitatory and tuned inhibitory. These cell types are excited or inhibited by a narrow range of stimuli at the fixation plane. The other two types, on the right, are excited by visual stimuli further or closer, respectively, than the fixation plane. For the opposite distance, these cells are suppressed. These are termed "far" and "near" cells, which correspond to uncrossed and crossed disparities, respectively. In the original study, these cell types were considered to be comprehensive [6]. In subsequent work, additional categories were added [7]. These are based on the notion of a discrete set of cell types rather than a continuum, which may be more appropriate. In any case, the original categorization was based on the idea that binocular disparity is encoded by relative position differences between right and left eye receptive fields.



**Binocular Vision. Figure 3** Dimensions involved in the threading of a needle. A typical viewing distance of 50 cm is used to illustrate this fine sensory task. A needle opening of 0.2 mm for an interocular distance of 65 mm corresponds to an angular distance of 10 arc s. This is much finer than a standard visual resolution task.

An alternative idea is that receptive field position between the two eyes is constant but the shape of one receptive field is different than that of the other [8]. The difference in these two schemes is depicted in Figs. 6 and 7.

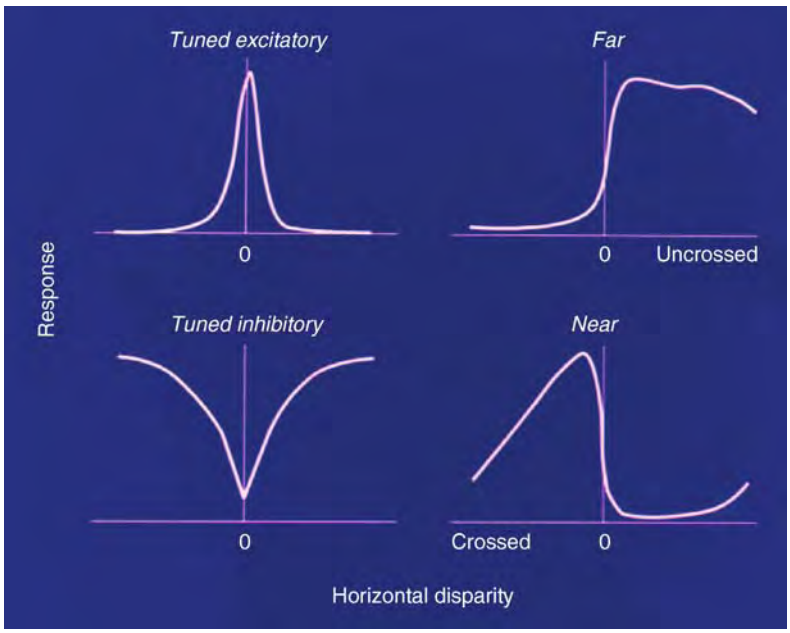
In Fig. 6, both eyes observe a target at the center of the plane of fixation. The images are represented by Gabor functions, white and yellow for left and right eyes, respectively. Planes closer and further than the fixation distance have conjugate images represented by blue and red Gabor functions, respectively. In this case all images are depicted by identical Gabor functions. Differences in binocular disparity occur via shifts in positions of these functions. The alternative idea is represented in Fig. 7.



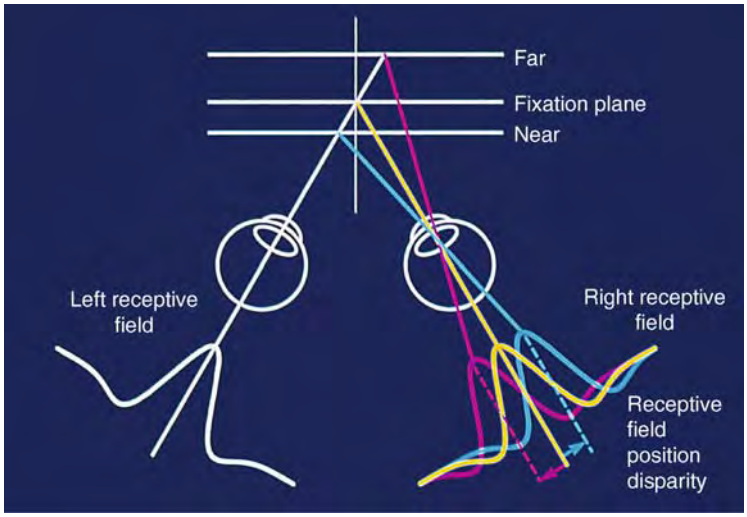
**Binocular Vision. Figure 4** A behaving monkey responds to targets at different depth planes. The monkey fixates a target and visual stimuli are presented at different depths. As the monkey performs behaviorally, neurons in visual cortex are recorded.

As in the previous case, distance planes are depicted which represent near, far, and fixation plane conditions. However, in this case, the positions of the receptive fields are superimposed for the three conditions. The internal shapes of the receptive fields, however, change which can be specified as a relative difference of phase in the Gabor functions. In this manner, the near and far distance planes may be encoded, as illustrated in the figure, not by position but by internal receptive field structural differences between the two eyes.

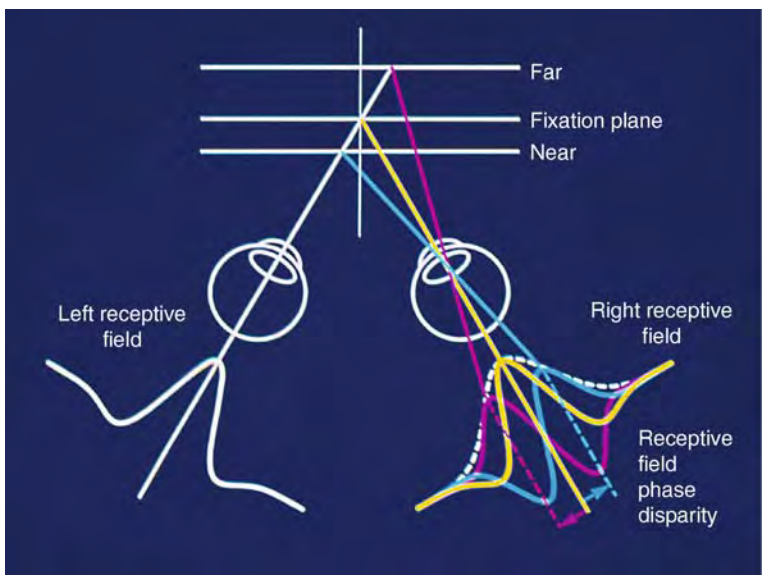
There are thus two basic mechanisms for encoding binocular disparity to enable depth processing. To determine the relative roles of these two mechanisms, it is necessary to study them both in a single investigation. This has been done by mapping left and right eye receptive fields in the primary visual cortex in order to estimate disparities by both position and phase encoding. The general finding is that position disparities are limited to small values so that large disparities are not



**Binocular Vision. Figure 5** Categories of tuning curves are depicted for neurons in the primary visual cortex. The two examples on the left are for cells that respond only when the visual target is at the plane of fixation. The cells are excited (*upper*) or suppressed (*lower*). Examples on the right respond to visual targets further away or closer than the fixation plane (upper and lower examples, respectively). These conditions represent uncrossed and crossed binocular disparities in upper and lower panels, respectively.



**Binocular Vision. Figure 6** Position binocular disparity. For this situation, receptive fields are represented by Gabor functions. Differences in far and near positions relative to the fixation plane are depicted by changes in the positions of the Gabor functions relative to that for the fixation plane. So, far (*red*) and near (*blue*) are shifted to the left and right, respectively.



**Binocular Vision. Figure 7** Phase binocular disparity. This is the same situation as that of Fig. 6 only the Gabor functions have different phase values. The one for the fixation plane remains as before with a phase angle of 0° (*yellow*). Far and near functions have phase angles near 90° (*red*) and 270° (*blue*). The Gaussian envelope for these conditions is centered at 0° (*dashed curve*).

encoded. On the other hand, phase disparities cover a wide range of disparities. In addition, phase disparities depend on orientation and spatial frequency of visual stimuli in ways that are consistent with a binocular encoding mechanism [8]. This work shows that binocular disparity is encoded mainly via a phase disparity mechanism. But position disparity may be important for neurons with high spatial frequency selectivity. These cells are constrained to small phase disparities.

The evidence that phase encoding plays a prominent role in the binocular apparatus forms the basis of a disparity processing system. In this model, stereoscopic depth information is encoded and transmitted according to a hierarchical series of transformations whereby

information from both eyes is combined in the visual cortex. In this process, the first stage of transmission from early visual pathways is to a specific neuron type, the *simple cell.* Depth information at this stage is encoded by a process based on differences in internal receptive field structure between the two eyes as noted above. The next stage involves transmission to second-order neurons, *complex cells,* which determine depth information independent of variations in the positions of visual objects (Visual cortical receptive fields). The ideas associated with this process are considered in previous reviews [9,10].

## Definition

Biofeedback refers to both scientific and clinical procedures. In the former context, biofeedback is synonymous with ►operant conditioning. When used in a clinical context, biofeedback is often used broadly to describe a wide range of psychological and physiological methodologies and interventions. In this essay the term will be limited to its scientific usage.

## Characteristics

### Historical Background

There has been almost 2000 years of research, theory and speculation about the organization and regulation of the autonomic nervous system. Of particular relevance to this essay are the notions about the extent to which individuals are conscious of their autonomically mediated responses, and the extent to which those responses are subject to voluntary control. The nature of the sympathetic ganglia intrigued investigators for hundreds of years. At one time it was believed that the ganglia were independent of the central nervous system; however, as it became clearer that the ganglia were connected to the spinal cord, ideas about its functional role changed [1]. For example, in the seventeenth century, Willis introduced the concepts of voluntary and involuntary movement, and proposed that visceral sensations were typically unconscious; however, they could become conscious if they were strong enough. In the eighteenh century, Johnstone proposed that the ganglia intercepted and prevented determinations of the will from reaching various organs. And in the nineteenth century Bichat introduced

the notions of organic and animal life, concepts, which exist today in the distinctions between visceral and somatic functions, respectively. By the end of the nineteenth and beginning of the twentieth centuries, autonomic function became linked to emotional behaviors through the theories of James, Lange and Cannon. Pavlov and his colleagues introduced the question of behavioral control of autonomic function and showed unequivocal evidence that autonomically mediated responses could be elicited as part of a learned pattern of behavior. In addition, it should also be noted here that among various Eastern religious traditions, (for example, Transcendental Meditation) it has been reported that many practitioners are able to demonstrate considerable skill at controlling viscero-motor behaviors. None of these studies directly address the question of whether visceral responses can be emitted voluntarily, or whether these responses are concomitants of somato-motor behavior. That question is at the heart of biofeedback of autonomic responses and will be addressed in the next section.

## Basic Research

The most robust studies of autonomic biofeedback have used animal models. In the natural environment, many mammalian species have been observed to mark their territories with their urine: a behavior pattern that certainly meets the criterion of learned, emitted behavior. In formal, laboratory studies non-human primates have been trained to emit blood pressure or cardiac responses to avoid electric shock [1]. Monkeys have been trained to decrease and increase their heart rates reliably, and to maintain this control over 15 min or more. In these experiments, the contingencies were signaled by different colored lights; however, the feedback and ►reinforcement was identical in both conditions.

Several studies have been carried out to show that animals that were trained to modify their heart rates could do so, even in the face of a stimulus that would elicit an opposite cardiac response. In one such study, animals that were trained to lower and raise their heart rates to avoid tail shock were challenged by infusions of nitroglycerin or phenylephrine, which elicited conflicting, baroreceptor-induced changes in heart rate. These trained animals consistently attenuated the elicited baroreflex (that is, the slope of the line measuring the change in heart rate per unit change in systolic pressure) [2]. In another study, it was shown that animals that were operantly conditioned to slow their heart rates could inhibit the tachycardia elicited by electrical stimulation in the hypothalamus [3].

It has also been shown that the cardiac response to exercise can be emitted independently of any reflexes. It has been shown that dogs, which are classically conditioned (►Classical conditioning) to exercise by walking on a treadmill, will increase leg blood flow in response to the conditional stimulus – that is, prior to the onset of the exercise, itself. Furthermore, if the animals are trained to discriminate between two conditional signals, one indicating a higher level of exercise than the other does, the animal will emit a greater blood flow response during the foreperiod of the higher-level cue [4]. This study showed that the anticipatory responses to exercise (both somato-motor and cardiovascular) could be conditioned. Biofeedback studies have extended that finding to show that operant training can modulate the regulation of the cardiovascular responses to exercise. Monkeys were operantly conditioned to exercise (lift weights) to avoid a tail shock. They were then operantly conditioned to slow their heart rate to avoid the identical shock. The two behavioral contingencies were signaled by different sets of cues. When the animals were performing the two behaviors reliably, they were taught to perform both tasks at the same time. Thus, the animals had to lift weights to avoid tail shock, and they had to attenuate the tachycardia of exercise to avoid tail shock. All performed highly reliably. In fact, some of the animals were able to attenuate the tachycardia of exercise, even while lifting the weights, more often than during control sessions when they were required to lift weights without the cardiac contingency [5]. In order to identify the autonomic mechanisms underlying this skill, these studies were repeated with three of the animals at times when they were receiving any of three autonomically active drugs: (i) atenolol, which is a cardiac-specific β-blocker; (ii) atenolol and prazosin, the latter being an α-adrenergic blocker; or (iii) methyl-atropine, which is a vagal blocker that does not cross the blood-brain barrier. Thus, these drugs completely blocked one or another efferent limb of the autonomic nervous system. None of the drugs interfered with performance. No matter which drug the animals received, they were able to attenuate the tachycardia of exercise consistently and reliably [6]. These exercise studies also address a poorly defined concept that has existed in the exercise physiology literature for many years: the notion that some aspects of exercise behavior are under "central command." In an experiment combining the exercise training procedure just described, animals were trained to exercise while their brains were electrically stimulated. A detailed analysis of the brain stimulation studies identified some areas that probably mediated central command [7].

Much of the work in biofeedback has been directed at clinical endpoints. Thus, it should not be surprising that many of the studies have been carried out with normal human subjects or patients. This review will be limited to clinical studies in which biofeedback met the operant conditioning criterion; a more complete review can be found in [1].

Bleecker and Engel [8] studied a group of patients with atrial fibrillation. In these patients the normal

cardiac rate control mechanism – modulation of the depolarization of the atrial pacemaker – is absent. Thus, the ability of these patients to regulate their ventricular rates must have been expressed either at the level of the atrio-ventricular node, or at the ventricle itself. They also reported success in training a patient with Wolff-Parkinson-White syndrome, a cardiac dysfunction characterized by accessory conduction pathways that bypass the atrio-ventricular node and often by uncontrollable tachyarrhythmia. The patient learned to produce normally and aberrantly conducted heart beats both in the laboratory, and subsequently in the clinic [9]. Burgio, Whitehead and Engel [10] trained patients with so-called, uninhibited urinary bladder contractions, to inhibit these contractions. Since the urinary bladder has only autonomic innervation, the ability to emit these responses could only occur through direct autonomic action.

### Commentary

From a scientific perspective, the findings from these studies of autonomic biofeedback are important because they underscore the integrative function of the nervous system. The autonomic nervous system certainly has unique features; however, it is not isolated from the overall regulatory conditions explicit in neural control systems. The fact that autonomically mediated responses can be brought under voluntary control through appropriate training conditions, is a strong testament to the role of the nervous system in enabling organisms to adapt to their environment. The clinical significance of such control – for example, in the control of the urinary bladder – is a demonstration of such adaptability. The findings also highlight an important distinction between anatomic and functional properties of the nervous system. While classification based on structure is rational, one must be careful not to equate structure with function.

### Definition

Bioinformatics refers to the computational analysis of complex biological datasets. Bioinformatics is a broad term, covering the analysis of DNA, RNA (cDNA) and protein sequences, the management of data from microarray (►microarrays) and proteomics experiments, structural biology, imaging techniques, protein binding studies and large scale mutagenesis screens, to name but a few. Given the vast amounts of biological data now stored in databases worldwide, the computational analysis of new data is now just as important as its generation at the bench.

### Characteristics

Bioinformatics is an essential part of the biological revolution of the last few decades. The development of high throughput methods for DNA and protein sequencing, followed by the completion of various genome projects, and, latterly, functional genomics and proteomics, has meant that we have been literally swamped with information. Development of sophisticated bioinformatic tools has allowed us to manage these data [1,2].

## Sequence Analysis

DNA sequencing was first developed using chemical methods by Maxam and Gilbert in 1973. However, the use of dideoxynucleotide chain terminators by Fred Sanger and colleagues allowed faster and simpler generation of sequence data; this is the method largely used, with modifications, today. Initial generation of DNA sequence proceeded slowly, but technological improvements in both the core method and in protocols for template preparation (cloning segments of foreign DNA into microorganisms and the development of the polymerase chain reaction (PCR) in particular) meant that DNA sequence data soon started to accumulate at a logarithmic rate. For example, GenBank, the repository for sequence data, started life in 1962 with 606 sequences (680,338bp). The same database contained over 52 million sequences, representing over 56 billion base pairs of DNA, by the end of 2005 (http://www.ncbi.nlm.nih.gov/Genbank/genbankstats.html). Numerous genome sequences have been compiled in the last few years; most notably, with respect to study of the nervous system, the eukaryotic genomes of the yeast (*Saccharomyces cerevisiae*), the worm (*Caenorhabditis elegans*), the fruit fly (*Drosophila melanogaster*), the mouse (*Mus musculus*), the rat (*Rattus norvegicus*), the chicken (*Gallus gallus*) and humans (*Homo sapiens*) are now complete. In addition to genomic sequence data, protein sequences, both determined directly and inferred from nucleic acid sequence, and RNA derived cDNA sequences are also stored in various databases such as GenBank, EMBL DDBJ, SWISSPROT and RefSeq ([2], Table 1).

Collation of genome sequence with sequence from ►ESTs, genes, sequence repeats and other features has allowed the annotation of genomes, which can be examined using genome browsers such as Ensembl or UCSC. Sequence analysis tools (e.g. ►BLAST), can be used for identifying similarities between different DNA and protein sequences. Evolutionary sequence comparisons can be carried out using ClustalW, Phylip, MultAlign and others, which identify highly conserved regions or domains within a gene or protein family, and can be used to build evolutionary trees, which assess the relationships between groups of species (see Table 1 for further bioinformatic resources). Such studies can help when forming hypotheses with regard to the function of unknown proteins.

## Gene Expression and Function

Curating, compiling, annotating and comparing sequence data is a challenge that is being met, thanks to improvements in computing power, the growth of the Internet and the development of genome databases and browsers ([1,2], see Table 1). However, we are left with the difficulty of interpreting function; even years after the completion of the first human draft genome sequence, many of the genes are still completely functionally uncharacterized. Expressed regions can be identified via comparisons between ESTs and the genome sequence. In this regard, large scale EST sequencing projects have been invaluable, as, owing to the presence of introns, the identification of coding sequences in eukaryotes is no simple matter [3–5]. Alignment of ESTs with the genome sequence has allowed us to identify the intron–exon structure and expression profiles of many previously uncharacterized genes; this information is available using the genome browsers. Furthermore, many large EST libraries derived from most tissue and organs have been sequenced and databased in recent years (UniGene, Riken, NIA, Table 1), allowing not only the annotation of expressed regions of the genome, but also the compiling of estimated full length gene sequence via so-called contigs built from contiguous ESTs. UniGene can be used to provide estimates of gene expression patterns, based on the tissue(s) of origin of ESTs from the same gene.

Non-coding regions can be important as well, however, as they contain regions which control gene expression, such as imprinting control centers, enhancers and promoters. Various computational tools, such as GRAIL and FGENES, are available that can be used to query sequences for likely exons, splice sites, promoters, polyA sites, CpG islands and other sequences of interest (Table 1); again, comparisons between conserved, homologous sequences derived from closely related species can be extremely useful.

## Microarrays, Large Scale Expression Studies

The development of microarray technology has allowed the large scale generation of expression data on an unprecedented scale. Microarrays were initially developed using chips upon which EST derived cDNA fragments were printed; however, the oligonucleotide arrays developed by Affymetrix (Santa Clara, CA, USA) have been just as widely used. Both can bind to labeled cDNA derived from cells or tissues of interest; the expression profiles of the genes on the array can thus be determined. The analysis of array data, however, is computationally intensive. Images scanned from array experiments are first processed using an image analysis programme that converts spot intensities into numerical values and calculates background (e.g., Spot, ImaGene). These raw data are then statistically analyzed; at this stage, differentially regulated genes can be identified. Finally, clustering analysis can be used to identify genes with similar expression profiles. Numerous packages are available for this purpose; lists are given on sites such as MicroArray World or Statsci.org (see Table 1). Since the introduction of MIAME standards (MGED site [6]), which aim to provide the minimum information about a microarray experiment in order to reproduce it fully, published data are also usually databased and publicly accessible. Results from large expression studies are

often made available online in a searchable manner (GEO and ArrayExpress, Table 1). Further methods used to assess gene expression profiles include large scale cDNA sequencing (see above) and serial analysis of gene expression (SAGE), which combines DNA based molecular tagging, cloning and sequencing to assess gene expression profiles (SageNet [7], Table 1).

## Protein Expression and Structure

RNA expression patterns, while easier to assay, do not always tally with final protein expression levels; for example, the control of gene expression, in many cases, is at the level of translation. Therefore, it is often useful to be able to assay large scale changes in protein expression levels, as well as those for RNA. Therefore, advances have been made, in both antibody based protein arrays and in imaging and analyzing 2D gels. Furthermore, the determination of protein crystal structures has become more high-throughput; as more structures become available, the structures of related proteins can be estimated computationally. Comparisons of protein secondary and tertiary structure can give valuable information with regard to likely subcellular localizations and possible functions. A large number of online tools are now available for the study of protein structure and prediction of possible function (Table 1).

## Mutant and Phenotype Databases

However, expression levels, while interesting, are often entirely uninformative with regard to gene function. The most useful indicators of gene function have undoubtedly been genetic mutants. Naturally occurring, often disease causing mutations have been documented for generations; however, the technology with which to map them on a large scale became widely available in the 1980s, initially using polymorphic markers, ►RFLPs, assayed by Southern blot. These were replaced by more informative ►microsatellite markers, assayed by PCR, in the early 1990s. Linkage analysis was then used to correlate the transmission of the mutant allele with mapped polymorphic markers. Inheritance of the mutant phenotype with a mapped polymorphic allele could be given a statistical score, or LOD score. A LOD of greater than 3 is considered statistically significant evidence of linkage. Multiple microsatellite markers in a given region can be assessed, and haplotypes generated, in order to more accurately pinpoint the location of the disease gene. Generation of a dense "marker map" of the human genome, the Genethon Map (CEPH site, Table 1) preceded the actual genome sequence and allowed the mapping and subsequent identification of thousands of genes that, when mutated, cause disease in humans. The Online Mendelian Inheritance in Man (OMIM) database maintains records of human phenotypes, and, where known, the location and/or identity of disease genes. Similar databases are maintained for animal models (OMIA, MGI, SGD, FlyBase, WormBase). Searchable linkage marker maps for the more widely used model organisms are also available (Table 1).

The functional study of human mutations can be taken further in animal models. The development of ►gene targeting has been invaluable in often confirming that mutation of a given gene results in the expected phenotype, and in modeling the mechanisms by which a mutation causes disease. The development of ►conditional mutagenesis has refined this process further, allowing genes to be turned on or off in specific tissues or at specific times in development. ►ENU mutagenesis is a method of introducing point mutations into the genome in a high throughput manner and has been used widely [8]. Plans to mutate every gene in the mouse genome, both by targeting and ENU, are underway and are being databased accordingly (Table 1). Similarly, phenotype databases, catalogues of available mutant mice, mutated ES cells, targeting vectors and phenotypes are now available online (Table 1, [9]). Single nucleotide ►polymorphisms (►SNPs) are being catalogued in order to determine the relationships between common genetic variants, predispositions to common disorders and differing responses to therapeutic pharmaceuticals. Advances in imaging have also taken place. An increasing number of databases and bioinformatic resources are becoming available with regard to virtual maps of the brain and nervous system. However, compiling these data in a searchable format is still an enormous challenge ([10], Table 1).

### The Interactome and Systems Biology

The wealth of pre-existing data with respect to protein-protein and protein-nucleic acid interactions and other functional data are being collated to unravel metabolic pathways. Databases such as BIND and DIP are collating information from previously published work and building searchable databases that catalogue how a given gene fits into previously established metabolic or signaling pathways ([2], 2003, Table 1). Data from individual gene studies and from large scale studies such as those involving yeast 2 hybrid screens are collated with a view to building models of the interactomes of various cell types. ►Systems biology approaches can then be used to collate the data from individual functional experiments, genomics, proteomics, phenomics etc. and build mathematical models that can mimic the behavior of cellular biochemical networks. Integration of information and training of models should allow predictions of treatment outcome and drug associated toxicity, which would be of great value to medicine [7].

### Overview

Advances in biology have led us, in 50 years, from the discovery of the structure of our genetic material, to the complete decoding of our genome and beyond. The major challenge is to interpret the structures and functions of the genes encoded in the genome. Fortunately, developments in information technology have led to rapid advances in bioinformatics, allowing the amateur bioinformatician easy access to a wide variety of research tools online (Table 1). Bioinformatic and systems biology approaches to analysis of currently available data will be essential to further progress, given the increasing complexity of the knowledge base.

## Biological Clocks

### Definition

Basis for periodic behavior under stationary environmental conditions. A genetic basis of biological clocks was discovered in the first halve of the twentieth century. Currently the molecular bases are studied. The most important clocks have periods of about a day (circadian), a lunar cycle (circalunar) or a year (circannual).

## Biological Databasing

## Biological Information Processing

►Bioinformatics

# Biological Motion Processing

## Definition

This term is used in the literature in two distinct ways. (i) "Biological" refers to the stimulus, specifically to patterns of motion characteristic of biological systems such as a walking human figure. There is evidence that in the human brain a region of the superior temporal sulcus is specialized to process such biological motion. (ii) "Biological" refers to the processing, so as to draw a distinction between the way in which visual motion is processed in animal brains and schemes for processing image motion in artificial computational or robotic systems.

## Introduction

The processes of life are dynamic, varying in response to both internal and external conditions. These dynamic variations may be arrhythmic, without regular occurrence, or rhythmic, marked by regular, cyclic changes (see ►arrhythmicity/rhythmicity). Rhythmic changes vary over a range of natural environmental ►cycles. Regular, predictable changes in day and night, the tides, the moon and the annual cycle of seasons over the course of evolution have shaped the temporal organization of life on Earth. ►Chronobiology, the study of these biological rhythms, has revealed that the timing of the rhythms of life is woven into the genetic fabric. Timekeeping is endogenous, marked by internal biological ►clocks, whose cycles are shaped, but not driven, by environmental signals. The regular, repeated nature of biological rhythms provides a time base upon which other internal processes become entrained. This enables organisms to anticipate predictable environmental features with which to align appropriately their physiology and behavior.

The most thoroughly studied biological rhythm is the ►circadian cycle (from the Latin *circa*, around + *diem*, a day), which is about 24 h in length. Circadian cycles that repeat with daily regularity are characteristic of all eukaryotic organisms, and some prokaryotes (e.g., *Cyanobacteria*, a blue-green algae that is a major component of Pacific Ocean plankton). In the absence of environmental cues, circadian rhythms repeat over a ►period that is about, but not exactly, 24 h. This small, but significant, mismatch between the internal circadian and external solar cycles is evidence that circadian rhythms are endogenous, and not driven by periodic external cues. Circadian rhythms characterize virtually every biological process: changes in the transcription of digestive enzymes in the liver, the release of growth hormone from the pituitary, the strength in large muscles of the forearm, and in global brain state and behavior that characterize the ►sleep-wake cycle.

This synopsis first will review circadian rhythms: basic timekeeping processes, ►cellular clocks and ►clock genes, temporal orchestration of the body clocks, regulatory signals, circadian systems in seasonal adaptation to the changing world, and ►circadian sleep phase syndromes. Next, it will consider sleep and wakefulness: sleep-wake states, sleep regulation, mechanisms that generate sleep and waking states in the brain, and the effects of sleep-wake states on body systems. Lastly, future directions and opportunities of these highly active research areas will be highlighted.

## Circadian Rhythms

### Circadian Fundamentals

We know from casual observation of the natural world that organisms perform different behaviors at different times in the day–night cycle. The wolf hunts for prey in daytime, searching for food while the owl sleeps. When night comes, their behaviors reverse: the wolf is sleeping while the owl hunts. These ►nocturnal/diurnal differences in the timing of behaviors enable animals to compete effectively in different niches for the basic necessities of life, e.g., acquisition of nutrients, mates and shelter, and to partition restorative processes and growth to the alternate phase of the cycle. When these behaviors are quantified over time, they are observed to recur each day in a rhythmic pattern, with peak and trough occurring over the day–night cycle at roughly the same time every 24 h. For crepuscular, twilight-active animals, two activity peaks, proposed to be driven by ►morning (M) and evening (E) oscillators, are evident [1].

Chronobiology has identified a core set of fundamental characteristics that are hallmarks of circadian rhythms. (i) Despite the tendency to think that daily rhythmic patterns are governed by the environmental cycle of light and darkness, these rhythms persist with regularity under constant conditions, or ►free-run, in the absence of timing cues from the environment. (ii) The period of the ►free-running rhythms, ►*tau* (►$\tau$), is significantly different from the solar cycle, which is invariantly 24.0 h. This period length is endogenous and bears a predictable relationship to diurnality or nocturnality. These relationships follow ►Aschoff's Rules under various constant lighting conditions [2]. For example, the free-running period in constant darkness is generally >24 h for diurnal animals and <24 h for nocturnal species. (iii) Circadian rhythms are precise in period and robust in amplitude. (iv) Circadian clocks show independency in the speed of circadian clock processes (compensation) for environmental variations, such as nutrients or temperature (see ►Circadian pacemakers – temperature compensation). Although the mechanism is unknown, contemporary models predict that temperature compensation emerges from two opposing and counterbalancing effects on the periodicity of the clock system [3]. (v) Circadian rhythms can be synchronized by appropriate extrinsic and intrinsic signals through a process termed ►entrainment.

## Cellular Clocks and Clock Genes

Circadian rhythms are expressed at the molecular, cellular, tissue, organ, organ systems and behavioral levels of organization. What is the basic autonomous timekeeping unit? Isolated single cells possess the intrinsic cellular mechanisms to generate regular, repeating circadian oscillations [4]. All cells within the body possess circadian clocks that tune the functions of the various differentiated types of cell to organismic state over the day–night cycle. However, tissue-level phenomena and communication among cellular clocks within and between tissues are necessary for organismic physiology and behavior to function in integrative, time-of-day appropriate ways [5].

Within the cell, timekeeping is governed by clock genes, whose action is necessary to generate the circadian cycle. Clock genes are any of a number of genes that interact with each other to form dynamic, autoregulatory ►feedback loops with a circadian period [6]. Both transcriptional activation and repression of clock genes cycle over a period of about a day. The first clock genes were identified by mutagenesis screens of *Drosophila* for flies with altered behavioral rhythms [7]. They were named Period, ►*Timeless* and *Cycle*, reflecting their effect on circadian behavioral rhythms. Homologous genes (*Period, Timeless* and *CLOCK*) were found in mammals, some of which could substitute functionally for fly homologs. Clock genes discovered initially encode transcription factors, a class of proteins that can either positively or negatively alter transcription of other clock genes. In addition, clock gene transcription factors can alter expression of ►clock-controlled genes, such that their transcription varies in a time-of-day-dependent manner. Clock genes have been identified that encode other types of proteins, as well. A major class of proteins encoded by clock genes cause critical post-translational modifications (PTMs), such as phosphorylation or ubiquitination, of the clock gene transcription factors and other substrate proteins [8]. Remarkably, a cyanobacterial protein, Kai, a tripartite protein kinase complex, oscillates with a period in the circadian range when provided with exogenous ATP in a cell-free system [9]. This finding suggests that, indeed, timekeeping may be invested in post-translational modifications of a few clock proteins. Very recently, small molecules, such as cADP ribose, which can regulate intracellular $Ca^{2+}$, also have been found to be key clock regulators [10]. Genes encoding proteins that regulate cADP ribose levels also would likely fulfill the criteria for clock genes. No doubt the classes of proteins encoded by clock genes will continue to increase as understanding of timekeeping mechanisms continues to expand.

## Orchestration of Body Clocks

In organisms with complex behaviors, circadian rhythms are orchestrated by discrete areas in the nervous system. With increased cephalization, regulation of circadian clocks throughout the body became centralized in the brain. In higher vertebrates and mammals, the ►suprachiasmatic nucleus (SCN) is key to circadian regulation. The SCN orchestrates the symphony of ►peripheral oscillators, the body clocks of mammals. Positioned at the base of the hypothalamus and directly above the optic chiasm, the SCN is central to other hypothalamic regions involved in regulating systems-level circadian rhythms in the sleep-wake cycle, feeding, drinking, body temperature, sexual functions and multiple hormones systems. The SCN comprises roughly 10,000 neurons that are among the smallest cells in the body (8–12 μm in diameter) and 3,000 glial cells [11]. The SCN is characterized by many intrinsic connections, but the functions of only a few are known. The SCN is highly peptidergic. Some SCN peptides contribute to synchronization among the SCN neurons (e.g., ►VIP), some are output signals to nearby hypothalamic regions (e.g., ►VP) and some contribute to ►gating responsiveness to input signals (e.g., ►GRP) [12]. Lesion and transplantation studies demonstrate that the SCN is necessary and sufficient to impart coordinated rhythms both to the brain and to circadian clocks of other cells and organs throughout the body. With the insight that the circadian rhythms of behavior,

physiology and metabolism are governed as ►multi-oscillator systems [13] that rely on the SCN for global synchronization, the search is on for ►clock-coupling factors. When discovered, these clock-coupling factors may have therapeutic potential for alleviating the adverse effects of ►internal desynchronization, the loss of synchrony between two or more circadian rhythms, which is caused by ►jet lag and ►shift work.

## Regulation of the Circadian System by Zeitgebers

A consequence of the circadian period being significantly different from 24 h is that, under constant environmental conditions, circadian rhythms drift away from the 24-h solar cycle over the course of days and weeks. This condition is called "free-running," and is found in some blind individuals, who pass in- and out-of-phase with day and night. Virtually all organisms ►entrain to the cyclic environmental conditions in the natural world. The circadian system relies on ►zeitgebers, time-giving cues, for adjustment to the solar cycle and other significant variables.

The most salient zeitgeber is environmental light. Special ►photoreceptor systems inform the circadian system of the presence of light in the environment. In organisms with translucent bodies, like *Drosophila*, light can be sensed directly by all cells with photoreceptive molecules. One such photosensor is ►cryptochrome, a molecular clock element. In higher vertebrates with large brains, a specialized ►photopigment, ►melanopsin, is localized in intrinsically photoreceptive ►retinal ganglion cells of the eye [14]. These photoreceptors are photon-counters, sensing the presence and intensity of light. Axons of the melanopsin-bearing retinal ganglion cells project directly to the SCN, forming the ►retinohypothalamic tract (RHT) [11]. This is the primary pathway by which light information reaches the SCN. The presence of light during the night is perceived by the melanopsin retinal ganglion cells and communicated to the SCN by neurochemical signals, glutamate and the peptide PACAP [15]. The input from these retinal ganglion cells changes the phase of the SCN, correcting for deviations of internal time with respect to day and night. The relation between the timing of the light signal and its effect on SCN phase is described by a ►phase response curve (PRC). This relationship is stereotypic: for all organisms, whether diurnal or nocturnal, it is characterized by a delay of clock phase when light is experienced in early night (correcting for a failure to reckon day as long enough) and an advance of clock phase in late night (correcting for an early dawn). ►Type 1 and Type 0 resetting describe the dependency of the response on *when* during the cycle the stimulus is received and the effect of *stimulus strength* on the rate of the phase-change in the circadian system.

Whereas light is the primary determinant of the phasing of circadian rhythms, including the timing of the sleep-wake cycle, many stimuli can entrain or modulate circadian rhythms. Beyond light, regularly occurring extrinsic stimuli can act as zeitgebers. Temperature cycles are effective entrainment signals for poikilothermic invertebrates. Social stimulation can entrain, especially when light is absent as in some blind subjects. Nutrient availability is a strong entraining stimulus when food is limited, either during the dry season of equatorial birds or experimentally induced in mammals (►food entrainment). Because the SCN drives circadian rhythms of feeding, the fact that under restricted conditions food can entrain indicates that that feedback loops communicate the timing of food availability to the SCN. Some retinal melanopsin cells also project to the ►intergeniculate leaflet (IGL) of the thalamus, which in turn projects back to the SCN via the ►geniculohypothalamic tract (►GHT) [16]. The IGL integrates information from >100 brain regions and transmits information regarding non-photic zeitgebers to the SCN via the GHT. A novel running wheel or the drug triazolam, a short-acting benzodiazepine derivative used as a sedative to treat ►insomnia, act on the SCN via this GHT projection. The IGL communicates with the SCN via ►neuropeptide Y (NPY) and enkephalins.

Intrinsic signals also can alter phasing of the circadian system. Emerging evidence indicates that the sleep-wake state is communicated to the SCN. ►Cholinergic brainstem signals from the sleep-wake system and the pineal hormone, ►melatonin, can feed back on the SCN to alter its phasing when sleep patterns are disturbed [17]. Eating more fat can shift the circadian rhythms, as well [18]. Furthermore, clock-controlled variables such as effects on locomotor activity by light and on core body temperature by posture and sleep, can enhance or attenuate a clock-controlled variable, phenomena termed ►masking (►positive, negative). Overall, the circadian system is finely tuned to align circadian rhythms appropriately with external and internal states.

## Circadian Regulation in a Changing World

In addition to night-to-day variations, the Earth undergoes long-term cyclic changes over the course of the year. Regardless of the latitude, seasonal changes in ambient temperature and/or rainfall restrict the availability of food. Animals anticipate the annual waning and waxing of nutrient poor or rich conditions by remodeling hormonal, physiological and behavioral systems. ►Seasonality occurs in systems that control energy balance and reproduction, as well as behavioral aggression and immune function. ►Hibernation, adaptive behaviors that allow animals to survive winter by minimizing exposure to the harsh conditions, is widespread in the animal kingdom [19]. Seasonal changes include ►circannual rhythms, which cycle over the course of the year and have a component that allows

animals to initiate preparative changes in body state in anticipation of the forthcoming fall and spring [20].

The progressive change in ►photoperiod, the relative length of day vs. night, is the most reliable predictor of seasonal change. This dynamic signal cues a range of seasonal changes in physiology and behavior and may modulate circannual rhythms driven by an endogenous clock with a stable period of about a year [21]. Photoperiod is encoded in the duration of the nightly signal of the pineal hormone, melatonin. Melatonin is the internal signal of darkness in the environment. It is synthesized and secreted at night in a circadian rhythm under the control a neural pathway from the SCN to the ►pineal gland, and nocturnal light rapidly and acutely suppresses melatonin. The melatonin signal is transduced by ►melatonin receptors, which have restricted distribution in brain and peripheral tissues. Where and how the melatonin signal of changing photoperiod is interpreted to induce the range of seasonal changes in multiple systems is under study.

### Circadian Sleep Phase Syndromes

Certain classes of sleep disorders are embedded in the circadian system (►Process C). These include ►Advanced Sleep Phase Syndrome (ASPS), ►Delayed Sleep Phase Syndrome (DSPS) and free-running circadian rhythms [22]. Advanced sleep phase syndrome (ASPS) has been reported in human families with an altered form of *Period 2*, in which a post-translational site is missing. This inherited disorder results in a life-long, fast-running circadian clock. ASPS is also seen in the elderly, where the melatonin profile is advanced. Sleep maintenance insomnia may be related. Circadian sleep phase syndromes can be assessed using sleep times and the ►dim light melatonin onset (►DLMO), which are early in ASPS and late in DSPS. They can be treated by exposure to bright light (2,000–10,000 lux) at appropriate light-sensitive points in the phase response curve (PRC) and low-dose melatonin upon night-time awakening. The phase angle difference between DLMO and mid-sleep reports the degree of circadian misalignment. Circadian misalignment of the melatonin profile is high in ►seasonal affective disorder (►SAD, seasonal depression), and may contribute to other circadian sleep phase and psychiatric disorders.

## Sleep and Wakefulness

### Sleep-Wake States

The primary behavioral states of organisms alternate rhythmically over the circadian cycle between wakefulness and sleep. Active behaviors necessary for sustaining life, such as acquisition of nutritional resources and reproduction, are accomplished during the waking state and require a net expenditure of energy. Sleep, which also is necessary for life, suppresses active behaviors while facilitating anabolic activities that restore energy levels and process experiences of the waking state [23]. Sleep behavior is marked by distinct species-specific postures, reduced sensitivity to external stimuli and rebound after deprivation. These traits define sleep in diverse species from flies to man. Sleep in birds and mammals can be subdivided into two distinct ►sleep states: ►non-rapid-eye movement (NREM) and ►rapid-eye movement (REM) sleep. ►Electroencephalography (EEG) in sleep states reveals distinct ►brain rhythms. EEG patterns during NREM sleep can be divided into four stages, with increasing amounts of ►slow wave activity (SWA). During REM or ►paradoxical sleep, EEG patterns resemble those of quiet wakefulness, but are associated with ►rapid eye movements (REM) and lack of tone in skeletal muscles. These changes in EEGs during sleep states are thought to report changes in synchronized cortical activity, although subcortical actions can modify these cortical activity states. In wakefulness, EEGs reveal distinct patterns of massed neuronal activity associated with the specific behaviors and the fully activated brain.

Why do we sleep? The answer to this most fundamental question remains elusive [24]. Studies of ►sleep phylogeny in mammals indicate that sleep stages are conserved, but show wide variations in sleep duration that correlate with body size and the energetics of food intake. Body mass is inversely related to mass-specific metabolic rate, such that metabolic rate is high in small animals and low in large. Carnivores and omnivores sleep more than predicted based on relative body weight. The strong correlation between high metabolic rate and longer sleep time suggests that "sleep need" may be based in metabolism. If this were the case, sleep could serve to reverse oxidative stress. Additionally, brain protein synthesis and neurogenesis increase during sleep. ►Dreaming, an altered state of awareness familiar to us all, is characterized by accurate simulation of experiential flow and contents and occurs during ►REM sleep. Possible functions that would increase adaptive fitness have been tied to this simulation process. During certain brain rhythms exhibited in ►slow wave sleep (SWS), neuronal patterns appear to repeat those observed during specific training sessions in the previous period of wakefulness. These observations together with ►microarray studies of gene expression suggest cellular and molecular associations between sleep and processes underlying memory formation [25].

### Sleep Regulation

Regulation of the complex set of state changes underlying sleep can be distilled into two fundamentals that your mother first told you: sleep when you are tired and nighttime is for sleeping. In other words, sleep regulation has a homeostatic restorative component and

a time of day component. These fundamentals were formalized in Borbély's ►two-process model of sleep regulation [23]. One process, ►sleep homeostasis (►Process S), is based on the observation that the need for sleep accumulates during wakefulness and requires sleep to be alleviated. The greater the sleep need, beyond a threshold, the greater the cognitive deficit and negative health consequences, and the more sleep it takes to restore the waking state. The circadian process (Process C) defines the thresholds between which Process S oscillates, and thus determines what times within the circadian cycle are permissive for sleep and waking. Superimposed upon these processes is the alternation between the two main sub-states of sleep, NREM and REM sleep, both of which show homeostatic and circadian features. These processes work in concert to maintain the temporal occurrence and duration of sleep and wakefulness within a range that enhances health and evolutionary fitness.

## Mechanisms of Wake and Sleep States

►Sleep-wake mechanisms are complex, emerging from actions and interactions of the many neural and neurotransmitter systems that generate wake, NREM (slow wave sleep, SWS) and rapid eye movement (REM), or paradoxical sleep states [26]. The waking state is defined by ►alertness level [27]. The ability to direct and sustain attention is enabled by cortical activation. Alertness levels vary over the course of the waking period and are affected negatively by ►sleep deprivation. Individuals exhibiting reduced alertness experience sleepiness and fatigue, negative effects on mood, cognitive impairment and decreased attention, which may reflect sleep processes intruding into wakefulness. Many brain ►arousal systems contribute to the waking state: monoaminergic neurons of the rostral pons, midbrain and posterior hypothalamus, neurons of the cholinergic brainstem and basal forebrain, dopaminergic neurons in the ventral tegmentum, and ►hypocretin/orexin neurons of the lateral hypothalamus. Neuronal activity in these arousal systems is characterized by low-voltage, fast-frequency cortical EEG patterns, providing a tonic level of brain activation that is manifest as behavioral alertness.

►Sleep generating mechanisms cause coordinated inhibition of these arousal systems, so that their level of activity decreases rapidly with the onset of sleep. This is accomplished through the action of three interrelated systems: (i) activation of neurons in the ►preoptic area (►POA) of the hypothalamus – sleep-active neurons of the ►ventrolateral preoptic nucleus (VLPO) and median preoptic nucleus (MnPN) that impose GABA- and ►galanin-mediated inhibition of arousal systems; (ii) modulatory effects of endogenous sleep-promoting factors, such as ►adenosine, cytokines, prostaglandins and growth hormone-releasing hormone; and (iii) SCN efferent signals, which may be both neural and hormonal, that control the timing of sleep generation via circadian changes in excitatory modulation of hypothalamic arousal systems and inhibition of the VLPO [28]. Activity in the monoaminergic arousal system during waking inhibits neurons of the VLPO, thereby preventing inappropriate activation of the sleep-generating neurons during the active period. Mutually inhibitory interactions between monoaminergic arousal systems and sleep-generating neurons of the VLPO act coordinately as a "flip-flop switch," facilitating rapid, stable sleep-wake transitions [29]. Deficits in one element of the arousal system, hypocretin/orexin signaling, result in ►narcolepsy, a hereditary neurological disorder marked by excessive daytime sleepiness.

## Effects of Sleep-Wake State on Brain and Body Systems

So profound are the changes in brain state between waking and sleep, that the transition into sleep is marked by significant shifts in activation state of the major neural systems. ►Sleep–sensory changes diminish sensitivity in all sensory systems via alterations in the ascending arousal systems and activation of sleep-generating systems [30]. ►Sleep–motor changes affect motoneuron pools that innervate skeletal and respiratory muscle fibers. Motoneurons are hyperpolarized during NREM sleep relative to waking, and even more so during REM states. This accounts for muscle atonia during REM. Sleep movement disorders, including ►periodic limb movements of sleep (PLMS), sleep bruxisms (e.g., tooth grinding, jaw clenching), REM sleep behavior disorder, sleep waking, sleep-related eating disorder and obstructive sleep apnea, may arise from neurological defects in accomplishing sleep-appropriate motor changes. ►Sleep–Wake Autonomic Regulation support the shift from catabolic activities during waking to anabolic physiology during SWS [31]. Somatic inactivity and parasympathetic activity cause respiration, heart rate, blood pressure, core body temperature and basal metabolism to be low, commensurate with rest. Mobilization of amino acid uptake and protein synthesis enables repair, growth and replenishment of energy stores throughout the body. During excursions into REM sleep, antigravity skeletal muscles remain anabolic, but brain activity is catabolic. Surges in sympathetic outflow during REM sleep raise respiration, heart rate, and blood pressure, which may reflect dreaming activity.

►Sleep–endocrine changes are significant. Many hormones are rhythmically released over a circadian period, with specific phase-relationships to day and night (e.g., melatonin), or with a shorter ultradian period but strongly influenced by the sleep-wake cycle (e.g., thyroid stimulating hormone), or with a longer than 24-h infradian period, but possibly still gated within the sleep-wake cycle, as for reproductive

hormones [32]. High glucose levels and insulin secretion are characteristic of the anabolic processes that dominate during sleep. Sleep deprivation or curtailment impacts the profiles of many hormones, including growth hormone, cortisol and thyroid-stimulating hormone. Sleep debt-induced hormonal imbalances also occur in rhythms in ghrelin, the appetite-stimulating hormone, with concomitant decrease in leptin, the counter-balancing satiety-stimulating hormone. This may account for the observation that lifestyles that are short in sleep (≤6 h) correlate strongly with extreme weight gain and metabolic syndrome [33].

►Sleep–developmental changes start shortly after birth, as all parents know, and span the life cycle. These changes affect total sleep time, the proportion and timing of sleep states, and electrophysiological features of sleep. ►EEGs in sleep states emerge by the third prenatal trimester. Neonates sleep >16/24 h, largely in daytime. This shifts to nighttime as the ►circadian pacemaker matures. Early in life, NREM and REM sleep oscillate over 60 min, whereas in adults this cycle is ~90 min. REM occupies ~50% of sleep at birth, then declines to 15–20% at the end of puberty when slow wave activity (SWA) during NREM sleep also declines. Thus, sleep patterns reflect maturational changes in brain structure and function, and sleep doubtlessly contributes importantly to normal development of the nervous system [24]. It follows that abnormal sleep patterns in early life may have profound cognitive and emotional consequences.

## Conclusions and Future Directions

Biological rhythms and sleep are fundamental organizers of behavior, physiology and metabolic state. Over the course of evolution, they have been shaped by daily oscillations of day/night, food availability, temperature, predation and the need for counter-balanced catabolic/anabolic states within brain and body that enhance adaptive fitness. Thus, not surprisingly, they are based in evolutionarily conserved mechanisms and processes and shaped by the needs of adaptation to specialized niches. Recognition of the fundamental nature of biological rhythms and sleep and their underlying general mechanisms poises them for remarkable discovery that is both broad and deep. Important advances will be forthcoming in basic science as well as in applications to health and disease. Significant opportunities are highlighted here.

Advances in understanding biological rhythms will yield basic discoveries regarding novel timekeeping elements, how clocks impinge on the range of life functions of eukaryotic organisms, clock-to-clock coupling and SCN organization.

- Circadian clock elements have been thought to be transcriptional regulators, but the types of cellular elements necessary to timekeeping is growing and extends well beyond nuclear processes. Small molecule and metabolic regulators have emerged as potential timing elements. Studying roles of these novel forms of potential clock elements surely will generate new insights as to biological-clock gears.
- Discovery that circadian clocks orchestrate all cellular states over a near 24-h timebase demands that we re-evaluate the myriad processes in the range of cell and tissue types in the context of dynamic circadian regulation. New insights on *rheostasis*, the range of fluctuating homeostatic states, will emerge [34].
- Although each and every cell in multicellular organisms appears to function as a circadian clock, all cells rely on the SCN for global synchronization. We know little about how the SCN conducts the cellular orchestra to play in synchrony. Opportunities abound for identifying and understanding clock-coupling factors that function within the SCN, communicate to brain, transmit entraining signals to peripheral clocks and coordinate clocks within each tissue [35].
- Complex brains have a specialized clock tissue that is required to orchestrate the cellular rhythms. How do SCN cells and tissue process light information? What are the special SCN coupling properties? What is the range of zeitgebers, and how and when do they interact? How are seasonal signals transduced into changes in multiple tissue and organ systems?

Knowledge that sleep is an active and necessary state together with new methods of analysis positions this field for remarkable discoveries. Advances in understanding will be possible regarding the most fundamental nature of sleep and its processes, and their molecular, cellular and systems substrates.

- Why do we sleep? Why is sleep necessary? Understanding the "why" of sleep from molecular to systems levels and in brain and periphery will be possible. The relation of brain states reported by EEG and brain imaging to the functions of sleep and the molecular, cellular and brain circuits will emerge.
- What is the array of conserved molecular and cellular substrates of sleep, and how and why are they necessary to sleep processes in various brain regions?
- If fundamental features and molecules of sleep are conserved, why do sleep states differ so markedly in phylogenetically different organisms?
- How do Process S and Process C intersect in waking and sleep?
- How and why does sleep deprivation negatively impact the brain and body?
- Why do we dream? How does the process of dreaming access circuits encoding prior experience?
- What is the relationship between sleep and learning and memory?

Both biological rhythms and sleep are subject to dysregulation by lifestyle pressures and by acquired or inherited disorders. Determining the mechanisms of the real-life consequences for these systems in the "24-7" global business enterprise are major challenges before us. Understanding how these fundamental processes function in health and disease is a primary goal that will yield tremendous practical benefit.

# Biomarker

## Definition

A characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacological responses to therapeutic intervention.

# Biomechanics

Walter Herzog
Faculties of Kursiology, Engineering and Medicine, University of Calgary, Calgary, AB, Canada

## Introduction

*Biomechanics* is the science that deals with explaining the ►mechanics of living things and life itself [1]. Living involves movement, growing, aging, adaptation, degeneration, reproduction. Living requires metabolic ►energy (►energy/energetics), and energy requirements change with movement demands. Living processes occur on the molecular, cellular, organ, system, and organism level and all these processes must obey the laws of mechanics.

Biomechanics is a composite term containing the words biology and mechanics ►Classical Mechanics, ►Coutiunum Mechanics, ►Constitutive Theory, ►Continuous growth and Remodeling, ►Principle of Virtual Work, ►Statics. It is defined as the science that deals with the mechanics of biological systems. Mechanics can be divided into ►*kinematics of Deformation* and *kinetics*, and may deal with rigid and deformable bodies. The most frequently considered system in biomechanics research is the human body, however animal and plant biomechanics are firmly established disciplines. Biomechanics is an umbrella term for many associated sub-disciplines such as *biophysics* which deals primarily with biological systems at the cell level and smaller, or *biomedical engineering* which is primarily concerned with advances in human health through mechanical approaches.

## Historical Background

Biomechanics is a relatively new science that emerged in an organized manner in the 1960s, although its origins may be seen in the dynamic drawings of athletes and working people in the ancient Greek culture, and the rendering of anatomically correct surface anatomies in antiquity. The Italian Renaissance also saw a revival of the ancient Greek philosophy and its associated interest in human movement and the workings of the body. Leonardo da Vinci (1452–1519) contributed substantially to the understanding of biomechanical problems such as the flight of birds, and made careful analyses of human movements by considering the actions of muscles around ►joints. Giovanni Borelli (1608–1679) is often considered the father of biomechanics. Borelli, like many of his contemporaries, was a "multi-disciplinary" scientist: a mathematician, physicist, and physiologist, who wrote treatises on the Jupiter moons, on fever and blood, but made his impact on the world of biomechanics with his book "*De Motu Animalium*" published after his death.

Modern biomechanics was first introduced in the early twentieth century in Faculties of Physical Education and was aimed at improving the efficiency of sports movements and performance. The first International seminar on biomechanics was organized by E. Jokl and J. Wartenweiler and was held in Zurich, Switzerland in late August of 1967. This seminar series proceeded with an international gathering of scientists every 2 years, and in 1973, at the meeting held at Penn State University, the *International Society of Biomechanics* (ISB – (http://isbweb.org/)) was founded and J. Wartenweiler became its first president. The Congress of the International Society of Biomechanics has continued in a 2 year cycle and presently attracts approximately 1,000 scientists from all continents. Other "international societies of biomechanics" have emerged successfully: for example the *World Council of Biomechanics* organizes a scientific conference every 4 years that attracted almost 3,000 scientists at its latest gathering in Munich, Germany in 2006 (http://www.wcb2006.org/worldcouncil.htm. Sub-groups, such as the International Society of Biomechanics in Sports (ISBS – (http://www.twu.edu/biom/isbs/) also make important contributions to furthering the field in specialized areas. Many countries in Europe, North America, and Austral-Asia have a national biomechanics organization, and efforts of establishing national biomechanics chapters in South America and Africa have been initiated, some of them with great success.

Biomechanics was defined above generically as the science that deals with the mechanics of living, biological systems. More specifically, it is the science that deals with the ►forces acting on and within biological systems and the effects that are produced by these forces [2]. These effects include movements of biological systems, be it locomotion in humans and animals, the bending of trees and plants exposed to air, fluid flow in ►cardiovascular mechanics, or the random displacements of molecular motor proteins exposed to ►Brownian motion. Movement is one of the primary outcomes of biomechanical analyses, and has provided many problems and spurred numerous scientific investigations.

## Kinematics

The part of biomechanics that deals with *movement* is called kinematics. ►*Kinematics of Deformation* is formally defined as that part of mechanics that deals with the geometric description of motion and deformation. Movement involves locomotion of humans and animals; locomotion may occur in the air, in water or on land and the specific environment places different mechanical demands on the system. Locomotion may occur on the molecular (►molecular and cellular biomechanics) level, for example the "walking" of processive myosin proteins on actin tracks, a situation where gravitational forces have little significance, viscosity dominates the mechanics, and thermal noise provides randomness.

Human and animal movements are under voluntary control. Muscle coordination patterns that produce smooth movements for such actions as writing or playing the piano, are finely tuned and precisely executed. Muscle forces producing these movements are controlled by voluntary commands from the brain, by spinal feedback loops from a variety of proprioceptive organs in skin, joints, muscles and other tissues, and by pattern generators intrinsic to the spinal cord. Musculoskeletal systems are typically redundant with respect to the number of muscles available to produce movements and those strictly required from a mechanical point of view [3]. Therefore, movements, such as walking could be produced theoretically with an infinite number of muscle coordination strategies, but they are not. Repeat steps are associated with similar, albeit not identical coordination patterns, and coordination patterns across individuals are similar as well, although anatomical and structural variations in the neuro-musculoskeletal system are thought to account for individual differences. This redundancy has the advantage that loss of isolated muscle function can typically be compensated for with little functional reduction in performance [4].

Movement is associated with energy consumption. The generic metabolic fuel for muscle contraction is adenosinetriphosphate (ATP) which becomes hydrolyzed (ADP + P) and so provides the energy for movement, breathing, beating of the heart and many other vital functions in living systems. Typically, more vigorous movement or exercise is associated with a greater rate of energy demand. When a person changes from walking to running to sprinting, the rate of breathing increases and so does the pumping of blood, all aimed at providing more oxygen to the working muscles and thereby increasing the rate of energy supply. Exceptions seem to exist in the animal world. For example, it has been observed that increasing the hopping speed of kangaroos is not necessarily associated with an increase in metabolic energy demand as one would expect, presumably because of the extraordinary ability of these animals to store (and release) elastic energy in their hind limb musculature and ►tendons [5].

The precise measurement of movements of biological systems has produced great developments in commercially available ►motion analysis systems. Movements have been depicted in the drawings of the ancient Greeks and the paintings and sculptures of Renaissance artists. However, sophisticated motion capture devices became available with the invention of photography. E. J. Marey (1838–1904) is associated with transforming the study of locomotion from an observational, qualitative science to an objective, quantitative description of movement (►Measurement Techniques, Optical Techniques). With support from the federal government, Marey established a scientific facility devoted to biomechanical analysis of human and animal movement. His studies of locomotion remain exceptional to this day. A contemporary of Marey's, E. Muybridge (1830–1904) was an avid photographer with interest in human and animal locomotion. He introduced sequential photography as the primary tool for movement analyses, and is probably best known for his discovery that there was a brief phase in a horse's trot where all four hooves were off the ground.

With the advent of modern biomechanics in the early 1970s, sequential photography and single exposure photography, such as chronophotography or stroboscopy were replaced by high-speed cinematography [6]. Pin registered high-speed cameras could produce up to 500 frames/s while rotating prism cameras provided sampling frequencies of up to 10 kHz. However, the costs associated with "conventional" cinematography, the delay from filming to viewing (associated with processing film), and the problems associated with filming in low or changing light conditions favored the development and use of high-speed video for biomechanical analysis. Today, video motion analysis systems with sophisticated software for three-dimensional analysis of movements are commercially available, and motion analysis tasks that took days to complete just three decades ago, can now be accomplished virtually instantaneously, thereby providing unique opportunities for instantaneous movement feedback as required in the training of athletes or rehabilitation of patients.

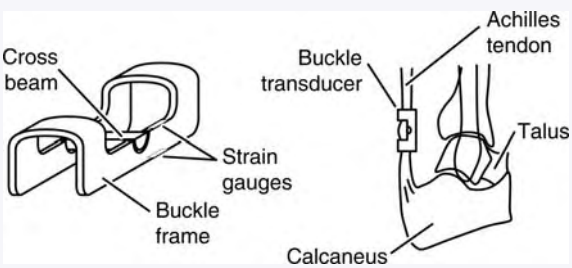
## Kinetics

The part of biomechanics that deals with the effects of forces (►Measurement Techniques (forces)) on systems is called *kinetics*. Forces in biomechanical investigations have been obtained principally in two ways: by theory or direct experimental measurement. Although foundations for force measurements had been made in the nineteenth century, commercial "force measuring devices" for biomechanical applications started to emerge in the 1970s. One of these devices, the force platform, is used to measure the ground reaction

forces exerted by humans (or animals) during locomotion. From its humble beginnings as an instrument built for specific applications by individual investigators, force platforms can now be obtained from various manufacturers, and they have become a standard tool in biomechanical analysis, not only in scientific laboratories, but also in hospitals, rehabilitation centers, and sport shoe stores where they are used to characterize gait abnormalities in patient populations, assess rehabilitation programs, and identify individual foot ►pressure patterns for fitting optimal recreational shoe ware.

Specialized force measurement devices have also been invented to determine the forces inside the human or animal body. One such example is the tendon force transducer aimed at measuring muscle forces continuously in a freely moving subject. Conceptually, two devices have been used for this purpose: one that is attached to the outside of the tendon (Fig. 1); another that is implanted within the tendon. The action principle is the same in both. The transducers are shaped such that they deform when a muscle produces force and stretches the corresponding tendon. This deformation is sensed by a set of strain ►Measurement Techniques (strain) gauges which emit a voltage signal in proportion to the deformation, and this signal can then be translated into tendon (muscle) force by appropriate calibration [7]. Measurements of this kind in several muscles crossing a given joint have provided novel insight into the control of muscle coordination during voluntary movements and have served to estimate forces acting on musculoskeletal structures, such as diarthrodial joints, ►ligaments, tendons, and ►bones.

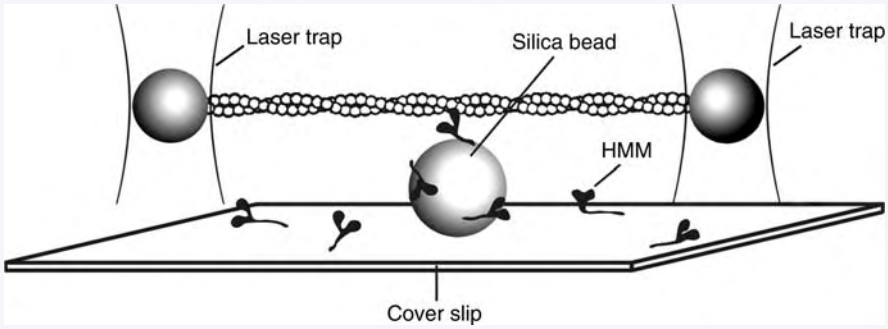
Force measurements in biomechanics are made across all structural levels of a system, and the two devices mentioned above suffice to measure relatively large forces with technology that is generally available and can be built in any scientific laboratory. Recent advances in technology have opened the doors to measure pico-Newton ($10^{-12}$ N) forces which are forces that occur at the interactions of single proteins of molecular motors. Jim Spudich and collaborators [8] were the first to measure the forces of a single cross-bridge of a skeletal muscle attaching to an isolated actin protein. Thus, the elementary force of skeletal muscle contraction could be quantified. The forces were measured using a so-called laser trap (Fig. 2). Measurements of cross-bridge forces were achieved by attaching micron-sized beads to either end of the actin protein, capturing the beads with two independent laser beams, and focusing the beams in such a manner that the beads were held in the focal plane like in a potential energy well. Upon attachment of the cross-bridge to actin and force production, the actin protein is pulled away from the center of the laser beam and knowing the displacement of the bead and the stiffness of the laser trap, the force exerted by the cross-bridge on actin could be determined. This system was copied quickly, and commercial laser trap systems are now available.



**Biomechanics. Figure 1** Schematic illustration of a buckle tendon force transducer (*left*) and a possible arrangement on an Achilles tendon (*right*) (from Salmons, 1969, with permission).

There are many situations in biomechanical research when forces cannot be readily measured. For example, in vivo human muscle forces cannot be determined directly, and although tendon force transducers (as discussed above) have been used in humans (e.g. [9]), proper calibration is difficult in these situations because tendons cannot be detached for independent and known force application required in the calibration process. Similarly, forces and stresses in biological tissues typically cannot be measured but are thought to be of great importance. For example, ►articular cartilage degeneration, leading to osteoarthritis in joints is thought to be mechanically mediated. However, the pathways linking ►pressure (►measurement techniques (pressure)) on articular cartilage surfaces, to the corresponding stress within the tissue and cartilage cells, is not known for in vivo dynamic situations, and the corresponding effects of these stresses on adaptive and degenerative processes within the tissue remain a mystery. In order to address these types of problems, theoretical approaches are used, as illustrated with examples below.

One of the basic questions that have eluded satisfactory explanation in biomechanics research is the so-called ►distribution problem. The distribution problem deals with the determination of the forces across joints. A human diarthrodial joint is typically crossed by many muscles (tendons), ligaments and contains bony contact areas. For example, the knee has four major extensor muscles, three major flexor muscles, four ligaments and at least three distinct and separate bony contact areas. Thus, a complete understanding of knee mechanics requires that all these forces (seven muscle + four ligamentous + three bony contact forces) are known at each instant in time. However, only the resultant joint forces and moments can be readily obtained through the so-called inverse dynamics approach [10]. These resultants, by definition, are equivalent to the sum of all forces across the joint; that is:



**Biomechanics. Figure 2** Schematic illustration of single Heavy Meromyosin (HMM) cross-bridge interaction with an actin filament. The silica bead on the cover slip is coated with skeletal muscle heavy meromyosin cross-bridges. Coated polystyrene beads are attached to the ends of actin. The actin filament with its two beads is caught and suspended in laser traps. The suspended actin filament is lowered to the silica bead, and single HMM interactions with the actin filament are now possible (reprinted by permission from *Nature*, Finer et al., 1994. Copyright 1994 Macmillan Magazines Ltd.).

$$F = \sum_{i=1}^{N} \left(F_i^m\right) + \sum_{j=1}^{P} \left(F_j^l\right) + \sum_{k=1}^{Q} \left(F_k^c\right) \qquad (1)$$

$$M_0 = \sum_{i=1}^{N} \left(r_{i/0} \times F_i^m\right) + \sum_{j=1}^{P} \left(r_{j/0} \times F_j^l\right) + \sum_{k=1}^{Q} \left(r_{k/0} \times F_k^c\right) \qquad (2)$$

where
$F$ = variable resultant external joint force
$M_o$ = variable resultant external joint moment
$F^m$ = internal muscular forces
$F^l$ = internal ligamentous forces
$F^c$ = internal bony contact forces
$r_{i/0}$ = location vector for muscular force i
$r_{j/0}$ = location vector for ligamentous force j
$r_{k/0}$ = location vector for bony contact force k
$N$ = integer indicating the number of muscular forces
$P$ = integer indicating the number of ligamentous forces
$Q$ = integer indicating the number of bony contact forces

Equations (1) and (2) are two vector (or equivalently six scalar) equations, and therefore can be solved for a maximum of two vector or six scalar unknowns. However, for the example of the human knee, there are at least 14 vector unknowns, and although the direction of the muscle and ligamentous forces may be assumed to coincide with the long axis of the tendons and ligaments, respectively, this would still leave 11 force magnitudes (muscles and ligament forces) and three force vectors (bony contacts) to be determined. Most diarthrodial joints have this redundancy; that is less system equations than unknowns. In order to obtain the internal forces of interest, biomechanics researchers have adopted various strategies. The most frequently used approach to solve the ►distribution problem in biomechanics is optimization theory. In this situation, muscles are assumed to be recruited during normal movement in such a way as to minimize, maximize or optimize a specific physiologic criterion, for example, the minimization of metabolic energy [3]. With such a criterion, muscle forces can be determined in a unique way, but the accuracy of such predictions are the topic of intense scientific debate, and the distribution problem remains one of the foremost challenges in biomechanics research. Experimental approaches, such as electromyographical, ►EMG (Wavelet analysis of Electromy grains), ►measurements of muscle excitation and relating these to muscle forces, are fraught with problems.

When determining forces and stresses inside a tissue, such as skeletal muscle, theoretical models describing these tissues are required. Representing biological tissues can take two basic forms: either phenomenological or structural [11]. Phenomenological models of muscle contraction typically treat muscle as an assembly of rheological components (►Rheological Models) that provide the appropriate force output for given contractile conditions. Such models are collectively referred to as "Hill-type" models in reference to AV Hill, a Nobel Prize winner in 1922 for his work on oxygen consumption in muscle. Hill models of muscle function have the advantage that they are simple to describe, require little mathematical knowledge for implementation and provide force output as a function of the contractile conditions. However, they provide little insight into the molecular mechanisms underlying contraction.

Structural models of muscles either have focused on the molecular mechanisms of contraction or the description of anatomically accurate muscles. Muscle contraction, as we know it today, is based on the sliding filament and the cross-bridge theory [12–14]. The ►sliding filament theory suggests that muscle contraction is achieved through the relative sliding of two sets of filaments, the actin or thin, and the myosin or thick filament. The cross-bridge theory proposes that the relative movement of these two filaments, and its associated muscle shortening and force production, are produced by cross-bridges arising from the myosin filament that attach and detach cyclically at specific binding sites on the actin filament, and when attached pull actin past myosin through a configurational change of the cross-bridge (Fig. 3). Each cross-bridge cycle is associated with the hydrolysis of one ATP. Alternative theories of muscle contraction, such as molecular ►ratchet theories, (►brownian ratchet), myosin shortening, and electrostatic considerations [15] have received limited attention, but are driven by observations, such as ►force depression/enhancemence in skeletal muscles, that cannot be explained within the framework of the classic cross-bridge theory.

Structural models of non-contractile biological tissues, such as articular cartilage, bone or tendon, are aimed at simulating the mechanical and biological (adaptive) behavior of these tissues by appropriate representation of the important structural features. In articular cartilage, for example, collagen fibrils, the proteoglycan matrix and the fluid phase are thought to play important roles in the transmission of forces across the tissue, and the regulation of cell volume and the associated stresses and strains experienced by the cells. These structural components can be captured using ►*continuum mechanics* approaches in which the various phases of the tissue (e.g. matrix and fluid phase) can be represented, and structural components that are essential for the understanding of the tissue biomechanics can be added [16,17].

## Applications

The initial applications in modern biomechanics were focused on human movement and human performance. This bias reflected the background and interests of the founders of modern biomechanics. However, animal and plant biomechanics and areas other than human performance have become increasingly strong in the past three decades.

Biomechanical applications in the field of orthopedics, medical imaging and blood flow resulted in a strong emergence of the field of biomedical engineering. This evolution was helped by private foundation sponsors, such as the Whitaker Foundation in North America (http://www.whitaker.org/home.html) which provided financial support between 1975 and 2006 for the development of biomedical engineering scholars and research centers in Canada and the USA. From an unknown discipline in the mid 1970s, biomedical engineering has evolved into a driving research force at many academic institutions.

From its humble beginnings in the 1960s, biomechanics has become a scientific discipline with specialized journals, organizations and conferences. The field has grown exponentially and the future looks bright with nano-biomechanics applications in the health and wellness field, and an ever growing population that wants to be active and mobile into old age. As in the renaissance, when science was a single person venture and required multi-disciplinary talents to address the problems of the time, biomechanists of the twenty-first century need to be multi-disciplinary, equally conversant in the laws of physics and evolutionary or molecular biology. Only such people, organized in cross-disciplinary teams, will be able to successfully address the problems facing biomechanics research today and in the future.

# Biotinylation (Biotinylated)

## Definition

Biotinylation involves covalent linking of biotin to another molecule. Biotin binds with an extremely high dissociation constant ($K_d = 10^{-15}$) to the avidin protein and is one of the strongest known noncovalent interactions. Therefore when linking of two macromolecules is desired without the use of conditions to create covalent linkages, one macro-molecule is first linked to biotin while the other is linked to avidin. When the two macromolecules are mixed in solution they form a very stable complex.

## Synonyms

Bipolar disorder; Manic-depressive illness (MDI); Bipolar depression; Mania

## Definition

Bipolar affective disorder is one of the most common, severe and persistent mental illnesses. Bipolar disorder is characterized by periods of deep, prolonged and profound depression, alternating with periods of excessively elevated and/or irritable mood (mania).

The symptoms of mania include a need for less sleep, pressured speech, increased libido, reckless behavior with no regard for the consequences, grandiosity and severe thought disturbances, which may or may not

include psychosis. Between depressive and manic episodes, patients usually experience periods of greater functionality and are able to lead a productive life. Bipolar disorder is a lifelong challenge.

## Characteristics

### History/Background

Bipolar affective disorder or manic depressive illness has been recognized since at least the time of Hippocrates who described such persons as "amic" and "melancholic." In 1899 the German psychiatrist Emil Kraepelin defined manic-depressive illness and noted that sufferers lacked deterioration and dementia, normally associated with schizophrenia.

Both modern classification systems (ICD and DSM) contain categories for both single episodes and recurrent episodes of mood disorder, and repeatedly alternating high and low mood is described as cyclothymia. ►Hypomania is distinguished from mania because of the difference in the degree of severity of symptoms and social incapacity.

### Diagnostic Considerations

Bipolar affective disorder is a recurrent and disabling mental illness, typically beginning early in life. It constitutes one pole of a spectrum of mood disorders including bipolar I (BP I), bipolar II (BP II), cyclothymia (oscillating high and low mood) and major depression [1]. BP I is also referred to as classic manic depression and is characterized by distinct episodes of major depression contrasting vividly with episodes of mania which lead to a severe impairment in function. In comparison, BP II is a milder disorder consisting of depression alternating with periods of hypomania [2].

Although bipolar affective disorder is defined by manic and hypomanic episodes, in most cases the depressive episodes constitute the more virulent aspect of the illness. The depressive episodes are usually more frequent, of longer duration, and are more difficult to treat than the manic episodes. Moreover, depression is the principle cause of the illness's high suicide rate [3,4].

### Epidemiology

Findings from recent studies generally report an overall lifetime prevalence of bipolar I disorder of around 1–1.5%. This percentage range hardly varies from country to country. In the United States, Europe, Scandinavia, the South Pacific, South America and the United Kingdom the lifetime prevalence of bipolar I disorder ranges from 0.2% (Iceland) to 2.0% (The Netherlands and Hungary). Exceptionally low prevalence rates can be found in Iceland (0.2%) and three Asian countries (0.015–0.3%). The reasons for the particularly low rates in Asian countries are unclear (e.g. genetic, cultural or diagnostic factors) [5].

The two types of disorder differ in adult populations, BP I occurring in approximately 0.8% and BP II in approximately 0.5%. Studies involving a broad bipolar spectrum produce much higher lifetime prevalence rates of 3.0–8.3%. The validity of such studies, however, may be questionable in view of the fact that it is difficult to distinguish between normal mood and mild hypomania.

Most studies have not shown large differences in bipolar disorder rates with regard to gender. The illness is more prevalent in divorced or separated than in married persons. Differences concerning social class and ethnic group are less well documented. Pregnancy and the menopause represent periods of greater vulnerability for the development of manic episodes in females. A family history of bipolar disorder in a first-degree relative remains the strongest predictor.

The WHO has ranked bipolar disorder among the top ten disabling disorders in both developed and developing countries.

### Course and Outcome

The age of onset of bipolar disorders varies greatly. It ranges for both BP I and BP II from childhood to 50 years, with a mean age of approximately 21 years. Most cases commence at the age of 15–19 years, the second most frequent age range is 20–24 years. Some patients diagnosed with recurrent major depression may indeed have bipolar disorder and develop their first manic episode after the age of 50 [6]. They may have a family history of bipolar disorder. However, if manic episodes develop after the age of 50, it is advisable to examine the patient for medical or neurological disorders such as cerebro-vascular disease. Almost all bipolar patients experience relapse, given adequate observation time. Cycle length does not change predictably over time, although it may shorten progressively in the initial stages of the illness in a sub-group of individuals.

A significant proportion of bipolar patients develop ►rapid cycling [7]. Manic episodes are briefer than depressive or ►mixed episodes. The average episode duration remains stable throughout the illness.

About 1–2% of unipolar depressive patients per year experience a first manic or hypomanic episode, suggesting that over a long follow-up period a significant minority of patients previously diagnosed with unipolar depression will subsequently have their diagnosis changed to bipolar disorder. Initial episodes of depression are commonly misdiagnosed and this not only often delays starting appropriate therapy but also increases the likelihood of the illness being treated with antidepressants alone. Unfortunately, the correct diagnosis is often only arrived at after a treatment-emergent affective switch has occurred [4].

Psychosocial and physical stress situations still appear to be strong predictors for relapse, although such severe life events most likely interact with the patients' underlying vulnerability in a complex manner. Life events appear to be more strongly associated with relapse in earlier than in later phases of bipolar illness.

Long-term data suggest that up to one third of bipolar patients achieve complete remission, and a similar number achieve complete functional recovery. Although syndromal recovery is at least twice as frequent, fewer patients ultimately recover pre-morbid levels of functioning. Chronic persistence of symptoms can be expected in about 20% of cases, and social incapacity in about 30% [5].

Early age of onset, depression, mixed episodes, psychosis, substance abuse, medication non-compliance and probably the long-term use of antidepressants are all associated with poor outcome. Mortality and suicide rates are higher in bipolar illness, but can be substantially reduced by adequate lithium treatment.

## Pathophysiology

Up to now, no objective biological markers have been found that correspond definitively with the illness state. However, twin, family and adoption studies all indicate strongly that bipolar disorder has a genetic component. In fact, first-degree relatives of bipolar patients are approximately seven times more likely to develop the disorder than the rest of the population.

Findings from gene expression studies of post-mortem brain tissue from bipolar disorder patients have stressed that levels of expression of oligodendrocyte-myelin-related genes appear to be decreased in brain tissue from bipolar disorder patients [8]. Oligodendrocytes produce myelin membranes that wrap themselves around axons, insulating them and permitting the efficient conduction of nerve impulses in the brain. Therefore, loss of myelin is thought to disrupt communication between neurons, leading to some of the thought disturbances observed in bipolar disorder and related illnesses.

Brain imaging studies in patients with bipolar disorder also show abnormal myelination in several brain regions associated with the illness [9]. Interestingly, gene expression and neuroimaging studies in persons with schizophrenia and major depression also demonstrate similar findings, indicating that mood disorders and schizophrenia may share some biological underpinning.

Another approach to investigating the pathophysiology of bipolar disorder involves studying changes in gene expression induced in rodent brains after administration of pharmacological agents used to treat bipolar disorder. For example, two chemically unrelated drugs used to treat bipolar disorder, lithium and valproate, both up-regulate the expression of the cytoprotective protein Bcl-2 in the frontal cortex and the hippocampus of rat brains. Neuroimaging studies of individuals with bipolar disorder or other mood disorders also suggest evidence of cell loss or atrophy in these same brain regions. Thus, another suggested cause of bipolar disorder is damage to cells in the critical brain circuit that regulates emotion. According to this hypothesis, mood stabilizers and antidepressants are thought to alter mood by stimulating cell survival pathways and increasing levels of neurotrophic factors to improve cellular resiliency.

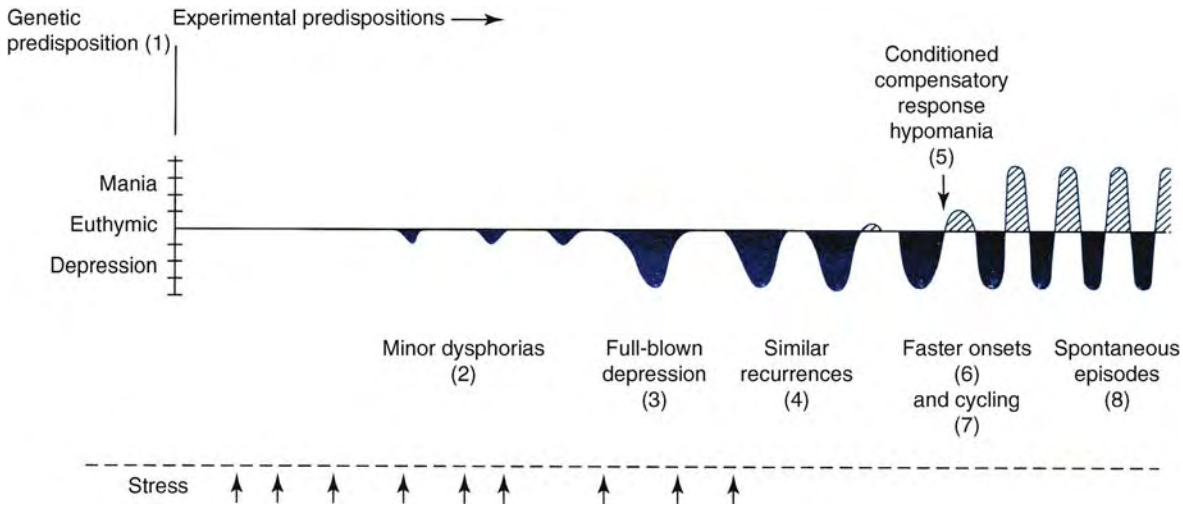
Post and Weiss [10] proposed a mechanism involving electrophysiological ►kindling and behavioral sensitization processes, a method also seen in previous hypotheses based on neuronal injury. Post asserts that an individual susceptible to bipolar disorder experiences an increasing number of minor neurological assaults, perhaps caused by drug-abuse, and excessive glucocorticoid stimulation, resulting from acute or chronic stress or other factors, which eventually results in mania. Subsequently, sufficient brain damage might persist causing mania to recur even with no or only minor environmental or behavioral stress (see Fig. 1). This type of formulation helps explain the effective role of anticonvulsant medications, e.g. carbamazapine and valproate, in the prevention of highs or lows in bipolar disorder. It also suggests that the more episodes a person experiences, the more he or she will have in the future, underlining the need for long-term treatment.

## Psychopharmacotherapy

There are no specifically approved treatments for bipolar disorder in youth and, among antidepressants, only the selective serotonin-reuptake inhibitor fluoxetine has received approval.

When bipolarity is suspected, treatment with mood stabilizers, both conventional (lithium) and the anticonvulsant medications (valproate and carbamazapine) and those more recently classified (lamotrigine), and atypical antipsychotics should be prioritized. When antidepressants are indicated in combination with mood stabilizers, first-choice options include bupropion and the selective serotonin-reuptake inhibitors.

The manic patient presents multiple clinical challenges beyond the choice of medication, such as dealing with law enforcement and deciding when to hospitalize the patient against his/her will, how best to involve the family and how to enhance adherence to the treatment regimen. For those patients whose manic episodes are heralded by a hypomanic period, the clinician may have the opportunity to prevent escalation by prescribing drugs to restore normal sleep. An on-going relationship



**Bipolar Affective Disorder. Figure 1** Behavioral sensitization paradigm of progressive course of illness leading to rapid cycles [10].

with the family and the patient is the best way of assuring that the clinician is alerted in time.

### Psychotherapy and Psychosocial Interventions

While in most cases drug treatment is effective in eliminating the severe disruptions of manic and depressive episodes, the best treatment results for bipolar affective illness are achieved by combining mood stabilizers or other medications with psychotherapy. Psychotherapy can help the patient come to terms with the repercussions of past episodes and to comprehend the practical and existential implications of the illness.

Educating patients and their families is essential as it helps them recognize the symptoms of emerging episodes. The charting of moods appears to be useful to provide an objective record of mood patterns and treatment response and to give the patient a sense of control and collaboration.

Various forms of psychosocial intervention have been found effective as adjunctive treatments for bipolar disorder. These include family-focused therapy, interpersonal and social rhythm therapy, cognitive-behavioral therapy and individual or group psycho-education. When used in conjunction with pharmacotherapy, these interventions may prolong the time up to relapse, reduce symptom severity and increase medication adherence.

Family-focused therapy aims at reducing the high levels of stress and conflict in the families of bipolar patients, thereby improving the course of the illness. Interpersonal and social rhythm therapy focuses on stabilizing the patient's day and night routines and resolving key interpersonal problems. Cognitive-behavioral therapy helps patients to modify dysfunctional cognition and behavior that may aggravate the course of the disorder. Group psycho-education provides a supportive, interactive setting in which patients learn about their illness and how to cope with it. Participation in a self-help group can also supplement, or in some cases, replace formal psychotherapy.

## Bistability (Neuron)

### Definition

The ability of a neuron, in isolation, to have two stable states of activity at different voltages. Typically one is below threshold and is silent, while the other is above threshold and the neuron fires tonically. Brief synaptic excitation or inhibition can switch the neuron between the two states.

## Bistable Neuronal Network

### Definition

A neuronal network that can switch between two distinct states, e.g. silent and active. The switch can either be caused by an external trigger, e.g. one stimulus switches the network from its silent state to an active state, whilst a second stimulus switches the network from its active to a silent state. Alternatively, intrinsic network properties can cause rhythmic alternations between the two network states resulting in a two phasic activity pattern.

## Bladder

►Visceral Afferents

## Bladder Control (Neural)

### Definition
The nervous system regulates the storage and release of urine by coordinating the activity of the urinary bladder and the urethral outlet. In infants and young children the elimination of urine (also known as voiding, urination or micturition) is purely involuntary and is mediated by reflexes triggered by bladder afferent nerves in response to bladder distension. In adults, micturition is voluntary and is dependent upon neural circuitry located in the brain, spinal cord and peripheral nervous system that regulates autonomic and somatic nerve inputs to the lower urinary tract. Micturition is one of the few visceral functions under voluntary control.

►Micturitionn, Neurogenic Control

## BLAST

### Definition

Basic Local Alignment Search Tool. BLAST is used to align high scoring, short stretches of sequence identity at speed. BLAST replaced FASTA, a previous method of analysing sequence similarities. Various different types of BLAST can be used, depending on requirements.

Discontinuous megablast, blastn, or megablast can be used to assess the similarity of nucleotide sequences. Protein sequences can be tested from DNA sequence using tblastx (which uses a translated database to match a translated query) or blastx, (which uses a protein sequence database to match a translated query). Peptide or protein sequences can be matched using standard protein BLAST (blastp), or more sophisticated analysis of domains within a protein query can be carried out using PSI-BLAST, PHI-BLAST or RPS-BLAST. Protein sequences can also be used to query translated nucleotide databases (tblastn).

►Bioinformatics

## Blepharospasm

### Definition

Dystonia of eyelid closing and frowning muscles (orbicularis oculi, corrugator, and procerus muscles) characterized by usually symmetric forceful eyelid closure for a few seconds at a time. Meige symdrome is a combination of blepharospasm and dystonia of lower facial, oromandibular, or cervical muscles.

►Dystonia

## Blind Spot

### Definition

A light-insensitive area in the visual field for each eye corresponding to the photoreceptor-free region in the eyeball called the optic disc where the ganglion cell axons go out and the central retinal artery comes in. An oval-shaped area of approximately 5 degrees wide in the human eye, located at approximately 15 degrees nasally from the fovea of the retina, or temporally in the visual field.

►Retinal Ganglion Cells
►Visual Field

## Blindness

### Definition

Blindness is, of course, loss of the ability to see and may be caused by damage to the eye, the retina of the eye, areas of the brain involved in processing visual stimuli or the nerve tracts connecting these. Blindness can be subtotal in that vision is only lost in particular regions of the visual field either in one or both eyes. Blindness affecting one entire side of vision (e.g. everything to the left of the direction of gaze) is known as hemianopia.

►Hemianopia

## Blindsight

Robert W. Kentridge
Psychology Department, University of Durham, Durham, UK

### Synonyms

Residual vision following loss of striate cortex.

### Definition

"Blindsight" is a term coined by Weiskrantz **(ref?)** to describe a condition found in patients who have suffered brain damage to the rearmost area of the cortex of the brain or to the nerve fibers leading immediately to it. This area, known as ►primary visual cortex, is, as its name suggests, involved in the initial stages of processing visual information in the cerebral cortex. It has been known for over a century that damage to this area can render patients blind (or blind within a specific portion of the ►visual field if the damage does not destroy the primary visual cortex in its entirety). In 1973 Pöppel et al. (see [1] for an account) discovered that although patients with damage to this area reported that they were blind, they could nevertheless perform well in simple visual tasks such as indicating the location of a

spot of light. The patients denied that they saw the spots of light and thought that they were just guessing at the spots' locations. Their "guesses" were, however, consistently related to the positions of the spots. Subsequent studies have revealed that visual abilities other than location of simple targets are also spared in blindsight. Blindsight can therefore be defined as residual visual abilities remaining despite lack of acknowledged awareness of visual stimuli following damage to primary visual cortex or its immediate afferents.

## Characteristics

Most visual information reaches the brain through a pathway in which neurons in the ►retina of the eye send their signals to the ►lateral geniculate nucleus (LGN) (a part of the ►thalamus), the LGN, in turn, projects to primary visual cortex which then sends signals to other parts of the cortex. Spared visual function in blindsight is likely to depend upon other pathways which also convey information from the eyes to the brain but do not pass through primary visual cortex. The nature of the information that can be carried over these alternative visual pathways determines the extent of visual functions spared in blindsight. It has, however, also been suggested that the brain damage in patients with blindsight might have left sufficient primary visual cortex functioning to mediate their residual visual abilities. If this suggestion is correct then blindsight becomes less interesting as an example of an anatomical dissociation between conscious and unconscious processes. In order to characterize blindsight we therefore need to consider its anatomical basis, the extent of the functions that are spared and the strength of evidence for and against sparing of primary visual cortex as an explanation for blindsight.

### Anatomy

Information from the eyes is used for many things other than vision – the control of ►eye-movements, coordination of head and eyes, setting ►circadian rhythms, to name but a few. These functions are controlled by a range of subcortical structures which receive signals from the retina. Some of these structures also send signals to areas of the cortex beyond primary visual cortex. In particular the ►superior colliculus, which is involved in eye-movement control, receives substantial input from the retina in which the relative spatial positions of signals are retained. These projections could therefore, in principle, mediate ►spatial vision (information about the structure of the visual scene as opposed to unstructured information like overall light levels). The superior colliculus sends dense projections to the ►pulvinar (a major division of the thalamus, rather larger than the LGN). The pulvinar sends and receives connections from many areas of cortex and is implicated in a range of visual functions. For example, it contains cells that are sensitive to visual motion (►Visual motion processing) and even cells whose activity is modulated by visual attention (►Visual attention). It is conceivable that information conveyed through retino-collicular inputs to the pulvinar (together with a smaller number of direct retinal inputs) could be forwarded to the cortex and mediate some aspects of blindsight (this depends, however, on the specific relationship between the destinations of collicular projections within the pulvinar and the origins of pulvinar projections to the cortex which are not fully understood). In addition to projecting to cortex the pulvinar also sends signals to the ►amygdala, a forebrain structure centrally involved in the control of emotion. It has been suggested that these connections mediate responses to unseen emotionally significant stimuli in blindsight. Again, the plausibility of this suggestion relies upon there being a correspondence between cells receiving visual signals in the pulvinar and those projecting to the amygdala. Finally, the LGN itself does not send all of its projections to primary visual cortex, it is also known to project directly to a number of ►extra-striate cortical areas (i.e. areas other than primary visual cortex, which is also often referred to a striate cortex or, in the monkey, area V1), including ►areas V2, ►V4 and ►MT. The projections to area MT in particular may mediate residual discrimination of visual motion (Visual motion processing) in blindsight. There are, therefore, a range of pathways via which visual abilities might be retained in the absence of primary visual cortex.

### Visual Abilities in Blindsight

Blindsight has been studied in a relatively small number of patients, although estimates of its frequency vary, it may occur undetected in many patients who have suffered damage to primary visual cortex. The patients in which it has been studied have almost all had damage which did not destroy all of primary visual cortex. These patients lost conscious vision in the part of their visual field subserved by the damaged visual cortex. So, for example, if primary visual cortex is lost only in the left cerebral hemisphere then conscious vision will be lost in the right visual field (the patient will have ►homonymous hemianopia). Such patients may exhibit blindsight in their ►scotomata (regions of visual loss). In these regions the patients deny experiencing visual stimuli yet may still respond systematically to stimuli they do not see. This type of subtotal loss must not be confused with the notion that tissue *within* an area of damage might be spared. This possibility will be considered when criticisms of blindsight are discussed later.

The earliest studies of blindsight revealed patients' ability to localize spots of light presented within their

scotomata using either eye-movements or pointing as a behavioral measure. It is conceivable that this ability might be mediated entirely by the collicular eye-movement system. Even pointing responses might be guided by patients monitoring incipient eye-movements whose final execution is suppressed. It was, however, soon shown that blindsight patients could also make a range of simple visual discriminations including discriminating straight from curved lines, discriminating stimuli differing in color, discriminating the orientation of lines or gratings (patterns of bright and dark bars) and the spatial frequency of gratings (the fineness of these patterns) [1]. These abilities could not plausibly be explained in terms of eye-movement monitoring. It is, however, also important to stress that spatial vision in blindsight is very limited compared to normal vision. Although blindsight patients can discriminate properties of the components from which objects are constructed they do not appear to be able to integrate this information into representations of objects. For example, blindsight patients cannot discriminate between an equilateral triangle with its apex oriented upwards and one with its apex pointing down. Both triangles are constructed of the same three line segments, it is the spatial relationship between these components that defines their difference and, apparently, residual visual function in blindsight does not extend to extraction of such relationships. Blindsight patients can, however, determine whether a pair of targets presented in their scotomata match or differ in terms of the simple properties just discussed. There is one probable exception to the rule that complex shape discrimination is absent in blindsight. There is recent evidence that blindsight patients can discriminate the emotional expression of faces [2]. It has been suggested that this ability is mediated by projections to the amygdala. As the amygdala has a specialized role in processing social signals and emotion this might explain why discrimination of facial expressions, but not other complex shapes, is spared in blindsight.

When blindsight patients are asked to grasp objects in their blind fields they do not, in general, shape their hands to match the size and shape of the objects. There is, however, an exception. If part of the object is visible (i.e. falls in the undamaged part of the visual field) then the unseen part can influence grasp [3]. It is possible that there are weak residual inputs to the visual control of action (►Visual space representation of action) which are normally insufficient to guide action in blindsight but which can be brought into play when actions are at least partially shaped by conscious vision.

It has been known since the early twentieth century that motion perception survives damage to primary visual cortex. Residual vision of motion can be (but is not always) conscious. Conscious perception of motion by cortically blind patients is known as the ►Riddoch phenomenon. Blindsight patients also often report conscious experience of rapidly moving stimuli or ones which change brightness very quickly. Again, it would be a mistake to assume that residual motion perception in blindsight, be it conscious or otherwise, resembles normal perception of motion. Blindsight patients can detect the onset of motion and can discriminate the direction and velocity of motion of isolated individual targets. They cannot, however, discriminate the direction of motion when that motion is made up of the average trend of many small movements (in what is known as a random dot kinematogram) despite the fact that such tasks are trivial for a normal person [4].

Finally, it has been shown that blindsight patients can orient spatial attention (Visual attention) within their blind fields – that is, if they are cued to the likely location of a stimulus within their blind field patients are quicker and more accurate at discriminating its properties than if the stimulus is presented at an unattended location [5]. It is noteworthy that stimuli which can be shown to be attended by virtue of advantages in the speed or accuracy of their discrimination nevertheless still remain unseen. This demonstrates dissociation between visual attention and ►visual consciousness (often thought to be closely related).

We have noted that some stimuli can elicit conscious experience in blindsight patients. The nature of that experience is the subject of considerable controversy. It has been argued that it is in some sense a non-visual experience, for example a “feeling of knowing” that a stimulus has been presented rather than an experience of seeing the stimulus. Attempts to establish the quality of such experiences are fraught with difficulty. It is, however, clear that there are differences in the pattern of activity in the brain elicited by stimuli which do or do not give rise to experience in blindsight patients [6].

## Objections

As the phenomenon of blindsight has such great implications beyond neuropsychology for our understanding of consciousness it is not surprising that it has been the focus of intense scrutiny [7]. The first class of objection revolves around anatomy. It is common in brain damage caused by ►stroke, for example, for some tissue to survive within an area of damage. It has been argued that blindsight is, in fact, mediated by spared primary visual cortex rather than the non-striate routes described earlier. Patients can indeed be found who retain small patches (or “islands”) of viable tissue within a larger area of damaged primary visual cortex. These patients can detect stimuli presented in the tiny regions of their visual fields corresponding to these islands of sparing [8]. Moreover, they deny awareness of such stimuli. It is, however, unlikely that islands of

sparing can account for all cases of blindsight. Experiments in which stimuli in many locations are tested using equipment which tracks eye-position and hence prevents eye-movements from allowing the stimuli to activate anything but a very small region of the retina (and hence cortex) suggest that blindsight is too spatially extensive to be accounted for by undetected islands of sparing. High-resolution neuroimaging has also failed to detect islands of activity within the primary visual cortex of blindsight patients even when it is sufficiently powerful to detect activity elicited in extrastriate areas.

As nearly all blindsight patients retain undamaged regions of vision it is also possible that what appear to be residual abilities are in fact based on response to light that has scattered so as to fall within these regions of normal vision. Although scatter in the environment can be controlled for it is much harder to ensure that light is not scattered within the eye itself. Elegant experiments suggest, however, that intraocular scatter cannot account for residual vision in blindsight. In the normal retina we all have a region called the ►blind-spot where the ►optic nerve leaves the eye and hence where there are no ►photoreceptors. Although we do not notice it, we are all completely blind within this region. A stimulus presented in the ►blindspot of a blindsight patient cannot directly elicit any neural signals, it should, however, scatter just as well as a stimulus presented outside the blindspot. If blindsight is mediated by light scatter then stimuli should be detected just as well whether they fall in or out of the blindspot. Blindsight subjects fail to detect targets presented at their blindspots although they do detect adjacent stimuli outside the blindspot – good evidence that blindsight cannot depend upon light scatter [9].

If blindsight is somehow mediated by an impoverished signal to the primary visual cortex (although this seems unlikely) then it should resemble weak normal vision. It has been suggested that blindsight patients' denial of visual experience is due to a bias against reporting stimuli in what they know to be an abnormal area of vision. Experiments using techniques based on signal detection theory permit such biases to be distinguished from patients' discriminative abilities [10]. These experiments suggest that bias in conjunction with poor normal vision cannot explain blindsight.

All of the objections raised against blindsight can be addressed, so the phenomenon itself seems genuine. It is, however, important to note that findings from individual patients or specific experiments might nevertheless still be accounted for in terms of one or more of these objections. Careful control of stimuli and detailed anatomical data are essential in conducting and assessing experiments on blindsight.

# Block Diagram

## Definition

A diagram of a system as blocks connected by wires.

Each block performs a function and passes the results to all the blocks connected to it.

►Signals and Systems

# Blocking

A well-established CS presented on later conditioning trials in compound with a new stimulus blocks the new stimulus from associating with the US.

►Conditioned Taste Aversion

# Blocking in Classical Conditioning

## Definition

The failure of a conditioned stimulus (CS) to elicit a conditioned response when its pairings with the unconditioned stimulus (US) take place in the presence of a previously established signal for that unconditioned stimulus. Assessment of the magnitude of blocking is made through comparison with an overshadowing control group that receives identical pairings of the CS and US but in the presence of a neutral stimulus.

This is one of several examples of cue competition or stimulus selection effects that prompted development of predictive-driven learning models.

►Theory on Classical Conditioning

# Blood Brain Barrier

## Definition

The blood brain barrier (BBB) acts to protect the brain extracellular fluid from fluctuations in blood composition. Because of the BBB, not all blood constituents can pass freely into the brain extracellular space.

# Blood Volume Homeostasis

## Definition

The human body's total blood volume (V) of approximately 5L is not uniformly distributed along branchings of the cardiovascular system, from left heart to right heart, and back to left. The blood volume can be divided as follows: (i) the systemic circulation (where ≈85% of blood is contained), the pulmonary circulation (≈10%), and the heart chambers (∼5%); (ii) the high-pressure system (≈15%), the low-pressure system (≈80%), and the heart chambers (≈5%); (iii) the systemic venous system versus the remainder of the circulation; and (iv) the central blood volume (volumes of the right heart + pulmonary circulation) versus the rest of the circulation. Changes in blood volume are mostly determined by the degree of fullness of various regions of the cardiovascular system, which includes neural mechanoreceptors and non-neural mechanoreceptors, and by physical factors.

## Synonyms

Physiology of body fluid balance; Control of extracellular fluid (ECF) and blood volume

## Definition

Body water is the fluid environment of the cells, and all life depends upon the stability of this "internal sea." The homeostasis of body fluids is primarily maintained by the balance between those mechanisms controlling the intake of water and electrolytes, and those regulating water and electrolyte loss in the kidneys.

## Characteristics

### Quantitative Description

Water, the largest constituent of the body, makes up 55–65% of the body weight in animals and humans. Total body water is distributed between intracellular fluid (ICF) and extracellular fluid (ECF) compartments, with 55–65% in the former and 35–45% in the latter. The ECF can be further subdivided into the interstitial fluid (ISF) surrounding the cells and the plasma volume within blood vessels. The intravascular fluid averages 7–8% of total body water or, approximately, one fifth of the ECF. The body's total blood volume (V) of approximately 5 L is not uniformly distributed in the body: the high-pressure arterial circuit contains 13% of the blood volume, the capillary bed 7%, and the low-pressure venous bed 64%. The pulmonary circulation contains 9% of the blood volume, and the heart 7%.

Total body fluid compartments differ not only in their volumes but also in the solutes that are dissolved in them. Specifically, membrane-bound $Na^+/K^+$ pumps maintain $Na^+$ primarily outside the cells, whereas $K^+$ is largely found inside them. However, the osmotic pressure, which reflects the concentrations of all solutes in a fluid compartment, is always equivalent in the ECF and ICF because most biological membranes are freely permeable to water. Thus, water flows across the membranes by osmosis from a relatively dilute compartment into one

with a higher solute concentration until a steady state is reached in which the osmotic pressure is equalized on both sides of the cell membrane.

## Higher Level Structures

### Relevant Sensing Structures

#### Low-Pressure Volume Sensors

A loss of blood is detected by stretch receptors in the great veins entering the right atria/ventricle of the heart and in the pulmonary artery (low-pressure volume receptors), and provides an afferent vagal signal to the ►nucleus tractus solitarius (NTS) in the brain stem (Fig. 1). These receptors are located at the end of afferent axons – either A or B fibers – that join the vagus nerve (X). The A fibers fire in synchrony with the atrial systole and therefore monitor the heart rate. The B fibers fire in a burst during the ventricle systole and gradually increase their firing rate as the atria fill. Thus, the B fibers monitor the rising atrial volume. As the central venous pressure (CVP) – the pressure inside large systemic veins leading to the right heart – is the main determinant of right atrial filling, the B fibers also detect changes in the CVP. Therefore, the B-type low-pressure stretch receptors primarily monitor the effective circulating volume and venous return. The afferent pathways for the low-pressure receptors are similar to those for high-pressure ►baroreceptors along the vagus nerve and project to the NTS and other nuclei of the medullary cardiovascular center. To some extent, the efferent pathways and effector organs (i.e., heart and blood vessels) are also similar. However, whereas an increased stretch of the high-pressure baroreceptor decreases generalized sympathetic outflow, an increased stretch of the atrial B-type receptors decreases sympathetic vasoconstrictor output only to the kidney. The net effect of an increased atrial stretch (i.e., tachycardia and renal vasodilatation) is an increase in renal blood flow and an increase in urine output. A decreased atrial stretch has little effect on the heart rate but increases sympathetic output to the kidney. Therefore, as far as their direct cardiovascular effects are concerned, the high-pressure baroreceptors respond to a stretch (i.e., increased blood pressure) by attempting to decrease blood pressure. The low-pressure volume receptors respond to a stretch (i.e., increased fullness) by attempting to eliminate fluid.

#### High-Pressure Baroreceptors

Even larger decreases in blood volume may also lower arterial blood pressure, which reduces the stretch of receptors in the walls of distensible arterioles in the carotid sinus and aortic arch (high-pressure baroreceptors). That information is similarly communicated to the NTS and integrated there with neural messages from the low-pressure, venous side of the circulation. The activity of these sensors modulates both sympathetic nerve outflow and vasopressin (ADH) secretion. For example, a decrease in the filling of the pulmonary vessels and cardiac atria increases sympathetic nerve activity and stimulates vasopressin secretion. Conversely, distention of these structures decreases sympathetic nerve activity. In general, 5–10% changes in the blood volume and pressure are necessary to evoke the response.

#### Cardiac Sensors

The cardiac atria possess an additional mechanism related to the control of blood volume. The myocytes of the atria synthesize and store a peptide hormone, termed atrial natriuretic peptide (ANP), which is released when the atria are distended.

#### Renal Sensors

The kidney also contains volume/pressure sensors, the juxtaglomerular apparatus (JGA), which respond directly to changes in pressure. If perfusion pressure of the afferent arterioles is reduced, renin is released from the myocytes. Renin determines the blood levels of angiotensin II and aldosterone, both of which play an important role in regulating renal $Na^+$ and water excretion.

#### Hepatic Sensors

The liver contains sensors to changes in pressure and $Na^+$ concentration that, although not as important as the vascular sensors in monitoring the effective circulating volume, can modulate renal NaCl excretion. Afferent signals from both types of sensors are carried to the central nervous system (CNS) in the hepatic vagal nerves. Increased pressure within the hepatic vasculature, or an increase in portal vain [$Na^+$], results in a decrease in renal sympathetic nerve activity [1].

#### Osmolality/$Na^+$ Sensors in the CNS

The whole-body $Na^+$ content determines the ECF volume, whereas the whole-body water content determines the ►osmolality. As the body generally stabilizes the osmolality, an increase in extracellular $Na^+$ content will increase the ECF volume.

The osmoreceptors/Na receptors appear to be located in two areas: the organum vasculosum lamina terminalis (OVLT) and the subfornical organ (SFO), two of the circumventricular organs (OVLTs). Neurons in these regions are thus able to sense changes in plasma osmolality/Na concentration. They apparently behave as osmometers, responding to elevated osmolality/Na concentration by increasing the activity of mechanosensitive ►(stretch-inactivated) cation (SIC) channels located in their cell membranes, resulting in significant membrane depolarization that increases the frequency of action potentials [2]. In addition, vasopressin and oxytocin secretory neurons themselves in

the ►paraventricular (PVN) and supraoptic (SON) nuclei have osmo- /Na-sensitivity.

## Higher Level Processes

### *Efferent Systems*

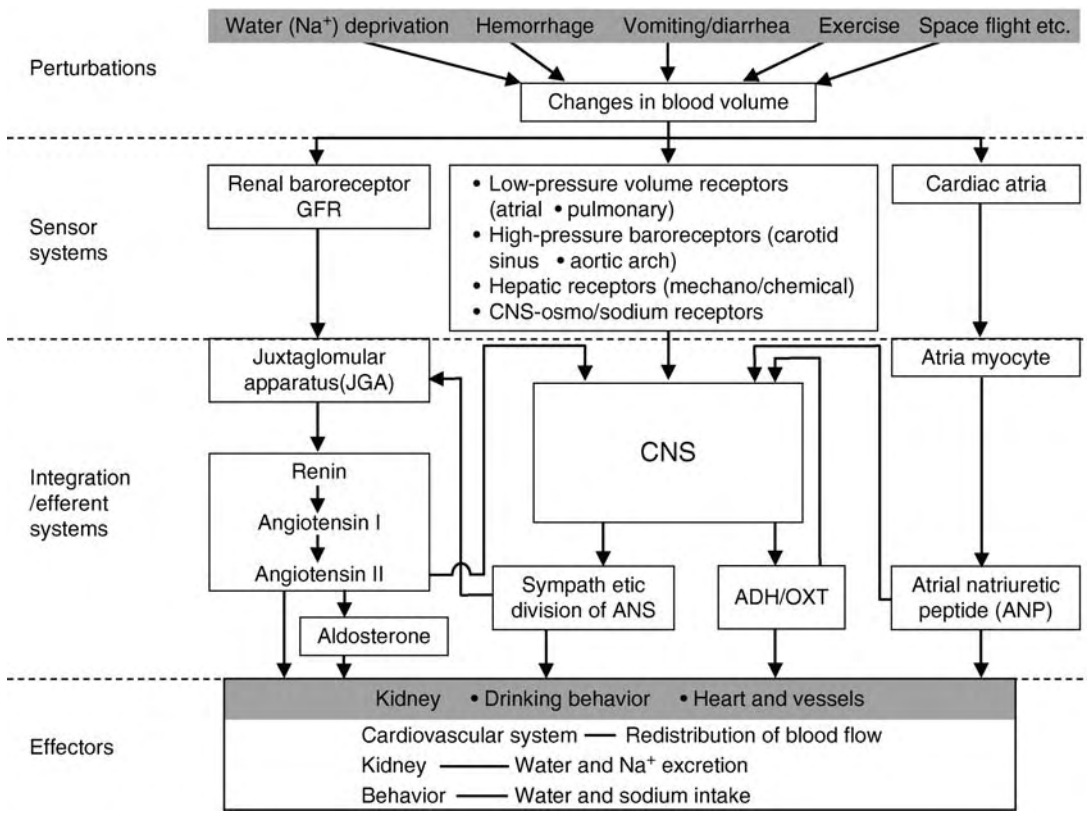
The kidneys (output) and drinking behavior (input) play important roles in body water fluid balance. Both neural and hormonal regulating signals are involved (Fig. 1).

#### *Renal Sympathetic Nerve Activity*

Renal sympathetic nerves innervate the afferent and efferent arterioles of the glomerulus as well as the ►nephron cell. With negative $Na^+$ balance (i.e., volume depletion), the $Na^+$ sensors (especially the low- and high-pressure vascular baroreceptors) stimulate renal sympathetic nerve activity. Increased renal sympathetic nerve activities produce the following: (i) decreased hydrostatic pressure within the glomerular capillary lumen and, thereby, a decreased ►glomerular filtration rate (GFR); (ii) renin secretion via activation of beta-adrenergic receptors; (iii) enhanced NaCl reabsorption along the nephron via activation of alpha-adrenergic receptors [3,4]. The combined effects of these actions contribute to overall decreases in NaCl and water excretion, an adaptive response that works to restore the euvolemia.

#### *Renin-Angiotensin-Aldosteron System*

Three factors play an important role in stimulating renin secretion: (i) reduced perfusion pressure to the kidney results in renin secretion; (ii) activation of the renal sympathetic nerve results in an increase in renin secretion; (iii) decreased NaCl delivery to the macula densa results in an increase in GFR and an increase in renin secretion. Renin alone does not have a physiological function; it functions solely as a proteolytic enzyme. Its substrate is a circulating protein, angiotensinogen,



**Blood Volume Regulation. Figure 1** Basic mechanisms involved in blood volume regulation. The most important organs involved in the regulation of blood volume are shown (for explanations, see text). In these organs, a variety of different cell types and molecular events are related to blood volume regulation. Adaptive responses are initiated by the detection of changes in volume/pressure and osmolality/Na concentration, then the following four parallel effector pathways that act on cardiovascular function, kidney and drinking behavior, are triggered: (a) sympathetic nerve activity; (b) renin-angiotensin-aldosterone system; (c) natriuretic peptide; (d) vasopressin (ADH)/oxytocin (OXT). Additional events linked to blood volume regulation involve the need to drink water and sodium appetite. GFR, glomerular filtration rate.

which is produced by the liver. Angiotensinogen is cleaved by renin to yield a 10-amino acid peptide, angiotensin I. Angiotensin I has no known physiological function and is cleaved to an 8-amino acid peptide, angiotensin II, by a converting enzyme (angiotensin-converting enzyme [ACE] found on the surface vascular endothelial cells (pulmonary endothelial cells are important sites for the conversion of angiotensin I to angiotensin II). Angiotensin II has several important physiological functions: (i) stimulation of aldosterone secretion; (ii) arteriolar vasoconstriction; (iii) stimulation of vasopressin secretion; (iv) enhancement of NaCl reabsorption; and (v) drinking behavior.

#### *Atria Natriuretic Peptide (ANP)*

ANP is released with an atrial stretch, as would occur with positive $Na^+$ balance and blood volume expansion. The circulating form of ANP is 28 amino acids in length. In general, ANP actions, as they relate to renal NaCl and water excretion, antagonize those of the renin-angiotensin-aldosterone system. ANP, as its name implies, promotes natriuresis (i.e., $Na^+$ excretion). ANP plays a role in the diuretic response to the redistribution of ECF and plasma volume into the thorax that occurs during water immersion and space flight. ANP inhibits renin secretion, aldosterone secretion, NaCl reabsorption, ADH secretion, and drinking behavior [5].

#### *Vasopressin (ADH)*

The posterior pituitary releases vasopressin primarily in response to increases in extracellular osmolality. Indeed, ADH mainly increases distal-nephron water permeability, thus promoting water retention. However, the posterior pituitary also releases ADH in response to large reductions in circulating blood volume (hemorrhage). Vasopressin is a nonapeptide with a molecular weight of 1,084. It is synthesized in the cell bodies of magnocellular neurons in the paraventricular (PVN) and supraoptic (SON) nuclei of the hypothalamus, where it is packaged along with neurophysin into neurosecretory vesicles. These vesicles are transported along the axons of these neurons to the posterior lobe of the pituitary, where they are stored. Stimuli for vasopressin release, acting via neural inputs to the PVN and SON, result in the depolarization of these neurons and the release of vasopressin and its accompanying neurophysin into the circulation via the process of exocytosis. The primary physiological stimuli for the release of vasopressin are an increase in the osmotic pressure of the plasma and reductions in blood pressure/volume. Other stimuli, such as nausea and "stress" may also affect vasopressin release. Vasopressin can increase reabsorption of water in the kidney by activating $V_2$ receptors on the distal nephron. Vasopressin is also a potent vasoconstrictor as a result of activation of $V_{1a}$ receptors on vascular smooth muscles.

#### *Oxytocin (OXT)*

The neurohypophysial hormone oxytocin has traditionally been considered to be associated with the female reproductive functions of lactation and parturition. However, more recent evidence suggests oxytocin may also play a role in body ►fluid homeostasis. Oxytocin is a natriuretic factor that may be involved in the volume expansion response. Blood volume expansion increases circulating oxytocin, and oxytocin has been shown to facilitate the release of the atrial natriuretic peptide (ANP) from isolated atria. Thus, during volume expansion, vasopressin is inhibited to decrease water retention and increase vasoconstriction, while oxytocin is secreted to increase natriuresis directly at the level of the kidney and indirectly via the release of ANP [6].

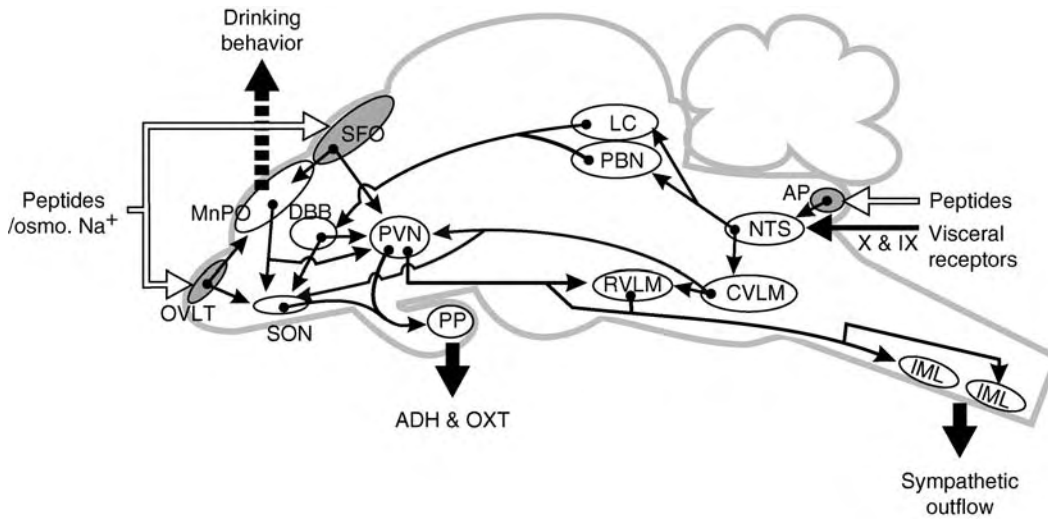
## Process Regulation

### *Integrative Sites in the CNS Relevant to Blood Volume Regulation*

Changes in blood volume affect a number of regions in the CNS, including the area postrema, NTS, caudal ventrolateral medulla (CVLM), locus coerulus (LC), diagonal band of Broca (DBB), PVN, and SON (Fig. 2). In regard to vasopressin release to a decrease in blood volume/pressure, two afferent pathways are proposed: one, NTS→A1 noradrenergic neurons in the CVLM→AVP-secreting neurons in the PVN/SON; another, the NTS→LC→DBB→perinuclear zone in the PVN/SON→AVP-secreting neurons in the PVN/SON [7]. In regard to the activation of renal sympathetic nerve activation to a decrease in blood volume, central pathways mediating the baroreceptor reflex may be involved and, in some part, overlapped. In addition, the parvocellular neurons in the PVN are involved in mediating volume-related signals directly projecting to the intermediolateral cell column (IML) of the spinal cord or indirectly via the ►rostral ventrolateral medulla (RVLM) [8,9].

Circumventricular organs (CVOs) are sites for mediating humoral signals relevant to ►blood volume homeostasis to the CNS.

The small restricted areas that lack a ►blood-brain barrier (BBB) are called the circumventricular organs (CVOs) because they surround the ventricle system; these areas include the area postrema (AP), posterior pituitary, SFO, median eminence, pineal gland, subcommisural organ, and organum vasculosum lamina terminalis (OVLT). Neurons in the CVOs are directly exposed to blood solutes and macromolecules; this arrangement is believed to be part of a signal transmission system for detecting endogenous systemic peptides. Peptide hormones, such as vasopressin, angiotensin II (AII) and ANP, are believed to exert their central effects primarily through actions at the CVOs. The CVOs maintain numerous reciprocal connections with brain regions that are intimately



**Blood Volume Regulation. Figure 2** Drawing showing how afferent (neural and humoral) information from the internal environment relevant to body fluid balance is transmitted in the central autonomic and endocrine network of the brain, and selected neural pathways subserving blood volume regulation in the CNS. Abbreviation: AP, area postrema; CVLM, caudal ventrolateral medulla; DBB, diagonal band of Broca; IML, intermediolateral cell column; LC, locus ceruleus; MnPO, median preoptic nucleus; NTS, nucleus tractus solitarius; OVLT, organum vasculosum lamina terminalis; PBN, parabrachial nucleus; PP, posterior pituitary; PVN, paraventricular nucleus; SFO, subfornical organ; SON, supraoptic nucleus.

involved in the regulation of blood volume/pressure and osmolality/Na homeostasis.

## Function

### *Homeostasis of Blood Volume*

Hemorrhage, water (sodium) loss, or localized sequestration of ECF (edema) decreases the blood and interstitial fluid (ISF) volume. The immediate response to hypovolemia is the activation of the components of the autonomic nervous and endocrine systems in a manner that mitigates the consequences of reduced cardiac output and falling blood pressure. The activation of the sympathetic nervous systems contributes to increased vascular tone, venous return, heart rate and contractility, and renal sodium and water reabsorption. Elevated vasopressin (ADH) and renin-angiotensin-aldosterone act directly or indirectly to retain sodium and water or to redistribute blood and interstitial fluids in an attempt to maintain critical regional blood flows. In addition, drinking behavior participates in adaptive responses. The blood volume that is necessary to achieve adequate perfusion of key organs is sometimes referred to as the effective circulating volume.

## Pathology

Disorders of body fluid homeostasis can result either from disturbances in the physiological mechanisms that control the conservation, distribution, and excretion of water and solutes or from disturbances in the behavioral mechanisms that control the intake of water and solutes.

Generally speaking, water balance is more finely regulated by changes in osmolality, whereas sodium balance is regulated to a greater degree by changes in effective ECF volume. Therefore, disorders of osmotic homeostasis are mainly caused by abnormalities of water balance, and disorders of volume homeostasis largely result from abnormalities of sodium balance.

Representative disorders relevant to ECF/blood volume homeostasis: ►Adrenal insufficiency (Addison's disease); Hypovolemia (hemorrhage, diarrhea, excessive sweating); ►Hyperaldosteronism.

Representative disorders relevant to body osmolality homeostasis: ►Diabetes insipidus; ►Syndrome of inappropriate ADH secretion; Osmoreceptor dysfunction; Primary polydipsia.

# Blood-Brain Barrier

James M. Staddon, Toshal Patel, Terence Smith
Eisai London Research Laboratories, University College London, London, UK

## Definition

The blood-brain barrier (BBB) serves to protect the brain from the potentially adverse effects of fluctuations in molecular and macromolecular components of the blood. Such fluctuations may be due to diet, metabolism and disease. The anatomical basis of the BBB is attributable to the endothelium of the brain capillaries. Here, the endothelial cells differ from those in the periphery by being sealed to their neighbors by extremely well developed ►tight junctions, limiting paracellular flux of blood-borne substances. Additionally, the cells (which are only about 0.2–0.3 μm thick) lack channels and fenestrations, restricting transcellular traffic of agents. Transporters ensure that nutrients and other essential substances cross the BBB to support the metabolically active but environmentally sensitive cells of the CNS.

## Historical Development

In 1885 the German microbiologist Paul Ehrlich reported that when vital dye was injected intravenously in animals, peripheral organs became stained as dye leaked from the blood into the tissue; in contrast, the brain did not. Ehrlich's interpretation was that the brain had a low affinity for the dye. His student Edwin Goldmann subsequently showed that the brain was capable of being stained and concluded that it didn't stain in his mentor's experiment because the dye could not cross the walls of brain capillaries. This was an early realization that the brain is somehow separated from blood, leading to the concept of the BBB. Now, the physical and cellular basis of the BBB is fairly well understood. Its most important role is to carefully maintain and protect the brain parenchymal environment to ensure optimal neuronal and glial functioning. Excessive glutamate, for example, is toxic for neurons and oligodendrocytes. Nutrients and factors that the brain needs for efficient activity are allowed in; toxins and undesirable agents are excluded and, indeed, can be actively ejected. It is believed that there are approximately 400 miles of capillaries perfusing the human brain with a surface area of endothelium of about 20 $m^2$. The BBB is the major interface between blood and brain.

## Ultrastructure and Cellular Basis

It was not clear if the structural basis for the BBB was at the level of the endothelium, the basement membrane (to which the endothelial cells are attached) or the glia or pericytes ensheathing the endothelial cells. In the late 1960's, Ehrlich's experiment was repeated by Reese, Karnovsky and Brightman [1,2] but with analysis at the ultrastructural level using the, then new, electron microscope. Rather than using dyes, they exploited horseradish peroxidase as a relatively small protein tracer. This could be chemically fixed in place and sensitively detected by allowing enzymatic reaction with a suitable substrate to generate an electron-opaque product. The electron microscope images showed that the tracer was prevented from entering the brain by tight junctions between the endothelial cells. Similar findings were made using lanthanum ions as an even smaller tracer. In peripheral organs such as heart, the tracers could be seen passing across the capillary endothelium, apparently through the looser interendothelial cell junctions. Tight junctions had been identified previously by Farquhar and Palade as a structure of the junctional complex in epithelium, known to possess well-developed barrier properties. From the ultrastructural studies, it was also realized that brain endothelial cells, unlike those in the periphery, have very few endocytic vesicles that are usually involved in internalization and transcellular movement of substances in the bulk-phase.

## Permeability Properties

A picture of the anatomical basis of the BBB thus emerges. Endothelial cells lining brain capillaries are connected to each other by a seamless organization of epithelial cell-like tight junctions. The plasma membrane of the endothelial cell, as in any cell, is continuous and hydrophobic and therefore restricts transcellular movement of charged or large molecules from blood to

brain. The low rate of endocytosis and vesicular transcytosis additionally limits transcellular movement of substances via the bulk phase. Well-developed tight junctions inhibit the paracellular movement of substances from blood to brain. Therefore, the barrier functions because substances in general are limited from getting across (transcellular route) or around (paracellular route) the endothelial cells lining brain capillaries. Later on it was realized that the tight junctions of brain endothelial cells are so well developed that they even limit the passage of small ions. Indeed, transendothelial electrical resistance is often used to measure the permeability of brain endothelial tight junctions, which in vivo is believed to be of the order of a few thousand $\Omega.cm^2$ (Fig. 1).

## Transport across the BBB

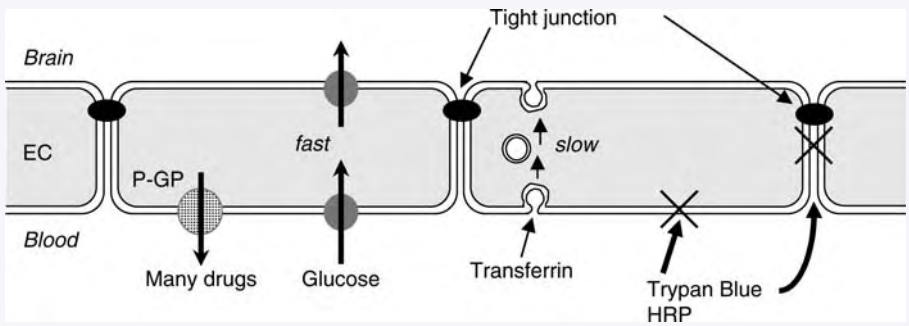
The term, BBB is, however, somewhat misleading. Literally, it implies that there is an impenetrable seal between blood and brain. For certain types of blood-borne substances, this is true to a large extent. However, the brain is highly active metabolically, so, clearly, it cannot be completely sealed off from the nutrients and cofactors that blood carries. If a toxic or undesirable substance in blood is hydrophilic it cannot cross the BBB by either the paracellular or transcellular routes. Nutrients such as glucose and amino acids would likewise be excluded from the brain. These, however, are enabled to cross the BBB due to appropriate expression of ►transporter proteins in the endothelial cells. Transport can be either active or facilitative. The tight junction is also important in this respect because it separates the plasma membrane, and therefore polarizes membrane proteins, into apical and basolateral compartments. Other important molecules such as ►transferrin are selectively transcytosed across the endothelial cells. Therefore, the BBB is a barrier but it is selective rather than being completely exclusive. Clinically, transport across the BBB can be exploited for therapeutic purposes. For treatment of Parkinson's disease, peripherally administered L-DOPA is transported into the brain via the ►large neutral amino acid transporter type 1 (LAT1). Once in the brain it is enzymatically decarboxylated, giving rise to dopamine.

## Ejection Out of the CNS: The Role of P-Glycoprotein

Unfortunately, some noxious substances do manage to get across the BBB. These tend to have hydrophobic character, meaning that they can cross via the transcellular route by simple partitioning. However, the BBB is sophisticated further in that it has additional mechanisms to deal with this problem. This realization derived from the mechanism of resistance of tumor cells to many chemotherapeutic drugs. These cells express drug-transporting ►P-glycoprotein (P-GP), a large plasma membrane protein that actively extrudes a large variety of cytotoxic drugs from the cell. From mice in which P-GP had been genetically removed, it emerged that P-GP is expressed in brain endothelial cells and is very actively involved in removal of certain substances that had managed to enter the CNS. Drugs that have CNS side effects can be improved by making them better substrates for P-GP. Conversely, CNS acting drugs have to escape ejection by P-GP [3]. Many drug-metabolizing enzymes are also expressed in the endothelial cells of the BBB, acting as another level of defense against xenobiotics.

## The Role of the Microenvironment

Brain endothelial cells have become much more specialized than those in peripheral tissues. How this has developed and evolved is not clearly understood. However, the microenvironment seems to have an important



**Blood-Brain Barrier. Figure 1** Essential features of the blood-brain barrier. Endothelial cells (ECs) lining brain capillaries are connected to each other by extremely well developed tight junctions, limiting paracellular flux of ionic, membrane-impermeant substances. Rates of transcytosis are low but receptor-mediated mechanisms exist to ensure transport of essential macromolecules such as Fe-transferrin. Carriers and transporters (active or facilitative) mediate rapid entry of nutrients such as glucose and amino acids into the CNS. P-glycoprotein (P-GP) is a non-selective transporter that removes many hydrophobic and amphipathic molecules (drugs, metabolites etc.) from the CNS environment.

influence. In 1981, Stewart and Wiley performed tissue transplantation studies between quail and chick embryos [4]. When gut tissue was transplanted into brain, the transplant was vascularized by brain endothelial cells that became leaky. Conversely, brain tissue transplanted to gut became vascularized by gut endothelial cells that became brain-like in terms of their barrier properties. The specialized phenotype of brain endothelial cells is perhaps due to contact or interaction with other cells of the CNS, the glial and neuronal cells. Astrocyte endfeet (the terminal regions of astrocytic processes) are known to cover much of the basal surface of brain capillaries, and there has been speculation and some evidence that these may provide inductive factors.

## Proteins at Tight Junctions

Understanding of the molecular basis of the specialized cell-cell adhesion that is necessary for the blood-brain barrier has also advanced [5]. Tight junctions were identified as anatomical entities in the early 1960's. There seems to be a lot of similarity in terms of the molecular composition of tight junctions in both epithelial cells and the endothelial cells of the BBB. Peripheral proteins such as ►zonula occludens-1 (ZO-1) are localized to tight junctions on the cytoplasmic side of the cell. ►Occludin is an integral membrane protein with four transmembrane domains that localizes to tight junctions and seems to form a complex with cytoplasmic protein components. The extracellular loops of occludin may have some intercellular adhesive function. Occludin expression is very high in brain endothelial cells but much lower in those of peripheral organs, suggesting that it may contribute to the paracellular properties of brain endothelial cells. Another group of transmembrane proteins localizing to tight junctions are the ►claudins, a multigene family consisting of greater than 20 members. Like occludin, claudin bears four transmembrane domains and is also believed to be involved in intercellular adhesion at the tight junction. In particular, claudin-5 may be responsible for the limited paracellular permeability of brain endothelial cells [6].

## Proteins at Adherens Junctions

The intercellular adhesion of brain endothelial cells is also crucially dependent on ►adherens junctions. Tight junctions provide the barrier properties of brain endothelial cells but the adherens junction generates mechanical strength between the cells. Adherens junctions are based on ►cadherins, the $Ca^{2+}$-dependent adhesion molecules [7]. Cadherins also form a multigene family; VE-cadherin (vascular endothelial cadherin) being important for interendothelial cell adhesion. Cadherins span the plasma membrane once (a type I membrane protein) and, in a homophilic and $Ca^{2+}$-dependent manner, interact with and bind to cadherins on neighboring cells. The cytoplasmic domain of cadherin is fairly well conserved between classical members of the family. This links cadherin to the actin-based cytoskeleton through a group of proteins termed ►catenins that physically associate with the cytoplasmic tail. β-catenin binds directly to cadherin and, via α-catenin, links to the actin cytoskeleton. ►p120 is another catenin that may play a signaling and regulatory role (Fig. 2).

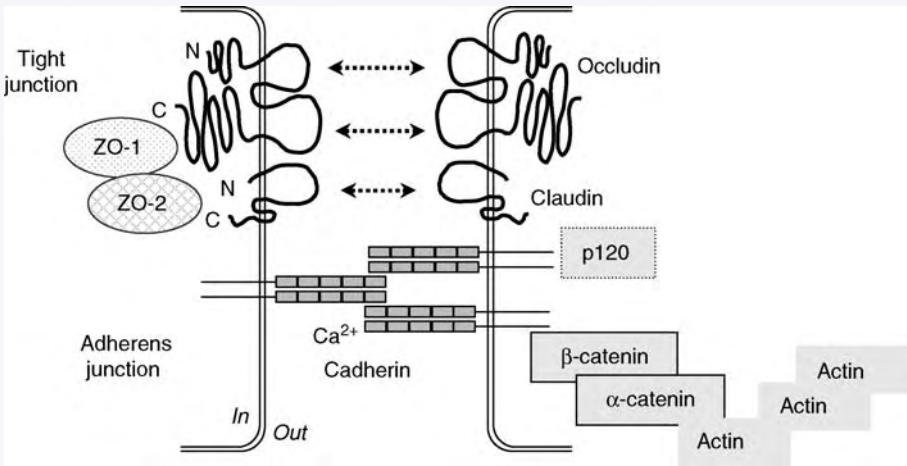
## Cell Culture Models

In order to study the BBB, cell culture models have also been employed. These mainly involve the isolation of brain capillaries by homogenization and filtration of the tissue. Incubation with a nutrient medium encourages the endothelial cells to migrate out of the capillaries and proliferate. After some days in culture, many cells are generated. These can then be trypsinized off the culture dish and transferred to special filters for culture where the apical chamber is separated from the basolateral, thus mimicking the separation of brain and blood environments. Once a confluent monolayer of cells has been generated, the development of tight junctions can easily be measured by determining transcellular electrical resistance. A variety of experiments can then be performed.

## The Blood-brain Barrier in Disease

### Multiple Sclerosis

The BBB also plays a role in pathology, especially as relates to CNS inflammation [8]. ►Multiple sclerosis (MS) is a devastating neurological disease of the CNS, which develops when the body's immune system apparently attacks the myelin sheath which wraps axons of neurons in the brain and spinal cord (autoimmune hypothesis). Demyelination results in decreased efficiency of saltatory conductance of nerve impulses to and from the CNS. This in turn manifests itself in a variety of symptoms from blurred vision to complete paralysis of one or more limbs. The pathological hallmark of MS, the MS plaque, is a clearly defined region of demyelinated axons interspersed with a network of astrocyte scar tissue, giving the lesion a shiny or "sclerotic" appearance at post mortem. Historically, the CNS was considered an immune privileged organ, but now it is realized that a degree of immune surveillance does occur in the normal brain without causing inflammation. In this process, lymphocytes have to bind to brain endothelial cells and cross the BBB to migrate in to the CNS. Adhesion molecules on lymphocytes and endothelium enable a passing T-cell to bind, initially loosely, and roll along the endothelium. Firmer adhesion results in the T-cell finally stopping close to the endothelial tight junction. Engagement of lymphocyte and endothelium activates a series of signaling events, which culminates in transmigration of the leukocyte. In MS, the T-cell becomes activated and



**Blood-Brain Barrier. Figure 2** Overview of some of the proteins involved in tight junction formation in the blood-brain barrier. Occludin and claudin are localized to tight junctions. These integral membrane proteins span the plasma membrane four times, and their cytoplasmic domains interact with peripheral tight junction proteins such as ZO-1 (zonula occludens-1) and ZO-2). The extracellular loops are believed to mediate adhesive interaction with protein on the neighboring cell. The claudin family has many members. Cadherins are responsible for calcium-dependent adhesion between adjacent endothelial cells and are localized to adherens junctions. These transmembrane proteins are made up of repeats that create calcium binding sites in the protein. The binding of calcium alters the conformation of the protein, rendering it adhesion-competent with neighboring molecules. The cytoplasmic tail of cadherin is linked to the actin-based cytoskeleton via β- and α-catenins. p120, another catenin, may play a regulatory role.

a variety of inflammatory cytokines are released which further up-regulate the expression of additional adhesion molecules in the brain endothelial cells. The BBB becomes more adhesive for blood borne T-cells and macrophages, which are further enticed into the CNS by a gradient of chemokines and cytokines. Trafficking and activation of lymphocytes compromises the BBB further, allowing the ingress of plasma from blood to brain, causing edema, which also interferes with nerve impulse conduction. Dysregulation of the BBB is the earliest detectable event in the evolution of inflammatory demyelinating lesions that characterize MS. Clinically, extravasation of the MRI imaging agent gadolinium from the cerebro-spinal vasculature, is used as a paraclinical marker to diagnose and monitor disease progress and to assess efficacy of therapeutic agents in MS. Thus, in early relapsing-remitting and secondary progressive multiple sclerosis, where around ten new or enhancing lesions are detected for each clinical relapse, interferon-β has been reported to block BBB leakage and gadolinium enhancement within 2 weeks. The BBB itself is a potential therapeutic target in MS in that humanized anti-adhesion molecule antibodies have shown promise in clinical trials of MS.

## Stroke and Head Trauma

Strokes can be either infarct or hemorrhagic in origin. Strokes due to infarct involve the blockage of the large cerebral arteries and starvation of brain tissue of oxygen and glucose. Hemorrhagic strokes are the result of ruptures of the blood vessels and the leakage of blood into brain tissue. Inflammatory mediators are believed to cause the increases in BBB permeability that develop as the pathology of stroke develops. These include matrix metalloproteases, free radicals and ►vascular endothelial growth factor (VEGF). The current definitions of brain edema are based upon Klatzo's classifications into cytotoxic or vasogenic. An increase in brain water content, known as vasogenic edema, is due to influx of protein from the vasculature. Normally, the interstitial protein content of brain is about 100 times less than that of plasma. Cytotoxic edema is also a problem in stroke. This involves a failure of ion pumps in neurons and glia and cell swelling can ensue. Understanding and managing edema in stroke and head trauma is a major cause of clinical concern [9,10].

## Brain Tumor

In brain tumors, e.g. gliomas and neuroblastomas, the usual features of the BBB are lost and the endothelium lining the capillaries supplying the tumor adopts a more peripheral phenotype [9]. The capillaries become leaky due to poorly developed tight junctions and increased fenestration. The basis of these differences is not clear but probably relates to the more hypoxic environment and VEGF. Also, the normal astrocytic influence may be lost or subverted. In both stroke and brain tumor, the edema can displace normal brain tissue resulting in pressure on areas of the brain that regulate vital functions. As a result, it is important to treat the causes of brain

edema. Corticosteroids are the mainstay treatment of tumor but side effects have to be carefully monitored. Osmotherapy (administration of hyperosmotic agents via the carotid artery) and surgery may be used in emergency situations. Novel and safer therapies continue to be sought and evaluated.

### Other Pathologies

Neurological disorders such as Alzheimer's disease or HIV- induced dementia alter the integrity of the BBB. Inflammatory stimuli, free radicals or toxic proteins (e.g. TNF-α, superoxide anions, β-amyloid) produced during the course of the disease can cause the loss of tight junction proteins and BBB breakdown [9].

A blunt-end DNA double helix terminates in a base pair.

►Serial Analysis of Gene Expression

## Bmal

### Definition

Brain Muscle ARNT-Like is a protein that forms an essential component of the molecular circadian clock machinery. A member of the PAS-domain family, this protein is stimulated by retinoic acid-related orphan nuclear receptor a (RORa) and repressed by REVERBα to resulting in a circadian periodicity in its expression. Together with CLOCK, it forms the positive arm of the primary feedback loop that regulates molecular circadian rhythmicity in mammals. It forms heterodimers with CLOCK that bind to E-boxes in to drive transcription from the Period, Cryptochrome and Timeless loci. It is the mammalian ortholog of the Drosophila Cycle gene.

### Synonyms

SMAD Signaling; TGF-β; Signaling

### Definition

Bone morphogenic proteins (BMPs) are members of the transforming growth factor beta (TGF-β) superfamily of secreted polypeptide growth factors. These proteins regulate a wide variety of developmental processes including cell proliferation, differentiation, cell fate specification, tissue patterning and apoptosis [1,2]. Multiple functions and molecular components of BMP signaling are evolutionarily conserved across many species from fly to human. Canonical BMP signaling begins by binding of secreted BMP ►ligands to cell surface receptors followed by activation of intracellular ►SMAD transcription factors and culminates in transcriptional regulation of target genes. Recently, genetic and functional experiments have uncovered a key role for BMP signaling in the regulation of synaptic growth and plasticity.

## Characteristics

### SMAD-Dependent BMP/TGF-β Signaling

BMPs/TGF-β ligands signal through two transmembrane serine/threonine ►kinases known as the type I and type II receptors (Fig. 1). Upon ligand binding, type I and type II receptors form a heterotetrameric complex allowing for phosphorylation of the type I receptor by the type II receptor (Fig. 1).

The Phosphorylated type I receptor, now activated, interacts with and phosphorylates intracellular proteins known as receptor-regulated SMADs (R-SMADs). Phosphorylation of R-SMADs is followed by their co-assembly with the common partner known as the Co-SMAD and the subsequent translocation of the phospho-R-SMAD/Co-SMAD complex to the nucleus. The presence of phosphorylated R-SMADs in the nucleus is commonly used as an index for the activation of BMP/TGF-β signaling. Once in the nucleus, this complex, together with other cofactors, can either activate or repress gene transcription depending on the cellular context. The human genome encodes eight SMAD proteins, 42 BMP/TGF-β ligands and 12 receptors [1]. This diversity of signaling molecules portrays the complexity and specificity of this signal transduction pathway.

### Function of BMP Signaling in Synaptic Growth and Plasticity
