►Synapsins are neuron-specific phosphoproteins that are among the most abundant synaptic vesicle proteins. Three synapsin genes (I-III) have been identified in mammals; each undergoes differential splicing to yield at least nine isoforms [1]. The N-terminal domains of synapsins are highly conserved, containing sites for phosphorylation by cAMP- and $Ca^{2+}$/calmodulin-dependent protein kinase while the C-terminal portions are variable. The central domain, which accounts for more than half the sequence, forms multimers and binds ATP. This region has structural similarities to some ATPases, suggesting that synapsin may have enzymatic activity requiring ATP.

Neither deletion of the single synapsin gene in the Drosophila genome, nor the deletion of individual synapsin genes in the mouse genome, has strong effects on synaptic transmission. Deletion of all three synapsin mouse genes is not lethal but does affect behavior. It induces changes in synaptic transmission and plasticity that differs in excitatory versus inhibitory synapses. The functions of the synapsins are unclear, but may include recruiting synaptic vesicles to a reserve pool. Synapsins associate with the surface of vesicles, and bind to both vesicular phospholipids and proteins. They also interact with cytoskeletal proteins including actin, spectrin and tubulin. These binding reactions are regulated by phosphorylation. Synapsins thus seem to be involved in tethering vesicles to the cytoskeleton and defining a reserve pool that is not immediately available for docking and fusion. Synaptic activity leads to phosphorylation of synapsins, which dissociate from vesicles allowing their mobilization and migration to the plasma membrane to prepare for fusion. However, synapsins may have additional functions. Mice with deleted synapsin I and II genes show a global decrease in the number of synaptic vesicles, suggesting that synapsins play a role in stabilizing vesicles. Finally, synapsins may also act at a step closer to fusion by regulating priming or fusion competence.

### Synaptic Vesicle Protein 2 (SV2)

►SV2 is a synaptic vesicle glycoprotein of about 90 kDa, containing twelve potential transmembrane segments and N- and C-termini oriented towards the cytoplasm [1]. Sequences linking transmembrane regions are fairly short, although one highly glycosylated intraluminal loop is considerably larger. The sugar chains in this loop may contribute to the intravesicular matrix that is thought to bind neurotransmitters. Three SV2 genes in vertebrates encode homologous SV2A, SV2B and SV2C proteins that display distinct expression patterns in the brain, although SV2A is present in most neurons. The transmembrane and cytoplasmic linker sequences are

highly homologous between different SV2s, whereas the N-terminal domain and the intraluminal linkers diverge.

SV2s have significant homology to the Major Facilitator Superfamily of transporters for organic anions and cations, phosphates and sugars, and were initially thought to be transporters of neurotransmitters. However, their ubiquitous distribution rules out this possibility and indicates that they fulfill a more general function common to all synaptic vesicles. This function is still unknown, although a reasonable hypothesis is that they transport an unidentified substrate from the cytoplasm into the vesicle lumen.

Mice with deletions of the SV2A gene and the double SV2A/SV2B knockout display severe seizure activity and die postnatally. Cultured neurons from knock-out mice display increases in $Ca^{2+}$-dependent synaptic transmission that can be blocked by buffering cytoplasmic $Ca^{2+}$. Lack of SV2 thus seems to lead to abnormally high cytoplasmic $Ca^{2+}$ levels. SV2 might therefore be involved in $Ca^{2+}$ transport into synaptic vesicles to counterbalance the effects of burst firing in the nerve terminal. Furthermore, the N-terminal domain of SV2 interacts with, and may regulate the function of, the synaptic vesicle calcium sensor protein synaptotagmin. SV2 also constitutes the binding site for the antiepileptic drug levetiracetam (KEPPRA), which perhaps enhances the ability of SV2 to limit electrical hyperexcitability [9].

## Pathology

### *Botulism and Tetanus*

These two potentially fatal diseases result from the inhibition of neurotransmitter release by BoNT and TeNT, which proteolyze presynaptic SNARE proteins. BoNT and TeNT are produced by the soil-borne bacteria *Clostridium botulinum* and *Clostridium tetani* [4]. Human botulism, mainly due to BoNT serotypes A, B and E, is typically caused by either eating contaminated food, wound infection, or in infants by intestinal proliferation of ingested clostridial spores. Botulism is a flaccid paralysis with classic symptoms: double/blurred vision, drooping eyelids, slurred speech, difficulty in swallowing, dry mouth, and muscle weakness. In severe cases, death can result from respiratory failure. Tetanus, which typically results from contamination of a deep puncture wound with *C. tetani*, involves muscular hypercontraction with symptoms including headache, muscular stiffness in the jaw (lockjaw) and neck, difficulty in swallowing, rigidity of abdominal muscles, spasms, sweating, fever and convulsions.

The differences between botulism (flaccid paralysis) and tetanus (muscle contractions and spasms) are due to differences in the neuronal populations affected. BoNT inhibits motoneurone terminals, blocking acetylcholine release and subsequent muscle contraction. In contrast, TeNT acts specifically on inhibitory neurones in the spinal cord, diminishing tonic inhibition that indirectly activates acetylcholine release from motoneurones inducing muscle contractions.

### *Therapy*

BoNTs (usually BoNT/A or B) are used as therapeutic agents that can be injected into muscles to reduce hypercontractions in dystonia, blepharospasm, strabism and a multitude of other indications. They are also widely used cosmetically (e.g., Botox) to reduce the muscle activity that underlies facial wrinkles.

# Pretectal Area

## Synonyms

►Area pretectalis

## Definition

Situated immediately behind the superior colliculus, this nucleus plays a vital role in pupillary reflex and adaptation. Afferents come from the retina and

occipital cortical fields. Efferents go to the ipsi- and contralateral accessory oculomotor nucleus and superior colliculus.

The pretectal area includes the following nuclei: pretectal olivar nucleus, medial, anterior and posterior pretectal nuclei and optic tract nucleus.

►Mesencephalon

## Pretectal Nuclei

### Definition

Part of the subcortical visual shell. The pretectum consists of 7 nuclei in the visual midbrain, the n. of the optic tract, posterior limitans n., the olivary pretectal n., the anterior pretectal n., the posterior pretectal n., the medial pretectal n. and the commissural pretectal n. All connect substantially with the intergeniculate leaflet (IGL) and with each other.

They serve a variety of different functions. Perhaps the most well known is control of the pupillary light reflex by the olivary pretectal nucleus. This reflex is mediated by intrinsically photoreceptive retinal ganglion cells, as well as the classical rod/cone photoreceptors.

►Intergeniculate Leaflet
►Neural Regulation of the Pupil
►Photoreceptors
►Pupillary Light Reflexes

## Pretectum

### Definition

A midbrain region just rostral (forward) of the superior colliculus. It consists of a superficial nucleus (the nucleus lentiformis in frogs) containing migrated, large-celled neurons and a deep subnucleus. Cells of the nucleus lentiformis mesencephali are involved in horizontal optokinetic nystagm. Pretectal neurons respond more selectively to slowly moving vertical patterns, although horizontally sensitive neurons likewise been reported.

Directional information is encoded in a large population of motion-sensitive units, which includes both narrowly and broadly tuned individual response profiles.

►Evolution of the Visual System: Amphibians
►Optokinetic Nystagmus
►Superior Colliculus

## Prevertebral Ganglia

### Definition

Prevertebral ganglia are autonomic ganglia that are found in the abdomen, around the origins from the aorta of the major vessels – the coeliac, superior mesenteric and inferior mesenteric arteries – and in the pelvis, close to the pelvic organs. The ganglia have various names applied to them the most common being: coeliac ganglia (also semilunar ganglia, solar plexus), superior mesenteric ganglia (inter-renal ganglia), inferior mesenteric ganglia and anterior (hypogastric) and posterior pelvic ganglia.

►Autonomic Ganglia

## Prey-catching Behavior

### Definition

Hunting animals show this type of behavior when trying to catch prey. This involves searching behavior, localization of prey and striking as well as killing of prey.

## PRG

### Definition

The Pontine Respiratory Group (PRG) is the region of respiratory neuron groups situated in the nucleus parabrachialis medialis (NPBM) and Kölliker-Fuse (KF) nuclei. The PRG is also termed as the pneumotaxic center.

►Respiratory Neurotransmitters and Neuromodulators

## Primary Acoustic Cortex

### Definition

Cerebral cortex areas in which the auditory tract terminates and which are involved in the first cortical processing steps for auditory signals. These include especially Brodmann areas 41 and 42 on the temporal plane.

►Telencephalon

## Primary Afferent Depolarization (PAD)

### Definition

A prolonged decrease in membrane potential usually produced by the activation of ionotropic $GABA_A$ receptors at the presynaptic terminals of afferent fibers.

This depolarization is propagated antidromically in an electrotonic manner and can be detected either (i) directly by intra-axonal recordings of afferent fibers, (ii) as a dorsal root potential (DRP) from the central stump of a cut dorsal root filament, or (iii) as a positive potential (P wave) from the cord dorsum. Given that intra-axonal recordings are normally obtained in the dorsal horn, PAD recorded intra-axonally reflects the summed membrane potential changes occurring in all the collaterals of an individual afferent fiber.

PAD is accompanied by an enhanced excitability of afferent fiber terminals. Changes in excitability of intrapinal terminals can be estimated from threshold changes in response to intraspinal current pulses. The activation of pathways mediating PAD produces a threshold decrease and a consequent increase in amplitude of the antidromic compound action potential (Wall's technique).

►Action Potential
►GABA
►Presynaptic Inhibition

## Primary Afferents

### Definition

Primary afferents are tracts ascending without interneurons.

One example is the posterior spinocerebellar tract which conducts impulses without interneurons from Clarke's nucleus of the thoracic cord to the cerebellar hemispheres.

►General CNS

## Primary Cultures

### Definition

Primary cultures are the first stage of cell culture in which cells removed from tissue are cultured but before cells are removed from the primary culture to start the next culture.

## Primary Hyperalgesia

### Definition

Hyperalgesia at a site of injury or inflammation.

►Hyperalgesia and Allodynia
►Joint Pain

## Primary Lateral Sclerosis (PLS)

### Definition

PLS designates a syndrome of progressive upper motor neuron dysfunction and shows consistent differences from ►amyotrophic lateral sclerosis (ALS), which is characterized by progressive degeneration of both upper and lower ►motoneurons. Unlike ALS, which is familial in 5-10% of the cases, PLS appears to be sporadic in adults. Initially, stiffness is more prevalent in PLS than in ALS patients, but limb wasting, pronounced in ALS patients, is rare in PLS patients. ►Spasticity is the most prominent sign in PLS. Cortical atrophy is most pronounced in the ►precentral gyrus and expands into the ►parietal-occipital region. The course of PLS is very slowly progressive.

►Amyotrophic Lateral Sclerosis (ALS)

## Primary Motor Cortex (M1)

### Definition

A part of the cerebral cortex that is most directly involved in controlling the activity of motoneurons. In primates, primary motor cortex is located in the precentral gyrus of the frontal lobe just anterior to the central sulcus. An orderly representation of movements by body part exists within primary motor cortex. From medial to lateral the representation is lower extremity, trunk, upper extremity, face and tongue. Many corticospinal neurons in primary motor cortex make monosynaptic linkages with motoneurons. A distinctive feature of primary motor cortex is the presence of large pyramidal cells (Betz cells) in cortical layer V.

►Motor Cortex: Output Properties and Organization

## Primary Progressive Aphasia

### Definition

Presenile progressive degenerative disorder characterized by initially isolated loss of language abilities for at least two years, but mostly transcending into muteness and ►dementia (often ►frontotemporal dementia). It is due to a degeneration of cerebro-cortical regions around the ►sulcus lateralis (Sylvii) of the left hemisphere. The most frequent variants are: (i) progressive non-fluent aphasia (characterized by labored speech, agrammatism); (ii) semantic aphasia (characterized by loss of word and object meaning and dyslexia); (iii) logopenic progressive aphasia (characterized by word-finding problems and impaired sentence comprehension).

## Primary Reinforcer

### Definition

Sensory stimulus with intrinsic rewarding properties such as food or water.

►Operant Conditioning

## Primary Sjögren's Syndrome

### Definition

A chronic, multisystem autoimmune disorder characterized by dryness of mouth and other mucous membranes that occurs in the absence of an associated rheumatic disease (secondary Sjögren's syndrome) and may involve extraglandular manifestations such as arthralgias, Raynaud's syndrome, pulmonary involvement, renal tubular acidosis, peripheral and central nervous system (CNS) disease.

►Central Nervous System Disease in Primary Sjögren's Syndrome

## Primary Somatosensory Cortex (S1)

### Definition

Primary somatosensory cortex comprises four cytoarchitectonic regions, areas 3a, 3b, 1 and 2 (going from rostral to caudal), located in the anterior portion of the parietal lobe. Each region has a complete representation of the body. Areas 3a and 2 receive inputs mainly from deep receptors (the hand representation is characterized by receiving inputs from both skin and deep receptors), while neurones in areas 3b and 1 largely respond to skin stimulation.

►Somatosensory Cortex I (SI)
►Somatosensory Cortex, Plasticity

## Primary Visual Cortex

### Definition

Cerebral cortex in the occipital lobe of the mammalian brain.

The primary visual cortex (also known as Brodmann area 17, V1 or striate cortex) is the principal site at which visual information enters the cortex. It lies in the calcarine sulcus of the occipital lobe and receives visual signals from the retina relayed via the lateral geniculate nucleus (LGN) of the thalamus. Efferent projections

terminate in various visual areas in the cortex. Primary visual cortex has a complete map of visual space.

## Principle of Neurological Minimization

### Definition

Underlies responses of the neuromuscular system to changes in control variables and/or external forces; a tendency of system's elements to minimize, in the limits defined by neural, biomechanical and environmental constraints, the imposed activity by returning the system to the same or bringing it to a new steady state, depending on conditions; a solution to the redundancy problem.

►Equilibrium Point Control

## Principle of Virtual Work

Marcelo Epstein
Schulich School of Engineering, University of Calgary, Calgary, AB, Canada

### Definition

From the physical point of view, the ►principle of virtual work is an attempt to characterize unequivocally an equilibrium ►configuration of a mechanical system (as defined in statics (q.v.)) by observing how it reacts to a small kinematical perturbation, called a *virtual displacement*.

### Description of the Theory

In ►classical mechanics (q.v.), a mechanical system is defined from the kinematical point of view by means of its *configuration space*, whose dimension is an expression of the number of *degrees of freedom* of the system. A (local) system of coordinates in the configuration space is known as a set of *generalized coordinates*. It is important to stress that the generalized coordinates $q^i (i = 1, ..., n)$ are mutually independent, since they already incorporate any geometrical constraints that the system may have. In the case of the double planar pendulum discussed in the article on classical mechanics (q.v.), for example, the number of degrees of freedom of the system is exactly two and so is the number of its generalized coordinates, whether the angular deviations from the vertical or any other set of appropriate geometrical parameters that are mutually independent and sufficient to define a state of the system are chosen. Another way to state this independence is to say that any description of a possible configuration of the system by means of coordinates, $x^I (I = 1, ..., n' > n)$ say, can be eventually boiled down to $n'$ (smooth) functions of $n$ generalized coordinates:

$$x^I = x^I(q^1, ..., q^n), \ (I = 1, ..., n'). \qquad (1)$$

In the case of the planar double pendulum, a system of Cartesian coordinates may be chosen and an arbitrary configuration of the system expressed by means of the two pairs of coordinates, each corresponding to the position of one of the two masses. Thus, in this simple case, $n' = 4$. Nevertheless, it is clear that (given the lengths of the two links) all four Cartesian coordinates can be expressed in terms of the two angles, $q^1$ and $q^2$, formed by the links and the vertical direction. The original four coordinates are interdependent, since they must satisfy the two constraints imposed by the assumed rigidity of the links. The generalized coordinates, on the other hand, by their very nature, already take these constraints into consideration and can,

P

therefore, be varied independently without violating these constraints. A *virtual displacement* of a mechanical system consists precisely in a set of small (infinitesimal) perturbations or *variations* $\delta q^i (i = 1, ..., n)$ of the generalized coordinates away from a given configuration $q^i (i = 1, ..., n)$. The forces acting on the system, whether internal or external, will in general perform work on any given virtual displacement, a scalar quantity appropriately designated as *virtual work*. In many cases, however, the forces necessary to maintain the constraints will not perform any virtual work. For example, in the case of the pendulum it is clear that the constancy of the length of the links is physically attained by intermolecular forces, which result in an internal state of tension. The work of these tensile forces would be equal to the magnitude of the force multiplied by the change of length of the corresponding link. Since, by their very definition, virtual displacements *respect the geometrical constraints* (the constancy of the length of the links) the virtual work of these internal *forces of constraint* will vanish. For a different example, consider a body that is constrained to slide freely on a surface. As long as there is no friction, the force necessary to maintain the contact between the body and the surface will be perpendicular to the surface and, therefore, will perform no virtual work on any virtual displacement. If friction is considered, however, this will no longer be the case, and it is a philosophical point of view whether or not the frictional force should be called a force of constraint. Be that as it may, it is clear that by purposely defining a virtual displacement as a possible displacement of the system, namely one that respects its geometrical constraints, the virtual work of some forces will automatically cancel out. If therefore, an equilibrium configuration is characterized by means of some property of the virtual work, it will follow that the forces of constraint will automatically play no role in the determination of equilibrium, a feature that would be almost unthinkable in an approach based on the concept of a free-body diagram of statics (q.v.). The principle of virtual work, in fact, provides such a characterization.

According to the principle of virtual work, a mechanical system in classical mechanics (q.v.) is in an equilibrium configuration if, and only if, the virtual work of all the forces acting on the system vanishes *identically* for all possible virtual displacements that can be impressed away from this configuration. This principle, therefore, characterizes an equilibrium configuration as one for which the system is work-wise indifferent to small perturbations compatible with its constraints. It is important to notice that the principle of virtual work is not an equation but an identity. Only so can it be understood that a single scalar statement is equivalent to a number of vector equations. For consistency, the principle of virtual work, when applied to a rigid plate in two dimensions, will be shown to deliver the classical equations of equilibrium. The plate is assumed to be free to move in the *x*-*y* plane (no other constraints) and to be acted upon by $N$ concentrated forces $\mathbf{F}^\alpha (\alpha = 1, ..., N)$ acting at points with coordinates $x_\alpha, y_\alpha (\alpha = 1, ..., N)$. In this case, the two Cartesian coordinates, $x_p$ and $y_p$, of a point $P$ of the plate and the (counter-clockwise, say) angular deviation θ of a material line drawn in the plate from, say, the *x*-axis can be adopted as generalized coordinates. A virtual displacement consists of any arbitrary combination of variations $\delta x_p, \delta y_p, \delta\theta$. The virtual displacement of the point of application of the force $\mathbf{F}^\alpha$ is the vector with components:

$$(\delta x_p - (y_\alpha - y_p)\delta\theta,\ \delta y_p + (x_\alpha - x_p)\delta\theta), \qquad (2)$$

so that the principle of virtual work can be stated as:

$$VW = \sum_{\alpha=1}^{N} F_x^\alpha (\delta x_p - (y_\alpha - y_p)\delta\theta) + F_y^\alpha (\delta y_p + (x_\alpha - x_p)\delta\theta) \equiv 0, \qquad (3)$$

with an obvious notation. Since this is an identity, any combination of $\delta x_p, \delta y_p, \delta\theta$ may be chosen. Choosing first $\delta x_p \neq 0, \delta y_p = \delta\theta = 0$:

$$\sum_{\alpha=1}^{N} F_x^\alpha = 0. \qquad (4)$$

The choice $\delta x_p = 0, \delta y_p \neq 0, \delta\theta = 0$ yields:

$$\sum_{\alpha=1}^{N} F_y^\alpha = 0. \qquad (5)$$

Finally, the choice $\delta x_p = \delta y_p = 0, \delta\theta \neq 0$ yields:

$$\sum_{\alpha=1}^{N} -F_x^\alpha (y_\alpha - y_p) + F_y^\alpha (x_\alpha - x_p) = 0. \qquad (6)$$

Equations 4, 5 and 6 are immediately recognized as the standard equations of equilibrium of a rigid body in two dimensions. In particular, Eq 6 is the equation of moment equilibrium around point *P*. Considering now the case in which the plate is hinged at point *P* by means of a frictionless hinge, the configuration space of the system becomes one-dimensional and the rotational coordinate θ is a valid generalized coordinate. Obviously, in this case Eqs. 4 and 5 are no longer valid, and the equilibrium of the system is governed by Eq. 6 alone. Notice the essential difference with the conventional free-body diagram approach. In a free-body diagram the reactive forces at the hinge form an essential part of the package. The reactions thereat will intervene in the equations of equilibrium. In the virtual work approach, on the other hand, it is imperative not to disengage the plate from the hinge. Quite to the

contrary, the presence of the hinge, by reducing the number of degrees of freedom of the system, reduces the number of equilibrium equations. Naturally, this simple example alone would not justify the use of the principle of virtual work, but in more complicated situations its use, by eliminating the participation of reactive forces, results in a considerable simplification of the equations of equilibrium.

The virtual work expression can always be brought to the form:

$$VW = \sum_{i=1}^{N} Q_i \, \delta q^i, \tag{7}$$

by simply collecting all the terms that affect the variation of each generalized coordinate. The multipliers $Q_i$ are called *generalized forces* and, in statics, can be at most functions of the generalized coordinates. The forces acting on a mechanical system are said to be *conservative* if there exists a scalar function $V$ of the generalized coordinates such that:

$$Q_i = -\frac{\partial V}{\partial q^i}, i = 1, ..., n. \tag{8}$$

This function, if it exists, is called a ►*potential energy* of the forces, and the forces are said to *derive from this potential* (which is determined uniquely up to an additive constant). It is important to realize that the property of the forces being conservative is independent of the particular choice of generalized coordinates, as can be verified easily by using the chain rule of differentiation. Combining Eqs. 7 and 8, it may be concluded that in a conservative system the virtual work of the forces can be calculated as the exact differential of the negative of the potential, namely:

$$VW = -\delta V. \tag{9}$$

The principle of virtual work for conservative systems establishes, therefore, that the potential energy is *stationary* at a position of equilibrium. It can be shown that the equilibrium is *stable* if the potential energy attains a strict *minimum* at the equilibrium configuration. A simple example is that of a cherry at the bottom of a wine glass (stable equilibrium, minimum gravitational potential energy), as opposed to a ball at a mountaintop (unstable equilibrium, maximum gravitational potential energy). The idea of virtual displacements as small perturbations of a putative equilibrium configuration is particularly clear in such simple examples.

In the case of continuum mechanics (q.v.), the principle of virtual work is also applicable provided the so-called *internal virtual work* is carefully accounted for, that is the work of the stress tensor upon the small virtual variations $\delta\mathbf{F}$ of the ►deformation gradient. To see how this thought can be formalized, the Lagrangian equation of equilibrium is obtained from the Lagrangian equation of balance of ►linear momentum (Eq. 15 in ►balance laws (q.v.), whose notation is adopted) by eliminating the ►acceleration terms as:

$$T^I_{i,\,I} + B^i = 0. \tag{8}$$

Multiplying this equation by a *virtual displacement field*, that is, a field of the form $\delta x^i(X^1, X^2, X^3)$ and integrating over the referential volume of the body:

$$\int_\Omega (T^I_{i,\,I} + B_i)\delta x^i d\Omega = 0, \tag{9}$$

where the summation convention is used. This equation is obviously valid for any virtual displacement field. Considering the first term, the divergence operator is eliminated by invoking the divergence theorem. The price to pay is the appearance of a term at the boundary. Indeed:

$$\begin{aligned}\int_\Omega T^I_{i\,,I}\,\delta x^i d\Omega &= \int_\Omega (T^I_i\,\delta x^i)_{,I}\,d\Omega - \int_\Omega T^I_i\,\delta x^i{}_{,I} d\Omega \\ &= \int_{\partial\Omega} T^I_i \delta x^i N_I\, dA - \int_\Omega T^I_i \delta F^i_I\, d\Omega \\ &= 0.\end{aligned} \tag{10}$$

In the boundary integral the ►surface traction is immediately recognized, namely, $S_i = T^I_i N_I$. Putting together the results of Eqs. 9 and 10 the identity:

$$\int_\Omega B_i\,\delta x^i\,d\Omega + \int_{\partial\Omega} S_i\,\delta x^i\,dA \equiv \int T^I_i\,\delta F^i_I\,d\Omega\,. \tag{11}$$

is finally obtained.

The left-hand side represents the *external virtual work (EVW)* of the ►body forces and the surface tractions, while the right-hand side can be identified with the *internal virtual work (IVW)* of the (first Piola-Kirchhoff) stress. It is not difficult to reverse the steps of this derivation and conclude that the identical satisfaction of the principle of virtual work in the form:

$$EVW \equiv IVW, \tag{12}$$

is equivalent to the equations of equilibrium of a deformable continuum. No restrictions have been specified upon the virtual displacement fields. Assume, however, that the ►deformation of part of the boundary is prescribed (for example, part of the boundary is fully supported). Then, the virtual displacement fields must vanish at that part of the boundary. One of the useful features of the principle of virtual work in continuum mechanics is that it delivers not only the interior equations of equilibrium, but also the appropriate

boundary conditions of the problem. The Lagrangian formulation has been presented, but a similar treatment delivers also the Eulerian form of the principle. In this case, the internal virtual work is given by $IVW = \int_\omega t^{ij} \delta D_{ij} \, d\omega$.

In the case of a deformable continuum, the concept of potential energy can be extended to the stresses themselves. If the constitutive equation of the material is such that the ►first Piola-Kirchhoff stress tensor is derived form a scalar potential function of the deformation gradient, the material is said to be *hyperelastic* (►*hyperelasticity*). Configurations of equilibrium can be associated with a stationary value of the total potential energy of the system.

# Processing of Tactile Stimuli

Heather E. Wheat, Antony W. Goodwin
Department of Anatomy and Cell Biology, University of Melbourne, Parkville, VIC, Australia

## Definition

Tactile here refers to that which is concerned with the sense of touch or the perception of touch. When we touch or manipulate objects, four classes of low-threshold cutaneous mechanoreceptor sensors are activated by the stresses and strains arising from the interaction between skin and object. These four receptor types have different response characteristics because of differences in their structure and in their location in the skin. During manipulation, the receptor responses are determined by many different features of the manipulated object and of the hand movements. Such features include: contact or grip force, the presence of shear forces, the area and shape of the contact region, the surface texture, the shape and compliance of the object, and the presence of slip between the object and the skin. This information is conveyed to the central nervous system by mechanoreceptive afferents (peripheral nerve fibers) which innervate these mechanoreceptors. A population of mechanoreceptive afferents is able to simultaneously encode multiple stimulus parameters because each parameter has a different representation in the spatial and temporal patterns of activity across the afferent population.

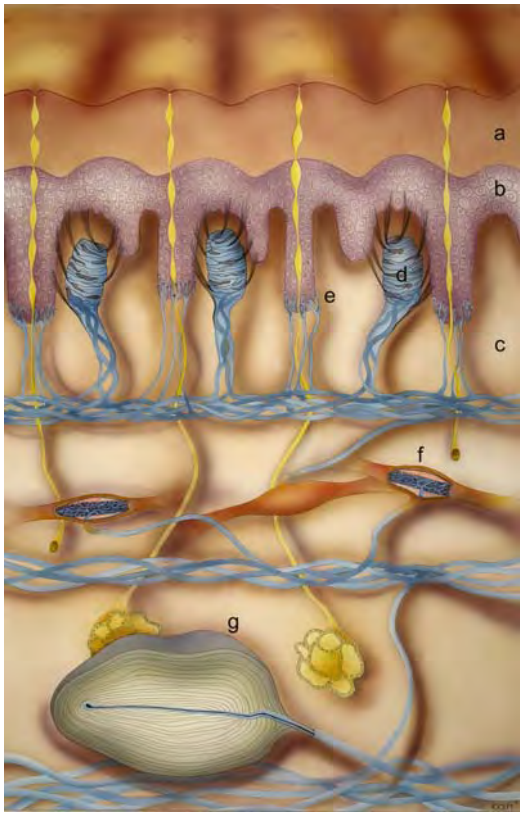
## Characteristics

### Tactile Sensors of the Glabrous Skin

The glabrous (ridged) skin of the fingers consists of two main layers, an outer epidermis and an inner dermis, which are arranged in an interlocking pattern of grooves and ridges (Fig. 1).

Within the skin are thermoreceptors, nociceptors and low-threshold mechanoreceptors; these vary in structure from free nerve endings to mechanically complex end organs. In this chapter the focus is on the four low-threshold mechanoreceptors: Merkel cell-neurite complexes at the epidermal-dermal junction, Meissner corpuscles in the outer papillary layer of the dermis, and Pacinian and Ruffini corpuscles in the deeper reticular layers of the dermis. These receptors are innervated by large-diameter myelinated nerve fibers, classified as Aβ fibers, which conduct action potentials rapidly. A single fiber may end in a single mechanoreceptor, but more commonly will innervate many mechanoreceptors. Conversely, a single mechanoreceptor may be innervated by a single fiber or by multiple fibers [1].

In humans, the fibers (also termed afferents) fall into four distinct groups classified by their response properties. Slowly-adapting type I (SAI) and slowly-adapting type II (SAII) afferents are associated with Merkel endings and Ruffini corpuscles respectively and respond to both the static and dynamic components of the stimulus. Fast-adapting type I and II (FAI and FAII) afferents are associated with Meissner corpuscles and Pacinian corpuscles respectively and respond only to dynamic components of the stimulus. Monkey



**Processing of Tactile Stimuli. Figure 1** A cross-section through glabrous skin. The upper layer, or epidermis (b), is covered in thick keratin (a). Both the epidermis and the underlying layer, the dermis (c), have a wave-like structure. Peripheral nerve fibers, shown in blue, terminate on four types of mechanoreceptors, the Meissner corpuscles (d), the Merkel endings (e), the Ruffini organs (f) and the Pacinian corpuscles (g). Reproduced with permission from Ian Darian-Smith.

P

glabrous skin lacks SAII afferents, but the remaining three afferent types, common to humans and monkeys, have similar response properties in both humans and monkeys. Fast adapting afferents are also referred to as rapidly adapting afferents. The density of SAI and FAI afferents innervating the hand decreases proximally from a maximum at the fingertip of 0.7 $mm^{-2}$ for SAI afferents and 1.4 $mm^{-2}$ for FAI afferents. The proximo-distal gradient is less pronounced for SAII and FAII afferents which in the human fingertip have lower densities than the type I afferents (0.1 and 0.21 $mm^{-2}$ respectively). The receptive fields of type I mechanoreceptive afferents (with more superficial receptors) are small and well demarcated whereas those of the type II afferents (with deeper receptors) are large and diffuse with some extending across the entire hand.

## Tactile Sensors of the Hairy Skin

The mechanoreceptors of the hairy skin are either associated with the hairs on the skin or are situated between them. There are three hair types – specialized sinus or vibrissae (which are not present in humans), vellus or pelage, and guard. The hair follicles are innervated by: free nerve endings, Merkel nerve endings associated with SAI afferents, lanceolate nerve endings associated with rapidly-adapting afferents, and Ruffini corpuscles associated with SAII afferents. Most sinus hairs are also innervated by lamellated corpuscle of Pacinian type which are associated with rapidly-adapting afferents. Between the hair follicles are dome-like elevations, the so called "touch domes" or *Haarscheiben* of Pinkus which are innervated by slowly-adapting Merkel endings and free nerve endings [2].

## Central Nervous System Pathways

The peripheral afferent nerve fibers described above are the peripheral processes of bipolar cells with cell bodies in the dorsal root ganglia, which lie in close proximity to the spinal cord. The central processes of these bipolar cells enter the spinal cord via the dorsal roots and it is at this point that axons conducting information from the low-threshold mechanoreceptive afferents become segregated from those carrying nociceptive or thermal information. The predominant spinal pathway for the low-threshold mechanoreceptive afferents is via the dorsal columns (cuneate and gracile fascicles); most axons enter the spinal cord and ascend to the brainstem without synapse.

The dorsal column axons project principally to, and synapse on, cells within the ipsilateral cuneate and gracile nuclei (the dorsal column nuclei) in the brainstem. Axons of cells in these nuclei cross to the other side of the brainstem and ascend as the medial lemniscus, synapsing primarily in the ventroposterior nuclear complex of the thalamus. The axons of these thalamic cells project predominantly to the primary somatosensory cortices in the postcentral gyrus – Brodmann areas 3a, 3b, 1 and 2. Throughout, the ascending pathways are organized largely on somatotopic principles. Furthermore, neurons to this point retain many of the functional properties of their primary afferent input in terms of basic response functions and receptive field characteristics.

## Overview of Tactile Processing

Tactile processing falls into two separate, but overlapping, broad categories. In the first category, touch informs pattern and form perception which allows us to identify objects. Such information includes the object's shape, size, softness and its surface texture. Commonly this is a conscious process. In the second category, touch forms a vital component of the sensorimotor integration that is essential for precision grip and effective manipulation. Object characteristics such as compliance and surface microgeometry, as well as task related characteristics such as position of contact on the skin, linear and torsional loads, and contact or grip forces are relayed by touch to the central nervous system, often without deliberate or conscious tactile perception. To assess what tactile information is signaled to and used by the brain, psychophysical measurements of the human capacity to detect, discriminate, scale and identify specific features of a stimulus have been conducted. Such behavioral studies provide an indication of the minimum information about a particular stimulus parameter that must be received by the brain for conscious perception. Many of these studies have been accompanied by neurophysiological experiments, employing the same stimuli, in order to determine how the essential stimulus parameters are represented in the responses of different neural populations.

The responses of single mechanoreceptive afferents innervating the skin have been recorded by inserting micro-electrodes through the skin into human peripheral nerves and by micro-dissection (fiber splitting) of monkey peripheral nerves. The response characteristics of the different afferent types will be discussed within the context of a range of functionally relevant parameters. Important to note is that all four low-threshold cutaneous mechanoreceptive afferent types are potentially activated by contact with an object but the extent to which each class contributes to the coding of essential task-related information varies depending on the stimulus and task parameters. Furthermore, for all but the simplest stimuli the parameters of the stimulus and task are only represented or encoded unambiguously in the responses of a population of fibers, and not in the responses of isolated single fibers. The studies described in the following sections are based on single fiber responses but for the most part, because of the manner in which the stimuli were presented, they can be extrapolated to represent population responses.

## Neural Representation of Object and Task Parameters

### *Simple Stimuli*

The principal value of simple stimuli, such as punctate probes indenting the skin or vibrating in and out of the skin, has been a clear-cut classification of the afferent types (Fig. 2). The temporal characteristics of the responses divide the afferents into slowly and fast adapting groups and the spatial characteristics (mainly size) of the receptive fields define the type I and type II groups. Thresholds of the responses correspond to human detection thresholds measured psychophysically.

### *Pattern and Form*

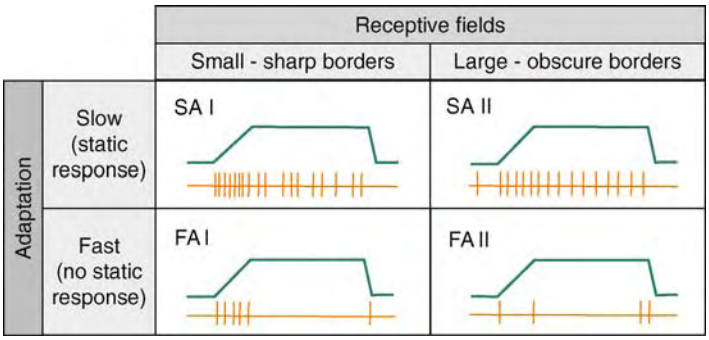
The earliest measure of spatial resolution in the tactile system was the two-point limen, a simple but unreliable measure that underestimates the capacity of the system. More recently, tactile coding of spatial characteristics or fine form has been investigated using a range of relatively simple stimuli such as edges, bars and gratings as well as more complex patterns such as embossed letters and Braille-type characters [3]. Human psychophysics experiments are matched with single fiber recordings, commonly in monkeys and more rarely in humans. Such studies have found that SAI afferents resolve the spatial details of the stimuli with greater clarity than either FAI or FAII afferents in monkeys or FAI, FAII or SAII afferents in humans. Recognition and discrimination of patterned stimuli are enhanced when they are scanned across the finger, rather than pressed into the finger. This can be explained in part by the increased resolution in SAI responses when such stimuli are moved tangentially across the skin compared to stationary presentation. Variations in scanning speed and contact force have little effect on the spatial resolution of fiber responses or on human perception. Although there is strong evidence for the role of SAI afferents in encoding fine spatial detail, the other afferents do play a role, particularly the FAI afferents when there is lateral movement between the stimulus and the skin.

### *Texture*

The most common perceptual descriptor of surface texture is the sensation of roughness. In early psychophysics experiments common materials, such as sandpaper, were used. More recent stimuli consist of precisely manufactured three-dimensional features, which can be defined mathematically. These allow quantitative neural studies, usually in monkeys, which can be compared with human psychophysics. Stimuli commonly used are either gratings of alternating grooves and ridges, or embossed dot arrays.

Perceived roughness increases monotonically with the spatial period of the texture up to spacings of around 3 mm for both gratings and dot arrays. The most critical feature underlying perceived roughness is the groove width for gratings and the dot spacing for dot arrays. Tangential movement between the stimulus and the skin affects roughness perception. The difference threshold for the spatial period of gratings is degraded from a threshold of 5% when there is movement to a threshold of 10% when there is no movement. Roughness perception is independent of whether the tangential movement is active or passive and is little affected by variations in the rate of movement, but perceived roughness increases when contact force increases [4].

Textures affect both the spatial and temporal patterns in peripheral neural population responses as well as intensive parameters like total neural response. How these population features are used by the central nervous system appears to depend on the nature of the stimulus and the task.



**Processing of Tactile Stimuli. Figure 2** Classification of the four types of low-threshold mechanoreceptive afferent fibers innervating the glabrous skin of the human fingerpad. Upper trace (*green*) in each panel shows the indentation amplitude (*vertical axis*) as a function of time (*horizontal axis*) for a probe indented into the skin for 1 s. Traces below (*orange*) show neural responses; each vertical tick represents an action potential. Adapted with permission from Johansson RS and Vallbo AB (1983) Trends in Neuroscience 6:27–32.

### Shape

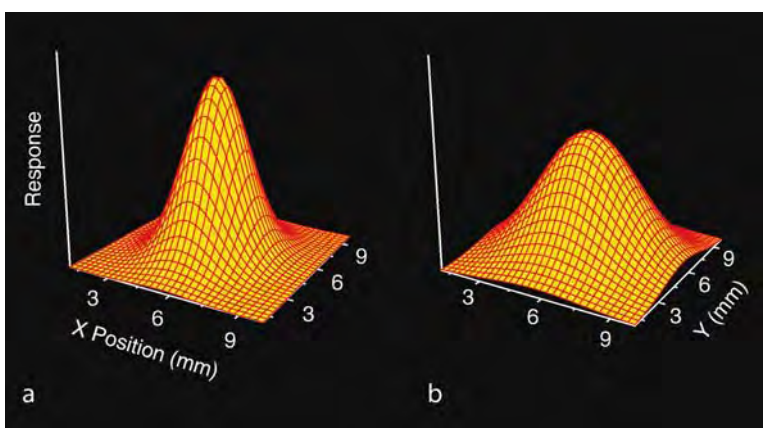
The identification of an object's shape is essential for dexterous manipulation and often involves active exploration of the object. This brings into play a spectrum of sensory mechanisms which relay information about the position and movement of the joints in the hand and arm, as well as cutaneous tactile information. Objects range in shape from a simple sphere to the complex shapes of eating utensils and tools we routinely use. All shapes can be described in terms of their local curvatures. Shapes such as spheres, cylinders, and toroids can be quantified easily; this facilitates analysis of the neural representation of their shape and subsequent correlations with human performance. When simple shapes such as spheres are applied to the skin so that only cutaneous information can be utilized, humans are able to discriminate a difference in curvature (reciprocal of the radius) of the order of 10%. When spheres are indented into a monkey's fingerpad, a clear monotonic relationship exists between single fiber responses and stimulus curvature; both the SAI and FAI afferent responses are modulated but the effect is more pronounced and more reliable for the SAI afferents [5]. Comparable responses in human afferents to spheres and cylinders applied to the fingerpad have been reported; curvature significantly modulates responses in SAI, SAII, and FAI afferents.

For any shape more complex than a sphere, more than one parameter is needed to define it. For example, a cylinder is defined by the orientation of its long axis and the radius or curvature in the orthogonal direction. A toroid is defined by three parameters – two orthogonal curvatures and an orientation. SAI afferent responses are monotonically related to the curvature of these shapes and are modulated by stimulus orientation [6]. When stimuli such as toroids, cylinders and more complex arrays of alternating convex and concave cylindrical shapes of differing curvature are scanned across the monkey's fingerpad, both SAI and FAI afferent responses are modulated. FAI afferents however require higher stroke velocities to elicit responses. The major geometrical features of three-dimensional objects scanned across the skin such as spheres, cylinders and toroids varying in shape, orientation and stroke trajectory are reproduced in the spatiotemporal responses of SAI afferents and to a lesser degree FAI afferents.

When a complex shape is explored or handled, all the parameters of the stimulus and the manipulation affect the responses of individual primary afferent fibers. Nevertheless, independent information about each of the parameters is relayed to the central nervous system because each parameter is represented or encoded uniquely in the primary afferent population response (Fig. 3).

### Manipulation

When we manipulate objects, the sensorimotor system optimizes the forces applied by the fingers. The motor control system must adopt forces that are sufficiently large to prevent slips but are not excessive in order to avoid fatigue and to ensure that delicate objects are not damaged. In addition, force magnitudes and directions must suit the shape of the object and the load conditions, and must take account of parameters such as friction. Also, the control system must rapidly and automatically adjust the grip forces to meet the demands imposed by any unexpected changes in loads during a task. Our ability to manipulate objects with dexterity is itself



**Processing of Tactile Stimuli. Figure 3** Representation of object shape in an ideal SAI afferent population response. The stimuli are spherical with radii *A*, 1.44 mm (curvature 694 $m^{-1}$) and *B*, 3.9 mm (curvature 256 $m^{-1}$). The differences in object shape are reflected in the population response profiles. The smaller, more curved sphere (a) elicits a response profile which is narrower and more peaked than that elicited by the larger, less curved sphere (b). These response profiles will be distorted by the characteristics of real peripheral neural populations including the pattern of innervation and the responsiveness of the individual fibers.

testimony to the accuracy of the underlying sensorimotor control system. This is only possible because of sensory feedback from the hand, a large component of which arises from the cutaneous mechanoreceptive fibers. Studies which mimic the forces occurring in everyday manipulations, such as lifting a container of liquid and tilting it, show that humans are able to scale and discriminate, independently, forces acting normal to the skin surface (grip force), forces acting tangential to the skin (load force) and rotational forces (torques) [7]. The magnitudes and directions of these forces and torques are encoded in the responses of whole populations of peripheral afferents along with precise information about the shape of the object being manipulated and the positions of contact on the skin [8]. Such studies demonstrate that the mechanoreceptors in the glabrous skin of the digits provide a rich and accurate source of information during complex manipulations. This information underlies both feedforward and feedback motor control.

### *Representation in the Central Nervous System*

Many of the object and task parameters discussed above have been used in studies of the response properties of cells in the somatosensory cortices of non-human primates [9]. Studies of single cells in somatosensory cortex SI have shown that responses reproduce essential object features presented to the skin and show response patterns similar in many cases to the primary afferent input signals. For example, the configuration of embossed dot ensembles is clearly evident in the response patterns across arrays of single cortical units. Some single cortical units have characteristics which appear to combine response characteristics of more than one afferent type, e.g., SAI and FAI afferents, providing an additional layer of information. The SII somatosensory cortex appears to have some higher level functions than SI, such as extracting the orientation of a stimulus independent of the position of contact on the finger [10]. How input from tactile sources is combined with other sources of sensory input such as afferents from the joints, muscles and hairy skin is not known but information from all of these sources are potentially important in controlling precise hand movements.

# Progenesis

## Definition

Paedomorphosis (retention of formerly juvenile characters by adult descendants during evolution) produced by precocious sexual maturation of an organism still in a morphologically juvenile stage.

►Evolution and Phylogeny: Chordates

# Progenitor Cell

## Definition

A progenitor cell is a cell maintaining its capacity for self-renewal and differentiation. Although the distinction between progenitor cells and stem cells is often ambiguous, the term “progenitor cell” includes undifferentiated cells with more limited plasticity and in some cases is used for cells in which multipotency is difficult to demonstrate.

►Adult Neurogenesis

# Programmed Cell Death

Hiroyuki Yaginuma
Department of Anatomy, School of Medicine, Fukushima Medical University, Fukushima, Japan

## Synonyms

Naturally occurring cell death; Physiological cell death; Developmental cell death; PCD

## Definition

►Programmed cell death (PCD) in the developing nervous system is defined as spatially and temporally reproducible and species–specific loss of large numbers of individual cells (neurons and glia) during development [1].

## Characteristics

### Types and Extent of PCD

Development of the neuronal cells can be divided into three phases, (i) proliferating neuronal precursors or founder cells, (ii) postmitotic young neurons before contacting their targets and (iii) maturing neurons after establishing synaptic contact with their targets. In early developmental stages, the neural tube consists of a population of proliferating cells organized into a pseudostratified columnar epithelium, known as the ventricular zone (VZ). Postmitotic young neurons derived from the VZ aggregate and mature between the VZ and the pial surface to form the intermediate zone (IZ). In some areas in the forebrain, such as the dorsal thalamus, a second proliferative zone, the subventricular zone (SVZ) is formed between the VZ and the IZ. In the cerebral cortex, young neurons derived from both the VZ and SVZ migrate through the IZ to form a cortical plate. Programmed cell death can be observed in all three phases of neuronal development [1,2].

After the generation of neuronal cells, glial cells differentiate from glial precursor cells that are derived from the VZ and SVZ. A considerable number of differentiated glial cells are also known to undergo PCD.

#### *PCD of Neuronal Precursors*

In the mouse embryo, PCD of proliferating precursor or founder cells can be observed as early as embryonic day (E) 8.5, when the closure of the neural tube is not yet completed. In early developmental stages, massive PCD occurs in specific regions of the developing neural tube. These include ventral and dorsal regions of the spinal cord, floor plate, neural crest, the lamina terminals, ventral region of the forebrain, dorsal region of the hindbrain and the optic vesicle [3,4]. Sporadic small amounts of PCD continue to occur in the VZ and SVZ from early to later developmental stages. But because cell proliferation occurs at the same time, it is difficult to elucidate the quantity of PCD. Estimated amounts of PCD vary from 0.3% to more than 50% depending on the regions analyzed and the methods that were used to detect dying cells. However, since it is reported that inhibition of PCD of neuronal precursors resulted in malformations of the nervous system, such as exencephaly and spina bifida, cell death of proliferating neural precursors is significant for normal development.

#### *PCD of Postmitotic Young Neurons*

Although this type of PCD is less common, there are some examples. Approximately 25% of postmitotic motoneurons in the non-limb innervating cervical spinal cord die before they establish synaptic contact with their target muscles [5]. In the dorsal root ganglion and the retina, a significant percentage of postmitotic neurons die before their axons reach their targets [4].

#### *PCD After Establishing Synaptic Contacts with the Targets*

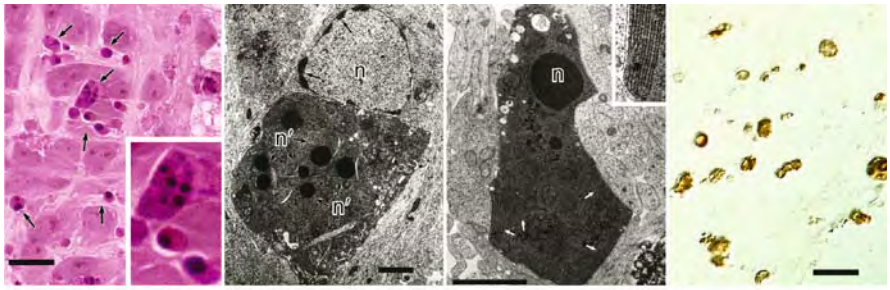
Neurons that have survived earlier phases of PCD begin to establish synaptic connections with other neurons and target cells. During this period, postmitotic differentiating neurons undergo PCD. This type of PCD has been found to occur virtually everywhere that it has been looked for and includes motoneurons, sensory neurons, autonomic neurons, retinal neurons, optic tectum, isthmo-optic nucleus, basal ganglia, cerebellum and cerebral cortex. Despite this widespread occurrence of PCD, it is also known that PCD does not occur in spinal interneurons and neurons in the medial and lateral pontine nuclei of the chick embryo. Quantitative analyses performed in the neuronal groups that are easily defined revealed that ~20–80% of postmitotic neurons undergo cell death. This type of neuronal death has been well studied and it is known that inadequate neurotrophic support derived from their targets, afferent inputs and other sources regulate this type of cell death [1].

#### *PCD of Glial Cells*

Both oligodendrocytes and astrocytes are known to undergo PCD. About 50% of oligodendrocytes normally die in the developing rat optic nerve and significant numbers of dying cells in the neonatal rat cerebellum are astrocytes [2].

In most cases, cells die by ►apoptosis. They shrink in size, the nuclear chromatin becomes pyknotic and condenses against the nuclear membrane (Fig. 1 a–c) and cytoplasmic organelles remain intact.

Eventually, the cytoplasm and nucleus break up into apoptotic bodies that are phagocytized and digested by macrophages or by adjacent healthy cells. In contrast to ►necrosis (necrotic cell death), which is caused by



**Programmed Cell Death. Figure 1** Light and electron micrographs of the ventral horn of the cervical spinal cord of the E4.5 chick embryo showing dying motoneurons. (a) Hematoxylin and eosin staining showing pyknotic dying neurons (*arrows*). *Inset* shows higher magnification of typical pyknotic neurons. (b, c) Electron micrographs showing typical examples of apoptotic degeneration. In the nucleus (*n*) of the upper cell in b, chromatin begins to condense against the nuclear membrane (*arrows*), suggesting that this cell is in the earliest stage of apoptosis. In the lower cell in b, the nucleus has been fragmented (*n'*) and the cytoplasm has become electron dense. The condensed nucleus and cytoplasm are conspicuous in the cell in (**c**). Aggregated ribosomes are often observed (*arrows and insets* in (c)). (d) TUNEL staining. Bar in (a) and (d), 10 μm. Bars in b and c, 2 μm.

acute cellular injury, apoptosis occurs as an ordered process without evoking inflammation. Another feature of apoptosis is nucleosomal DNA fragmentation and degradation. This can be observed in tissue sections by terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) (Fig. 1d). The estimated time for the whole process of apoptosis is from a few hours to at most one half day.

## Lower Level Processes

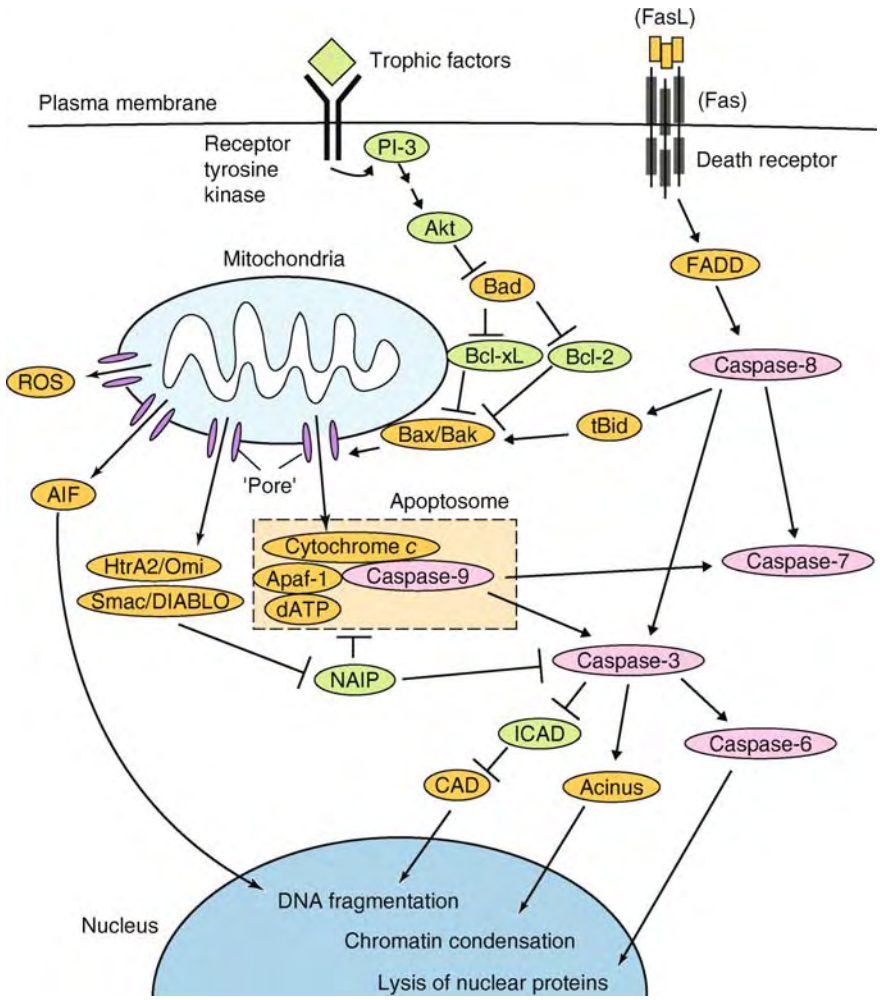
### *Intra-Cellular Mechanisms of PCD*

Cells in the developing nervous system share the same basic apoptosis mechanisms with all other cell types (Fig. 2).

The characteristic morphology of apoptosis is the result of activation of executioner ►caspases, such as caspases-3, -6 and -7. They activate a DNase (CAD) and acinus, which in turn cause DNA fragmentation and chromatin condensation (Fig. 2). Cytoplasmic and nuclear skeletal proteins are also cleaved by the executioner caspases, leading to cellular and nuclear shrinkage. The executioner caspases are activated by initiator caspases including caspase-8 and caspase-9. Caspase-8 and caspase-9 are activated through two different pathways, the death receptor pathway and the mitochondrial pathway, respectively. Association of a death receptor ligand (e.g. FasL) with its receptor (Fas) leads to recruitment of a death domain containing protein, FADD. This, in turn, recruits procaspase-8. Procaspase-8 undergoes auto-proteolysis to release active caspase-8 (Fig. 2). The key step in the mitochondrial pathway is the release of ►cytochrome *c* through pores formed in the mitochondrial outer membrane. Cytochrome *c*, ►Apaf1, procaspase-9 and ATP form the apoptosome, which is a multimeric active holoenzyme that activates executioner caspases (Fig. 2).

►Bcl-2 family proteins play fundamental roles in the process of mitochondrial pore formation. The Bcl-2 family consists of three subgroups, anti-apoptotic, pro-apoptotic and BH3-only proteins. When pro-apoptotic Bax or Bak is activated, they homo-oligomerize within the mitochondrial outer membrane to form large enough pores for cytochrome *c* release. Alternatively, Bax can change large channel proteins that reside in the outer mitochondrial membrane to allow cytochrome *c* to escape. Anti-apoptotic Bcl-2 family members, including Bcl-2 and Bcl-xL, can inhibit the effects of pro-apoptotic Bax or Bak through combining with them to form dimers. BH3-only proteins can bind to Bcl-2 and Bcl-xL to release pro-apoptotic, Bax or Bad, resulting in apoptosis. Therefore, BH3-only proteins serve as a key in the mitochondrial pathway (Fig. 2). It is also known that one BH3-only protein, Bid, can be cleaved (activated) by caspase-8 to form tBid, which in turn activates Bax and Bak. This allows cross talk between the two pathways (Fig. 2).

Besides cytochrome *c*, several other cell death-inducing molecules are known to escape through the pores formed in the outer mitochondrial membrane. These include ►AIF (apoptosis inducing factor), EndoG (Endonuclease G), Smac/DIABLO and Omi/HtrA2. Reactive oxygen species (ROS) are also released from dysfunctional mitochondria. These molecules activate caspase-dependent or caspase-independent cell death pathways serving as initiators of collateral cell death pathways (Fig. 2). It is also known that there are intrinsic molecules that antagonize caspase activities to prevent apoptosis. These include ►NAIP (Neuronal Apoptosis Inhibitory Protein) and XIAP.



**Programmed Cell Death. Figure 2** A simplified scheme of cell death pathways in cells in the developing nervous system. ►Caspases are indicated in *pink*, pro-apoptotic members in *yellow*, anti-apoptotic members in *green*. For details, see text.

## Process Regulation

### *Inter-Cellular Regulation of PCD*

#### *Regulation by Trophic Factors (the Neurotrophic Theory)*

The favored explanation as to why neuronal and glial cells die in the developing nervous system is "the neurotrophic hypothesis." This proposes that developing neurons and glial cells require trophic support for survival and compete for a limited supply of trophic factors. Cells that cannot obtain enough trophic support undergo cell death. This hypothesis has been supported by many experimental studies in which the quantitative relations between neuronal groups and their synaptic targets or afferent inputs were altered. For example, removal of a limb bud on E2 in the chick embryo resulted in total disappearance of limb innervating motoneurons by E10 because of excessive motoneuron death. On the other hand, addition of a supernumerary limb bud resulted in the survival of more motoneurons. Similarly, it has been proved that alteration of afferent inputs also affects the number of surviving neurons. However, it is not yet clear whether neurons compete for limited amount of trophic factors or limited sites where trophic factors are transferred to neurons. An important source of trophic support for developing neurons is their targets. In addition, signals derived from afferent inputs as well as from nonneuronal cells, such as central and peripheral glia, are recognized as possible sources of trophic regulation of cell death and survival.

Trophic factors that are required for survival of developing neurons vary depending on the neuronal population. For example, neurons in the sympathetic ganglia require target-derived NGF as a survival factor, whereas sensory neurons in peripheral ganglia require one or more of the ►neurotrophins, NGF, BDNF, NT-3 or NT-4/5. Several candidates for muscle-derived trophic

factors for motoneurons have been identified and include BDNF, NT-4/5, IGF, HGF, CT-1 and GDNF [1].

The binding of trophic factors to their specific receptors induces rapid protein phosphorylation and the activation of complex cascades of intracellular signals. Among them, the phosphatidylinositol 3-kinase (PI3-K)-Akt pathway is known to be directly involved in inhibition of cell death. Activated Akt phosphorylates the BH3-only protein, Bad. Phosphorylation of Bad dissociates Bad and the anti-apoptotic Bcl-2 family, Bcl-xL, allowing Bcl-xL to prevent cell death by blocking pore formation in the mitochondrial outer membrane (Fig. 2).

The neurotrophic hypothesis also proposes that the intrinsic default fate of developing neurons is to undergo PCD. Although the mechanism of the intrinsic cell death pathways is not known for most kinds of neurons, it has been suggested that the death receptor pathway that is activated by FasL and Fas may play a role in the PCD of motoneurons [6].

### *Regulation of Target-independent PCD*

Little is known about the mechanisms that regulate PCD of proliferative precursor cells or young postmitotic neurons. Since massive cell death of proliferative cells often occurs in specific regions of the neural tube, cell death may be the result of determination of regional specificity. In fact, following perturbation of sonic hedgehog signaling, which determines the regional specificity of the ventral half of the spinal cord, distribution of dying cells was altered [7]. Moreover, death-factor signaling may also induce early neuronal death. For example, in early retinal development, postmitotic young neurons are known to undergo cell death by NGF signaling through ►$p75^{LNTR}$ and by TGFβ, which are provided by macrophages and local surrounding cells respectively [8,9].

## Function

### *Role(s) of PCD*

Since perturbation of normal PCD results in various kinds of defects in the nervous system, cell death during development plays a significant adaptive role. Possible functions of cell death in the developing nervous system are:

1. Pattern formation and morphogenesis
2. System or size matching
3. Removal of cells of an appropriate phenotype or cells that have no function
4. Error correction
5. Removal of harmful cells that have defective DNA

## Pathology

One genetic disease in humans in which cell death has been implicated is infantile ►spinal muscular atrophy (SMA). A clear link between SMA and failed inhibition of cell death has been proposed. In severe SMA, the neuronal specific inhibitor of apoptosis (IAP) family member known as NAIP is often dysfunctional due to missense and truncation mutations. IAPs such as NAIP potently block the enzymatic activity of executioner caspases (3 and 7) suggesting that NAIP mutations may permit unopposed developmental apoptosis to occur in sensory and motor systems resulting in lethal muscular atrophy [1].

Since neurons need their targets for their survival, loss of one neuronal group or target tissue often results in a secondary loss of other neuronal groups. For example, the "cerebelless" mutant mouse lacks the entire cerebellar cortex. The primary defect is a specific inhibition of GABAergic neurons including Purkinje cells, resulting in secondary and complete loss of external germinal layer, pontine and olivary nuclei during development [10].

## Programmed Cell Death

### Definition

Cell death by design, in which the cell uses specialized cellular machinery to kill itself. Programmed cell death is a process essential to cell termination, homeostasis, and development. This process allows metazoans to control cell number and eliminate surplus or erroneous cells.

## Progressive Bulbar Palsy

### Definition

►Motoneuron disease of the ►brainstem (*bulb* stands for ►medulla oblongata and *palsy* for weakness) with dysarthria (difficulty articulating) and dysphagia (difficulty swallowing).

## Progressive Multifocal Leukoencephalopathy

### Definition

Infrequent disorder of the nervous system that primarily affects individuals with suppressed immune systems (including, allograft recipients such as kidney transplant patients; patients with cancers such as leukemia or lymphoma; and nearly 10% of patients with ►acquired immune deficiency syndrome (AIDS). The disorder, which is caused by a common human polyomavirus, JC virus, is characterized by ►demyelination or destruction of the ►myelin sheath that covers nerve fibers.

►Acquired Immune Deficiency Syndrome (AIDS)

## Progressive Supranuclear Palsy

### Definition

Progressive degenerative disease belonging to the family of tauophaties with widespread pathology involving cortical and subcortical structures. In Progressive supranuclear palsy, oculomotor disturbance, early postural instability with falls, and frontal dementia predominate. There is symmetric onset of parkinsonism, early postural instability, severe axial rigidity, absence of tremor, and poor response to dopaminergic therapy. supranuclear gaze palsy, especially of downgaze, is the defining characteristic. Blepharospasm and eyelid opening apraxia are also common.

►Parkinsonism

## Pro-inflammatory Cytokines

### Definition

Pro-inflammatory cytokines such as interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α, are overexpressed at the lesion site for several hours to days after central nervous system (CNS) injury. The cells of origin of these cytokines are neurons, astrocytes, microglial cells, infiltrated macrophages, and neutrophils. They are involved in the secondary tissue damage that is produced through a series of autodestructive events (e.g., apoptosis) initiated by the primary trauma. Low concentrations of pro-inflammatory cytokines can be beneficial; however, high concentrations mediate cell death and widespread tissue disruption. Thus, manipulation of this inflammatory response is one of the major therapeutic approaches for CNS injury.

►Transplantation of Neural Stem Cells for Spinal Cord Regeneration
►Tumor Necrosis Factor- α (TNF-α)

## Pro-inflammatory Mediators

►Central Nervous System Disease – Natural Neuroprotective Agents as Therapeutics

## Projection Neurons

### Definition

Neurons that send ("project") their main axon outside a morphologically defined area or nucleus in which their cell bodies are located. The length of the axon depends on the distance between the structures they connect.

Thus, in the cerebral cortex, association axons linking adjacent areas are short compared to corticospinal axons. In the superior colliculus, projection axons to the pretectum are short compared to tectoreticulospinal axons. By opposition, neurons participating exclusively in the intrinsic connections of a given structure are called "local neurons" or "interneurons."

►Modulatory Projection Neurons

## Projections

### Definition

Axonal extensions, ranging from short to very long, that possess chemical synapses allowing for the electrochemical communication of neurons with other neurons over distance. A neuron with an axon possessing a chemical synapse in relation to another neuron at some distance is said to project to that neuron.

Axons carrying impulses away from a structure comprise efferent projections. Axons carrying impulses into a structure comprise afferent projections.

## Prokineticin 2

### Definition

A 102 amino acid polypeptide that may function as an output molecule from the suprachiasmatic nucleus (SCN) in transmitting timing behavioral circadian rhythms. It may also function locally within the SCN to synchronize cellular clocks. Receptors for PK2 (PKR2) are abundantly expressed in major target nuclei of the SCN output pathway. Intracerebroventricular infusion of PK2 at night, when endogenous PK2 mRNA levels are low, markedly reduces the nocturnal increase in locomotion.

Mice with a disruption of the PK2 gene display significantly reduced rhythmicity for a variety of circadian physiological and behavioral parameters including sleep-wake cycle, locomotor activity, body temperature, and circulating glucocorticoid as well as glucose levels.

►Circadian Rhythm
►Clock Coupling Factors
►Locomotion
►Sleep-wake Cycle
►Suprachiasmatic Nucleus

## Proliferation

### Definition

Production of new daughter cells by cell division.

►Neural Development

## Promoter

Julia Kim, David H. Farb, Shelley J. Russek
Laboratory of Molecular Neurobiology, Department of Pharmacology and Experimental Therapeutics, Boston, MA, USA

### Definition

A promoter contains all the gene regulatory information that is necessary for the expression of its protein product in vivo. The DNA sequence of the promoter can be contiguous lying upstream of the transcriptional start site or it can be separated by large distances dependent upon the presence or absence of key regulatory elements, such as enhancers or silencers, in introns and exons.

The binding of transcription factors to the sequence(s) of the promoter are believed to alter DNA conformation in such a manner that stabilizes the binding of RNA polymerase to enable regulated transcription. A promoter can also be regulated at the epigenetic level through the recruitment of chromatin modulators such as HAT, HDAC, mSin3A, and Swi/snf, that control the accessibility of transcription factors to DNA elements. Cell-and developmental-specific expression often relies on the presence of promoter elements, such as enhancers or silencers, that are located at a distance from the start site in exons, introns, or intergenic regions.

### Characteristics

#### Structure

Core: Core promoters are the minimal elements needed for RNA polymerase II to initiate transcription at basal levels using a particular ►transcriptional start site (TSS). The most well-known core promoter region contains a TATA box, around 35 bp upstream of the TSS, and an Initiator element (Inr) that contains the TSS. Not all core promoter regions contain TATA boxes. In fact, many of the regulated genes in the human genome are TATA-less. TATA-less core regions often contain other elements such as the GC box or a binding site for a strong activator protein such as Specificity Protein 1 (SP1). Diversity in core promoter

regions is just beginning to be identified suggesting that this region of the gene is highly specialized and plays an important role in the regulated nature of gene transcription.

Proximal Region: Proximal promoter region contains the Core and around 500 bp of sequence upstream of the ►TSS. They contain upstream binding sites for activators that are necessary to increase transcription above basal levels.

Distal Region: Distal promoter region is upstream of the Proximal and in most cases contains the recognition sites for activators and repressors responsible for full transcriptional activation, consistent with the levels of gene expression *in vivo*. The Distal region usually contains a few kilobase pairs of DNA lying upstream of the Proximal promoter region that contains the core.

Cis-acting elements and trans-acting factors: A particular set of regulatory sequences that are found within the promoter of a gene are referred to as cis-acting elements. The proteins that bind to these elements, as well as to related elements in multiple genes, are referred to as trans-acting factors, also known as transcription factors.

Gene clusters: A set of two or more genes that are derived from a common ancestor and are functionally related, or encode related gene products, are often found in gene clusters on a particular chromosome. For example, subunit genes coding for the major inhibitory neurotransmitter receptor, type A γ aminobutyric acid (GABA, $GABA_AR$) are organized as β–α–α–γ or β–α–γ on four human chromosomes [1]. This unique genomic structure suggests that there may be regulatory elements shared by the promoter regions or a single locus of control (as seen for the β-globin genes) that has been preserved throughout evolution.

Alternative Promoters: Many genes use more than one promoter to control either development or cell specific expression. The transcripts produced from these promoter regions increase the diversity of protein products or the stability of their mRNAs. The alternative promoters can be located in a downstream intron or in a distant region upstream from the dominant ►TSS.

## Examples of Promoters, Their Elements and Transcription Factors Studied in the Brain

- Neural Specific Genes

GABRB1 [2] – A gene that codes for the beta 1 subunit of the $GABA_AR$, the major inhibitory receptor in the nervous system that contains an integral chloride ion channel gated by GABA. GABRB1 is organized in a head-to-head orientation with the α4 subunit gene (GABRA4). The human GABRB1 promoter lacks a ►TATA-box and contains an Inr element that by itself can determine the cell specific expression of the gene and its autologous regulation by GABA.

GLUR2 [3] – GLUR2 has multiple ►TSSs that are development and cell-specific. None of the TSSs identified contain TATA boxes and their transcription is modulated by Sp1, within a methylated CpG island, and a GLUR2 silencer that shares 71% similarity to the restrictive silencing factor REST/NRSF (see below).

GABBR1 [4] – A gene that codes for the R1 subunit of the $GABA_BR$, the G-protein coupled receptor that is activated by GABA. Use of alternative promoters, rather than alternative splicing as previously speculated, contributes to the generation of isoforms for the $GABA_BR1$ subunit. $GABA_BR1a$ expression is marked in the fetal brain and may regulate the formation of presynaptic $GABA_B$ receptors while it is modest in the adult brain. GABABR1 expression is low during development and marked in the adult where it may regulate the formation of postsynaptic $GABA_B$ receptors. The promoter regions of both isoforms are TATA-less and contain functional DNA sequence elements for regulation by the cAMP regulatory binding protein (►CREB).

Neuropeptide Y (NPY) [5] – NPY is the most abundant neuropeptide in the brain and is expressed in a wide variety of cell populations of the nervous system. Its promoter region contains the partial consensus sequence for transcription factors such as SP1, Activator Protein 1 (AP1) and CAAT box. However, CT-rich, instead of GC-rich, sequences are used by Sp1 to promote transcription.

- A signal-induced transcription factor

Early growth response gene (Egr) and Egr response element (ERE) [6,7]: While the most well known signal activated transcription factor in the nervous system is the ubiquitously expressed CREB, there is a family of immediate early gene (IEG) products known as Egrs that are increasingly being identified in the dynamics of brain function. Egrs bind to the consensus motif (depicted below) in response to signals elicited by neurotransmitters, altering the expression level of certain genes that contain a GC-rich ERE in their promoter region. Egrs link a short-term change in neurotransmission to a functional change via the synthesis of new proteins.

ERE consensus sequence

$$5' - GCG(G/T)GGGCG - 3'$$

Egrs are implicated in the transcriptional control of multiple genes via their zinc-finger motif located in the C-terminal region. So far, four family members have been identified (Egr1–4). All of them recognize the same ERE sequence and are homologous, although different spatial and temporal expression is observed. Of the four members, Egr1 is the most well defined and its expression is dependant on activation of the *N*-methyl-D-aspartate receptor (NMDAR) and mitogen activated protein kinase (MAPK) signaling. However,

the target or the specific mechanisms controlling transcriptional regulation of the other Egr family members is not completely known. Egr3 has recently been identified as a seizure-induced protein controlled by brain derived neurotrophic factor (BDNF, see below) and it plays an important role in learning and memory. Multiple forms of Egr3 that differ in their N-terminus have been described and are being investigated.

- A major target gene for Egr 1 and 3

Activity-regulated cytoskeleton-associated (Arc) protein [8] – A putative target of Egr1 and Egr3 transcription factors, Arc expression is upregulated by robust synaptic activity, such as observed in kainic-acid induced seizures or exploration of a novel environment by rodents. Egrs bind to the ERE site in the Arc promoter. Similar to Egrs, Arc expression is dependant on NMDAR activation and MAPK signaling, highlighting its association with long-term potentiation (LTP) and learning and memory.

- Repressor factor involved in neural specific gene expression

Neuron-Restrictive Silencer Element (NRSE) and Neuron-Restrictive Silencer Factor/RE1 Silencing Transcription factor (NRSF/ REST) [9] – Neuronal specificity can be conferred via unique transcriptional activators or via repressors that silence transcription in non-neuronal cells. Identification of the silencer element NRSE is one of the most important accomplishments in neural specific gene regulation today and its importance to brain function as well as disease is accumulating in the literature. NRSE is found primarily in non-coding sequence and is evolutionarily conserved. NRSEs are found in neuronal genes coding for proteins such as the $Na^+$ channel, Synapsin I, BDNF, NMDAR, nAchR, GABAAR, and Neurofilament M, and in non-neuronal genes coding for proteins such as Keratin, human/bovine P450–11β, and skeletal actin. NRSF binds to a 21-nucleotide sequence called the neuron-restrictive silencer element (NRSE/RE1).

NRSE consensus sequence

$$5' - \text{ttCAGCACCaaGGAcAGcgcC} - 3'$$

Uppercase letters: conserved Lowercase letters: less conserved

Although it was initially believed that NRSE containing genes are silenced only in non-neuronal cells via the binding of NRSF, more recent studies have revealed that they also bind to genes within neurons. NRSF contains a zinc-finger DNA-binding domain and interacts with the co-repressors CoREST and mSin3a via two repressor domains found at each end. Once bound to NRSF, the co-repressors recruit histone modifying proteins such as Histone Deacetylase (HDAC) and Methyl CpG binding protein 2 (MeCP2), altering conformation of the ►chromatin to a transcriptionally silent form (heterochromatin).

NRSF expression in neuronal cells decreases as they become more differentiated and its gene targets are involved in neuronal function, such as ion channels, neurotransmitter receptors, neurotransmitter-synthesizing enzymes, neuronal cytoskeleton, neuropeptides and neurotrophic factors. A truncated splice variant of NRSF, REST 4, has been shown to bind to NRSE rather weakly in neurons and is also found at high levels in biopsies of Small Cell Lung Carcinoma patients.

- A ubiquitous transcription factor with important brain function

Sp1 [10] – Sp1 is a transcription factor that regulates the expression of genes throughout the body. Particular to the brain, it regulates expression of the acetylcholine receptor (AchR) and Huntingtin (Htt). Sp1 is known to bind specifically to GC-rich DNA elements via its zinc-finger motif. With its strong glutamine-rich activation domain, Sp1 recruits basal transcription factor TFIID to DNA and induces marked transcription. TFIID contains TATA box binding protein (TBP) and TBP-associated factors (TAFs) of variable sizes. Of these TAFs, human TAFII130 is of particular interest due to its specific interaction with Sp1. Both Sp1 and TAFII130 bind to the mutant form of Htt, an association that is implicated in Huntington's Disease.

- Activity dependent neural specific signaling molecule

BDNF [11] – There are five exons in the rat BDNF gene and exon I through IV contain promoters that are upstream of one another (designated promoters I-IV). Use of alternative promoters ensures specificity and diversity of gene regulation. For example, BDNF transcription via promoter I is activated after $Ca^{2+}$ influx through L-type voltage-dependent $Ca^{2+}$ channels (L-VDCC), whereas promoter III is activated when $Ca^{2+}$ influx occurs through the NMDAR. The activation of both promoters occurs via binding of phosphorylated ►CREB.

## Techniques Used to Study Promoters

Electrophoretic Mobility Shift Assay (EMSA, also referred to as gel shift assay) – EMSA is an in vitro assay used to determine whether a particular transcription factor binds to a known sequence of DNA by identifying if there is specific binding activity in a given nuclear extract when exposed to a particular sequence of DNA or RNA. Extracts of nuclear proteins are incubated with a radiolabeled DNA probe that contains a sequence of interest and the resulting DNA/protein complex is resolved using non-denaturing acrylamide gel electrophoresis. In the absence of extract the probe migrates rapidly towards the bottom, however, in the presence of specific binding protein, the probe's migration is slowed in the gel. Competing cold oligonucleotides of various sequences are used to demonstrate

sequence specificity for the binding interaction. In addition, to determine the identify of nuclear proteins, a specific antibody is added to the binding reaction and presence of a "supershift" (because of the increased size of the complex with the antibody attached, the probe will migrate even more slowly) occurs if the epitope of the binding protein is accessible.

Luciferase Reporter Assay – The luciferase reporter assay is especially useful in studying mammalian transcription because the natural expression of the luciferase gene product is restricted to fireflies. In molecular neurobiology, a vector containing the promoter sequence of interest is placed upstream of the luciferase reporter and promoter activity is studied in transfected primary neuronal cultures derived from different embryonic brain regions by assaying for the amount of light production from cleavage of the luciferase substrate luciferin.

Chromatin Immunoprecipitation (ChIP) – ChIP is utilized to examine the *in vivo* binding of a given protein to a specific promoter segment. After DNA is crosslinked to the DNA-binding proteins, the genomic DNA is sheared into small fragments of 300 bp or less and immunoprecipitated with a specific antibody that recognizes the protein of interest. Upon reverse-crosslinking, detection of the resulting precipitated DNA fragments are done using standard polymerase chain reaction (PCR) or quantitated via real-time PCR with taqman probe and primers. This assay is useful for identifying potential endogenous genes regulated by a particular transcription factor.

## Disease

*Single Nucleotide Polymorphism (SNP) within the promoter region*. Single Nucleotide Polymorphism is characterized as a genetic deviation or change in DNA of more than 1% of a population. Generally, SNPs do not result in any phenotypic changes. However, when the SNPs occur within a coding region or a promoter of a gene, consequences such as a differential response to a drug or an increased predisposition to certain diseases have been observed.

*Brain-derived Neurotrophic factor (BDNF).* In particular, a genetic variance in the BDNF promoter I was recently identified. This novel variation has a cytosine replaced by adenine at 281 bp upstream of the TSS and causes reduced DNA binding by factors yet to be identified. In addition, this "A" allele decreases BDNF promoter activity in rat hippocampal neurons and an association of the allele with a decrease in psychopathology is reported in a phenotype-genotype analysis using human samples.

*Neuropeptide Y (NPY).* Lowered activity of NPY has been implicated in the pathophysiology of Schizophrenia. A novel polymorphism within the Japanese population at −485T>C in the promoter region of the NPY gene has been reported in patients suffering from Schizophrenia. The −485 nucleotide is contained within the Sp1 consensus site and abolishes potential binding site detection.

# Property

Volker Gadenne
Department of Philosophy and Theory of Science, Johannes-Kepler-University, Linz, Germany

## Definition

Properties are ways things are; they are features, attributes, traits, characteristics or aspects.

## Description of the Theory

### Property and Object

Suppose that Jack is bald. Jack belongs to the category of *things* (or *objects*, including persons). Baldness, by contrast, is a *property*. Jack has this property and many other individuals possess it too. Things are bearers of properties and different objects may share the very same property. Things are also said to *exemplify* or *instantiate* properties.

But things are not the only entities that possess properties. Properties can themselves have properties and so can events. "Bald" is exemplified by individual persons and has itself the property of being physical. "Bold" and "shy" are properties of persons too, they are however mental. An event, like having a toothache, may have the property of being short or of occurring after breakfast.

When philosophers speak of objects and properties, they use these concepts in a wide sense. The category of objects may include tables, trees and persons, but also electrical fields or points in space-time. As to properties, many of them are denoted by adjectives, like "green" or "round". But there are also properties denoted by rather complex predicates. For example, a neuron instantiates (at certain times) a special property denoted by the term "resting potential." A person may be ascribed the property of being in pain, of believing that snow is white or of wanting to study philosophy. In such cases a person can also be said to be in the *state* of being in pain or in the *state* of believing that snow is white [1].

### Ontological Status of Properties

The ontological status of properties has been discussed since Plato [2,3]. *Realists* (in a specific sense of the term) believe that words like "white" or "horse" name the ►universals "whiteness" and "horseness." Unlike particulars, universals are abstract entities (►abstract entity). They belong to the real (►Realism (as an ontological position)) world though they are not located in space and time. Some realists (Platonists) think a universal can exist even if it has no instances. Others (following Aristotle) assume that for a universal to exist it has to be exemplified by at least one individual thing.

According to ►nominalism, abstract entities do not exist at all. There are only particulars (and perhaps classes of particulars), like individual white things or individual horses. Different things are said to have the same property or belong to the same sort or kind, if the same predicate applies to, or *is true of*, these different things. (Exchange "predicate" with "concept" to get concept nominalism.) Realists object that for a predicate to be true of a particular (or a particular to fall under a concept), that particular must be connected with some real ►entity to which the predicate (or concept) refers. Otherwise the ascription of predicates to particulars would be an arbitrary matter. The nominalists' standard reply is that predicates do not function like names (see for the controversy between realists and nominalists [4,5]).

Some philosophers believe there are *essential* and *accidental* properties. A property F is said to be essential to an entity a, if a could not exist without exemplifying F. For example, the number two has essentially the property of being even. It is hard to see how it could lack that property and still be the number two. With respect to concrete objects, it is more difficult to decide whether a property is essential or accidental. It seems that Jack is essentially a human being. In contrast, his property of being a philosopher is accidental, since he could instead have become a postman. In ►possible world semantics, the idea of an essential property is expressed as follows; a has the property F essentially if and only if a has F in every ►possible world [6]. For a critique of ►essentialism, see [7].

### Property and Predicate

If properties are regarded as parts of the real world, they must be distinguished from predicates. Properties are designated by predicates. In the sentence "Jack is bald," the word "Jack" denotes an individual and the predicate "is bald" refers to a property. Unlike names and predicates, properties are not linguistic entities but real features of the world (an assumption not shared by austere nominalists). It is less clear whether properties are different from concepts (meanings of words). They are different if properties are taken as real and concepts as something in the minds of persons (or as something existing in dependence on minds). However, properties may come close to concepts, if concepts too are conceived as mind independent entities or if both properties and concepts are conceived as mind dependent.

## Intrinsic and Extrinsic (Relational) Properties

Objects possess some of their properties in their own right. For example, an object may be round (spherical) and have a mass of two kilograms and it has these features independently of how other things are. Such features are called *intrinsic* properties or *qualities*. Other properties are *extrinsic* or *relational* [1]. Socrates is a teacher of Plato and he is married to Xanthippe. These are relational properties of Socrates, since he has them not independently of other things. (According to some philosophers there are no relational properties; they regard properties and relations as ontologically different, and categorize both as attributes.) Though intrinsic properties are not themselves relational, their specification or measurement usually involves relations between objects. Consider for example how mass (an intrinsic property) is specified. To say that this rod has a

mass of two kilograms is to say that it would balance, on an equal arm balance, two objects each of which balances the standard kilogram.

### Dispositional Properties, Causal Powers, and Functional Properties

Special kinds of relational properties are *dispositional properties* and *causal powers*. This billiard ball has the qualities (intrinsic properties) of being spherical and solid. In virtue of these qualities, it has the disposition to roll when placed on an inclined surface. Other dispositional properties are solubility in water or fragility. Having a special disposition is to produce certain behavior under certain conditions. It seems that dispositions are always grounded in non-dispositional properties. For example, being fragile is grounded in a particular molecular structure. An object is fragile in virtue of having that molecular structure. If an object has the dispositional property G in virtue of the non-dispositional (intrinsic, qualitative) property F, F is called a *first-order property* and G a *second-order property.*

Another special kind of relational properties are *functional properties*. Many things are defined by functional descriptions, for example, a knife, a clock or an eye. An object has the property of being a clock, not because of the material of which it is made, but because it satisfies a certain job description – it keeps time. Similarly, an eye can be made of different materials and take different forms (compare our eye to that of the horse or the honeybee). What makes it an eye is a special functional property or functional role – it extracts information from light radiation and makes that information available to the system it subserves. Functional roles can best be described with the help of causal relations. Therefore, philosophers often speak of "causal roles" instead of functional roles.

### Mental Properties

A major problem in the philosophy of mind is the status of mental properties. Physicalists have tried to demonstrate that the mental is nothing over and beyond the physical organism and its physical/biological properties. This view includes the theory that all mental properties are realized as physical/biological properties; according to advocates of reductionist physicalism, mental properties are even reducible to physical/biological properties. Similarly, functionalists have held that mental properties can be understood as functional properties (which are themselves realized as physical properties). Consider for example the property of being in pain. According to functionalism, roughly speaking a mental state is a pain if it is caused by specific stimuli (e.g. tissue damage), gives rise to specific thoughts and wants (e.g. about how to end the unpleasant state) and causes specific behavior (e.g. withdrawal).

It has been objected against physicalism and functionalism that they could not adequately account for *phenomenal qualities* or ►qualia (singular: quale). Some mental states, especially, sensations and feelings, are characterized by specific phenomenal qualities. Think of the painful, hurting character of a sharp headache. Such phenomenal qualities seem to be intrinsic properties not extrinsic (relational) ones. It is hard to see how phenomenal qualities could by identified with or reduced to physical properties, causal powers or functional roles. But if they cannot be reduced to the physical domain, it seems difficult to understand how they can have any effect on the physical organism and its behavior. The status of mental properties, especially phenomenal ones, is still controversially discussed.

# Proposition, Propositional Attitudes

## Definition

A proposition is what is asserted as the result of uttering a sentence; propositions are considered to be the meanings of closed sentences (as opposed to open sentences or predicates), and they are considered to be the bearers of truth and falsity. Propositions are expressed by that-clauses (the sentence "Hannah laughs," for instance, expresses the proposition (means) that Hannah laughs) and can be thought of as pairs consisting of objects and properties (like <Hannah; laughs>) or relations (like <<Hannah, Fred>; is taller than>).

A subject S can have different mental postures towards a proposition P, for example believing, remembering, desiring, intending, fearing, hoping etc.

In that case, S has a propositional attitude. A propositional attitude is an intentional relation R between a subject S and a proposition P, such that S bears R to P. Propositional attitude ascriptions are made

up of a name for some thing, like "Fred," followed by a name for an attitude, like "believes," followed by an expression for a proposition, like "that Hannah laughs."

►Epiphenomenalism
►Possible World

## Propositional Knowledge

### Definition

Propositional knowledge is the kind of knowledge one can communicate using some proposition, i.e. in English using some phrase of the form "that p" where "p" can be replaced by some complete declarative sentence.

►Knowledge

## Proprioception

Simon Gandevia
Prince of Wales Medical Research Institute, Sydney, NSW, Australia

### Introduction

The production of ►voluntary movements usually occurs effortlessly with few errors. We rarely drop objects held in the hand or fall while walking. This requires coordinated activity involving cognitive, sensory and motor areas of the cerebral cortex. Ultimately the correct output is generated by ►motoneurons in the ►spinal cord and ►brainstem which then produce the correct changes in force and length of muscles. For muscles to exert continuously the proper forces on the skeleton requires the brain to plan, initiate and control movements. A set of sensory processes underlies this ability. It is variously termed "proprioception" or "►kinaesthesia." These terms are now often used interchangeably, although proprioception is broader in its scope.

Proprioception and kinaesthesia refer to a class of sensations or sensory-motor processes which include the ability to detect movement and position at different joints and the ability to judge forces exerted by muscles and the heaviness of objects they lift. Knowledge about the timing of muscle contractions and knowledge about the overall body image are now also covered by these umbrella terms. Deficits that impair proprioception impair the control of voluntary movement and posture, whereas diseases that impair movement and posture usually have deficits in some aspects of proprioception. This synopsis focuses on the sensations of joint position and movement although some other areas are briefly mentioned.

The neural mechanisms underlying proprioception have been hotly debated for more than a century [1]. Much of this controversy has arisen because experimentalists and clinicians have taken a narrow view of what proprioception encompasses. In contrast, theoreticians have proposed complex models of how proprioception might contribute to movement control, but these have been difficult to validate.

On the "input" side, groups of specialized sensory receptors in the skin, joint and muscles respond to mechanical strains and signal the state of the limb to the spinal cord and brain. Evidence of the contribution of each of these receptor groups is summarized below. For these signals to be transformed into useful sensations which can be reported verbally requires central processing so that the different input signals are calibrated to the Newtonian state of the body, and combined or amalgamated to provide a body map (or "representation") which can help guide movement (see also ►Phantom limb sensation and pain).

Because a particular proprioceptive state (e.g., the angle of a joint) can arise under passive conditions with muscles relaxed, or active conditions with muscles contracting, most proprioceptive models also include an input from motor command signals. Peripheral signals provide feedback that is evaluated against what movement has been commanded and what proprioceptive state might be expected. Various terms for these command signals have been coined including an ►efference copy or ►corollary discharge. A requirement for such signals is not unique to evaluation of proprioceptive signals, but is equally necessary in other modalities such as cutaneous, visual and ►vestibular sensation, in which changes in the peripheral signals can be produced by self-generated forces or externally-generated events. An interesting example occurs when a tickling skin sensation is felt when generated externally but not when the same stimulus is self-generated [2].

### Peripheral Proprioceptive Signals

There are two steps in the establishment of a proprioceptive role for a particular class of sensory receptors. First, the receptors must encode variables such as the forces exerted by muscles or changes in joint angles in their discharge. Second, the discharge must be capable of producing a change in perception of that

proprioceptive variable. The first step is achieved by recording the discharge of the receptors. The second requires that changes in the discharge evoke changes in sensation. This can be achieved by finding a proprioceptive illusion when the receptors are activated selectively. Alternatively, performance in a proprioceptive test may diminish when the receptors are eliminated, such as when a diseased or damaged joint is replaced by an artificial one.

Of the peripheral proprioceptive signals, those arising in specialized muscle receptors are considered the most important [1,3,4] (see ►Proprioception: Roles of Muscle Receptors, and ►Movement Sense). ►Muscle spindle endings can be activated by local length changes and their firing can also be modified by a specialized ►fusimotor system that can modulate the background firing rate and gain of the endings. The ►primary muscle spindle endings are exquisitely responsive to muscle length changes including vibration. When a muscle (or its tendon) is vibrated at ~100 Hz, subjects experience an illusion consistent with the muscle lengthening, but also occupying a more lengthened position [5]. When the vibration is adjusted so that secondary spindle endings are more effectively activated, the illusion is more one of position than of movement. The central nervous system interprets these unexpected proprioceptive signals according to the current body map (see ►Phantom limb sensations and pain), and this leads to errors in voluntary movements and posture [6]. Muscles also contain specialized receptors (►Golgi tendon organs) which encode the active forces generated by voluntary contraction. These signals probably contribute to sensation of muscle force.

Until recently, specialized receptors in the skin were not considered to have a role in proprioceptive sensations, although it had long been realized that such receptors discharge with movement of nearby joints and that their activity contributed to the reflex control of movement in activities such as walking and grasping. Some populations of ►cutaneous receptor encode the pattern of local skin strain and its change with changes in joint position [7], while others encode the timing of voluntary movement and any disturbances to it (see ►Proprioception: Role of cutaneous receptors). Stretch receptors in the skin (probably innervating ►Ruffini endings) discharge when the skin around a joint is stretched by moving it via threads attached to tape stuck to the skin. Subjects then commonly report that the underlying joints are moving in a direction consistent with the pattern of artificial skin strain. These illusory sensations of movement are amplified when combined with muscle spindle signals evoked in appropriate muscle spindle ending populations by tendon vibration. Illusions evoked by skin stretch can be evoked at joints in the hand as well as at large proximal joints such as the elbow and knee [8]. Insight into the predictive capacity of the cortical proprioceptive decoders comes from observing that when skin and muscle receptors are activated artificially to produce proprioceptive illusions, subjects may report completely impossible anatomical positions. To the subject of the illusion, this extraordinary disruption of reality seems completely natural. Supportive evidence for the proprioceptive role of non-muscle, presumably skin receptors, derived from studies of the hand when nerves innervating the fingers (but not their muscles) have been anaesthetized [9].

Throughout most of the last century, joint receptors were considered so influential in proprioception that the term "►joint position sense" was adopted by clinicians in the belief that such receptors were crucial contributors. Evidence for the belief was much weaker than admitted. Specialized slowly adapting receptors in joint capsules and ligaments usually discharge only at one (or more) extreme of the usual physiological range of joint movement, or they discharge when abnormal stresses are put upon a joint [10]. Relatively few receptors discharge progressively across the movement range in a way that allows them to signal the angular motion (see ►Proprioception: Role of joint receptors). Electrical stimulation of digital nerves or single joint receptors can evoke illusory sensations of joint distortions and movement [11,12]. The difficulty of selectively activating a natural population of these receptors precludes a quantitative assessment of their role. Intra-articular anesthesia or joint replacement does not produce major deficits in proprioceptive sensation, which may simply indicate the redundancy in afferent sources of information (see ►Proprioception and orthopedics).

## Motor Commands and Central Processing

In the planning and execution of movement, signals related to the voluntary command are generated. These signals have a number of roles to play in the control of movement and posture [13], but exactly how this is achieved for limb movement is uncertain. Lessons from robotics and engineering, as well as studies in insects and fish, reveal that access to command signals for movement control through predictive modeling of their action on the body, and through monitoring of their outcome via feedback is likely to be important in control of human movement and posture [14].

The oculomotor system is one example where central command signals help ensure the perceptual stability of our visual world. A second example is found in the judgment of exerted force and the heaviness of objects lifted by muscle contraction. Here, signals related to the size of the outgoing command bias the judgments. As a result, we are familiar with the increase in apparent heaviness of objects we lift when muscles become fatigued [15]. This type of perceptual illusion

has been rigorously investigated under many circumstances affecting the relationship between the motor command required and the actual muscle force achieved, and the maxim holds that objects appear heavy wherever the efficiency of the neuromuscular apparatus is impaired [3]. However, the perceived force is not a simple readout of the motor command delivered (nor of the motor cortex output), because this readout must be interpreted in the light of ongoing afferent signals.

Experimental studies have usually focused on the role of command-related signals in highly volitional tasks requiring, or triggered by, an external cue. In activities such as walking in which the contractions occur more automatically, the access and processing of command signals may differ. Thus, the voluntary effort required to generate the force that can lift you onto the ball of one foot exceeds that during walking when similar forces are required. An additional complication that has not been resolved is how the muscle spindle signals from voluntarily contracting muscles are interpreted, because their signal is a resultant of the local strain on the receptor induced by the environment and that induced by the fusimotor system. This independent motor supply to muscles can alter the gain and set point of the spindle's response [16]. One way to resolve this complication is the reliance on several afferent sources of input (from the skin, joints and non-contracting muscles) rather than a signal arising solely in the active muscles.

It had long been thought that motor commands did not play a major role in sensing the position and movement of joints. However, recent work with normal subjects in whom a phantom hand has been induced by deafferentation and paralysis challenges this view. The phantom hand moves in the direction in which it is willed to move, and the size of the movement increases with the level of motor command and effort [17]. Hence, the isolated command to move, in the absence of any input from proprioceptors, generates an illusion. If this applies, as seems likely, when there are normal sensory signals, it will be clear that this group of proprioceptive sensations, like force-related sensations, is also biased by the command signals.

Presumably, the brain devises its best estimate of the proprioceptive state based on an amalgam of inputs, some command-related, some originating in different classes of sensory receptors, and some derived from internal predictive models. Visual signals and vestibular signals provide additional frames of reference against which the proprioceptive state of the limbs in extra personal space can be gauged. Vestibular signals extend the proprioceptive system by providing information about the head's position and its movement relative to gravity. Visual signals extend the proprioceptive system by calibrating it against external objects and in some circumstances visual inputs override proprioceptive ones.

This proprioceptive amalgam can adapt to rapidly changing conditions brought about, for example, by muscle fatigue or by changes in a limb's orientation to gravity occurring acutely with natural movements and posture, and chronically in the microgravity of an orbiting spacecraft (see ►Proprioception: Effect of gravity). Here, some receptors may act as "load" sensors. Proprioception must also adapt to other changes brought about by musculoskeletal growth, damage and disease, as well as the impairments accompanying ageing (see ►Proprioception: Effect of ageing). In the elderly, reduced proprioception contributes to postural instability and falling.

Studies using non-invasive imaging of the human brain have revealed that proprioceptive inputs from muscle receptors have specific projections to major cortical areas, particularly the primary motor cortex and its adjacent area (area 3a in the so-called "somatosensory" cortex). These areas have a direct role in movement production [18] as they contain cells projecting to the spinal cord and even to motoneurons. In addition, some other cortical areas are activated in a less specific way, for example, part of the supplementary motor area is active when either the left or right hand is vibrated to produce illusory movements and part of the cingulate motor area is active when the hand or foot is vibrated on the contralateral side. Other parietal and frontal cortical areas are active in producing the proprioceptive "amalgam" that is integrated with our "body image," with visual circuits, and with cognitive centers.

## Conclusions

Proprioception is a broad term encompassing several sensations which are needed for normal movement. It is likely that the brain optimizes the use of both peripheral signals from muscle, skin and joint receptors together with signals about the timing, destination and strength of centrally generated command signals. The proprioceptive system must continually determine what changes in the proprioceptive state are self-induced and what represent changes brought about by external forces. It must also adapt to changes occurring to the musculoskeletal system.

While many of the afferent mechanisms are now well established, the central mechanisms are less well understood. Current studies are using a range of non-invasive methods to extract the location, strength and timing of the responsible neural activity. Further studies will focus on the precise deficits that occur when movement control is disrupted by a range of diseases, from schizophrenia to Parkinson's disease. Although it is clear that central processing in traditional

somatosensory, motor and associative frontal and parietal areas is involved, the way in which cerebellar and basal ganglia circuits contribute is poorly understood.

## Synonyms

Kinesthesia; Movement detection; Position sense; Movement discrimination

## Definition

Proprioception refers to the group of sensations related to limb position and movement, muscle force, timing of muscle contractions and posture and size of a body "schema" of one or more joints. Peripheral proprioceptive signals arise from discharge of receptors located in muscle, joints and cutaneous tissue, although there is continuing debate concerning their relative contribution to conscious proprioceptive sensations and the nature of their contribution. Proprioceptive sensations are also derived from centrally generated motor commands and the interaction between the afferent and efferent signals.

## Characteristics

### Quantitative Description

Each of the proprioceptive sensations requires a different method of testing, with consequent different levels of acuity according to the test method. Acuity varies among joints in a single individual, even when tested with the same method. The only proprioceptive sensation to be systematically measured for human joints in the same individual is the sensation of joint movement, measured using detection levels for perception of passive movement. In both the leg and the arm, proximal joints have better acuity than distal joints when expressed as angular displacement. For example, in the leg, for passive movements imposed at 0.5°/s, movements of ~0.2° can be detected at the hip, ~0.6° at the knee, ~0.5° at the ankle and ~21° at the interphalangeal joint of the big toe. Similarly in the arm, for passive movements imposed at 1°/s, movements of ~0.2° can be detected at the shoulder, ~0.6° at the elbow and ~5° at the distal interphalangeal joint of the finger.

Test conditions can be manipulated to increase or decrease proprioceptive acuity. Small contractions of the muscles around the joint can improve acuity tenfold whereas fatigue increases the error in position matching tasks. Muscle history can also alter acuity. Finally, proprioceptive acuity improves with increasing velocity and decreases with increasing age.

Proprioceptive performance cannot be generalized across the wide variety of tests in common use because there is no relationship between the different tests. Therefore a single test is not adequate to make judgments about

general proprioceptive status in health or after injury. This lack of relationship is likely to account, at least in part, for the conflicting results found for the effect of injury on proprioception.

## Higher Level Components

Cortical projections must exist for a role to be assigned to the peripheral receptor discharge measured during movements. Such projections have been established for all proprioceptors.

## Lower Level Components

Three classes of afferent contribute to proprioceptive sensibility, including cutaneous, muscle and tendon and joint capsule and ligament afferents. The adequate stimulus for all three is stretch of the tissue in which they are located, although cutaneous and joint receptors also respond to other stimuli. The major debate over the last century has concerned the contribution of each to proprioceptive sensations. It is now clear that all classes contribute to proprioceptive sensations and the debate is now directed at the nature of the contribution. Although it was hypothesized that cutaneous afferents may facilitate muscle afferents, more recent evidence suggests that such facilitation is unlikely. Based on both psychophysical and microneurographic evidence, the contemporary view is that cutaneous input is integrated with that from muscle spindles to provide accurate perception of joint position and movement.

## Function

The ability to perceive limb movement and position is essential to normal movement and posture. Without this ability, function is severely disturbed because attempts to move must be guided and monitored using vision. Proprioception underlies all normal movement and its control.

## Orthopedic Pathology

Interest in the effect of orthopedic pathology on proprioception has most often been directed at osteoarthritis, joint replacement and ligament injuries and rarely at non-specific conditions such as low back and neck pain. The effect of orthopedic pathology on proprioception varies with the pathology but a proprioceptive deficit has been found consistently in very few conditions. In most orthopedic pathologies, a deficit is not evident, the literature is inconsistent or a deficit has been found in some but not all of the different proprioceptive tests. The more important question concerns the relevance of a deficit and the magnitude of deficit required for it to impact on function.

### *Osteoarthritis (OA)*

Proprioception has been extensively investigated in knees with OA. All studies have consistently found impairments in both joint position sense and detection of movement compared with healthy controls [1]. The magnitude of the deficit in movement detection was ~1.3° (normal ~2.3°) and in joint position sense ~2.9° (normal ~2.6°). Such a deficit has also been found in the contralateral unaffected knee, with proprioception in both knees being impaired compared with healthy controls [1], leading to speculation that this could indicate central changes. However, no correlation has been found between proprioceptive impairment and severity of disease [1], function or pain. Given the lack of correlation between proprioceptive deficit and function and the small magnitude of the deficit, the consequence of this deficit is unlikely to be functionally relevant.

### *Total Joint Replacement*

It is of particular interest that total joint replacement for knee OA does not necessarily impair proprioception, despite removal of the articular surface. Different studies have found total joint replacement to variously impair, not change or even improve proprioception, although probably not to normal acuity. The magnitude of reported deficits was small, being between 0.3° and 0.72° for threshold to movement detection. However, even when proprioception was found to be impaired after surgery, balance measurements remained normal and clinical outcome was reported as excellent for replaced knees [2], indicating that small proprioceptive impairments do not manifest as functional deficits.

The most common *ligament* injuries involve the anterior cruciate ligament (ACL) at the knee and the lateral ligament complex at the ankle. Proprioception has been extensively investigated in both injuries, motivated by the belief that proprioceptive deficits are associated with persisting disability.

## Anterior Cruciate Ligament Rupture

It has been suggested that the ACL has an important proprioceptive role via the fusimotor system and that its loss should therefore cause a significant proprioceptive deficit. However, the evidence does not uniformly support this proposal. A deficit in threshold to movement detection of 1.5° has been found compared with the contralateral uninjured knee and of 0.5° compared with healthy controls [3], but others found no impairment. Furthermore, no impairment was found in joint position sense in ACL deficient knees compared with healthy controls by most authors, although a deficit of up to 4.5° was found by others [4] and the deficit was significantly worse in the mid-range of movement [4]. When both threshold to movement detection and joint position sense were measured in the same subjects, there was no correlation in performance [5], suggesting that a deficit may be specific and that performance on a single proprioceptive test cannot be generalized. However, no study investigated proprioception in

rotation movements, the direction of instability in ACL-deficient knees.

The effect of reconstructive surgery after ACL rupture on proprioception is also unclear. After surgical reconstruction, some authors found that movement detection was restored to normal, others found improved acuity but not to normal levels and unexpectedly, Co et al. [6] found that reconstructed knees were even more accurate than healthy controls by 0.4°. The findings for joint position sense were also inconsistent; reconstruction was variously found to confer no benefit [6] or to improve acuity, but not to normal [3]. These conflicting results potentially arise because not all ACL-deficient knees have a proprioceptive deficit to address. It is tempting to suggest that any improvement is due to the improved stability of the joint, but proprioceptive acuity correlated poorly with mechanical stability [4,3]. Alternatively, improved joint kinematics may normalize input from the muscles, thereby enhancing proprioceptive signals.

Even when proprioceptive deficits were found, they were generally small. Nevertheless the impact on function is uncertain. Although some authors found a high correlation (range, $r$ = 0.6–0.9) between proprioception and function [4], others failed to find a relationship [3]. It is difficult to explain these conflicting results. It is possible that the different findings relate to different comorbid pathologies included in the studies, such as associated meniscal damage, although again the findings are inconclusive; concomitant meniscal or chondral damage was found to relate to proprioceptive deficits by some but not others [3].

### *Lateral Ligament Sprain at the Ankle*

Persisting symptoms of pain and instability are common after ankle inversion sprain and are frequently attributed to a deficit in proprioception. Impaired movement detection has been found by most authors in the inversion-eversion plane after recurrent sprain compared with healthy controls, the deficit in movement detection being <1° and in some cases <0.5°. However, in the plantarflexion-dorsiflexion plane most authors found no impairment [7]. Findings for joint position sense in the inversion-eversion plane are less consistent; a significant impairment was found by some authors but not by others. Joint position sense in the plantarflexion-dorsiflexion plane has yet to be investigated. Consistent with other ligament injuries, there was no correlation between proprioceptive performance and mechanical stability.

These findings suggest that any proprioceptive deficit after ankle inversion sprain is specific to the inversion-eversion plane of movement and to particular proprioceptive tests. The deficit is potentially related to the anatomical structures involved in the sprain, particularly those that resist inversion rather than plantarflexion forces. Damage to these structures may therefore cause impairment only in proprioceptive tests specific to the inversion-eversion plane of movement.

## Therapy

Proprioceptive training is considered an integral part of rehabilitation after many orthopedic injuries to improve assumed deficits and to prevent further injury, despite lack of knowledge about: the magnitude of deficit that is clinically meaningful; whether proprioception can be trained; and, if a deficit does exist and proprioception can be trained, whether improved proprioception is associated with improved function and reduced risk of re-injury.

The magnitude of proprioceptive deficit, when it exists in orthopedic pathology, is small in most test paradigms, generally being within one standard deviation of the average performance of control subjects. Although this difference is statistically significant in some cases, it is unlikely to be functionally relevant, because a deficit has not consistently been associated with pain or loss of function. It is possible, however, that a small deficit may be critical in situations where small errors could have considerable impact on highly skilled performance.

The most common forms of "proprioceptive training" are performance of tasks on an ankle disc or wobble board and agility training. It is indisputable that such training improves motor control; however, whether proprioception is improved is largely unknown. In the two studies that examined the effect of training on joint position sense at the ankle, one found selective improvement of ≥0.5° in error reduction at some, but not all, test angles [8], while the other found no change with training. There is currently insufficient evidence to conclude that either joint position sense or movement detection can be improved.

The major purpose of "proprioceptive" training, however, is to prevent re-injury. There is no direct evidence of a role for proprioception in prevention of injuries because the relationship between proprioception and injury risk has not been established. The few studies that have investigated the efficacy of "proprioceptive" training for injury prevention, have found the risk to be reduced, although the relationship between proprioception and injury was not investigated. Risk of ACL injury was reduced by 88% by agility training compared with control intervention. The pooled results of Wedderkop et al. [9] and Verhagen et al. [10] show that ankle disc training programs significantly reduced incidence of ankle injury, with an odds ratio for the pooled data of 0.41 (95% CI 0.268–0.629). This reduction in risk of injury has not been correlated with changes in proprioception and proprioception has not been used as an outcome measure.

## Conclusions

Taken together, the findings suggest that a proprioceptive deficit has been consistently found for degenerative joint disease, but not for any other pathology and these deficits may be improved, perhaps to normal, by surgical intervention. Selective proprioceptive deficits occur in unstable joints, but the deficit is generally small. The lack of consistent findings may be attributed to the lack of relationship in proprioceptive acuity among different proprioceptive tests and therefore identification of a deficit is likely to depend on the specific proprioceptive test measured.

Given the poor relationship between proprioception and function, the relevance of small proprioceptive deficits is unknown. Potentially these small deficits could impair highly skilled performance, but are unlikely to manifest as functional problems in normal daily activities and therefore may not require remedial therapy.

# Proprioception: Effect of Aging

Stephen R. Lord
Prince of Wales Medical Research Institute and University of New South Wales, Sydney, NSW, Australia

## Definition

Proprioception is the discrimination of the positions and movements of body parts based on information other than visual, auditory or verbal. The immediate stimuli come from changes in length and from tension, compression and shear forces arising from the effects of gravity, from the relative movements of body parts and from muscular contraction [1]. Studies assessing proprioceptive age changes have used the terms proprioception, kinaesthesis and joint position sense interchangeably and both passive and active movement paradigms have been used to assess proprioceptive judgments.

Ageing is an orderly or regular transformation with time of representative organisms living in representative environments.

## Characteristics

### Function

In 1937, Laidlaw and Hamilton [2] were the first researchers to demonstrate an age related decline in proprioception. They measured the ability of 60 subjects to detect movement in the shoulder, elbow, wrist, metacarpophalangeal joints in the upper limb and hip, knee, ankle and first metatarsophalangeal joints in the lower limb. They found that subjects aged 17–35 years had lower thresholds and superior ability to detect direction of joint movements than subjects aged 50–85 years. The hip was the most sensitive joint and the metatarsophalangeal joint was the least sensitive. They also found a wide range in perceived movement threshold and that this variability was most marked in the older age group.

More recent studies and referenced in Lord et al. [3] have, in general, confirmed Laidlaw and Hamilton's findings. Kokmen et al. [3] measured the threshold at which subjects could detect metacarpophalangeal and metatarsophalangeal joint motion. These joints were passively moved in an increasing sinusoidal flexion extension mode (a nonspecific test of joint movement only). They found that there was no difference in metacarpophalangeal joint motion detection between young subjects (aged 19–34 years) and older subjects (aged 61–84 years) at all frequencies between 0.5 and 8 Hz. They did find, however, a significant difference in metatarsophalangeal joint motion detection between young and old subjects at the lowest frequency of 0.5 Hz. At higher frequencies, the older age group

showed higher but insignificant increases in metatarsophalangeal joint motion thresholds. Variability in threshold perception performance increased with age and joint motion thresholds for the metacarpophalangeal joint were significantly smaller than for the metatarsophalangeal joint in the older group at all frequencies except for 8 Hz. No such trend was evident in the young age group, which suggests that joint motion sense may decline more with age in the lower limb compared with the upper limb.

In a recent study, Ferrell et al. [3] used a position-matching task to assess the ability of subjects to detect displacements at the proximal interphalangeal joint of the index finger. These displacements were imposed at an angular velocity of 2°/min, which is below the threshold for movement detection. An older group of subjects (mean age = 57 years) showed significantly poorer performance in detecting the position of the index finger than a group of younger subjects (mean age = 24 years). The size of the matching error had correlation of 0.47 with age.

Two studies have examined the effect of age on the joint position sense of the knee. Skinner et al. [3] measured joint position sense of the knee in 29 subjects with normal knee joints ranging in age from 20 to 82 years. Joint position sense was determined by the threshold of detection of an experimenter-induced movement of the knee joint and by the ability to reproduce passive knee positioning. They found that joint position sense as measured by both tests deteriorated significantly with age.

Kaplan et al. [3] used a clinical goniometer to measure the ability of 29 women to match the position of each knee with the other knee and like Skinner et al. to reproduce a knee joint position after a period of rest. They found that an older age group (aged 60–80 years) performed significantly worse than a young group (aged 22–27 years) in both tests. In the experimental paradigm where subjects had to match the position of a knee with the other knee, they found no difference between the number of trials undershot and overshot in the young group, but a tendency to underestimate knee joint angle in the older group. The reported failure of the older group to reproduce the knee joint position may however have resulted from motor deficits as well as proprioceptive deficits.

In a study of 550 women aged 20–99 years Lord et al., there was a decline in proprioception with age as measured with a seated lower limb-matching task [4]. The average error in aligning the great toes either side of a vertical protractor placed between the legs increased from 0.7 degrees (SD = 0.3) in subjects in their twenties to 1.9 degrees (SD = 1.7) in subjects aged 65 plus years. Overall, there was a weak but significant association between error size and age across all age groups, $r = 0.20$.

Three clinical studies have investigated whether there is a decline in proprioception beyond 65 years of age. Howell [3] examined the ability of 200 patients aged 65 years and over to detect joint position sense of the great toes and to touch their noses with their eyes closed. He found that most patients could determine experimenter-induced movements of their toes but that approximately 44% of patients in all age groups above 65 showed abnormalities in the nose touching test. There were no significant changes with age in either test.

MacLennan et al. [5] also examined the ability of 308 elderly persons to identify the position of their great toes after they were manually moved by the experimenter. They found that the prevalence of inability to appreciate changes in position of the toe was significantly greater in the age group 75 years and over than in the age group aged 65–74 years for both males and females. Similarly, Brocklehurst et al. [6] measured the ability of 151 persons aged 65 years and over to detect experimenter-induced movements of the toe and ankle. They found no association between age and proprioception, but acknowledged that this may be due to the imprecision of their test.

It has been suggested that caution should be used in assessing proprioception in the lower limb when assessments are made while subjects are in the seated position [7], as is the case in the above studies. This is because thresholds in the ankle and knee are much lower when measured in the standing, weight bearing position where engagement of the leg muscles is greatly increased [1,3].

In a recent study, Bullock-Saxton et al. [7] assessed the effects of age on the accuracy of a knee joint repositioning test in both full and partial weight-bearing conditions in 60 healthy, pain-free subjects from three age groups (young: 20–35 years old, middle-aged: 40–55 years and older: 60–75 years). They found that subjects in all three groups performed better when full weight bearing than when partial weight bearing, and significant age related increases were found only in the partial weight bearing condition. However, other studies assessing position sense of the ankle joint when weight bearing have reported increased thresholds with age. Thelen et al. [3] compared the ability of young and older women to detect dorsiflexion and plantarflexion movements of the foot when weight bearing on a moveable platform and reported that the threshold for movement detection was 3–4 times larger in the older group. High detection thresholds for inversion and eversion movements of the ankle when standing either unipedally or bipedally on a rotating platform have also been found in older people [8]. Finally, Blaszczyk et al. [3] have reported that old subjects are significantly worse than young subjects in reproducing ankle joint positions when standing on a rotating platform.

## Pathology

Reduced proprioception is associated with instability and falls in older people. Hurley et al. found that reduced proprioceptive acuity at the knee was significantly associated with an increased aggregate time to perform a range of function tasks comprising a timed walk, the get up and go test and stair ascent and descent in a combined group of young, middle aged and older people. In large prospective studies Lord et al., impaired lower limb proprioception was also associated with multiple falls in older people living independently in the community [9] and in those living in residential care [10]. Brocklehurst et al. [6] also reported a significant association between impaired proprioception in the ankle and/or great toe and falls in people aged 75–84 years.

## Conclusion

There is a significant decline and an increase in variability in proprioception with age, particularly in the lower limbs. Proprioceptive thresholds for the ankle and knee are much lower when measured in the standing, weight bearing position. One study has reported no significant age related change in knee proprioception in this condition, but other studies have reported age related declines in the ankle joint when weight bearing. Reduced peripheral sensation is associated with falls in older people, when the measures of peripheral sensation are accurately and quantitatively ascertained.

# Proprioception: Effect of Gravity

James R. Lackner, Paul DiZio
Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA, USA

## Synonyms

Kinesthesia

## Definition

Proprioception is the sensory registration of the ongoing spatial configuration of the body. Sherrington invented the term to denote responsivity to the internal, self-generated state of the body based on mechanoreceptors embedded within body tissues, subserving both conscious awareness and automatic control of posture and movement [1]. The term "kinesthesia" refers more specifically to the awareness of the position and movement of body parts. The perception of force, effort or heaviness relies on some of the same sensory and central mechanisms as proprioception and kinesthesia.

On earth, posture and locomotion are always carried out against the omnipresent force of gravity that accelerates objects downwards toward the earth's surface. The musculature of the body has to exert forces across the joints to keep the body straight so that it does not buckle and fall to the ground. In this context, proprioception is highly dependent on interrelating signals from the muscle spindle receptors within intrafusal muscle fibers to patterns of alpha and gamma motoneuron activation innervating the muscles that support the whole body or an individual limb against the acceleration of gravity [2]. Golgi tendon organs and Ruffini endings of the joints may participate as well, though their contribution is less well understood. Slowly adapting cutaneous stretch receptors are stimulated by distension of skin overlying moving joints and contribute to the sense of position and movement. The fingertip is especially rich in cutaneous mechanoreceptors and dragging or holding the finger lightly over a stable surface augments the perception and control of arm movements and of locomotor activity. During standing posture, the support surface exerts a contact

force on the soles of the feet that counteracts the downward acceleration of the body's center of mass, and the distribution of the contact forces on the soles of the feet provides information about the orientation of the body to gravity. The vestibular system is an extension of the proprioceptive system because it senses head movement relative to gravity, and various sensor types in the viscera and vasculature [3] also contribute to estimates of body orientation. Although vision and audition are not typically considered part of the proprioceptive system, there are strong interactions among seen, heard and felt body configurations and the localization of external objects [4]. A rough estimation of body configuration and motion could perhaps even be acquired through the sense of smell. These examples illustrate the domain and sources of proprioception.

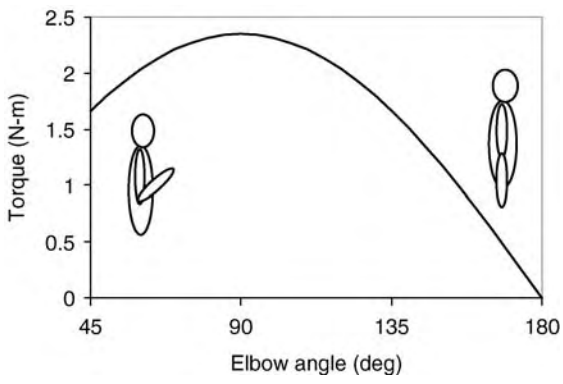
## Characteristics

### Higher Level Processes

#### *Dynamic Sensory-Motor Calibrations to 1g*

Until relatively recently in history, humans were not exposed to force levels other than the 1$g$ ($g$=9.8 m/s$^2$) background acceleration of Earth gravity, except momentarily, for example during jumping or running or horse riding. With the advent of powered vehicles including aircraft and space craft and orbiting space stations, exposure to weightlessness and to high force fields has become commonplace. On Earth, if an arm is raised, it is subjected to a gravity torque that must be opposed. This torque is not constant but depends on arm angle, see Fig. 1.

Nevertheless, it seems to require roughly constant effort – except in cases of fatigue – to position the arm relative to gravity. Under normal conditions, one does not sense the different force demands associated with changes in body configuration or body movements relative to gravity. The effects of gravity on movement control seem relatively transparent – as if they were not there. This transparency actually represents a form of sensory-motor calibration to earth gravity – based on an internal model of the consequences of gravity on body actions, so that equal extents of movement seem equivalent regardless of the actual muscle force demands to achieve them [5].



**Proprioception: Effect of Gravity. Figure 1** Joint torque.

Muscle spindle gain is affected by background force level. As a consequence, tonic vibration reflexes are attenuated in weightless conditions and augmented in greater than 1$g$ background force levels. These reflexes occur because mechanical vibration of a muscle can excite muscle spindle primary and secondary endings, which leads to a reflexive contraction of the vibrated muscle. The g-dependent modulation of the tonic vibration reflex probably reflects a vestibulo-spinal modulation of the gain of spindle receptors of postural muscles, but could include altered patterns of alpha-gamma coactivation as the load demands on the muscles vary with force level. Studies of arm movement control in non-earth gravity force levels indicate patterns of change consistent with variations in spindle discharge levels [6]. When individuals practice in normal conditions to make arm movements of particular velocities and amplitudes and then attempt the same arm movements in parabolic flight in 0$g$ and 1.8$g$ force backgrounds, they exhibit systematic changes. Movements made at a natural speed in 0$g$ are smaller in amplitude and have more dynamic overshoots of final end positions than movements of the same attempted velocity and amplitude in 1.8$g$. This pattern is consistent with decreased spindle gain in 0$g$. With long-term exposure to weightlessness, astronauts display an adaptive modification of their internal model of the effects of gravity on movement, which also may involve a recalibration of proprioception.

#### *Self/Environment Discrimination*

Proprioception figures prominently not just in the awareness of ongoing body configuration but also in the maintenance of a stable perceptual distinction between changes in afferent input due to self-motion versus motion of or within the environment. This is reflected in the adaptive resetting of internal models of the environment. The function of these tuning mechanisms becomes apparent when the body is exposed to a background force level different in magnitude from earth gravity. Then, until adaptation occurs, misperceptions of body motion and of the stability of the support surface result. Changes in background force level can be achieved in an aircraft flown in a parabolic trajectory to generate alternating periods of 1.8$g$ (nearly twice Earth gravity) and of weightlessness (0$g$). In this circumstance, the body alternately becomes much heavier and much lighter than usual respectively. The consequences of this sudden weight change become apparent when an individual attempts to make deep knee bends in the 1.8$g$ background force level [7]. Lowering the body involves eccentric

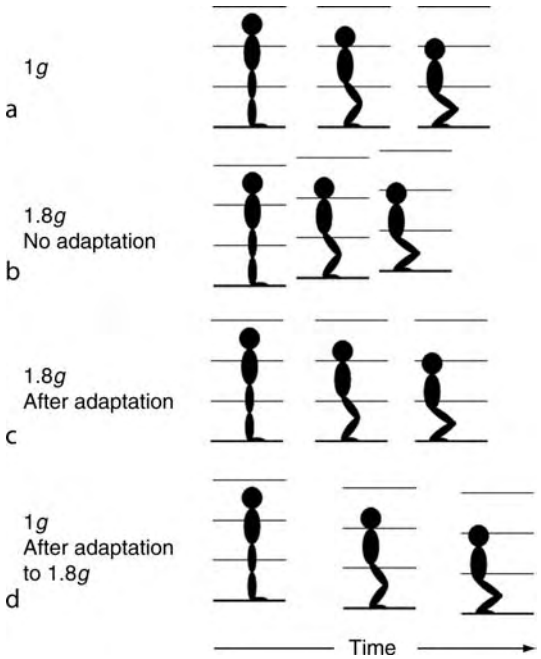
contraction (controlled lengthening) of the body's antigravity muscles (e.g. the quadriceps and gastrocnemius muscles of the legs). More activation of these muscles will be required during the course of the movement than is the case on earth, otherwise the body would descend too rapidly because of its increased weight. In this situation, the individual will experience him or herself as moving downward too rapidly and the support surface, the deck of the aircraft, as simultaneously rising upward against the feet. To return to the upright, much greater muscular force than normal is required, the body seems to rise too slowly and the aircraft deck seems to move downward. In 0.5*g* background force levels, the opposite pattern is experienced during deep knee bends. Body weight is less than normal and less muscle force is required throughout the movements. As the body is lowered, it seems to move downward too slowly and the deck simultaneously seems to move downward under the feet. On rising back to the upright, the body feels as if it has moved too rapidly and too far and that the deck floor has simultaneously moved upward under the feet, causing the whole body to displace farther than intended.

If an individual makes repeated deep knee bends during exposure to a steady state non-1*g* background force level, the movements soon begin to feel more normal and natural and the illusory displacement of the stance surface is correspondingly attenuated. After 50–100 repetitions, the movements will again feel normal and the support surface stable [8]. But then on re-exposure to a normal 1*g*-force background, deep knee bends will again feel abnormal and the support surface will seem to displace. Fig. 2 shows the patterns of motion and effort experienced on (a) initial exposure to 1.8*g* force levels in parabolic flight, (b) after the execution of many deep knee bends and (c) on return to normal 1*g* levels. As illustrated, full adaptation is achieved and the aftereffect experienced is opposite in sign to the effects experienced during initial exposure to the abnormally high force level.

This pattern means that motor control and position sense are recalibrated during exposure to the 1.8*g* force level and that this recalibration carries over on return to 1*g* where it is inappropriate. Animals evolved in the context of a 1*g*-background force level without any experience with steady state non-1*g* force levels. Nevertheless, significant adaptation to an unusual background force occurs within seconds or a few minutes.

The factors underlying adaptation to an increased force background can be understood as follows. As the body lowers in a deep knee bend in a 1.8*g* force background, the antigravity muscles that undergo controlled lengthening will be longer than normally would be the case for the levels of alpha and gamma motoneuron activation present, because body weight has nearly doubled. Consequently, these muscles need to be innervated at higher than normal levels. Signals from the spindle receptors within the muscles will be higher than normal also, because the spindles are under a greater degree of loading than normal. Position sense is generated in part by the CNS comparing patterns of spindle feedback with patterns of alpha-gamma activity. If the pattern of spindle feedback is aberrant in relation to the alpha-gamma activation patterns, a distortion of position sense occurs. Abnormally high levels of spindle activity in skeletal muscles evoke misperceptions of the joint positions controlled by the muscles, with the muscles being interpreted as being longer than they actually are. For example, an abnormally high level of quadriceps activity is associated with the knee joint being perceived as more flexed than it actually is.

When deep knee bends are initially made during exposure to 1.8*g*, the abnormally high spindle activity levels present in relation to the alpha motoneuron activity are interpreted as the legs being more flexed during the course of the lowering movement than they actually are. The CNS attributes this to external motion, the aircraft deck rising under the feet causing the knees to be more flexed than intended. With repetition the deep knee bends feel progressively more normal as the



**Proprioception: Effect of Gravity. Figure 2**
(a) Schematic illustration of the sequence of actual and perceived events as one desends in a deep knee bend. (b) During the first deep knee bend made in 1.8*g*, one's body seems to descend too fast while the floor (*thick lines*) and visual surround (*thin lines*) rise. (c) After adaptation to 1.8*g*, self motion is perceived normally and the environment feels stable. (d) Returning to 1.0*g* elicits after effects opposite to the original illusion in 1.8*g*, until re-adaptation is complete.

relationship between body movement, motor commands and expected spindle feedback is remapped in the internal model of movement control to be the "normal" state of affairs. On return to normal 1*g* background force levels, the relationship between motor commands and spindle feedback will again be abnormal. As the body is lowered, less innervation of the antigravity muscles will be necessary than in 1.8*g* to control the lowering of the body. Consequently, the spindle feedback generated will be less than expected; this is interpreted as the legs being less flexed than intended and attributed to the deck moving downward under the feet, preventing the knees from bending appropriately.

### Proprioception and the Body Map

That individuals born without a limb can still experience a phantom limb (see Phantom limb sensations and pain) attests to the fact that a map of body segments and their connectedness exists in the brain, which is complementary to proprioception. We normally experience this map as a sense of body topology, the connectedness of a set of body segments. This map both governs proprioception and can be altered transiently or be semi-permanently remapped by proprioceptive inputs, as shown by vibratory myesthetic illusions. For example, illusory forearm extension is perceived if 120 Hz vibration is applied over the biceps of the restrained arm. The perceived finger trajectory is constrained by the internal map, which represents the forearm with a specific length and the biceps muscle as acting across the elbow joint. However, if the index finger of the vibrated arm is touching the nose then illusory elongation of the nose is perceived simultaneously with arm extension, violating the internal mapping of the nose as a non-jointed semi-rigid body part [9]. Longer-term vibrotactile skin stimulation alters the cortical somatosensory map.

### Multisensory Body Maps

Multiple, interdependent representations of hand and arm position exist which are influenced by visual and muscle spindle inputs. This interdependence has been demonstrated in experiments involving vibratory myesthetic illusions of the forearm in a dark room with the test subject's finger made visible by phosphorescent paint [4]. When subjects feel their forearm move, they also see their finger move as well but through a smaller distance. The magnitude of felt motion of the forearm is greater in darkness than with the finger visible. Thus, vision affects the proprioceptive representation because the optically stationary finger attenuates felt motion, and proprioception affects the visual representation because the vibration-induced muscle spindle afferent signal makes the optically stationary finger appear to move.

If a visual-proprioceptive discrepancy is introduced for a longer exposure period, then semi-permanent adaptive changes in proprioception can occur. The nature of these changes depends on the exposure conditions. For example, a seated subject wearing laterally displacing prism spectacles will initially miss when pointing to a visual target. However, if the subject continues to reach and is allowed visual feedback of the reaches, accuracy will soon be regained. The adaptive change involves an arm-torso recalibration in terms of an internal shift in the felt position of the exposed arm but not of the other arm [10]. The adapted subject still wearing the prisms will reach accurately to the real target but see and feel the arm in its optically displaced location. The felt arm position then does not correspond to the real arm position but it does correspond to the visual arm position. By contrast, if subjects are allowed to walk around wearing the prism spectacles they are clumsy at first but ultimately learn to navigate. They also gradually adopt a deviated head posture but feel their head to be straight on their torso. This internal proprioceptive remapping of head to torso allows accurate body-relative localization and normal control of locomotion.

## Pathology

With the advent of manned space flight, humans have been exposed to weightless conditions for prolonged periods. On return to earth, they exhibit a variety of derangements of posture and gait. These disturbances are related to adaptive changes in neuromuscular structure and control occurring in weightless conditions that are inappropriate for terrestrial conditions. Postflight, when astronauts walk, the ground feels unstable under their feet and their movements require greater than normal effort. The simplest movement, e.g. raising the arm, can feel as if it requires immense effort and force. If the astronaut does a deep knee bend, then it feels as if he or she has moved downward too rapidly and that the ground has simultaneously moved upward. Precisely the same patterns are experienced as those by individuals, as described above, who are adapted to earth gravity and make deep knee bends in the high force phases of parabolic flight. These changes reflect the decreased muscle spindle gain associated with weightless conditions and the lack of appropriate contact cues to signal body orientation and configuration.

Proprioceptive loss is characteristic of a variety of diseases and injuries of the nervous system. The most severe cases involve loss in adulthood of large somatic sensory fibers, including muscle spindle, joint, tendon and cutaneous mechanoreceptor afferents. An affected individual with eyes closed has no ability to localize his or her limbs even during vigorous active or passive movement. Standing and walking in darkness are not possible. Affected individuals can reacquire functional movement using visual guidance. Even partial loss of proprioception has severe consequences for balance and locomotion.

In summary, the human body has a dynamic sensory-motor spatial calibration to Earth gravity. This calibration involves an internal model of the force background and its consequences for voluntary movement control. The calibration is continuously updated based on experience within the environment. Somatosensory, proprioceptive and visual signals contingent on self-produced movements are key elements contributing to updating. The continuous ongoing nature of the calibration process is probably why movement control adjusts so rapidly when the body is exposed to force backgrounds greater or less than 1*g* in magnitude and why patients can adapt to proprioceptive loss.

# Proprioception: Effect of Neurological Disease

Jonathan Cole
COPMRE, University of Bournemouth and Poole Hospital, Dorset, UK

## Synonyms

Large-fiber sensory neuronopathy and neuropathy; Sensory ataxia; Dorsal column ataxia; Sensory stroke

## Definition

Loss of movement and position sense due to disease of the peripheral or central nervous system.

## Characteristics

The perceptions of movement and position sense, as well as that of touch, are dependent on afferent information relayed by large myelinated sensory nerve fibers, with cell bodies in the dorsal root ganglia and which then ascend in the ipsilateral dorsal columns (DCs). They synapse in the dorsal column nuclei at the head of the spinal cord. The pathway then projects through the medulla in the medial lemniscus to synapse in the ventral-posterior thalamus and hence, via the internal capsule, to the sensory cortex. Within the brain information is relayed to coordinate movement as well as give consciousness of the position and movement states of the body and limbs. Loss of ►proprioceptive information can lead to in-coordination due to dysfunction in the motor cortex and the cerebellum. In-coordination due to peripheral ►deafferentation and cerebellar lesions can sometimes be difficult to distinguish completely.

Disease anywhere along the above pathways can result in ►proprioceptive loss, usually with cutaneous sensory loss. While selective losses are possible, in particular in the peripheral nerve cell and to an extent in the dorsal columns, more central lesions may also affect other areas, making the resultant physiological deficit more complex. Often, for instance, cortical lesions lead to reduced stereognosis (inability to manipulate and recognize objects placed in the hand without vision) and graphesthesia (ability to recognize figures touched over the hand without vision), as well as in reductions in cutaneous touch and ►proprioception.

►Proprioception is such a deep sense that in folk psychology terms it is almost unknown. People may imagine being blind or deaf, but not being without proprioception or touch. Diderot considered that of all the senses touch (and one presumes the then undiscovered ►proprioception) the most profound and philosophical. To understand what ►proprioception does therefore it is important to consider those rare individuals who have to live without it – without their witness the experience, and its effects on movement, are almost impossible to know.

Total loss of ►proprioception is rare but has been described in the ►acute sensory neuronopathy syndrome. Its effects initially are a complete inability to control or coordinate movement. When movements are made they are inappropriate in size and direction with poor coordination between both limbs and joints. With time, however, and with considerable conscious attention towards, and visual observation of, movement, people without movement or position sense may be able to move in such a fashion as to be almost able to pass unnoticed, in uncluttered, well lit areas (see Section on ►Large-Fiber Sensory Neuropathy).

Though these complete losses of ►proprioception are rare their importance is that they reveal both the consequences of the loss and the ability of subjects, at least partially, to mitigate its effects. In addition, there are less severe yet still important losses of ►proprioception associated with various neurological problems, from median nerve compression at the wrist to central strokes in which motor weakness predominates which may have clinical consequences and yet are often poorly recognized.

## Pathology

### *Peripheral Neuropathy/Neuronopathy*

The most pure form of ►proprioceptive loss is disease of the large myelinated sensory nerve fibres, either in their axons or their cell bodies (see Section on ►Large-Fiber Sensory Neuropathy). Lesser, but still important, losses of ►proprioception can occur with less selective sensory peripheral neuropathy, especially affecting the legs, leading to ataxia and a feeling of not knowing where the feet are unless they are looked at. Patients may volunteer that they are much worse in the dark and that they find it difficult to drive a car (because of the need to control foot pedals).

The division between cutaneous light touch and ►proprioception can also be somewhat artificial. In the hands and the face cutaneous information about stretch and deformation of the skin gives information about position. Then, loss of cutaneous sensation has effects on movement. This is sometimes seen in carpal tunnel syndrome. Patients with sensory loss in the thumb and first and second fingers may say they drop things, unless they look at them and think about it, without knowing why. Even small losses of cutaneous touch in the fingers may have affects on the coordination of grip strength and active touch.

### *Dorsal Column Disease*

►Proprioceptive (and cutaneous) afferents ascend with the spinal cord in the dorsal columns; disease of these structures is a well-known cause of loss of movement and position sense. One well-known cause of ►ataxia due to DC loss is vitamin $B_{12}$ deficiency.

Sub-acute combined degeneration of the spinal cord involves the dorsal and lateral columns of the spinal cord and presents often, in middle age, with ►parasthesiae of the feet, with tingling and even burning [1]. Difficulties in walking follow, if untreated, due to sensory ►ataxia and motor weakness, reflecting lateral (motor) column involvement. Loss of postural sense can be more severe than the cutaneous sensory deficit. These may be accompanied by optic atrophy and cognitive impairment. The pathology involves both demyelination and axonal loss and treatment is usually effective, especially if given early [2].

Historically, syphilis was a major pathogen affecting the dorsal columns (Wilson, 1940 for a clinical description of neurosyphilis) [3]. Tabes dorsalis usually emerges 10–25 years after the initial infection and can present with progressive ►ataxia and a high stepping gait, and with severe, intermittent, "lightning" pains in the legs and abdomen. More rarely, it can also been seen far earlier in congenital syphilis. The pathology may be demyelination and destruction of the dorsal roots. In this form of syphilis it is not solely the DCs that are affected; failing vision, impotence, deafness and arthropathy and ulceration, reflecting small fiber loss too, are often associated with it.

Others causes of DC loss are multiple sclerosis with a plaque involving the dorsal cord, tumor and, most rarely, penetrating wounds in the neck with DC dissection. It has also been associated with a rare form of retinitis pigmentosa, which offers the possibility to understand the genetic nature of DC delineation [4].

### *Intracerebral Lesions*

Pure sensory ►ataxias after sub-cortical stroke, or plaque or tumor are rare, since these diseases do not affect single pathways or classes of neuron. For instance, Russmann et al. [5] analyzed the Lausanne Stroke Registry between 1986 and 1998 for those with an ischemic episode affecting the area of the lenticular nucleus. Of 820 consecutive patients, 13 had pure lenticular infarction with four having an ataxic sensorimotor hemisyndrome, presumably due to a lesion of the internal capsule. Though examples of pure sensory stroke after small lacunar infarcts have been described after infarcts in the ventral posterior thalamus, brain stem, internal capsule and cerebral cortex, more often central lesions lead to more complex and subtle deficits.

It can, for instance, be difficult to distinguish, at the two extremes, between a pure motor weakness from an ►ataxia from in-coordination due to sensory loss. Kim [6] analyzed a group of patients with thalamic stroke with motor and sensory problems. ►Ataxia and involuntary movements were seen most after sensory loss, with ►dystonia, and in-coordination of movements associated with proprioceptive loss. Central sensory loss due to stroke can also be associated with dysesthesia and pain.

Though the commonest pathology associated with pure sensory stroke is ischemia, this syndrome occurs after hemorrhagic stroke too [7]. Pontine strokes involving the medial lemniscus, but sparing the spinothalamic tracts, lead to selective loss of vibration sensitivity and proprioception without an effect on pinprick and temperature sensation. More rostral strokes do not always lead to pure loss of proprioception as the dorsal column/medial lemniscal and the spinothalamic tracts become closer within the brain. Thus some thalamic strokes may lead to loss of all modalities of sensation over the opposite side of the body, with reduced temperature sensation and pin prick sensation as well as dysesthesia.

In central pure stroke syndromes Fisher [8] suggested that though objective sensory disturbances can be mild, larger losses are seen in fine motor control and coordination of the hand and fingers. This may reflect on the one hand the relative insensitivity of clinical tests of sensation, and the possible use of other cortical areas for these discriminations, and on the other the crucial importance of parietal cortex in the coordination of finger movements. Occasionally this role of the cortex in movement leads to confusion as to whether weakness is peripheral, say due to an ulnar nerve lesion, or cortical [9]. A relative lack of sensory symptoms and preserved power with clumsiness and reduced coordination may point towards a cortical deficit.

In addition it is important to realize that mixed sensory-motor strokes can prove difficult to rehabilitate due to underlying ►proprioceptive loss over and above the more obvious problems with motor weakness. Loss of information about movement and position superimposed on loss of power can add a significant additional problem, especially if not recognized. Correspondingly, there are some reports that exercises designed to improve coordination can add to any spontaneous recovery that occurs [10].

Though syndromes involving exclusively loss of movement and position sense are very rare in neurology, an awareness of the effects of proprioceptive loss may allow greater understanding of mixed sensory and motor syndromes and lead to different rehabilitation strategies.

# Proprioception: Role of Cutaneous Receptors

David F. Collins
Faculty of Physical Education and Recreation, Centre for Neuroscience, University of Alberta, Edmonton, AB, Canada

## Definition

### Proprioception and Kinesthesia

The term proprioception (proprius = Latin for "one's own") describes abilities related to the perception of different aspects of one's own movement. These include the sense of the position and movement of the body segments (kinesthesia) as well as sensations related to tension in muscles and tendons, balance and voluntary effort [1]. This essay reviews the evidence that cutaneous receptors contribute to kinesthesia, the ability to detect the position and movement of the body segments without using vision. Cutaneous receptors are sensory receptors located in the skin. During movement, the skin is stretched and compressed, activating cutaneous receptors in large areas of skin around the moving joint (Fig. 1) [2].

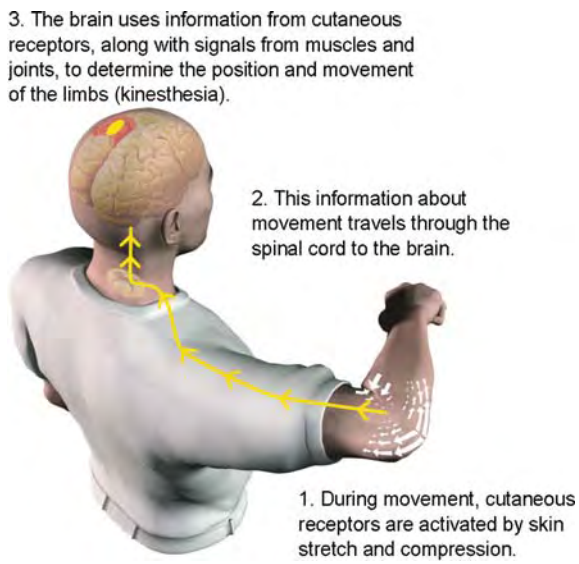
The pattern of skin strain is different for movements of different speeds and amplitudes and this information is encoded in signals from large numbers of receptors that discharge during movement. These signals travel along peripheral nerves to the spinal cord and pass to the brain where, along with feedback from sensory receptors in muscles and joints, they provide the information responsible for kinesthetic awareness and proprioceptive judgments (see ►Proprioception: Role of Muscle Receptors and Proprioception: Role of Joint Receptors). Kinesthetic information is used for the planning and execution of movement.

## Characteristics

### Sensory Receptors and Kinesthesia

During movement, sensory receptors in muscles, joints and the skin send movement-related information to the brain where it is used for kinesthesia. For more than 30 years, it was thought that the muscle spindle, a

specific type of muscle receptor, was the most important source of kinesthetic information [1,3]. Muscle spindles respond to muscle stretch and thus signal the changes in muscle length that occur during joint movement. Many experiments have shown that this information is important for kinesthesia, such as those investigating the strong illusions of movement that are produced when vibration is applied over a muscle or its tendon. Vibration causes spindles to discharge rapidly and results in powerful illusions of movement consistent with lengthening of the vibrated muscle. Recently, experiments have shown that movement illusions can also be generated by activating cutaneous receptors by stretching the skin around a stationary joint to mimic skin stretch patterns that occur during normal movement [4,5]. An example of one experiment is shown in Fig. 2 where skin stretch applied around the right elbow resulted in the illusion of elbow flexion (left panel).



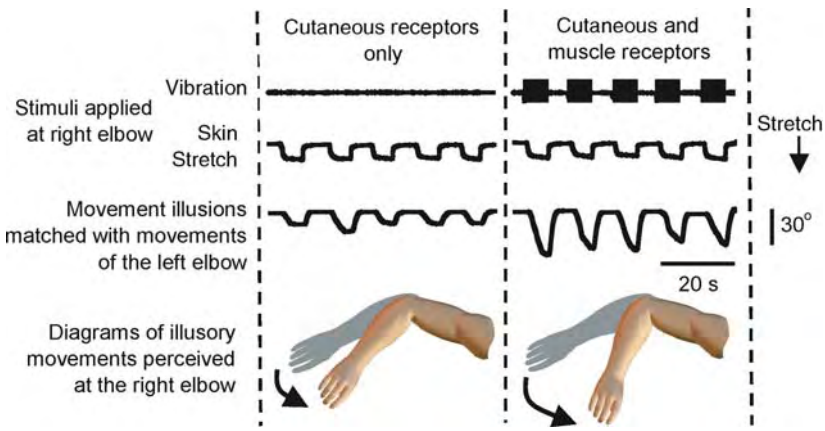
**Proprioception: Role of Cutaneous Receptors. Figure 1** Schematic representation of the role of cutaneous receptors for kinesthesia at the elbow.

The subject matched these illusory movements of the right elbow with voluntary movements of the left arm. These movement illusions initiated by skin stretch show that cutaneous receptors are also important for kinesthesia. Movement illusions also occur when skin stretch is applied around the fingers [4,5] (see Fig. 3) and knee [5]; thus cutaneous feedback is important for kinesthesia at joints throughout the body [5].

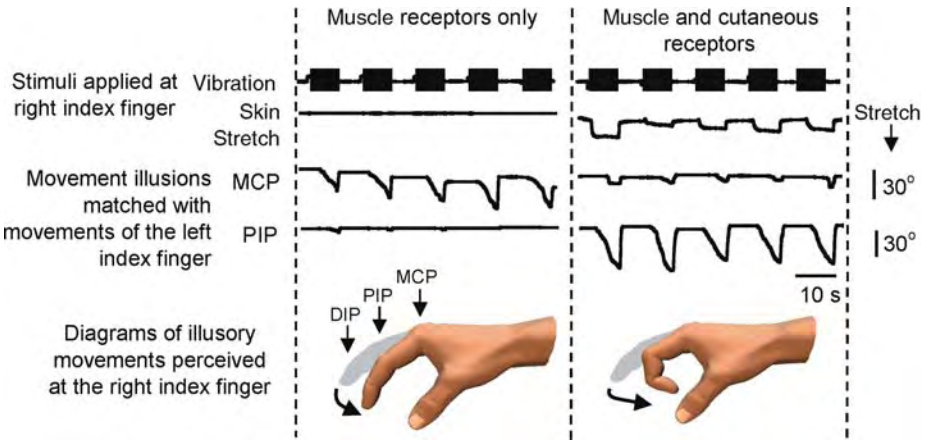
When skin stretch and vibration are applied simultaneously, movement illusions are larger than when either stimulus is applied alone (see Figs. 2 and 3). Hence, the brain uses a combination of information from muscle spindles and cutaneous receptors for kinesthesia. The role played by joint receptors for kinesthesia is unclear, but the decrease in the ability to detect movement when joint receptor feedback was removed by anesthesia suggests they also contribute [3].

## Cortical Structures and Kinesthesia

Kinesthetic information from sensory receptors enters the spinal cord through the dorsal horn and ascends to the brain along the dorsal columns. Before entering the brain the pathway crosses over to the opposite side of the body and projects to the main receiving area for kinesthetic information, the primary somatosensory cortex (shown in red in Fig. 1). Here, information from different parts of the body is received in different regions, resulting in a representative map of the body called a homunculus (Latin for "little man"). In the homunculus, regions of the body with the greatest



**Proprioception: Role of Cutaneous Receptors. Figure 2** Movement illusions of the elbow produced by stimulating cutaneous receptors alone (skin stretch) or with simultaneous stimulation of receptors in muscle (vibration). Stimuli were applied to the right elbow and subjects matched perceived movements with voluntary movements of the left elbow. Adapted from Collins et al. 2005 [5].



**Proprioception: Role of Cutaneous Receptors. Figure 3** Movement illusions produced at the index finger by stimulating muscle receptors alone (vibration) or with simultaneous stimulation of cutaneous receptors (skin stretch). The skin stretch was applied around the two distal joints (PIP, DIP) and the vibration was applied over a tendon on the back of the hand near the MCP joint. Subjects matched perceived movements with voluntary movements of the left index finger. Adapted from Collins et al. 2005 [5]. (*MCP* metacarpophalangeal joint; *PIP* proximal interphalangeal joint; *DIP* distal interphalangeal joint)

numbers of receptors, such as the hands, have the largest representation. The perception of movement, however, is not localized to this one part of the brain but involves activity in many brain regions [6]. Thus, kinesthesia is a distributed process involving the somatosensory cortex as well as the motor cortex, cerebellum and frontal parts of the cortex with a particular importance of the right hemisphere [6].

## Lower Level Components

### *Cutaneous Receptors*

Much of our knowledge about cutaneous receptors comes from work on the hand where four morphologically distinct types of receptor have been identified [7]. Merkel discs and Meissner corpuscles lie in the superficial layers of the skin and have relatively small receptive fields ($\leq$10 mm$^2$). Densities for these receptors are highest in the distal skin, with the digit tips containing 70 and 140 receptors/cm$^2$ for Merkel discs and Meissner corpuscles, respectively [7]. Pacinian corpuscles and Ruffini endings reside in the deeper layers and have larger receptive fields ($\leq$25 mm$^2$) and densities that are lower and more uniform [7]. Meissner and Pacinian corpuscles adapt rapidly to sustained stimuli such as constant velocity movements and discharge primarily at the beginning and end of movement. In contrast, Merkel discs and Ruffini endings adapt slowly to sustained stimuli and continue to discharge throughout movement with a discharge frequency that is often closely related to the amplitude and velocity of the movement. Receptors similar to those in the hand have also been found in the skin of the arm and leg, although there are regional differences in receptor densities.

## Higher Level Processes

### *Sensory Feedback and Movement Control*

The control of human movement involves a complex interaction between motor output from the brain and sensory feedback from peripheral sensory receptors. Sensory feedback from the limbs provides information about movement execution, sending an error signal to the brain when movements do not proceed as planned. Sensory feedback also contributes to movement control at the level of the spinal cord. Spinal reflexes provide automatic responses to external disturbances that help to prevent for example slips of hand-held objects [7] or trips during walking. Sensory feedback also influences the timing and amplitude of muscle contractions during rhythmic movements by modifying the activity of central pattern generators in the spinal cord that are responsible for generating the basic patterns of muscle activity.

## Lower Level Processes

### *Communication in the Nervous System*

Information travels through the nervous system in the form of action potentials, tiny electrical impulses generated by the transient passage of ions across the cell membrane. During movement, action potentials are initiated in a cutaneous receptor during movement of the skin within its receptive field. These signals travel along myelinated axons of the nerve cells (neurons) at 35–80 m/s to synaptic junctions with other neurons. At the synapse, the site for communication between neurons, the arrival of the action potential triggers the release of neurotransmitter, a chemical signal that activates receptors on the membrane of the post-synaptic neuron. Receptor activation initiates

ion movement across the post-synaptic membrane where, with a sufficiently large stimulus, another action potential is generated. Thus, communication between neurons (synaptic transmission) involves the conversion of an electrical signal (action potential) into a chemical signal at the synapse and back to an electrical signal in the post-synaptic cell.

## Process Regulation

### *Gating of Cutaneous Feedback During Movement*

Transmission along pathways from cutaneous receptors to the brain is suppressed during movement [8]. This suppression occurs in the spinal cord and brain and is thought to prevent these structures from becoming saturated by the massive amount of sensory traffic that is generated during movement. Control of information flow through the nervous system is selective; irrelevant signals are suppressed more than signals from receptors that provide information that is important for the successful performance of the movement [8].

## Function

### *The Cutaneous Contribution to Kinesthesia*

For many years it had been thought that cutaneous receptors play only a minor role in kinesthesia, perhaps acting to facilitate movement-related feedback from muscle spindles. This "facilitation" hypothesis was tested by measuring the ability to detect small finger movements when cutaneous feedback from adjacent digits was removed (by anesthesia) or enhanced (by skin stimulation) [9]. Movement detection was not decreased by cutaneous anesthesia nor was it enhanced by increasing cutaneous receptor discharge. Thus, the role for cutaneous feedback for kinesthesia is not one of general facilitation [9]. Instead, evidence has been mounting over the last 10 years that cutaneous receptors provide specific information about the movement itself [2] and this is used for kinesthesia [4,5]. Some idea of the relative roles of feedback from cutaneous receptors and muscle spindles has come from experiments investigating illusory movements of the fingers using vibration to activate muscle spindles and skin stretch to activate cutaneous receptors around specific finger joints (Fig. 3) [4,5]. When vibration was applied by itself, subjects perceived movements primarily at the metacarpophalangeal (MCP) joint (Fig. 3, left panel). When the skin around the proximal and distal interphalangeal joints was stretched and compressed during vibration, to mimic patterns that occur during movements of those joints, the perception of movement decreased at the MCP joint and increased at the joints where the skin stretch was applied. This supports the idea that one role for cutaneous feedback may be to help to distinguish which finger joint is moving [5]. Most muscles that control movements of the fingers are located in the forearm and cross more than one joint. Hence, the changes in muscle length detected by muscle spindles could arise from movement at one or more joints. The proximity of cutaneous receptors around individual joints enables them to provide specific information about which joint is moving. The receptors most likely to provide this information are the rapidly adapting Pacinian and Meissner corpuscles [2]. Information from the slowly adapting receptors, particularly the Ruffini endings, is more likely to be responsible for providing ongoing information about the position and velocity of the moving joint [2]. Cutaneous feedback is also important for kinesthesia at the elbow and knee and it is likely that feedback from muscle spindles and cutaneous receptors is used for kinesthesia for joints throughout the body [5].

## Pathology

### *Clinical Implications*

The idea that cutaneous receptors contribute significantly to kinesthesia is relatively recent and the clinical implications have yet to be fully explored. It had been suggested that improvements in joint stability associated with bandaging the knee might be due to enhanced cutaneous proprioception, but this was not supported by experiments assessing movement detection with and without a bandaged knee [10]. However, the cutaneous contribution to kinesthesia should be considered for tests of proprioception that make up part of standard neurological examinations. Clinicians should be careful to avoid generating conflicting signals from cutaneous receptors when applying passive joint movements. Finally, one would predict that persons who have suffered burns to large regions of skin would have reduced kinesthetic ability due to decreased cutaneous feedback and this may influence movement performance. An increased understanding of the importance of cutaneous receptors for kinesthesia may lead to new ideas for the treatment and assessment of movement disorders.

## Definition

Proprioception, literally the "sense of self" (from Latin "*proprius*" = "own"), is the group of sensory modalities that allow us to know the positions of our limbs in space and to detect and assess the magnitudes of movements and forces without vision. Classically, it had been assumed that this sense was subserved by joint receptors, specialized mechanoreceptors located in the capsular tissues of a joint. Indeed, the term "joint sense" – the capacity to detect movements or changes in position about a joint – is still used in clinical practice, though it is generally now accepted that joint receptors themselves do not bear primary responsibility for our proprioceptive acuity. Muscle spindles – exquisitely sensitive intramuscular stretch receptors – are generally believed to be the sensory endings primarily responsible. Perceptions of joint movement evoked by small amplitude vibration applied to muscles or tendons, either intact or surgically exposed, were the first convincing demonstrations that these receptors contribute importantly to proprioception (see ►Proprioception, Role of Muscle Receptors). The role of stretch receptors in the skin has come to increased prominence of late and there are many convincing studies implicating significant roles for cutaneous afferents in proprioception (see ►Proprioception, Role of Cutaneous Receptors).

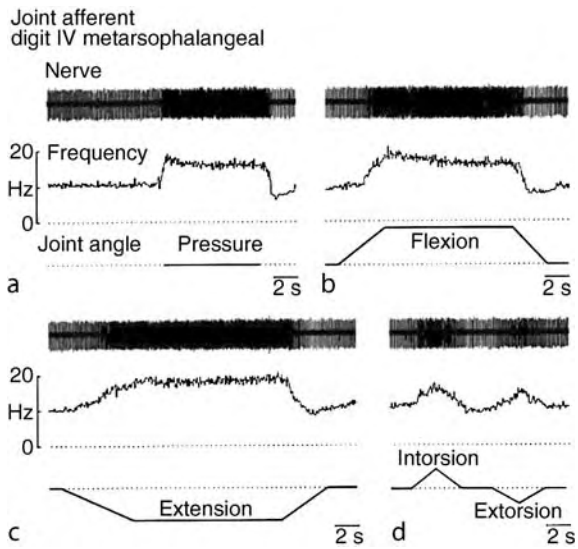
## Characteristics

### Quantitative Description

The consensus from the animal literature is that joint afferents mostly respond at the extremes of joint rotation [1]. Microelectrode recordings from the median and ulnar nerves of conscious human subjects have shown that mechanoreceptors associated with the interphalangeal joints and metacarpophalangeal joints do not respond to forces applied to bone when there is no movement of the joint and have very high mechanical thresholds to indentation applied over the joint capsule [2,3]. While they do respond to joint movements, they respond primarily at the limits of angular excursion. An example of a recording from a human joint receptor is shown in Fig. 1. This unit, located within the metatarsophalangeal joint of the fourth toe was spontaneously active at rest and responded to imposed extreme plantarflexion and dorsiflexion of the joint and to (unphysiological) internal and external rotation of the joint. Because joint afferents often respond in both directions (e.g. flexion and extension) and in more than one axis of rotation (e.g. abduction/adduction and extorsion/intorsion), as a group, joint afferents have a very limited capacity to encode changes in joint position. Nevertheless, a small proportion of interphalangeal joint afferents do respond across the physiological range [2,3]. Moreover, there is evidence that afferents associated with the dorsal aspects of human metacarpophalangeal joints consistently respond throughout the physiological range of joint rotation [4].

### Lower Level Components

Much of the early work on joint receptors, carried out mostly in the knee joint of the cat, supported the idea that joint receptors could encode changes in joint position [5]. However, it turned out that many of these were actually muscle spindle afferents coursing through the nerve supplying the joint. Nevertheless, a few receptors – unequivocally articular in origin – have been found that respond throughout the physiological range of angular excursion [6]. Histological and physiological studies have shown that mechanoreceptors in the posterior capsule of the cat knee joint, identified as Ruffini organs (i.e. similar to the stretch receptive SAII endings in skin) respond in a slowly adapting manner to strains applied in the plane of the tissue but have very high thresholds to compressive stresses applied perpendicularly – the adequate stimulus is the increase in tensile strain in the immediate environment of the receptor [7]. Ruffini endings have also been identified



**Proprioception: Role of Joint Receptors.**
**Figure 1** Microelectrode recording from a joint afferent associated with the metatarsophalangeal joint of the fourth toe in conscious human subject. The mechanoreceptor responded to pressure over its receptive field (a) and to passive flexion (b), extension (c) and longitudinal rotation of the joint (d). Changes in joint angle are represented schematically.

in the human finger and knee joints and the discharge behavior of human joint afferents associated with the interphalangeal and metacarpophalangeal joints fits with their being Ruffini endings; they have very high mechanical thresholds to indentation applied over the joint capsule and respond to joint movements that cause an increase in tensile strain within the joint capsule [2].

## Higher Level Processes

Proprioceptive acuity is optimal when inputs from muscle, skin and joints are intact [8]. Anesthesia of the joint capsule attenuates and intra-articular fluid expansion augments proprioceptive acuity at the interphalangeal joint, arguing for a role of joint afferents in proprioception [9]. Intraneural microstimulation of a single joint afferent in conscious human subjects can be perceived as pressure over the joint or as a small movement, so joint afferents do have a strong synaptic coupling to higher order sensory neurons [3]. This means that, should a joint receptor be exposed to an adequate tensile strain within the joint capsule or extracapsular ligament, it could provide useful information. But given that these tensile strains are only reached during extreme joint rotations or direct pressure, their role in normal proprioception can be considered to be limited.

## Function

As noted above, joint receptors are considered to primarily encode changes in joint angle at the extremes of angular excursion. However, given that some joint afferents can encode joint rotation throughout the physiological range [2,6] they may play a role in proprioception when inputs from muscle and skin cannot contribute [9].

## Pathology

Loss of joint afferent input is not important; proprioceptive acuity is not greatly affected when people are fitted with prosthetic joints [10].

## Definition

When limbs are moved, under circumstances where vision cannot be used to monitor the movements, there is a quite accurate sense of where the limbs are in space and whether they are moving or not. This is the ►kinesthetic or the ►proprioceptive sense [1][9].

The neural basis of ►kinesthesia and ►proprioception has been the subject of debate for many years. In the mid nineteenth century it was believed that sensations arising from movements produced by contracting muscles were associated with the motor commands that produced the movements – a "sensation of innervation." This view was not shared by Sherrington [2] who believed that the kinesthetic sense arose from afferent signals generated in the muscles themselves. Interestingly, the debate about the central and peripheral origin of the kinesthetic sense has not entirely subsided to the present day.

During most of the twentieth century it was believed that ►kinesthetic sensibility was provided predominantly by peripheral signals, although some uncertainty persisted over what kinds of receptors were involved. At one stage it was thought that joint receptors were the main source of input. This idea has not been laid to rest and in recent years, for some joints, contributions from joint receptors [3] as well as skin receptors [4] have been emphasized.

The experiments of Goodwin et al. [5] provided the first direct evidence for a role of a peripheral signal of muscle origin in ►proprioception when they described illusions of both forearm position and movement during 100 Hz vibration of elbow flexor muscles. They concluded that muscle spindles were the principal ►kinesthetic receptor.

## Characteristics

### Higher Level Structures

A difficulty with muscle receptors as the ►kinesthetic sensors was that until the second half of the twentieth century it remained uncertain whether muscle afferents had access to the cerebral cortex. It is generally accepted that a cortical projection is a necessary prerequisite for access by sensory receptors to consciousness. In the event, it was shown that both spindle Group I afferents (primary muscle spindle endings) and Group II afferents (secondary muscle spindle endings) projected to areas 3a and 4 of somatosensory cortex [6].

### Lower Level Structures

The illusions reported by Goodwin et al. [5] were of both position and movement, although vibration at 100 Hz produced principally a movement illusion. When vibration frequency was reduced to 20–40 Hz, the illusion faded from one of movement to one of limb position [7].

Animal studies had demonstrated that the primary endings of spindles had both a dynamic length sensitivity and a static length sensitivity [8]. Furthermore, primary endings were very sensitive to high frequency muscle vibration. It was therefore inferred that the movement illusions experienced during high frequency vibration were the result of signals generated by primary endings.

Secondary endings had no dynamic sensitivity but they responded with maintained changes in discharge during changes in muscle length. They responded only to low frequency vibration. It was concluded that spindle primary endings signaled both movement and position information, while spindle secondary endings contributed only positional information.

### Lower Level Processes

Since muscle spindles are stretch receptors, whenever a muscle was stretched during movement of a limb, signals would be generated in both primary and secondary endings. A proportional relationship could be described between the size and rate of stretch and the dynamic and static components of spindle discharge [8]. All of this related to responses of spindles during length changes in the passive muscle. It was known that during a graded voluntary contraction, the ►fusimotor neurons to muscle spindles were ►co-activated [10]. So impulses can be generated in spindles by two fundamentally different processes, stretch and intrafusal contraction.

### Higher Level Processes

According to the ►hypothesis that kinesthesia represents two distinct senses, the sense of position and the sense of movement, there is some evidence that central projection sites for dynamic and static spindle signals are separate [6]. Further processing of spindle information must take place to distinguish between ►fusimotor evoked spindle activity (reafference) and muscle stretch evoked activity (exafference). A central subtraction process was postulated to take place [11]. According to this scheme, the motor command goes to both alpha and gamma motoneurons as part of the ►co-activation strategy. Gamma-evoked impulses are subtracted from the total spindle signal to extract movement and position related components. It means that spindles could provide this information at all levels of voluntary activation [7].

### Process Regulation

At the present time, we know little about the central processes and their regulation in the generation of ►kinesthetic sensations. Signals from area 3a (dynamic) and area 4 (static) must combine with exafferent information to produce the felt sensation. Where this takes places remains to be shown.

### Function

The ►kinesthetic sense, making reference to a central map, allows us to locate the body and body segments in space, in the absence of vision. It also provides us with information about movement of the body. Since in everyday life many of our movements are carried out without visual guidance, the ►kinesthetic sense is important for normal motor activities.

### Pathology

An indication of the importance of ►kinesthesia and ►proprioception for motor control is provided by subjects with a large fiber sensory neuropathy. These subjects carry out all activities under close visual control. In the absence of vision they exhibit large errors in ►kinesthetic tests and they are unaware of obstacles encountered during movements, unless they can see them [1].

## Prospero: Protein Localization in Neuroblasts

Xiaohang Yang
Institute of Molecular and Cell Biology,
Agency for Science, Technology and Research,
Proteos, Singapore

### Definition

Prospero belongs to a unique group of proteins that are enriched in either the apical or basal cell cortex, just under the plasma membrane, of dividing neuroblasts. The asymmetric cortical localization of Prospero protein is controlled by a sophisticated ►asymmetric cell division mechanism that secures the exclusive segregation of Prospero to the future ►ganglion mother cell during mitosis.

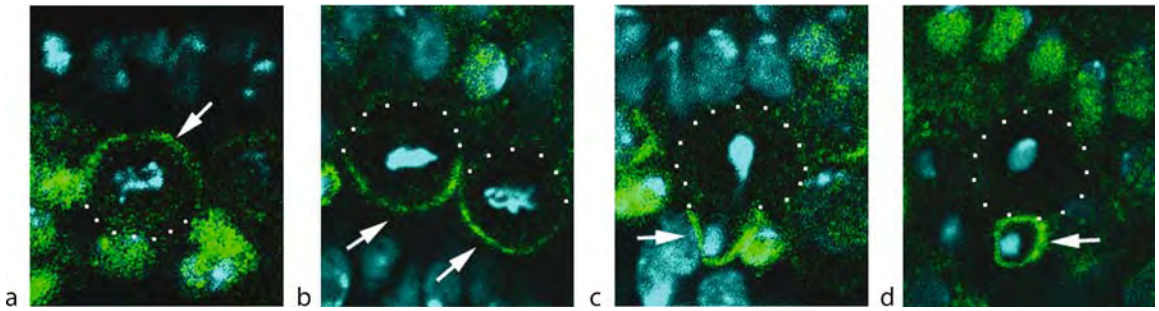
### Characteristics

The *Drosophila* embryonic central nervous system (CNS) is derived from an array of approximately 30 unique types of neuroblast. The highly diversified neurons and supporting cells in the CNS are the direct progenies of ganglion mother cells produced by neuroblast asymmetric divisions. The *Drosophlia* gene *prospero* (*pros*) is required for the generation of the ganglion mother cell.

*pros* [1] was identified in the early 1990s and named after the protagonist in *The Tempest*, a play by William Shakespeare. *pros* is located on the right arm of the third chromosome (86E2–86E4) and encodes three slightly varied large polypeptides (1535, 1403 and 1374 aa) due to alternative spicing. The Pros protein is a divergent homeodomain transcription factor that acts as a switch between self-renewal or terminal differentiation of a neural precursor cell. *pros* is evolutionally conserved and vertebrate homologs of *pros*, Prox1, have been identified in human, mouse, zebrafish and frog.

During early *Drosophila* embryonic neurogenesis, neuroblasts delaminate from the neuroectoderm and divide asymmetrically along the apicobasal axis to produce one large and one small daughter cell. The size difference between the two daughters is so prominent that it appears as if the small daughter buds off from the basal cortex of the telophase neuroblast (Fig. 1c).

The large apical daughter cell remains as the neuroblast and continues to divide asymmetrically. The small basal cell adopts the ganglion mother ►cell fate and divides terminally to make either two neurons or glial cells.



**Prospero: Protein Localization in Neuroblasts. Figure 1** Confocal images of cell cycle-dependent asymmetric distribution of Pros protein in mitotic neuroblasts. Embryos at developmental stage 10 were stained with anti-Pros (*green*) and ToPro3 (chromosomes, *cyan*). At late interphase or early prophase, Pros protein is transiently enriched in the apical cortex and forms an apical crescent (Panel a, *arrow*). Starting from late prophase, Pros is relocated to the basal cortex and remains basal (Panel b, *arrows*; late prophase and metaphase) throughout the rest of mitosis. At telophase, Pros protein is sequestered into the future ganglion mother cell (Panel c, *arrow*). After cytokinesis, Pros protein is exclusively inherited by the ganglion mother cell (Panel d, *arrow*) and translocated into the nucleus later. Apical is up. Neuroblast cell bodies are outlined with *white dots*.

Pros protein is made in neuroblasts and its cellular distribution is tightly regulated by the cell cycle [1]. Anti-Pros immunofluorescence staining shows that Pros protein transiently enriches in the apical cortex (membrane-associated or "apical crescent") (Fig. 1a) in late interphase and early prophase neuroblasts. Starting from late prophase, Pros is relocated to the basal cortex of mitotic neuroblasts and remains basal ("basal crescent," Fig.1b) throughout the rest of mitosis. In telophase, Pros protein is sequestered into the future ganglion mother cell (Fig. 1c). After cytokinesis, Pros protein is exclusively inherited by the ganglion mother cell (Fig. 1d). In newly formed ganglion mother cells, Pros is cortical (membrane-associated, Fig. 1d) and is translocated into the nucleus later, which is essential for its function. The membrane-associated form of Pros is highly phosphorylated and its translocation to the nucleus requires dephosphorylation [2]. Interestingly, *pros* mRNA exhibits similar asymmetric cellular localization patterns in mitotic neuroblasts and gets sequestered into ganglion mother cells [3].

Pros protein appears to act as a master player (reminiscent of Prospero who has the magic power in *The Tempest*) that controls the ganglion mother cell fate. In the absence of Pros, or failure to translocate Pros to the nucleus, the smaller daughter cell fails to adopt the ganglion mother cell fate and does not produce proper neurons. Thus, Pros is also called a "cell fate determinant." Another well studied cell fate determinant in neuroblast asymmetric division is Numb [4], which exhibits similar asymmetric basal localization and exclusive segregation into future ganglion mother cells as Pros. Numb antagonizes the Notch signaling pathway.

A number of protein complexes are involved in regulating Pros asymmetric localization in mitotic neuroblasts [5]. Proteins such as Bazooka (Baz), DaPKC, Par6, Inscuteable (Insc), Partner of Insc and the α-subunit of trimeric G-protein, as well as Locomotion defects, co-localize to the apical cortex of mitotic neuroblasts from late interphase and form a functional complex (apical complex). This apically localized complex exhibits three major functions: (i) regulating the basal localization of cell fate ►determinants such as Pros and Numb; (ii) re-orientating the mitotic spindle along the apicobasal axis by metaphase; and (iii) generating an asymmetric spindle (the apical half of the spindle arm is much longer than that of the basal half) which is responsible for the distinct cell size difference between the two daughters. Loss of function of any single protein (for example, in *baz* or *insc* mutants) from the apical complex usually causes mislocalization (randomized Pros crescent position) of Pros protein in early (prior to anaphase) mitotic neuroblasts. However, starting in anaphase, Pros protein in the majority of these mutant neuroblasts is redistributed as a crescent to the cell cortex where the future ►ganglion mother cell buds off. This redeployment of Pros protein late in mitosis in mutant neuroblasts has been referred to as "telophase rescue."

The asymmetric localization of Pros in mitotic neuroblasts also depends on a protein called Miranda (Mira) [6], which was named after Prospero's daughter who went into exile with him in *The Tempest*. In mitotic neuroblasts, Mira binds to Pros and functions as an adaptor protein for Pros asymmetric cortical distribution. In the absence of Mira, Pros loses its asymmetric localization and becomes cytoplasmic.

The cell-cycle dependent translocation of Pros protein from apical to basal cortex is regulated by the Snail family proteins of Zn-finger transcription factors Snail (Sna), Escargot (Esg) and Worniu (Wor) [5]. The members of the Snail family share homologous sequences and exhibit redundant functions. In the absence of all three Snail family proteins, two major players of the apical complex in the embryonic CNS, Baz and Insc, are down-regulated in the segmented CNS but not the brain. In these *snail* triple-mutant (*esg wor sna*) embryos, Pros protein remains tethered to its apical position and does not relocate late in mitosis to the basal cortex from where the future ganglion mother cells bud off. Since these small daughter cells do not inherit Pros, they do not adopt the ganglion mother cell fate. These observations indicate that in addition to the absence of Baz and Insc, the compensatory telophase rescue mechanism is also defective in *snail* triple-mutant (*esg wor sna*) neuroblasts. The detailed mechanism of telophase rescue remains largely unknown. A recent study of telophase rescue has indicated that two *Drosophila* homologs of mammalian TNF/TNFR molecules, Eiger and DTRAF1, are involved in Pros protein telophase rescue [7]. Interestingly, Numb telophase rescue requires neither Eiger nor DTRAF1, which suggests that a different pathway is involved.

Two tumor-suppressor genes, *lethal giant larvae* (*lgl*) and *discs large* (*dlg*), are also involved in the proper basal localization of Pros in dividing neuroblasts [8,9]. In contrast to its asymmetric localization to either the apical or basal cortex in wild type neuroblasts, in the absence of Lgl/Dlg Pros protein is evenly distributed in the cortex and is heavily associated with the mitotic spindle. It has been suggested that Lgl/Dlg may act in a secretory pathway involved in the basal intracellular translocation of Pros. The asymmetric basal localization of Pros protein also depends on the actin cytoskeleton, but not the microtubule structures inside cells. Disruption of the actin cytoskeleton results in loss of Pros from the membrane.

It appears that Pros asymmetric localization is only observed at embryonic stages. During late nervous system development, the asymmetric localization and

segregation mechanism do not seem to play a major role in Pros function and the conventional transcription/translation regulation mechanism prevails. For example, in the 3rd instar larval brain, Pros protein is expressed only in ganglion mother cells and not in neuroblasts, although Mira remains asymmetrically localized in mitotic larval neuroblasts and is exclusively partitioned into ganglion mother cells at telophase. Another example is the development of the adult external sensory organ. Pros protein is cytoplasmic in dividing sensory organ precursor cells and distributes equally to two daughter cells after cytokinesis [10]. Later the Pros protein level is down-regulated in one of the daughter cell (IIa), which divides to produce a hair and a socket. The daughter cell maintaining Pros protein (IIb) produces a neuron and a glial cell.

In summary, the cell fate determinant Pros protein is made in the mother cell (neuroblast) and only functions as a transcription factor in the nucleus of one of the two daughter cells (ganglion mother cell). The cell cycle-dependent asymmetric distribution of Pros protein during mitosis is a critical mechanism employed by dividing neuroblasts to secure the exclusive segregation of this protein to the ganglion mother cells. In vertebrates, it is not known whether Prox1 is involved in asymmetric divisions. Prox1 knock-out mice show embryonic lethality with impaired development of the lens, lymphatic system, liver and pancreas.

## Synonyms

Immune based-self maintenance, repair and renewal

## Definition

Immune response recognizing auto-antigens that contribute to maintenance, protection, repair and renewal of the relevant tissue; so far proven with respect to the central nervous system.

## Characteristics

### Description

As a result of tissue injury, physiological compounds flood the body in toxic amounts. ►T cells (T lymphocytes) directed to self-antigens serve as the fighting force against these self-derived threatening factors ("the 'enemy within'") [1,2], much as the classical immune response fights invading enemies, such as microbes.

T-cell specificity for self-antigens (►autoimmunity) is required for homing of the T cells to the autoantigen-populated site of damage and their activation there [5]. Following activation by their relevant antigens, the T-cell effect is independent of both antigen specificity and the existing toxicity. These "►autoimmune T cells," via secreted factors such as cytokines, activate the local ►microglia (brain-resident immune cells) to support neuronal survival and repair [2].

### Background

Damage to the central nervous system (CNS) results in irreversible functional loss that is often more extensive than would be expected from the severity of the primary insult [1]. This heightened impairment results from the inevitable degeneration of neurons that sustained the primary injury, as well as from failure of the tissue to withstand the self-perpetuating process of damage that spreads to neighboring neurons. The latter is due to a pathological disruption in homeostasis caused by self-compounds in concentrations that are beyond the buffering capacity of the tissue. In addition, the ability of CNS tissue to tolerate a defense mechanism mediated by its resident immune cells (microglia) is poor; thus, unless tightly controlled, microglial activation is itself likely to exacerbate the damaging conditions rather than help the tissue to withstand them. Poor recovery of the CNS is therefore a reflection of (i) the limited ability to regrow new fibers from cell bodies with damaged axons (regeneration), (ii) failure of the CNS to tolerate adverse conditions, including those caused by ineffectual attempts at repair, and (iii) the limited capacity of the adult CNS for spontaneous ►neurogenesis (cell renewal). T cell-based protective autoimmunity can be viewed as a means of controlling the brain's microglia-based system of self-defense in a way that the brain can tolerate.

That the effect of the ►immune system on CNS repair processes might be beneficial was not considered a possibility until the studies done by the Michal Schwartz group at the Weizmann Institute of Science in 1998 [3]. Up to that time, the consensus was that the healthy CNS is refractory to immune cells, and that the successful infiltration of immune cells into the damaged CNS would result in CNS malfunction and should therefore be minimized. Schwartz and her group discovered that – contrary to the traditional dogma – immune cells are pivotal for CNS repair [1,3]. T cells control the microglial response by producing growth factors and cytokines that empower the microglia infiltrating blood-brone macrophages to buffer the injury-induced toxicity [2], thereby avoiding overwhelming damage to neighboring cells. Thus, by acting as a well-controlled link between the damaged CNS and the healing immune system, suitably activated microglia/macrophages can carry out defensive tasks even in a tissue as fragile as the CNS [4].

Contrary to common wisdom, Schwartz's group suggested that protection, repair, and recovery after a CNS insult necessitate an immune response, but that the response produced is often too weak (and requires boosting) or inappropriate (and in need of modulation and rigorous control); in both cases the resulting modification must be one that the CNS can safely tolerate [4]. In rats or mice devoid of the ability to manifest an adaptive (T cell-mediated) response to CNS injury, the post-injury loss of neural tissue is significantly increased. Moreover, immunization of injured animals with self-antigens, a procedure that boosts accumulation of self-reactive (autoimmune) T cells at the site of injury, decreases neuronal cell death [5]. This phenomenon of ►neuroprotection mediated by autoimmune T cells residing at the site of injury, or "protective autoimmunity," was found to be physiological response to CNS injury that spontaneously occurs but is apparently insufficient for the repair [4].

### Quantitative Aspects

Injury to the CNS induces activation of microglia at the damaged site, beginning at the time of injury and reaching a peak 7–10 days later. Astrocytes, however, disappear from the site of injury, as demonstrated by immunohistochemical analysis of glial fibrillary acid protein, an astrocyte marker. Besides activated microglia, the injury site is also populated by T cells and infiltrating blood-borne monocytes. Their accumulation

starts immediately after the injury, reaches a peak 7–10 days later, and resolves itself by 2–3 weeks following the injury. A well-synchronized response in terms of amount, time and location is pivotal for the repair. Lately protective autoimmunity has been extented to include brain plasticity, not only in disease but also in health. Neurogenesis and spatial learning/memory capabilities were found to be dependant on the availability of T cells recognizing CNS antigens [6].

## Higher-Level Structures

T cells that participate in the healing process within the injured CNS are part of the adaptive arm of the immune system. The site of the insult determines the specificity of the T cells needed for protection and repair. In the case of injuries to white matter, the protective T cells must be reactive to antigens associated with CNS myelin whereas after gray matter injuries, the protective T cells are specific to other proteins that are abundantly expressed at the injury site.

## Lower-Level Components

Upon reactivation by encountering their specific antigens at the site of injury, the T cells can produce a variety of soluble proteins that are required for normal neuronal function. These include nerve growth factor, brain-derived neurotrophic factor, glial cell-derived neurotrophic factor, and others [7].

## Anatomy and Physiology of Regulation

According to the concept of protective autoimmunity, autoimmune T cells in healthy individuals exist in a state that represents a compromise between the need for autoimmune protection and the risk of autoimmune disease. Schwartz's group discovered that a subpopulation of T cells, identified as the naturally occurring regulatory CD4 + CD25 + T cells (Treg cells), constitutively suppressed the activity of autoimmune T cells, and that this population is itself regulated (i.e. the suppression can be abolished or at least weakened) by brain-derived compounds such as the stress-related neurotransmitter dopamine [5].

## The Regulatory Process

Naturally occurring Treg cells exert tight control over circulating autoimmune T cells, so that the latter normally exist in a state often described by immunologists as "nonresponsiveness." Treg cells are produced in the thymus and are released to the periphery, where they suppress the activity of autoimmune T cells. Depletion of Treg cells predisposes animals to the spontaneous development of autoimmune diseases. Animals depleted of Treg cells also demonstrate more efficient rejection of tumors, because their autoimmune Lately protective autoimmunity has been evtended to include brain plashcity, not only indisease but also in health. Neurogenesis and spatial learning/memory capabilities were found to be dependant on the availability of T cells recognizing CNS antigens [insert ref ziv et al] [6] T cells can be more easily activated [15]. In line with findings on cancer rejection, depletion of the Treg cell subpopulation enhances the animals' ability to withstand conditions of CNS neurodegeneration [5]. Thus, endogenous compounds such as dopamine, because of their ability to attenuate the activity of the Treg cells, might be useful as potential components of neuroprotective therapies.

## Pathology

After an injury, the damaged CNS tissue becomes accessible to immune cells. Although the post-injury inflammatory process that is mediated by self-reactive T cells is a protective physiological response, these autoimmune T cells appear to include the very cells that can also induce experimental autoimmune encephalomyelitis (EAE), an animal model for the autoimmune disease, multiple sclerosis [8]. Therefore, proper regulation is critical if the autoimmune response is to protect the organism from injury-associated damage without the concomitant induction of another kind of pathology, namely autoimmune disease [9].

## Therapy

The following immune-based therapies for CNS repair are currently under investigation:

- *T cell-based therapeutic vaccination*: This experimental treatment involves the boosting of T cells directed against weak agonists of self-antigens that cross-react with antigens residing at a site of stress or disease. The risk of autoimmune disease is avoidable by using weak agonists that exhibit only partial cross-reactivity with their relevant self-antigen. One such antigen is glatiramer acetate, also known as copolymer 1 (Cop-1), a synthetic copolymer composed of four amino acids (glutamate, lysine, alanine, and tyrosine). Immunization with Cop-1 was found to be neuroprotective in several models of CNS injury and neurodegenerative disorders [7]. Another possible way to boost autoimmune T cells is through the use of altered peptide ligands. An altered dominant peptide of myelin basic protein (MBP) that does not induce EAE upon immunization was found to be significantly neuroprotective in a rodent model of spinal cord injury [10].
- *Weakening of the activity of* ▶*regulatory T cells*: Neuroprotection is enhanced in mice depleted of Treg cells [5]. In human subjects such depletion is

impossible, as most of these cells are located in lymph nodes, and there is no known way to selectively remove them. Therefore, compounds that can selectively weaken the suppressive activity of Treg cells are potential candidates for therapy. One such compound is the neurotransmitter dopamine, which alleviates the suppressive activity of naturally occurring Treg cells. Injection of dopamine or dopamine-receptor type-1 agonists after CNS injury was found to be neuroprotective [5]. An additional compound found to be effective in modulating T reg is a copolymer of glutamate tyrosine, poly YE, show to be effective in stroke [5].

- *Autologous macrophages:* These cells constitute the basis of an immune-based cell therapy for spinal cord repair. Depending on their environmental conditions, cells of the macrophage lineage can acquire either the type of activation appropriate for fighting off invading microorganisms, or – activation leading to tissue maintenance and repair. Schwartz's group discovered that macrophages with the characteristic features of antigen-presenting cells can facilitate CNS repair [3]. Once activated by autologous tissue such as skin, these macrophages produce cytokines and neurotrophic factors, but not tumor necrosis factor-α or other cytotoxic agents. In a therapy currently under development, macrophages are prepared from the patient's own blood, activated on the patient's own skin in such a way that they adopt a repair-promoting phenotype, and reintroduced into the margin of the lesion site at the specific time and dosing, facilitates repair. Such macrophages are reminiscent of the ones recruited by immunization with CNS self-antigen following spinal cord injury [11].
- *Dendritic cells:* Bone marrow-derived dendritic cells are professional antigen-presenting cells, which can be loaded with antigens and used to treat the acutely injured CNS. Dendritic cells prepared from autologous blood and loaded with relevant CNS antigens, can (like macrophage therapy) be applied locally to the severed spinal cord, or administered systemically as a vaccination [12].

## Concluding Remarks

The immune system is the body's primary source of defense against danger and remedial assistance in the event of injury. The CNS, however, was long thought to have relinquished its claim on the immune system for such help, possibly as an evolutionary trade-off that protected its extraordinarily complex neural network from harmful immune (inflammatory) intervention. Similarly, immune cells directed against self-antigens, traditionally viewed as autoaggressors causing autoimmune disease, acquired an unfavorable reputation as an outcome of immune system malfunction. The studies described here, as well as studies from many other laboratories, provide persuasive evidence that the negative reputation of the immune system vis-à-vis the CNS is undeserved. Nevertheless, spontaneous activation of the CNS-resident microglia is often not sufficiently effective. Thus, additional assistance is needed from cells that constitute the adaptive arm of peripheral immunity, namely T cells specific to CNS self-antigens. Based on this concept, several approaches can be translated into workable therapies. The treatment of choice will ultimately be based on safety, feasibility, and efficacy, and the specific indication.

Protein Phosphatase 1, PP-1; Protein Phosphatase 2A, PP-2A; Protein Phosphatase 2B, PP-2B

### Definition

Protein Serine/threonine phosphatases are a family of protein enzymes, which specifically remove the phosphate group from the serine or threonine residues of the substrate proteins. These phosphatases termed PPPs include ►PP-1, ►PP-2A, ►PP-2B, ►PP-2C, PP-4, PP-5, PP-6 and PP-7.

### Characteristics

The reversible ►phosphorylation and ►dephosphorylation of proteins at the serine, threonine and tyrosine residues play fundamental roles in mediating different signaling transduction pathways and thus act as a major mechanism to regulate eukaryotic cellular events such as gene expression, cell proliferation, differentiation, homeostasis and apoptosis. The two processes executed by ►protein kinases and ►protein phosphatases can trigger conformational changes in regulated proteins that finally alter their biological properties and functions. In this regard, phosphorylation may endow a protein with a favorable conformation for binding by its relative substrates or partners, which in the end brings about some cellular and morphological changes; on the contrary, its dephosphorylated form may possess these features. And at any instant, a protein's specific phosphorylation status is a balanced result between its regulatory kinases and phosphatases.

Genome research has identified 147 genes coding for the catalytic subunits of protein phosphatases. According to differences in substrates, the protein phosphatases can be divided into three groups, including ►protein serine/threonine phosphatases (PPPs), protein ►tyrosine

phosphatases (PTPs), and dual-specific phosphatases (DSPs). On the basis of the selective inhibition of type-1 phosphatases (PP-1) by endogenous inhibitor-1 (►I-1) and inhibitor-2 (►I-2), the PPP family can be further divided into type-1 (PP-1) and type-2 (►PP-2) subgroups and a few minor phosphatases that include PP-4, -5, -6 and -7, although these phosphatases have a broad and overlapping substrate specificity. The PP-1 enzyme is composed of a catalytic subunit and one or more regulatory subunits, and it is hard to distinguish the regulatory subunit from its inhibitor or substrate. The PP-2 subgroup consists of three enzyme members, PP-2A, PP-2B and PP-2C, which can be distinguished by their substrate specificity, subunit number and the specific cations needed for function. For instance, PP-2A can dephosphorylate phosphorylase-a, while PP-2B and PP-2C do not. In addition, calcium is necessary for the function of PP-2B, which is also known as calcineurin. While PP-2A is composed of three subunits and PP-2B two subunits, PP-2C is a monomeric enzyme. In eukaryotes, 98% of dephosphorylation occurs at the serine/threonine residues, and more than 90% of protein ►serine/threonine phosphatase activity is contributed by PP-1 and PP-2A [1].

## Protein Phosphorylation in the Nervous System

Based on morphology and physiology, the adult nervous tissue is composed of two main cell types: neurons and glial cells. Neurons transmit high speed nerve signals through depolarization potentials, while glial cells are in direct contact with neurons to provide a basic support. Existing in variable sizes and shapes, neurons are the functional units of the nervous system. All neurons consist of three parts: dendrite, cell body and axon. Dendrites receive information from another cell and transmit information to the cell body. The cell body contains the nucleus, mitochondria and other organelles typical of eukaryotic cells, and processes the neuronal signals for further transduction. The axon sends information away from the cell body. Under normal conditions, glial cells surround neurons to modulate neuronal homeostasis and detoxification, and produce neuronal survival factors. The functions of crucial proteins in the nervous system are modulated by kinases and phosphatases. This essay focuses on the functions of three major protein phosphatases in the nervous system, PP-1, PP-2A and PP-2B.

## Protein Phosphatase-1 (PP-1)

Early studies showed that PP-1 accounts for 25–40% of the phosphorylase phosphatase activity in brain crude tissue extracts. In isolated synaptic junctions from rat forebrain, PP-1 accounts for 80% of the membrane-associated phosphatase activity. PP-1 can be inactivated by the inhibitor I-1 when phosphorylated by CAMP-dependent protein kinases, or by the inhibitor I-2 in the dephosphorylated form. In addition to the ubiquitous I-1 and I-2 inhibitors, brain tissue also contains a unique PP-1 inhibitor, ►DARPP-32, present predominantly in neural tissues. The localization of DARPP-32 is unique, for it is abundant in specific areas of the brain, including the basal ganglia which contains as much as 130 pmol of DARPP-32 per mg protein, but absent from most other tissues. Compared with the basal ganglia, the thalamus and cerebellum contain much less DARPP-32. In brain areas rich in DARPP-32, discrete populations of neurons show particularly high level of expression, such as the D1-receptor dopaminoceptive neurons, and the Purkinje cells of the cerebellum. The high phosphatase activity of PP-1 in the brain and its co-localization with the cognate inhibitors suggest that PP-1 might serve as an important regulatory enzyme in various neuronal events.

Neurons produce and transduce signals through alternative shifts in membrane potentials, which depend on different ion channels distributed in the plasma membranes. Ion channel activity can be regulated by closely associated kinases or phosphatases, which serves as a key mechanism for orchestrating neuromodulation. PP-1 is responsible for the dephosphorylation and modulation of some neuronal ion channels. In many instances, dephosphorylation is required for channel activity. An exemplary case is the peptide neurotransmitter Phe-Met-Arg-PheNH2 (FMRFamide) related serotonin-sensitive K + (S-K+) channel in Aplysia sensory neurons. Two PP-1 isoforms, with apparent MW of 170,000 and 38,000, were extracted from crude membrane preparations from the Aplysia nervous system. Biochemical and physiological studies suggest that of the two major protein phosphatases, PP-1 and PP-2A, PP-1 is associated preferentially with neuronal membranes and its activity is required for the induction of outward K + currents in Aplysia sensory neurons by FMRFamide [2]. Similarly, in rat brain and cerebellar Purkinje neurons, activation of the calcium-dependent potassium channels (BK channels) by neurotrophin-3 depends on their prior dephosphorylation by PP-1 or PP-2A. In addition, certain protein phosphatases are involved in the function of the nonselective cation channel that drives the after-discharge in Aplysia bag cell neurons. It has been shown that the reversal of the nonselective cation channel after addition of ATP was prevented by the PP inhibitor, ►microcystin-LR.

Various receptors in the nervous system play important roles in mediating signal transduction. Protein phosphatases can modulate the functions of these receptors through dephosphorylation. An example is the regulation of AMPA receptor by PP-1. The filamentous actin binding protein neurabin I (Nrb I) targets PP-1 to specific postsynaptic microdomains, where it can exert critical control over AMPA receptor-mediated synaptic transmission. PP-1 dephosphorylates

AMPA subtype glutamate receptor (GluR) 2 at Ser 880- to stabilize the basal transmission; while with long-term depression (LTD), PP-1 dephosphorylates GluR1 at both serine 845 and serine 831. These results suggest that in response to distinct synaptic activities post-synaptic targeted PP-1 could regulate the synaptic trafficking of specific AMPA receptor subunits [3]. In the western painted turtle, PP-1 or PP-2A dephosphorylates N-methyl-d-aspartate (NMDA) receptors and decreases their activity, which attenuates calcium influx and thus, excitotoxic cell death (ECD), a characteristic of mammalian brain following anoxia.

Physiological modulation of other target molecules by protein serine/threonine phosphatases also plays a role in the nervous system. Neural cell adhesion molecule (NCAM) has important functions during development and maintenance of the nervous system. NCAM 140 and NCAM 180 are transmembrane glycoproteins with large cytoplasmic domains of different lengths. PP-1 and PP-2A bind to both NCAM 140 and NCAM 180, suggesting possible functions of these two protein phosphatases during the development and maintenance of the nervous system. Further, doublecortin (DCX) is a highly phosphorylated protein in migrating neurons, whose mutation causes X-linked lissencephaly ("smooth brain") and double cortex syndrome in humans. It was reported that PP-1, by recruitment of Neurabin II, dephosphorylates the specific sites in DCX phosphorylated by JNK, which plays an important role in normal neuronal migration [4]. Finally, PP-1 may play an important in regulating brain and eye development. We recently demonstrated that PP-1 acts as a major phosphatase dephosphorylating the transcription factor Pax-6, which is highly expressed in the developing nervous system, and attenuates its transcriptional activity.

## Protein Phosphatase-2A (PP-2A)

PP-2A, also known as a polycation-stimutated phosphatase, is very abundant in brain where it is mainly cytosolic and represents 60–75% of the phosphorylase phosphatase activity. The PP-2A core enzyme is composed of a catalytic subunit (C) and a tightly complexed scaffolding subunit A. This core enzyme associates with a regulatory subunit B, whose function is to target the whole enzyme to specific intracellular locations and substrates. There are four subgroups of the B family subunits including B/PR55, B'/PR56/PR61, B''/PR72 and B'''/PR93/PR110. The major function of the ubiquitously expressed PP-2A seems to be related with a wide range of events under both physiological and pathological conditions in the nervous system.

PP-2A is implicated in Alzheimer's disease (AD), a progressive brain disorder that gradually destroys a person's memory and ability to learn, reason and communicate. The major brain abnormalities in patients with AD include extracellular deposits of beta-amyloid, intraneuronal neurofibrillary lesions, and the massive loss of specific subsets of telencephalic neurons. Dysregulation of the regulatory subunit of ►PP2A, B/PR55, has been implicated in AD. Since one of the major functions of the B subunit in PP-2A is to target the whole enzyme to its substrates, its dysregulation might lead to a failure of dephosphorylation of relevant brain proteins and finally AD. Further, researchers have found that the abnormal phosphorylation of paired helical filaments (PHF) tau resulting from the failure of PP-2A and PP-2B may disrupt the microtubule network, impair axonal transport, and compromise the viability of neurons, thereby also contributing to the onset and progression of AD [5]. In the non-diseased nervous system, research at the Drosophila neuromuscular junction suggests that the B' regulatory subunit of ►protein phosphatase 2A may regulate normal cytoskeletal organization, synaptic growth, and synaptic function.

The physiological function of PP-2A is also being revealed. It was reported that PP-2A is required for the differentiation of pluripotent neural crest (NC) cells into the sympathoadrenal lineage. A moderate activation of cAMP signaling induces both the transcription and activity of the proneural transcription factor Phox2a in NCs, whereas treatment with the ►organic phosphatase inhibitor, ►okadaic acid, at a concentration (1–10 nM) effective to inhibit PP-2A, suppresses sympathoadrenal lineage development. PP-2A also functions in the mature nervous system. During spinal cord ►central sensitization, PP-2A may play an important role in determining the excitability of ►nociceptive neurons in the spinal cord by modulating the phosphorylation state of certain critical proteins. For instance, infusion of the phosphatase inhibitor okadaic acid or ►fostriecin, a specific PP-2A inhibitor, into the ►subarachnoid space enhances secondary mechanical ►hyperalgesia and ►allodynia [6]. In addition, it was observed that blockade of protein phosphatase activity potentiates central sensitization of nociceptive transmission in the spinal cord following capsaicin injection, indicating that PP-2A may be involved in determining the duration of capsaicin-induced central sensitization. Finally, since cyclin G1 and the B' subunits of PP-2A are co-localized in neurons, the function of PP-2A in the nervous system may depend partly on its regulation of cell cycle in neurons [7].

## Protein Phosphatase-2B (Calcineurin)

PP-2B belongs to the family of $Ca^{2+}$ /calmodulin-dependent protein phosphatases and it is the only protein phosphatase regulated by a second messenger, $Ca^{2+}$. Furthermore, PP-2B is highly localized in the central nervous system, especially in those neurons

vulnerable to ischemic and traumatic insults. For these reasons, PP-2B is considered to play important roles in neuron-specific functions.

PP-2B has been extensively studied in nervous tissue. It was first purified as a major calmodulin-binding protein in brain (accounting for up to 1% of the total protein), and later identified as a protein phosphatase. The whole enzyme consists of two subunits, the catalytic and calmodulin-binding subunit calcineurin A, and the calcium binding regulatory subunit calcineurin B. PP-2B is essentially a neuronal protein due to its abundance in brain, where levels are 10–20 times higher than in other tissues. Nevertheless, it is distributed amongst a wide set of tissues in many species from yeast to mammals.

Some ion channels and receptors are regulated by PP-2B. In sympathetic neurons, the M current regulates neuronal excitability. Intracellular application of a preactivated form of PP-2B inhibited the macroscopic M current, while its application to excised inside-out patches reduced high open probability M channel activity. Thus, it is suggested that PP-2B selectively regulates M channel modal gating. PP-2B may also regulate the coupling between G protein and calcium channels in rat sympathetic neurons, as the alpha2 noradrenergic and somatostatin receptor-induced inhibition of N-type $Ca^{2+}$ channels was greatly reduced by inhibition of PP-2B. Interestingly, PP-2B in some cases may regulate both the function and the expression of a protein. For instance, PP-2B directly regulates type 1 inositol 1, 4, 5-triphosphate receptor (IP3R) function by dephosphorylation on a short-term time scale and IP3R expression over more extended periods.

The physiological functions of PP-2B in the nervous system seem to be quite diverse. On one hand, PP-2B regulates certain signaling transduction pathways in neurons by directly dephosphorylating target protein substrates. An example is its regulation of the NF-κB pathway in astrocytes of the injured brain. After brain injury a reactive phenotype of astrocytes is triggered which produces inflammatory cytokines and neurotoxic free radicals and leads to brain trauma. Under such circumstances, insulin-like growth factor-I (IGF-I) regulates the NF-κB pathway by activating PP-2B to dephosphorylate IκBα, which leads to a stabilization of IκBα and retention of NF-κB in the cytosol and hence inhibition of the inflammatory reaction [8].

In other systems, the signal transduction pathways regulated by PP-2B result in the activation of different transcription factor cascades. For instance, in the mammalian nervous system, PP-2B appears to regulate the number of excitatory synapses via myocyte enhancer factor 2 (MEF2). After dephosphorylation and activation by PP-2B, MEF2 promotes the transcription of a set of genes that restricts synapse number. Alternatively, regulation of other signaling transduction pathways by PP-2B involves the downstream transcription factor NF-AT. In calcium-regulated pathways related to learning and memory process, NF-ATc4/NF-AT3 in hippocampal neurons can be translocated rapidly from the cytoplasm to the nucleus to activate NF-AT-dependent gene transcription in response to electrical activity or potassium depolarization. The PP-2B-mediated translocation is critically dependent on calcium entry through L-type voltage-gated calcium channels. This indicates that PP-2B/NF-AT-mediated gene expression may be involved in the induction of hippocampal synaptic plasticity and memory formation. In addition, the PP-2B/NF-AT pathway is involved in neuronal axon outgrowth, the first step in the formation of neuronal connections. After stimulation by growth factors, PP-2B caused nuclear localization of NF-ATc4 and the activation of NF-AT-mediated gene transcription in cultured primary neurons. Blockade of this pathway prevented axon outgrowth, indicating that PP-2B/NF-AT signaling is required during nervous system development [9]. PP-2B also enhances NGF-induced neurite outgrowth.

The list of roles for PP-2B is ever growing in that PP-2B activity regulates synaptic function. For instance, PP-2B activity is required for three forms of synaptic plasticity in the hippocampus and associative learning in *Caenorhabditis elegans* and also reward-related learning in mice. The importance of PP-2B in synaptic function is illustrated by the fact that conditional calcineurin knockout mice exhibit multiple abnormal behaviors related to schizophrenia [10], and that PP-2B is also implicated in epileptogenesis.

## Conclusions

In summary, the protein serine/threonine phosphatases seem to be involved extensively in the regulation of neuronal development, differentiation, physiology and pathogenesis. The unscrambling of the signaling transduction pathways in nervous system would be a feasible solution for the ultimate conquering of various brain diseases such as Alzheimer's disease, epileptogenesis, and schizophrenia. Elucidation of the functional mechanisms of the protein phosphatases in the nervous system will provide a better understanding of neuronal function and brain disease.

# Protein Synthetic Machinery

## Definition

The protein synthetic machinery of a eukaryotic cell consists of ribosomes, endoplasmic reticulum (ER) and Golgi apparatus. Proteins destined to stay within the cytoplasm (cytosolic proteins) are synthesized on ribosomes and the product is released into the cytoplasm. Luminal proteins (proteins packaged in vesicles) and integral membrane proteins are synthesized on ribosomes that are docked on the endoplasmic reticulum, and the polypeptide chain is secreted in the lumen of the ER (luminal proteins), or is inserted into the membrane of the ER (integral membrane proteins). After trafficking through the Golgi apparatus the proteins are either released (secretory proteins), inserted into the cytoplasmic membrane (integral membrane proteins), or stored within vesicles in the cytoplasm (lysosomes).

►Extrasomal Protein Synthesis in Neurons

# Protein Tyrosine Kinase

## Definition

A protein that contains a domain that acts as a kinase, which transfers a phosphate group from ATP to a tyrosine of a protein.

# Protein Zero (P0)

## Definition

P0 was identified as the major protein component of Schwann cell myelin. The P0 gene is expressed throughout the Schwann cell lineage, from precursors in embryonic development to myelinating Schwann cells in the adult animal. During development, neurons do not express P0 gene, thus P0 gene expression can be used as an early marker of glial specification in neural crest development. In normal adult nerves, expression of P0 gene and protein is restricted to myelin-forming Schwann cells.

# Proteoglycan

## Definition

Proteoglycans are molecules that possess a protein core to which are attached one or more glycosaminoglycan chains at serine residues through a four sugar linker. In chondroitin sulfate proteoglycans the chains are made of repeating glucuronic acid and n-acetyl galactosamine, while in heparan sulfate proteoglycans the two

sugar repeat is glucuronic acid (which may be epimerized to iduronic acid) and n-acetyl glucosamine.

The glycosaminoglycan chains are modified by sulfation at various points on the two sugars. Particularly in heparan sulfates sulfation occurs in patches. The pattern of sulfation defines the charge pattern of the glycan and therefore its binding properties. Chondroitin sulfate proteoglycans often have barrier functions, while heparan sulfate proteoglycans are often found as part of a ternary complex presenting growth factors to their receptors.

## Definition

Proteomics encompasses a number of techniques and approaches. At its simplest, it could be described as the large-scale analysis of the proteins encoded by a given genome, or of those proteins present, at the time of sampling, in a given biological milieu (e.g., tissue/cell extract, bodily fluid, etc). The term, coined by Marc Wilkins and colleagues in 1994, describes a new discipline that has moved forward from genomics to enable a more mechanistic understanding of biological processes and disease states. While the genome provides information regarding the proteins (and mutations) potentially expressed by a specific organism, it does not identify which proteins are locally expressed at a specific time, under specific conditions, nor does it provide information concerning the myriad of potentially critical post-translational modifications that can affect specific aspects of protein localization and function. Furthermore, although assessment of mRNA levels (►transcriptomics) is sometimes used as a surrogate for more detailed protein analyses, this often does not accurately reflect the actual protein complement (e.g., functional players) at the time of sampling. Thus, the definition of proteomics has grown to include not only the presence of an array of proteins in a sample, but also the localization, post-translational modifications, activities, and interactions of these proteins with each other and with other molecules. In many ways, the original approach has spawned a variety of sub-disciplines that might be broadly defined as follows:

Functional proteomics – the tight coupling of quantitative functional assays with detailed protein analyses as a direct route to dissecting molecular mechanisms underlying physiological processes.

Structural proteomics – perhaps most akin to structural biology, with the goal of defining the three dimensional or atomic structure of a protein as a route to understanding functional interactions/mechanism(s) of action within the cellular environment.

Discovery or Clinical proteomics – scanning of ►proteomes to identify alterations that potentially underlie a disease pathway or that could serve as biomarkers for specific clinical conditions. The resulting "catalogues" generally serve as important databases for other ongoing work as well.

## Characteristics

What then separates proteomics from more traditional protein biochemistry/physical chemistry and cell physiology? This is generally seen to be a matter of scale, throughput, and automation. Rather than asking about the potential role of a single protein in a specific process, proteomics takes a global or systems approach to the integrated roles of proteins in physiological processes. Thus, as a discipline, proteomics has really arisen from the necessary interactions of protein (bio)chemists, cell physiologists, computer scientists, and engineers. The goal of this inter-disciplinary approach is to enhance the ►resolution and throughput of large-scale protein analysis, while simultaneously reducing any potential user bias in the assessment process. With the introduction of computer-driven automation, robotics, and data analysis, the result has been enhanced reproducibility, sensitivity, higher throughput, more objective analyses of the resulting protein data (particularly via subtractive analysis to identify critical differences between data sets), and the establishment of a myriad of databases, making information sharing one of the more important and successful priorities in proteomics.

## Techniques

Until relatively recently, proteomics was almost synonymous with two-dimensional polyacrylamide gel electrophoresis (2DE). Building from earlier work, this technique was introduced in the mid-1970s and immediately revolutionized protein analysis. Proteins are separated by ►isoelectric focusing in the first dimension, according to their ►pI (Isoelectric Point), and in the second dimension according (approximately) to their molecular weight (MW), using sodium dodecyl sulphate polyacrylamide gel electrophoresis ►SDS-PAGE (Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis) [1]. In principle, any physical attribute of a protein can be used to establish a separation/purification strategy; hydrophobicity is another commonly used characteristic to aid in protein isolation. For several

years, identification of specific protein spots could only be done by Western blotting (immunodetection) or Edman degradation. The real revolution in terms of proteomics developing as a discipline was the integration of ►mass spectrometry for protein identification. With an appropriately "clean" protein sample (see below), it is now routine to excise a spot of interest from a 2DE gel, digest it with a protease (usually trypsin) or another selective agent (such as cyanogen bromide), and analyze the resulting peptides using a variety of mass spectrometric methods. The simplest analysis is to derive a peptide fingerprint and attempt to identify the protein using computerized searches of available databases; essentially, archived protein sequences are digested *in silico*, and the best matches to the unknown protein identified. This approach has fallen out of favor due to a high rate of false-positives, although with a well-defined genome to search, this can be a useful scanning tool. More effort is now placed in using mass spectrometry for *de novo* protein sequencing and thus definitive protein identifications, as well as for the analysis of post-translational modifications [2].

Within the last several years, non-gel based approaches to large-scale protein resolution have been developed based on a combination of liquid chromatography and mass spectrometry (or other techniques "hyphenated" with mass spectrometry). Basically, a gross protein extract is proteolytically digested to yield a complex peptide mixture and this is then fractionated, generally by sequential cation-exchange and reverse-phase chromatography, and random samples of the separated peptides are then sequenced in a mass spectrometer [3]. Possible protein identifications are then made based on the presence of peptides "unique" to specific proteins. This so-called "shotgun" proteomics approach has proven to be an effective scanning tool. Most recently, additional proteomic applications for mass spectrometry have included analysis directly from tissue samples ("imaging" mass spectrometry); although not of high resolution, this technique does provide direct information on the localization of specific proteins [4].

## Pros and Cons

It is probably safe to say that 2DE remains the workhorse of proteomics and the current gold-standard in terms of protein resolution. It certainly remains the only method currently available with the capacity to resolve thousands of proteins in a single run. The major complaint that seems to be leveled against it is that it is "old," yet it is precisely this maturity that yields analytical power: problems have been identified and effectively addressed; in the case of newer approaches, most problems have likely not even yet been effectively identified. High throughput always comes at a cost; in the case of shotgun methods, information concerning the ►pI, MW, and post-translational modifications of proteins is lost, and the approach requires substantial computing infrastructure. Nonetheless, it is likely an integration of these scanning and higher resolution approaches that will define future proteomic efforts, particularly considering the current pace of developments in mass spectrometry.

Regardless of the analytical approach used, the biggest difficulty in proteomics is that of protein detection. While it is likely that we are currently capable of resolving most proteins, those present at lower abundance (e.g., a few to tens of copies per cell) are not detectable using currently available total protein stains [5]; if a protein of interest is known, it can however be detected by a quantitative, high sensitivity Western blotting protocol [6]. There is currently no simple solution to this general detection problem except to fractionate the sample in some way and thus increase the total protein concentration of a specific fraction prior to analysis. Such prefractionation techniques are currently under intense development, particularly for samples such as plasma and cerebrospinal fluid that are dominated by a few high abundance species that obviate the effective analysis of the rest of the proteome. Such prefractionation can be as simple as lysing a tissue sample or cell pellet and using ultracentrifugation to isolate total soluble and membrane protein fractions that can then be separately resolved [7,8]. A myriad of alternate techniques, including sequential extractions with different detergents and/or solvents, selective precipitation, or immuno-isolation of select components, each resulting in the concentration of certain proteins, are all being used. Notably, care must be taken to avoid potential non-specific alterations to the proteome using these more aggressive approaches. In this regard, it has also been found that 2DE gels can be post-fractionated to further enhance the resolution of this technique [8].

## Process

The primary caveat when embarking on any proteomic analysis is cleanliness. In the past, if all that was to be done with a 2DE gel for instance was staining or Western blotting, minor contaminants (most commonly, human skin keratin!) were of little or no consequence. Now however, the goal is to identify specific resolved proteins using mass spectrometry; more often than not, the first painful lesson is to find keratin everywhere, obviating any possible protein identification. All buffers and equipment must be scrupulously clean and maintained as such. The Brain Proteome Project initiative of the Human Proteome Organization is helping to establish criteria for sample handling and analysis (www.hbpp.org).

The goal of proteomics is thus an analysis that accurately represents the underlying biological complexity of the sample at the instant of sampling. Thus, regardless of the analytical technique eventually used to resolve the proteins, there must be a focus on optimal sample handling. All tissue dissections, isolations, and

extractions are done in the presence of broad-spectrum protease, kinase, and phosphatase inhibitors [7,8]. In the case of tissue samples, including brain and spinal cord, we have found that the only way to ensure integrity of the protein complement is to snap freeze the sample at the instant of sampling; subsequent automated frozen disruption effectively powders the sample, ensuring optimal protein extraction [7]. In this regard, optimal solubilization of membrane proteins has always been a major concern, spurring development of multiple different detergents to supplement/supplant the most widely used, CHAPS (3 [(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate); we have found that simply supplementing the CHAPS-based buffer with lysophosphatidylcholine substantially enhances the extraction and subsequent analysis of membrane proteins, particularly from neural tissue [9].

With an acceptable isolate in hand, the proteome can, as discussed above, be resolved by different techniques. In the case of 2DE, after the proteins are resolved on the second dimension gel, they must be detected. Currently, the favored total protein stain is Sypro Ruby due to its sensitivity, low variation in staining across protein species, and compatibility with subsequent mass spectrometric analysis. However, developments in this area are a major focus, and it is likely that another stain with enhanced sensitivity will be identified and widely used. Following staining, the gel is imaged, and it is this image that is then analyzed using specific software packages; these image analysis programs can warp and match images within sets of gels and then essentially overlay these, and carry out subtractive or differential analysis to identify statistically significant alterations in the proteome. In an effort to get as much information as possible from a single gel, "multiplexing" is gaining in popularity; here at least one other stain specific for a class of proteins (e.g., phosphorylated or glycosylated) is first used to identify select changes in the proteome, and then the total protein pattern is analyzed for more global changes. Proteins of interest are then excised, digested, and analyzed by mass spectrometry, as described above.

## Applications in Neuroscience

With respect to Basic research, the use of proteomics has focused largely on the analysis of synaptic vesicles and the post-synaptic density. Here the effort has been to define the protein components and, in some cases, more specifically the phosphoprotein sub-proteome due to the importance of this ►post-translation modification in neural function.

To date, the more widespread application of proteomics has been in the area of Neurological and related disorders [10]. This has included studies on Alzheimer's disease, spinal cord injury, muscular dystrophy, Parkinson's disease, and epilepsy, but this is far from an exhaustive list. The focus has largely been on identifying (phospho)protein alterations that may underlie the susceptibility, progression, or fundamental mechanism of a given disorder. Both in Neuroscience and other Clinical disciplines, the initial goal is most often to identify biomarkers of the condition in question so as to ensure more objective and accurate diagnoses and prognoses. The limitation is clearly accessibility, particularly in terms of acquiring samples from age-matched, "normal" controls; simply put, it is all but impossible to obtain samples from unaffected individuals. Thus, researchers must develop experimental designs that take into account the fact that human neural tissue is an unlikely sample source except in some specific instances of surgery. Although often used, post-mortem sampling must be recognized as insufficient in many regards due principally to the fact that tissue resection generally occurs at variable time intervals after death and that the expression levels of different proteins undergo significant alterations (both increasing and decreasing) during the time that precedes tissue sampling. In most cases though, a more serious and often overlooked caveat is that of disease progression; in most cases, sampling is only possible after clinical diagnosis, and thus after the damage has already occurred. What is to be reasonably learned at this stage? It would thus seem that, without appropriate animal models, much of the application of proteomics to questions in Clinical Neuroscience/Neurology will focus on identifying alterations that occur "after the fact." Although this is important from the standpoint of understanding the molecular mechanisms of disease progression or recovery from injury, it will unlikely be informative with regard to alterations underlying disease susceptibility and inception. Critical study design and focused application of techniques is mandatory to ensure successful experimental outcomes that will include the identification of effective diagnostic/prognostic biomarkers as well as components underlying fundamental disease mechanisms. This will largely hinge on the analysis of accessible diagnostic biofluids (e.g., cerebrospinal fluid, urine, plasma, and saliva). Thus, coupled with transcriptomics, ►metabolomics, and other, developing, molecular analytical tools, proteomics promises to drive substantial advances in Basic, Clinical, and Translational Neuroscience research.

# Protostome/Deuterostome

## Definition

The Deuterostome clade in the animal kingdom including chordates, Hemichordates and Echinoderms.

In Deuterostome animals the Blastopore develops into the anus of the animal. The protostome clade contains most invertebrate phyla. In Protostome animals the Blastopore develops into the mouth of the animal. The Protostome clade is further subdivided into Lophotrochozoans and Ecdysozoans. The Lophotrochozoan clade most animals pass a trochophora-larva stage or use a Lophophor (tentacle like structure). In the Ecdysozoan clade most animal go through a molting process by Ecdysis.

## Definition

"But when from a long-distant past nothing subsists, after the people are dead, after the things are broken and scattered, taste and smell alone, more fragile but more enduring, more unsubstantial, more persistent, more faithful, remain poised a long time, like souls, remembering, waiting, hoping, amid the ruins of all the rest; and bear unflinchingly, in the tiny and almost impalpable drop of their essence, the vast structure of recollection." (*Swann's Way*, trans. Moncrieff, 50–51).

The best known example of the power of smell to evoke memories and emotions is the "Proust effect," as described in the quotation above. This is based on a sensory experience described by Marcel Proust in *Remembrance of Time Past* [1]. The episode involves tasting a small cake dipped in tea, and being suddenly flooded with a childhood memory. The suddenness of the memory, and the strong emotions attached to it, have become symbolic, in both the realm of literary criticism and in sensory physiology, for the power of human taste and smell. Here we review the episode, and show that there is more than meets the eye (and nose).

## Characteristics

### The Madeleine Incident

Proust's character Marcel is in a depressed mood when he visits his mother. To soothe him she serves him a cup of tea and a madeleine cake. He dips the cake in the tea, tastes it, and is immediately seized by an overwhelming emotion: "an exquisite pleasure had invaded my senses, something isolated, detached, with no suggestion of its origin." He is aware that behind this is an as yet unidentified memory. After several more tastes and an intense period of searching his memory, he is suddenly transported back to his childhood summers in a seaside resort, Combray, which are associated with happy times. With repeated tasting the power of the memory fades.

### The Theory of Pure Memory

In Proust's view, he had uncovered an essential truth about himself, elicited by taste and smell from a "pure memory" unadulterated by being remembered during the intervening years. From this he erected a theory of involuntary (unconscious) versus voluntary

(conscious) memory. Samuel Beckett [2] followed with the view that voluntary (i.e., adulterated) memory cannot recall the exact (i.e., pure) sensation as it was originally experienced. Many literary critics have taken up this view and built on it, regarding it as showing how memory can spring suddenly and purely into mind, triggered after a long period of being forgotten. As a byproduct, they have maintained that conscious autobiographical memory is therefore artificial, a created fiction, compared with true, involuntary memory of the type evoked from the unconscious by the tea-soaked madeleine.

## Re-Examining the Theory

We have re-examined Proust's account to test this view [3]. A close textual analysis has revealed that the memory was not sudden, but was the result of considerable effort, as described by the author. Indeed, a page and a half of text is required to describe the repeated efforts of the author to recall the memory. Thus, it appears that as soon as involuntary memory is brought into the arena of consciousness, it too, like voluntary recall, is subjected to similar processes of selection, editing and revision. We have further argued that an understanding of those processes requires knowledge of the neural pathways involved.

## What does Neuroscience Tell Us?

Given its iconic status, the madeleine incident thus serves as a useful model for asking: What was happening in Marcel's brain, from the initial sensing of the taste of the tea-soaked madeleine cake to the emotions it called forth, and the memory that finally appeared? Recent research on the sensory mechanisms involved provides several insights that are generally unappreciated even among most neuroscientists.

First, we realize that the smell of an ingested item, cake or otherwise, is due to stimulation of the smell receptors in the nose not by sniffing in, but by breathing out. The volatiles released from the ingested food and liquid at the back of the mouth are carried by exhaled air by the retronasal route through the nasopharynx to reach the receptors (Sun and Halpern, 2005). This olfactory stimulation carries the major part of what appears to be the "taste," but it goes largely unrecognized as smell because it is referred to the mouth where the food and liquid are located. To avoid the confusion, the term "flavor" can be used to refer to the combined sense of taste and smell, as mentioned in the initial quotation from Proust. In fact, flavor also includes all the other senses associated with food intake: touch, pressure, pain, temperature, sound, and even the sight of the food before ingestion.

Second, the olfactory receptor cells connect to the olfactory bulb, where their responses are converted into spatial activity patterns, called variously odor images or odor maps [4]. Smell perception, by itself or as part of flavor, thus involves discrimination of different spatial images, which also vary with time. We can therefore hypothesize that Proust's effort to identify the memory of the smell of the madeleine involved matching the spatial pattern aroused by that smell with the similar spatial pattern contained in his memory. It may be similar to recognizing complex visual patterns such as faces.

Third, after processing by microcircuits in the olfactory bulb, the odor image is sent to the olfactory cortex, where it is converted by microcircuits into a distributed form called a content-addressable memory [5]. The output of this memory representation has two main destinations. One is to the prefrontal cortex, where it is processed by the highest cognitive centers of the brain [6]. The other is to centers in the limbic system, where emotions are generated. The olfactory pathway has privileged direct access to both these sites; hence the combination of intense emotion and intense cognitive effort experienced by Proust in recollecting the memory of Combray.

Finally, the olfactory pathway contains a series of mechanisms to reduce the stimulation with repeated odor exposure, called adaptation or desensitization, which appear to be reflected in Proust's account of the fading of the sensations with repeated tasting of his madeleine. Rather than intensifying over time, the memory/emotion diminishes with repeated tasting of the triggering stimulus.

## The Neural Basis of the Proust Effect

How is the entire memory of Combray recalled from a single sip of tea? This should not be surprising; our cognitive mechanisms have a gestalt quality, in which we perceive and recall things as integrated wholes. According to Nadel and Moscovitch [7], "recovery of remote memories always depends on re-activation of the hippocampal–neocortical complex that constitutes the memory trace." One may hypothesize that this trace, representing the memory of Combray, is distributed in the olfactory cortex and the hippocampal–neocortical complex in a content-addressable form so that a small part of it – the flavor of the madeleine – activates it in its entirety. The brain's ability to fill in the rest of the memory image is turned by Proust into metonym.

## Conclusion

We have here summarized only briefly the Proust effect, the literary superstructures built on it, and the recent neuroscience research that gives insight into the relevant brain mechanisms. Further information may be gained from the cited references. The present account may indicate the increasing attraction of this experience as a

model for the brain circuits underlying the power of human senses in general, and the chemical senses in particular. Indeed, the Proust effect may be one of the best instances in which literary criticism can benefit from brain research, and neuroscientists can benefit from literary studies that extend the significance of their experiments into the domain of public discourse.

Auditory psychophysics; Psychological acoustics

## Definition

Psychoacoustics is the area of auditory research in which behavioral methods are used to discern and describe how, and how well, listeners perceive sounds. Combining information obtained from such experiments with corresponding information obtained from physiological and anatomical experiments has resulted in several important descriptions, explanations, and quantitative models of auditory function. Many of the relevant data and phenomena are discussed elsewhere in this volume. Therefore, this discussion is limited to two examples chosen to help the reader understand the kinds of questions addressed by psychoacousticians. In order to provide an intuitive understanding of the field, several practical applications that incorporate knowledge derived from psychophysical experiments will also be highlighted. For further information, the reader is referred to reviews of many pertinent topic areas [1] and two excellent introductory textbooks, one at a more advanced level [2] than the other [3].

## Characteristics

### Types of Measures

Some experiments in psychoacoustics concern thresholds of detection. They measure the smallest *amounts* of physical stimulation required to produce a reliable behavioral response indicating that the signal is present. Other experiments concern thresholds of discrimination. Their goal is to measure the smallest *changes* in physical stimulation required for listeners to indicate reliably that two signals are different. Still other, "scaling", methods use listeners as meters and measure one of a number of perceptual attributes of sound, such as ►loudness and pitch.

### Ties to Physiology

It should be stressed that a comprehensive understanding of hearing also necessarily requires an appreciation of the whole auditory system. Consequently, psychoacousticians have traditionally attempted to understand behavioral data in light of knowledge concerning the anatomy and physiology of the auditory system. We will illustrate such attempts in the context of two important areas of auditory processing; intensity perception and frequency discrimination/►masking.

#### *Stimulus Intensity*

In terms of sensitivity to small changes in intensity, there are two general outcomes to be stated and understood. First, people are quite sensitive to changes in intensity, and can typically discriminate between stimuli differing by about one dB or so. This "just noticeable difference" of 1 dB corresponds to a difference of 25% in acoustic power. In turn, this degree of sensitivity is maintained over about 10–12 orders of magnitude of intensity (i.e. over a range of about 100–120 dB). One goal of psychoacousticians has been to explain this pair of findings in physiological terms. This has proved challenging, because individual neural elements that compose the peripheral auditory nerve have been shown to respond differentially only over the limited and small "dynamic range" of 20–25 dB. To overcome this difficulty, models of intensity perception have focused on ways in which information from a number of individual nerve fibers might be "pooled". The psychoacoustic and physiological findings are fairly well reconciled, using mathematical models that combine neural responses across small sets of neural elements. Portions of the set of neural elements are characterized as operating over different, albeit limited, ranges of intensity.

In order to understand changes in the perception of loudness, much larger changes of intensity must be considered. For example, it is universally found that one must increase the intensity of a signal by a factor of ten (or 10 dB) in order for it to be judged as "twice as loud". That is, perceptual increases along a loudness dimension are not "one-to-one" with increases in the physical stimulus, but rather increase at a much slower rate. This empirical outcome, which indicates a high degree of "compression" of the stimulus, has recently

become to be understood at a physiological level. Compression, much like that suggested by the psychoacoustic data has been found in the mechanical-to-neural transduction that occurs in the cochlea. It is of further interest that such peripherally-based effects of compression must also be considered in order to account for a variety of auditory phenomena (see the recent reviews in 4).

### Frequency Discrimination and Masking

In a sense, listeners are even more sensitive to changes in frequency than they are to changes in intensity. While the just noticeable increase of 1 dB discussed above corresponds to an increment of 25% in acoustic power, the just noticeable difference for listeners to discriminate between two different frequencies is typically much less. Over the range of frequency extending from about 200 to 8,000 Hz, the just noticeable differences in frequency are found to be less that 0.5%. That is, normal listeners can discriminate between tones of 1,000 and 1,005 Hz, 2,000 and 2,010 Hz, and so on.

A complementary question is how well a listener can analyze or resolve among the set of frequencies composing complex sounds (including noise, speech, music, etc). In effect, psychoacousticians determine how well a listener can "pick out" the presence of the particular frequency or set of frequencies that define the "signal". A classic type of experiment asks how intense a signal must be in order to be detected when it is presented along with a potentially obscuring background sound, the "masker". The number and variety of psychoacoustic experiments investigating such questions is remarkably large and constitutes the bulk of the published work in the field. One time-honored finding is that only a small fraction of frequency components composing the background masker actually affects detection of a tonal signal. For example, the detectability of a 1,000-Hz tone is determined by only the 160 Hz-wide portions of the masker that immediately surround the signal. That is, one can add or subtract large amounts of acoustic energy outside that region and not affect the signal's detectability. This means that other attributes of the masker, including its loudness and pitch, do not, by themselves, determine the degree of masking. It is handy to know that the bandwidth of the frequencies that are "critical" for masking tonal signals (nowadays termed the auditory filter) is approximately 16% of the frequency of the signal to be detected.

The links to physiology in these realms are both strong and pervasive. First and foremost, a "place" mapping of frequency exists within the cochlea, in that it is most sensitive to higher frequencies in its more basal portions, and most sensitive to lower frequencies in its more apical portions. This place mapping is preserved and reiterated throughout the auditory nervous system, including the auditory cortex. In addition, the frequency-tuning characteristics, or bandwidths, of individual nerve fibers are commensurate with the widths of psychoacoustically-determined auditory filters as a function of frequency. A second encoding of frequency is provided in the timing of neural discharges. That is, the time between neural discharges becomes smaller and smaller as the frequency of the signal is increased.

Many auditory scientists have debated the relative salience of place vs. time codes, while modeling a number of important auditory phenomena including frequency discrimination, masking, and the perception of pitch. Over time, one or the other view has been found to prevail. In our judgment, neither the acceptance nor the rejection of one of the two candidate codes may be logically possible, because changes in "place" and changes in "neural timing" both occur concomitantly as frequency is changed.

### Applications

Knowledge and techniques derived from psychoacoustic research are relevant and useful in a variety of practical endeavors. While many applications may be familiar to us all (e.g., the design of telephones for the efficient transmission and understanding of speech), others are much less apparent. Beginning with the familiar, many of the basic findings from psychoacoustic research have been used to define and depict "normal hearing." Such findings, in turn, have been used to create and refine tests of hearing that are used in many ways to aid in the diagnosis and treatment of various kinds of hearing impairment. Otolaryngologists and audiologists use such information in order to differentiate among various hearing deficits, and in the selection and fitting of patient-appropriate hearing aids. For more than a decade, psychoacousticians have played an integral part in the development, design, understanding and evaluation of complex issues surrounding the use of cochlear implants. Knowledge from psychoacoustics has also proved beneficial in all phases of the discovery and application of specialized, non-invasive screening tests of infant hearing. Similar types of tests and guidelines have been usefully applied in industrial and governmental settings, both as part of hearing conservation programs and to develop standards concerning acceptable occupational and community noise levels.

Knowledge obtained from psychoacoustics has always been useful in designing and evaluating high-fidelity sound systems. Today, because of advances in computing power and miniaturization, psychoacoustic data have become highly relevant, if not ubiquitous. For example, one can purchase inexpensive devices that digitally store incredibly large amounts of music. This is possible because psychoacousticians and electrical engineers found ways of using knowledge concerning auditory

sensitivity in order to greatly reduce the amounts of information required for satisfying reproduction. Specifically, only the necessary information, on a moment-by-moment basis, is preserved. Success of this technique is evidenced by the fact that listeners are typically unaware that the original sound has been modified. The same types of algorithms have also proved useful in the transmission of music and speech. These include the schemes used to send audio information to cellular telephones, satellite and digital television and radio devices and over the internet.

Another important arena for application of psychoacoustics is the concert hall. Here the thrust has been first to understand what physical variables differentiate successful concert halls from less successful ones. Such knowledge has been used to establish psychoacoustic-related dimensions that guide the design and determine the perceived quality of the halls. Finally, computer-based systems now exist that enable the designer to simulate candidate designs and to "preview" them. Similar schemes and technology are being applied to other aspects of architectural acoustics including improvements in the design of highly reverberant spaces such as churches and classrooms.

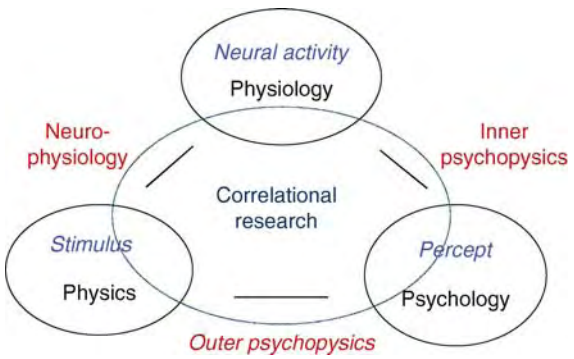
## Synonyms

Phenophysics

## Definition

Psychophysics, as first established by Gustav Theodor Fechner in 1860, concerns the science of the relations between body and mind, or, to put it more precisely, between *physical* and *phenomenal* worlds [1–6]. Objectively we have physical events as reflected by brain processes, subjectively these processes appear as processes of our mind. Fechner already distinguished between *inner psychophysics* or the relation of sensory experience to its corresponding neural activity, and *outer psychophysics*, which deals with the relation between percepts and variations of the ►stimulus itself (see Fig. 1).

For much of the century following Fechner's publication of *Psychophysik* in 1860, inner psychophysics remained just a theoretical option until objective methods for the study of brain functions became available. Thus, outer psychophysics has shaped not only the development of experimental psychology and phenomenology



**Psychophysics. Figure 1** *Interdisciplinary setting of psychophysics:* Percepts are related to corresponding physical stimulus properties (*outer psychophysics*) or to corresponding neural activity *(inner psychophysics)*. For a long time inner psychophysics remained a merely theoretical concept, whereas outer psychophysics provided the basis for methods to study sensory and brain processes. Now various objective methods afford a direct study of sensory and brain processes. This has made possible a new interplay between classic psychophysics and modern neuroscience that has come to be called ►correlational research [2,7].

[1,6], but also of sensory physiology, affording its pioneers (Aubert, Exner, Helmholtz, Hering, von Kries, Mach, Purkinje, Weber) to gain basic insights into sensory mechanisms [2–4]. Today, sensory and brain processes can be investigated by objective methods such as electrophysiology (single-unit recordings, EEG), functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and positron emission tomography (PET). The relative ease of use and non-invasiveness of most of these techniques has made a new interplay between classic psychophysics and modern neuroscience possible. The complementary research approach that concerns itself with subjective and objective correlates of sensory and neural processes has come to be called ►correlational research [2,7], see Fig. 1.

## Description of the Theory

Psychophysics accounts for the problem of measuring sensory experience by closely linking percepts to physical stimuli. No apparatus is necessary to obtain percepts; they are immediately present and available to each of us. The problem is thus not how to obtain sensory experience, but how to describe and investigate individual percepts so that they can be reliably communicated. An investigation might begin with a simple question such as "can you hear the tone?". This task requires *detection*. If we want to further determine which stimulus characteristics an observer can sense (e.g., the quality or spatial location of a sound), we arrive at the problem of *identification*. Detection and identification are solved quickly and almost simultaneously when the stimuli are strong and clear. However, under conditions of weak and noisy signals we often experience a stage at which we first detect only that something is there, but fail to identify what or where it is, exactly. In such a situation we try to filter out the consistent signal attributes, for instance, the sound of an approaching car, from inconsistent background noise. This task requires *discrimination* of the stimulus, or signal, from a noisy background, and the task is performed under uncertainty. As the car approaches and its sound becomes stronger, the probability of correct discrimination between signal and noise is enhanced. Even if we clearly detect and identify an object, we may still be faced with a further problem of ►perception, such as: "Is this car dangerously close?" or "Is the rattle under the hood louder than normal?" Questions such as these, concerning "How much x is there?", are part of another fundamental perceptual issue, that of *scaling*, i.e. to locate the magnitude of the stimulus on a psychophysical scale.

## ►Characteristics

### Quantitative Laws of Psychophysics

Psychophysics emerged out of the contributions of the sensory physiologist E. H. Weber (1795–1878) who

established perception as an experimental rather than observational discipline. Working with the discrimination of lifted weights, he demonstrated that the smallest difference between two weights *(ΔI)* which we can distinguish by way of feeling changes in muscle tension was a constant fraction *(k)* of the reference weight (I):

$$\Delta I / I = k \text{ (Weber's law)}$$

For example, if an increase of 1 g is needed in order to just experience that a weight is heavier than its reference of 40 g, an increase of 10 g would already be required for a weight to just appear heavier if its reference is 400 g. Accepting the validity of Weber's law, Fechner assumed that equal stimulus differences corresponded to equal perceptual differences or units. Sensory magnitudes could be assigned values according to the number of just noticeable differences. Inspired by Leibniz's concept of subliminal units of experience (*petites perceptions* or minute percepts as differential units of experience), Fechner postulated a relation between infinitesimal increase of stimulus intensity *(dI)* and corresponding subliminal increase in perceptual intensity *(dS)*, by deriving his fundamental formula: $dS = dI/I$. By integration we obtain a logarithmic relation between stimulus and sensation:

$$S = c \log I \text{ (Fechner's law)}$$

where $S$ is the subjective and $I$ the objective intensity and $c$ refers to a constant depending on the respective sensory modality.

Fechner's law roughly predicts that a doubling of perceived intensity requires a 10 times increase of physical intensity. It holds pretty well for stimulus intensities in a middle range of the stimulus dimension. With very low or very high stimulus intensities, however, observed and predicted values deviate markedly. As an alternative to threshold measurements supra-threshold psychophysical scaling procedures were already developed by Tobias Mayer in 1754 [4] and more systematically later by J. A. F. Plateau (1872) and Delboeuf (1873, 1875) who studied the lightness of different gray levels. S. S. Stevens [10] popularized scaling procedures, especially the procedure of magnitude estimation, in which the experimenter assigns a value to a standard stimulus, e.g., the number 100, and the observers then rate the magnitude of other stimuli in proportion to the standard. So, if a stimulus appears half or twice as intense as the standard, it would be given the numbers 50 or 200, respectively. The results obtained with these and other direct scaling methods, such as ►cross-modality matching, are best described by a power function:

$$S = c\, I^n \text{ (Stevens's law)}$$

where $S$ is scaled sensory intensity, $c$ is a constant, $I$ is physical intensity, and n is an exponent that varies for different sensory continua.

## Psychophysical Methods

The most basic function of any sensory system is to detect changes of energy which can consist of chemical (taste, smell), *electromagnetic* (vision), *mechanical* (audition, proprioception, touch) or *thermal* events. In order to be noticed, the stimulus has to reach a minimal amount of stimulus intensity that, according to Fechner [3], "lifts its sensation over the threshold of consciousness." This is the *absolute threshold*, which is the intensity an observer can just barely detect, whereas the *difference threshold* is based on stimulus intensities above the absolute threshold and refers to the minimum intensity by which a variable or *comparison* stimulus must deviate from a constant or *standard* stimulus to produce a just noticeable difference in perception.

### Method of Adjustment

The easiest way to determine thresholds is to let a subject adjust the stimulus intensity until it is just noticed or until it just becomes unnoticeable (absolute threshold); or until it appears to be just noticeably different from, or to just match some other standard stimulus (difference threshold). The observer is typically provided with a control of some sort that can be used to adjust the intensity, say of a sound, until it just becomes audible (or louder than a standard sound), and then the stimulus intensity is recorded to provide one estimate of the observer's threshold. Alternatively, the observer can adjust the sound from clearly audible to just barely inaudible (or to match the standard sound), providing another estimate of the threshold. Typically, the two series of measurement, one in which the signal strength is increased (ascending series) and one of decreasing signal strengths (descending series) are alternated several times and the results are averaged to obtain the threshold estimate. For example, if a tone is first heard at 5.0 or 5.5 dB on two ascending trials and first not heard at 4 or 4.5 dB on two descending trials, the resulting threshold estimate is 4.75 dB.

### Method of Limits

In the ►method of limits the stimulus is varied by the experimenter (or a computer program) and the observer's response is recorded to each stimulus presentation. As in the previous method, the stimulus should initially be too weak to be detected and increased until it is perceived (ascending trials). Conversely in a descending trial, stimulus intensity, say a light, is reduced from clearly seen until it becomes invisible.

### Method of Constant Stimuli

In the ►method of constant stimuli the experimenter selects a number of stimulus values (usually from five to nine) which, on the basis of previous exploration (e.g., using the ►Method of Adjustment), are likely to encompass the threshold value. This fixed set of stimuli

is presented multiple times in a quasi-random order that ensures each will occur equally often. After each stimulus presentation, the observer reports whether or not the stimulus was detected (for the absolute threshold) or whether its intensity was stronger or weaker than that of a standard (for computing a difference threshold). Once each stimulus intensity has been presented multiple times (usually not less than 20), the proportion of "detected" and "not detected" (or, "stronger" and "weaker") responses is calculated for each stimulus level. The data are then plotted with stimulus intensity along the abscissa and percentage of perceived stimuli along the ordinate (see Fig. 2).

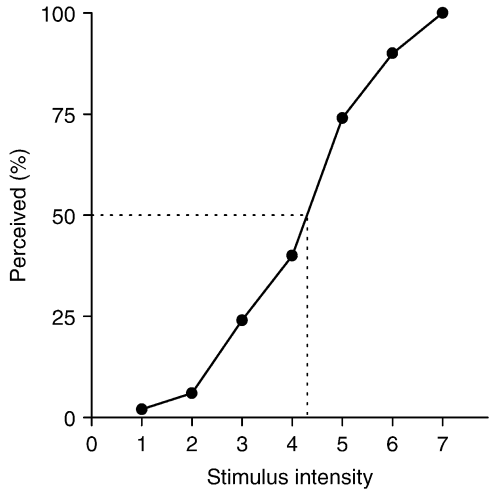
If there was a fixed threshold for detection, the psychophysical function should show an abrupt transition from "not perceived" (0%) to "perceived" (100%). Psychometric functions, however, seldom conform to this all-or-none rule. We usually obtain a sigmoid (S-shaped) curve that reflects that lower stimulus intensities are detected occasionally and higher values more often, with intensities in the intermediate region being detected on some trials but not on others. There are various reasons for obtaining an S-shaped rather than a sharp step function. A major source of variability is the continual fluctuations in sensitivity that occur in any biological sensory system (due to spontaneous activity or internal noise). Those inherent fluctuations mean that activity elicited by external stimulation is to be detected against a background level of activity. The threshold sensation that occurs with a certain *probability* can be defined statistically. By convention, the absolute threshold measured with the method of constant stimuli is defined as the intensity value that elicits "perceived" responses on 50% of the trials. Notice that in the example shown in Fig. 2, no stimulus level was detected on exactly 50% of the trials. However, level 4 was detected in 40% and level 5 in 74% of the trials. Consequently, the threshold value of 50% lies between these two points. If we assume that the percentage of trials in which the stimulus is detected increases linearly between these intensities (which is not unreasonable given that sigmoid functions are approximately linear in the middle range), we can determine the threshold intensity by linear interpolation as follows:

$$T = a + (b - a) \cdot \frac{50 - p_a}{p_b - p_a},$$

where $T$ is the threshold, $a$ and $b$ are the intensity levels of the stimuli that bracket 50% detection (with $a$ being the lower intensity stimulus), and $p_a$ and $p_b$ the respective percentages of detection. For the present case we obtain the following result:

$$T = 4 + (5 - 4) \cdot \frac{50 - 40}{74 - 40} = 4 + \frac{10}{34} = 4.29.$$

Although the method of constant stimuli is assumed to provide the most reliable threshold estimates, its major drawback is that it is rather time consuming and requires a patient, attentive observer because of the many trials required.



**Psychophysics. Figure 2** Psychophysical function which shows the relationship between the percentage of times that a stimulus is perceived and the corresponding stimulus intensity. The threshold is defined as the intensity at which the stimulus is detected 50% of the time [2].

### *Adaptive Testing*

Adaptive testing procedures are used to keep the test stimuli close to the threshold by adapting the sequence of stimulus presentations according to the observer's response. Since a smaller range of stimuli needs to be presented, adaptive methods are relatively efficient. Adaptive procedures were first introduced by Georg von Békésy in 1947, who applied his ▶staircase method to audiometry [2]. The staircase method is a modification of the Method of Limits. As long as the observer says "yes" (I perceive) stimulus intensity is decreased by one step, until the stimulus becomes too weak to be detected. At this point we do not, as in the method of limits, end the series, but rather reverse its direction by increasing the stimulus intensity by one step. This continues with increasing the intensity if the observer's response is "no" and decreasing the intensity if it is "yes." In this way, the stimulus intensity flips back and forth around the threshold value. Usually six to nine such reversals in intensity are taken to estimate the threshold, which is defined as the average of all the stimulus intensities at which the observer's responses changed.

## Research Fields and Applications

Psychophysics allows investigation of how living creatures perceive sensory stimuli in relation to their environmental setting as well as to compare the

P

phenomenal worlds of humans with closely related species (monkey, cat) or even fairly distant species (birds, insects). Comparative relational psychophysical research across different species and across different stages of development provides the intriguing option of an integrated framework of behavioral and brain research [9]. For instance, the combined psychophysical and electrophysiological study of sensory performance has established the concept of the ►perceptive field as psychophysical counterpart of receptive field organization with the conjecture that perceptual organization is largely determined by single-cell activity. Meanwhile, various perceptual properties, including contrast of brightness, color, orientation, and motion as well as Gestalt phenomena, such as illusory contours or border-ownership, have been shown to be linked to the highly specialized functions of receptive fields at various levels of the visual system [7]. Furthermore, computer-assisted adaptive psychophysical methods are increasingly used in clinical routine diagnostics to assess impairment of sensory and neuropsychological function [1,2]. Psychophysics can also assist in elementary decisions of daily life. For example, scaling of auditory intensity can provide firm evidence for the effectiveness of noise protection measures. Industrial and ergonomic norms, such as of lighting on streets or at workplaces, or individual norms, e.g., accounting for age-dependent changes of sensory performance, are or are to be based on psychophysical evaluation. Consequently, psychophysics is of utmost importance for the approach of Human Factors [10], a joint profession of engineers and psychologists to design and evaluate simple and complex systems in order to optimize working and life conditions.

## Pudendal Nerve

### Definition

A somatic nerve with cell bodies of the motoneurons located in Onuf's nucleus in the S2-S4 spinal segments; contains afferent and efferent pathways to the urethral and anal sphincters and afferent innervation to the perineum, urethra and the sex organs (penis and clitoris).

►Micturition

## Pulleys

### Definition

When the eyes move from the primary position, the eye muscles do not slide freely within the orbital tissue.

Instead their paths are restricted, possibly by rings of connective tissue and smooth muscle that have been termed orbital pulleys.

►Eye Orbital Mechanics

## Pulmonary Reflexes

►Respiratory Reflexes

## Pulvinar

### Definition

A component of the thalamus, relatively enlarged in carnivores and primates. It deals with salience (visual salience) and is involved in selective attention. It is reciprocally connected with much of the cerebral cortex. Its inferior and lateral parts also receive input from the superior colliculus. The homologous structure in lower animals is the Lateral Posterior thalamic group (LP-Pulvinar).

►Visual Attention
►Visual Role of the Pulvinar

## Punisher

### Definition

A punisher is any stimulus an animal will work to avoid, such as somatosensory pain, foot shock, timeout, or an unpleasant taste. In humans, monetary loss may also act as a punisher.

►Value-based Learning

## Punishment

### Definition

Punishment is a procedure whereby an aversive event (usually pain) following a response causes the reduction of that response. Punishment is considered by some behavioral psychologists to be a "primary process" – a completely independent phenomenon of learning, distinct from reinforcement.

►Aversive Learning

## Pupillary Light Reflexes

### Definition

Constriction of the pupils in response to increased light falling onto the retina. When light is shone on one retina, the pupil of the same eye constricts (direct response) as well as the pupil of the other eye (consensual response).

►Consensual Light Reflex
►Pretectal Nuclei
►Neural Regulation of the Pupil

## Purinergic Receptors

### Definition

Purinergic receptors are receptors that respond to adenosine triphosphate (ATP) and related agents.

Metabotropic (G-protein coupled receptors, P2Y) and ionotropic receptors (ion channels, P2X) have been identified. Excitatory P2X receptors are present in urinary bladder smooth muscle (P2X1) and in bladder afferent nerves (P2X2/3).

►G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages

## Purinergic Receptors in Urinary Bladder

### Definition

Excitatory P2X receptors are present in urinary bladder smooth muscle (P2X1) and in bladder afferent nerves (P2X2/3).

►Micturition
►Purinergic Receptors

## Purkinje Cell, Neuron

### Definition

Large, pear-shaped, GABAergic neuron located in the cerebellar cortex characterized by an intricate dendritic arbour and many dendritic spines.

The Purkinje cell sends the sole output from the cerebellar cortex. It receives excitatory synaptic inputs from parallel and climbing fibers and inhibitory synaptic inputs from basket, stellate, and other Purkinje neurons, and sends inhibitory outputs to the cerebellar or vestibular nucleus.

►Cerebellum
►Cerebellar Functions

## Pursuit Eye Movement

### Definition

An eye movement that matches the speed and direction of the eye to that of a moving target.

►Pursuit-Saccade Coordination

## Pursuit-Saccade Coordination

Robert H. Wurtz
Laboratory of Sensorimotor Research, National Eye Institute, National Institutes of Health, Bethesda, MD, USA

### Definition

Rapid or saccadic eye movements (►saccade, ►saccadic eye movement) allow us to shift our gaze from one part of a visual scene to another. This allows us to position objects in the scene of greatest interest on the region of the retina with the highest resolution, the central or foveal region. For example, we would make these saccadic eye movements several times per second as we looked out of a window onto a busy street scene. Smooth ►pursuit eye movements allow us to keep the fovea on objects that are moving so that we can have the sharpest vision of these objects in spite of their motion. As we look out the window, these pursuit eye movements would allow us to keep a person's face centered on the fovea even though they were walking along as we watched them. We can also make a saccade to the walking person and then immediately use the pursuit eye movements to keep that person's image on our fovea. As we continually use both of these eye movements in our everyday vision, these eye movements must be coordinated and the brain mechanisms underlying this coordination are beginning to be understood.

### Characteristics

#### Upstream Event/Conditions

Control of saccadic eye movements depends upon a circuit within the brain that extends from the highest levels of visual processing in the cerebral cortex, to the neurons connecting to the eye muscles that lie in the midbrain and pons in the brainstem [1] The cortical areas devoted to this processing are centered in the lateral intraparietal area of parietal cortex and the frontal eye field area of frontal cortex. Both areas project to the brainstem, particularly to the structure on the roof of

the brainstem, the ►superior colliculus (SC). Another pathway from the cortex passes through the basal ganglia to the superior colliculus. Pursuit eye movements also depend on activity in cerebral cortex for a critical feature of their function: the determination of the speed and direction of the object that is about to be followed by the eye. Areas providing this information are also distributed in cortex, but are concentrated in the visual region of cortex referred to as the middle temporal area and the medial superior temporal area, and in the frontal eye field in a region distinct from that related to saccadic eye movements. The processing related to saccades and to pursuit appears to be kept separate in the cerebral cortex.

## Downstream Events/Condition

The generation of saccades requires connections to nuclei in the midbrain and pontine reticular formations, which in turn connect to the motor neurons that innervate the eye muscles [1]. The connections necessary for pursuit eye movements are conveyed to visuomotor nuclei in the pons, primarily the dorsolateral pontine nuclei. The pathway reaches the oculomotor neurons via projections through the cerebellum to the vestibular nucleus.

## Involved Structures

The superior colliculus has a representation of the visual field spread out in each of its major layers [2]. In the superficial layers the neurons respond to visual stimulation, and in the intermediate layers the neurons are active before eye movements to that part of the visual field where the visual stimulation is located. The collicular neurons are organized into a map of the contralateral visual field, so that each neuron is active in relation to visual stimulation or eye movement in just one region of the visual field. It is in the intermediate layers that there is evidence for the coordination between saccades and pursuit. The intermediate layer neurons not only increase their discharge just before the saccade (or more generally an eye and head movement), but they show a buildup of activity that precedes that burst [3,4]. This buildup or prelude activity occurs whether or not the saccade related to the target actually occurs. If the saccade does occur, the buildup activity blends into the burst of activity preceding the saccade. If the saccade is not made, the activity decreases. Thus, the buildup activity can be largely independent of the actual generation of the movement, and it seems to be related to what must necessarily precede the movement including target selection.

One possibility is that the buildup activity simply indicates that there is an error between where the eye is looking now and where the target for the next eye movement is located – an error signal, not a saccadic movement signal. That is, each neuron on this map might indicate the error between where the eye is and where the target is, with large differences in the caudal colliculus and smaller ones in the rostral colliculus [5]. If the difference between where the eye is looking is very small (a fraction of a degree visual angle), the monkey frequently does not make any saccade. This activity has been referred to as fixation activity, but the most parsimonious interpretation of the activity is that it is the same buildup activity seen throughout the colliculus. The difference in eye and target position is just small, the error is small, and no movement need be made. With slightly larger errors, the buildup activity precedes a saccade to the target. If the target is moving, the monkey might make a not a saccade but a pursuit movement to the target, and this pursuit movement is also preceded by the increased buildup neuron activity [6]. Increased activity for both pursuit and saccades occurs only for movements in the visual field contralateral to the colliculus in which the neuron is found. Thus, the buildup neurons can be regarded as a shared error signal available to both the pursuit and the saccadic system, and this type of shared signal has been proposed as part of the mechanisms that coordinate these two movements. Further evidence supporting this view comes from experiments which showed that electrical stimulation or chemical inactivation altered pursuit eye movements [7]. Activity of the neurons can also predict the timing of pursuit as well as saccadic eye movements [8]. Thus, the same neurons that are involved in the preparation to make saccades might also contribute to the preparation to initiate pursuit. The test of this view would be to verify this pursuit – saccade interaction at points in the pathway after the signals for movement leave the superior colliculus, but this remains to be done.

## Methods to Measure This Event/Condition

All of the observations described are derived from single neuron recording in awake behaving monkeys who select the targets and move their eyes to them [9]. The monkeys are trained on tasks that allow the comparison of neuronal activity to the same behavior on a series of similar movements, and this reveals the consistency of the relationship of the neuronal activity and the eye movement behavior. The eye movements are recorded using a precise method for recording eye position, velocity and acceleration. The monkey's behavior is controlled by online computer systems that also collect and store all the data from the experiments.

## Pyramidal

### Definition

Refers to the triangular shape of an object; in neuroscience either to the shape of neocortical cell bodies in various laminae, or to the shape of the tract in the medulla oblongata of humans that is made up of axons derived from cortical upper motor neurons and destined for the spinal cord as the cortico-spinal path.

►Evolution of the Wulst

## Pyramidal Decussation

### Synonyms

►Decussatio pyramidum; ►Decussation of pyramids

### Definition

In the pyramidal decussation, 70–90% of the pyramidal tract decussate to the contralateral side. The decussation lies directly below the pyramid (of the myelencephalon), in the middle of the myelencephalon. The decussation joins the lateral pyramidal tract.

►Myelencephalon

## Pyramidal System Organization

►Motor Cortex: Output Properties and Organization

## Pyramidal Tract

### Synonyms

►Tractus pyramidalis

### Definition

The largest descending motor tract is formed by the axons of the pyramidal cells of the motor cortex and is thus called the pyramidal tract. It courses nonstop from the cortex to the corresponding segments in the spinal cord, explaining why it is also called the corticospinal tract. At the upper margin of the myelencephalon, this tract rises to the surface as the pyramid (of myelencephalon).

70–90% of the fibers then cross in the pyramidal decussation to the contralateral side, and continue to run in the spinal cord as the lateral pyramidal tract. The remaining fibers descend in the medial pyramidal tract. The fibers project directly or indirectly to the alpha

motoneurons, especially of the distal extremities (hand/forearm), hence the pyramidal tract plays a vital role in fine motor control.

## $Q_{10}$

### Definition

Quantification of temperature dependence of the rate of a process across a limited (10°C) temperature range. Passive rate changes of biological processes typically have a Q10 between 2 and 3. Deviating values for biological processes indicate active intervention by regulatory processes.

## Q of a Filter

### Definition

A relative estimate of the width of the filter's passband. Q often equals the center frequency of the passband divided by an estimate of the width of the filter's passband.

►Acoustics

## Quadrantanopsia/Quadrantanopia

### Definition

Quadrantic visual field defect resulting from lesion of the ►optic radiation. For example, lesion of the optic radiation fibers looping into the ►temporal lobe causes visual loss in the upper quadrant of the contralateral half of the visual field of both eyes.

►Optic Radiation
►Visual Field

## Quadrigeminal Plate

### Synonyms

Lamina tecti; Tectalplate

### Definition

Also called tectum or quadrigeminal plate. Composed of two pairs of hills: superior colliculus: the two upper hills belong to the visual system (control of eye movements). inferior colliculus: the two lower hills belong to the auditory system and are an integral part of information exchange from inner ear to auditory cortex.

►Mesencephalon

## Quadriparesis

### Definition

Mild form of ►quadriplegia.

►Quadriplegia

## Quadriplegia

### Definition

Bilateral paralysis involving all four limbs, trunk etc., with the site of lesion being at least as high as cervical level. One common cause is the ►Guillain-Barré syndrome.

►Guillain-Barré Syndrome

## Qualia

### Definition

Phenomenal, qualitative, experiential features of mental states are called "qualia" in philosophy of mind. These features show something of what it is like to undergo experiences, that experiences have their particular "feel."

## Qualitative Sex Differences

### Definition

Sex differences in the fundamental mechanisms underlying pain or analgesic responses (to be contrasted with quantitative sex differences). For example, that stress-induced analgesia can be reversed by opioid and/or NMDA-receptor antagonists in males, but not females indicates the presence of a qualitative sex difference.

►Gender/sex Differences in Pain

## Quantal

### Definition

Quantal refers to the mechanism by which transmitters are secreted from nerve terminals in packets released by the exocytosis of the contents of a single synaptic vesicle (a quantum). Individual quanta are released spontaneously when the $Ca^{2+}$ concentration briefly becomes high enough at a release site in the nerve terminal. When an action potential reaches the terminal, $Ca^{2+}$ entry is sufficient to release a quantum from many release sites, leading to a larger multiquantal response. These events are studied postsynaptically as currents or potentials.

## Quantal Release and Excitatory/Inhibitory Miniature Potential

### Definition

Quantal release refers to the mechanism by which transmitters are secreted from nerve terminals in packets released by the exocytosis of the contents of a single synaptic vesicle (a quantum). Individual quanta are released spontaneously when the $Ca^{2+}$ concentration briefly becomes high enough at a release site in the nerve terminal. When an action potential reaches the terminal, $Ca^{2+}$ entry is sufficient to release a quantum from many release sites, leading to a larger multiquantal response.

These events are studied postsynaptically as currents or potentials. These potentials are spontaneous activities of membrane potentials either more positive (excitatory) or more negative (inhibitory) than the resting membrane potential. Miniature potentials are due to irreducible units of transmitter release, namely quantal release.

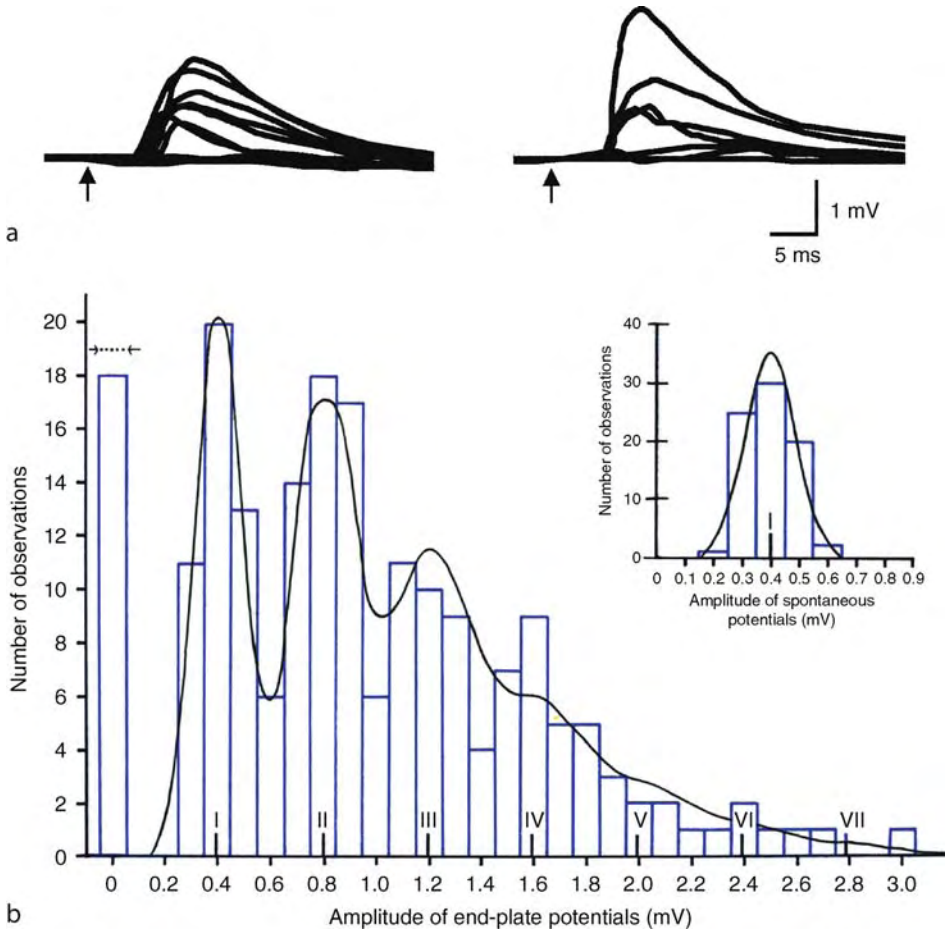
## Quantal Transmission

Hiromu Yawo
Department of Developmental Biologiy and Neuroscience, Tohoku University Graduate School of Life Sciences, Sendai, Japan

### Definition

Bernard Katz and his colleague found in their series of experiments in the 1950s that synaptic transmission at the frog neuromuscular junction consists of a unit, which they referred to as a quantum [1–3]. An endplate potential (EPP) was measured from the frog muscle fiber (postsynaptic cell) by a glass microelectrode, and evoked by the electrical stimulation applied onto the innervating motor nerve (presynaptic axon). The amplitude of EPP was dependent on the $Ca^{2+}$ concentration in the extracellular Ringer solution and was attenuated by the reduction of $Ca^{2+}$ and the increase of $Mg^{2+}$. The EPP attenuation was not continuous, but rather stepwise and fluctuated between steps (Fig. 1a). Statistically, the EPP amplitude is distributed with several peaks of even gaps (Fig. 1b).



**Quantal Transmission. Figure 1** Fluctuations in the end-plate potential (EPP). (a) Superimposed sample records of EPP. The amplitude of EPP fluctuates in a stepwise manner and sometimes resulted in null response (synaptic failure) to the nerve stimulation (applied at time point indicated by arrows). Modified after Fatt and Katz (1952). (b) Amplitude histograms of EPP (blue lines) and miniature EPP (mEPP, inset). The peak of the histogram occurs at 0 (failure), one (I), two (II), ≈ times of mEPP mean. The solid line represents the expected distribution according to Poisson statistics with mEPP mean and variance as units. On the experimentally obtained mean EPP amplitude (0.933 mV), the quantal content, m = 2.33 is predicted. Using the number of trials (198), the expected number of "failures" may be calculated from the Poisson equation as 19 (arrows), being almost identical to the experimental value. Modified after Martin (1966).

Q

The gap distribution was almost equal to that of miniature EPPs (mEPPs), small changes of postsynaptic membrane potential spontaneously occurs under the blockade of presynaptic activity by e.g., tetrodotoxin. They put forward the quantal hypothesis that: (i) EPP consists of a unit (quantum), (ii) the number of quanta is stochastic around a mean, and (iii) mEPPs are spontaneous quanta. It is a generally accepted idea that each quantum is the synaptic transmission induced by the exocytotic release of a single presynaptic vesicle containing a certain amount of neurotransmitters (vesicular hypothesis) [2]. Similar stochastic transmission is found in neuro-neuronal synapses in both the peripheral and central nervous system [2,3]. The fundamental nature of this chemical synaptic transmission has provided a remarkable idea that, like the flip of coin, how a neural network performs is unreliable.

According to the quantal hypothesis, a synaptic event is mathematically described. This description enables one to estimate both presynaptic and postsynaptic parameters (►quantal analysis), thus, enabling one to presume the presynaptic and postsynaptic contributions quantitatively, which otherwise are very difficult to estimate. The quantal analysis is applied on the peripheral and invertebrate nervous systems and provides an important quantitative description of synapses. When the synaptic transmission was changed by some neural activities or some chemicals as neuromodulators

and drugs, the primary cause could be attributed to either presynaptic, postsynaptic or both elements (pre/post problem). The pre/post problems have been revealed by quantal analysis in many synapses of peripheral and even central nervous systems. However, the quantal analysis has recently been challenged by "►silent synapse" phenomena, and its application should be careful for the CNS synapses.

## Characteristics

### Quantitative Description

According to the Katz model, neurotransmitter is prepackaged in discrete quantities of fixed size, called quanta, and each quantum is released probabilistically and independently of the others in response to the activation of presynaptic terminal. Hence, the size of the postsynaptic response, such as the EPP and the postsynaptic current, vary at random because it is assumed to be proportional to the number of quanta simultaneously released. The random process is quantitatively described by the application of probability theory. The probability that $k$ quanta are simultaneously released, $P(k)$, is thus assumed to follow a binomial distribution:

$$P(k) = {}_nC_k\, p^k (1-p)^{n-k},$$

where $p$ is the probability of a quantum to turn on release and $n$ is the total number of quanta. In other words, $p$ is the probability of a vesicle to be release and $n$ is either the total number of docked vesicles or the number of release sites if one vesicle is predocked in one release site. When $p/n$ is very small, as in the case of Katz' experiment with extracellular low $Ca^{2+}$ and high $Mg^{2+}$, this distribution is approximated to the Poisson distribution. That is;

$$P(k) = (m^k/k!)e^{-k},$$

and

$$m = np.$$

The parameter $m$ corresponds to the mean number of quanta simultaneously released (called "►quantal content" in the original works of Katz and collaborators). A Poisson process is one in which some event (like exocytosis) is unlikely to occur in any brief time window. The most familiar example of a Poisson process is the number of telephone calls made per day in your office. There are a large number of telephones connected to your office ($n$), and the probability of any one of them being active ($p$) is very low. On some days your office is quiet with no calls ("failure" response), on other days, one or perhaps two calls. Over a year, the number of days in which the number of telephone calls ($k$) is 0, 1, 2, 3 or more is distributed according to the above Poisson equation, using only the mean number of telephone calls a day ($m$) to determine the theoretically expected distribution without knowing $n$ or $p$. The number of "failures," for example, should be given by:

$$n_0 = \mathrm{Ne}^{-\mathrm{m}},$$

where $N$ is the total days of observation (e.g., 365). The number of single-call days by

$$n_1 = Ne^{-m} \cdot m$$

and so on.

The applicability of Poisson distribution to the ►quantal release of transmitter has been tested as illustrated in Fig. 1b. The quantal hypothesis predicts that the mean ►quantal size, $q$, a unit amplitude of quantum is equivalent to the mean amplitude of mEPP. The average size of postsynaptic response, $E$ is thus expressed as,

$$E = qm.$$

Since mEPPs appear to be distributed normally around a mean of $q$ with variance $\sigma^2$, the predicted $n_1$ also follows this distribution. Similarly the predicted $k$ unit responses ($n_k$) are distributed normally around a mean amplitude of $k$ $q$ with variance $k$ $\sigma^2$. The convoluted predicted distribution produces a smooth curve, as shown in Fig. 1b, which may be compared with the experimental histogram.

Since the value $m$ consists of pure presynaptic factors, $n$ and $p$, it has been widely used as a parameter sizing presynaptic releasing ability. The value $m$ can be independently calculated either by the following equations.

If one can measure $q$ on the ►miniature synaptic responses:

$$m = E/q.$$

If one can count the number of "failures," $n_0$:

$$m = ln(N/n_0).$$

Since the variance of Poisson distribution is equal to $m$, $m$ is related to the coefficient of variation ($CV$ = standard deviation/mean) as;

$$m = (CV)^{-2}.$$

If these values are all identical, the experimental distribution of synaptic responses almost follows the Poisson process. If not, there should be some deviations.

### Higher Level Structures

The structure of synapse has been described in the accompanying essay.

### Lower Level Components

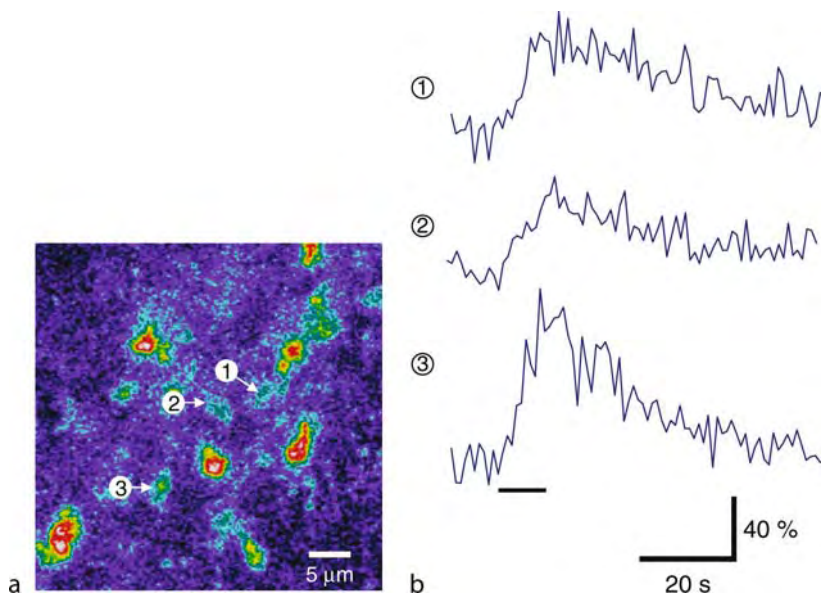
The synaptic vesicles and the molecular mechanisms of transmitter release have been described in the accompanying essay.

## Higher Level Processes

Hebb proposed in 1949 that, at the level of the synapse, learning follows a fundamental rule: "*When an axon of cell A is near enough to excite a cell B and repeatedly and persistently takes part in firing it, some growth or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased*." This theory led to the discovery of a cellular process, long-term potentiation (LTP), as one of the neuronal mechanisms underlying learning and memory. Since LTP requires coincidence of presynaptic activity with depolarization of the postsynaptic cell, it is indicated that a process very akin to that proposed by Hebb is involved. LTP is classically induced by the $Ca^{2+}$ influx through postsynaptic NMDA (*N*-methyl-D-aspartate) receptor, which works as a coincidence detector of synaptic transmission and postsynaptic depolarization.

Although the postsynaptic elevation of $Ca^{2+}$ triggers LTP induction, there have been debates on the cellular mechanisms of potentiation; either (i) enhancement of the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptor responses at the postsynaptic membrane (postsynaptic mechanism), or (ii) increase in the number of quanta of glutamate detected by the postsynaptic neuron in response to a presynaptic action potential (presynaptic mechanism). The latter mechanism is supported by the findings that LTP is associated with a decrease in the *CV* and in the failure rate, evidence for a presynaptic expression mechanism. Some retrograde signals may induce changes in presynaptic release mechanisms on the postsynaptic elevation of intracellular $Ca^{2+}$. However, LTP was accompanied by a relatively selective increase in the signal mediated by AMPA receptors, with little change in the NMDA receptor-mediated components. This finding is most easily explained by an enhancement in the AMPA receptor responses at the postsynaptic membrane.

To explain this apparent paradox, the idea of "silent synapse" is proposed [4]. The synapses are non-uniform in both morphology and physiology. Some synapses have NMDA receptor responses with no AMPA receptor responses (silent synapses) whereas others have both responses. After LTP induction, silent synapses may be replaced by dual component (AMPA and NMDA receptor-mediated) signals through one or a combination of the following mechanisms. (i) AMPA receptors are preserved in the intracellular vesicles and incorporated in the postsynaptic membrane by the LTP induction. (ii) LTP induction makes postsynaptic AMPA receptors sensitive to glutamate by accumulating them in a site just opposite the presynaptic releasing apparatus. (iii) Functionally inactive AMPA receptors are made active by biochemical reactions activated by LTP induction. (iv) Glutamate released by incomplete exocytosis, through the fusion



**Quantal Transmission. Figure 2** Direct measurement of quantal release by an optical imaging technique. (a) Mossy fiber presynaptic terminals were fluorometrically identified under confocal microscopy in the hippocampal slice obtained from a mouse genetically encoding synapto-pHluorin [Araki et al. 2005]. (b) The fluorescent intensity of the presynaptic terminal increased by repetitive stimulation of mossy fibers (10 Hz for 10 s, horizontal bar), indicating the relative magnitude of quantal release at the individual presynaptic terminal (numbers correspond to those in a).

pores between synaptic vesicles and presynaptic plasma membrane, ("►kiss and run" mechanism) elevates the glutamate concentration to a low level that is enough to activate NMDA receptors without activating AMPA receptors. (v) The weak elevation of glutamate concentration is induced by the activation of neighboring synapses and activates NMDA receptors without activating AMPA receptors. (vi) The glutamate concentration at the postsynaptic AMPA receptors is increased by either the change of synaptic cleft geometry or the reduction of glutamate uptake by glia.

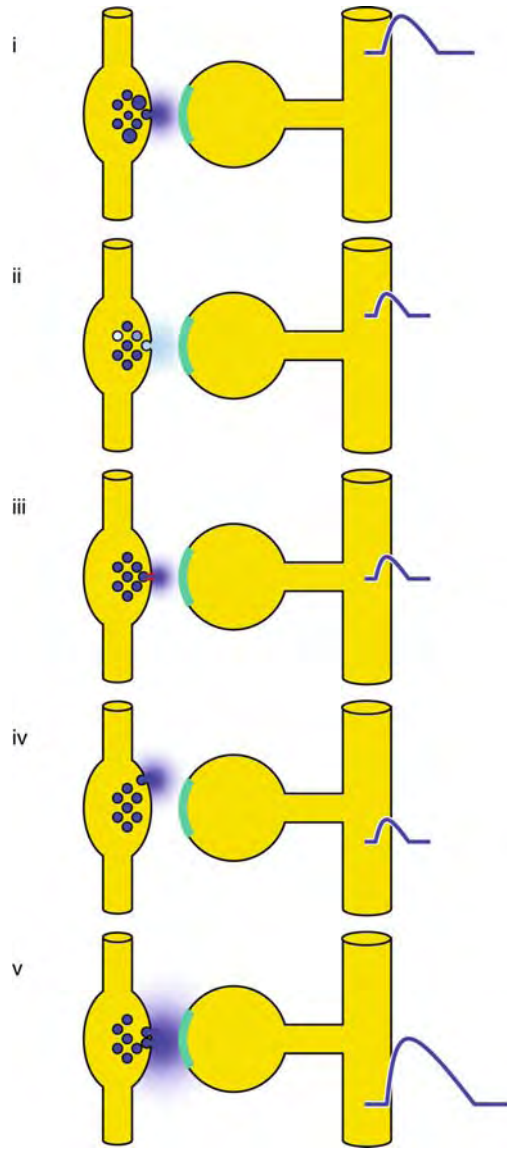
Therefore, the cellular mechanisms of LTP expression are not simple and involve both presynaptic (released amount of glutamate, mode of exocytosis) and postsynaptic mechanisms (number, distribution, functional modification). To test this, direct measurements of quantal release are promising by the use of presynaptic imaging techniques [5]: ►FM 1–43 and its analogue, and pH-sensitive form of green fluorescent protein (GFP) attached to the lumenal portion of a synaptic vesicle protein (e.g., synapto-pHluorin ►(synapto-pHluorin method)). The latter method has several advantages; (i) the optical signal changes instantaneously with the formation of a fusion pore between the vesicle membrane and the presynaptic plasma membrane, (ii) since recycled vesicles are rapidly re-acidified, both exocytosis and endocytosis of quanta are repeatedly measured at an individual synapse, and (iii) the reporter protein gene can be genetically introduced in experimental animal lines (Fig. 2).

These optical methods enable one to measure quantal release directly at individual synapses and to solve the pre/post problem of LTP.

## Lower Level Processes

The quantal hypothesis is based on the prediction that there is a unit in the synaptic transmission. This is supported by the finding that mEPP is normally distributed around the mean. However, the miniatures are variable in amplitude and distributed in a highly skewed form in CNS synapses. Since focal application of glutamate at individual postsynaptic sites evoked currents less variable than the quantal EPSCs, the concentration of glutamate is assumed to be variable in magnitude or in kinetics in the synaptic cleft [6]. Several mechanisms are proposed to explain variable quantal size (Fig. 3) (i) non-uniform vesicle volume, (ii) non-uniform vesicle filling of transmitters, (iii) incomplete exocytosis of transmitters via a fusion pore with variable diameter, expansion rate, or lifetime, (iv) variable site of release relative to postsynaptic receptors, and (v) synchronous release of multiple vesicles or release of pre-fused vesicles.

Since NMDA receptors have a 100-fold higher affinity for glutamate, slower unbinding rate of glutamate and slower rate of desensitization than do AMPA receptors, the occupancy and opening probability of receptors depend on both the concentration and the time course of the glutamate transient [4]. If the glutamate transient is large and extremely brief, both NMDA and AMPA receptors are activated. On the other hand, if the glutamate wave is small and slow, NMDA receptors might be selectively activated. This would be one of the



**Quantal Transmission. Figure 3** Possible mechanisms underlying variable quantal size: (i) non-uniform vesicle volume, (ii) non-uniform vesicle filling, (iii) incomplete exocytosis of transmitter via a fusion pore with variable diameter, expansion rate, or lifetime, (iv) release site variation relative to postsynaptic receptors (green), and (v) synchronous release of multiple vesicles. Modified after Kullmann (1999).

possible underlying mechanisms of "silent synapse" phenomenon [4].

## Process Regulation

Quantal transmitter release from the presynaptic terminal is regulated by various neuromodulators, which have their specific receptors on the presynaptic terminal. The inhibition of presynaptic voltage-dependent $Ca^{2+}$ channels plays a key role in presynaptic neuromodulations [7]. Up- and down-regulation of the exocytotic machinery are also involved in neuromodulations.

Use-dependent modifications such as ►paired-pulse facilitation, ►post-tetanic potentiation and LTP are also accompanied with changes in quantal release. While induction of LTP generally requires postsynaptic activation of NMDA receptors in the brain, LTP at the hippocampal mossy fiber (MF) pathway, the synapse between the dentate granule cells and the CA3 pyramidal neurons, is NMDA-independent [8]. The synaptic transmission can be measured from the postsynaptic CA3 pyramidal cell as an EPSC. Similar to EPPs at the neuromuscular junction, the EPSC amplitude was stochastically fluctuated from trial to trial and sometimes resultant in synaptic failure. When tetanic stimulation was applied on the mossy fiber pathway, the mean amplitude of EPSCs was increased with the reduction of synaptic failures for tens of minutes. The increase in the EPSC amplitude was accompanied by a linear increase in the $CV^2$ value. These results are consistent with a presynaptic mechanism for LTP expression in this type of synapse.

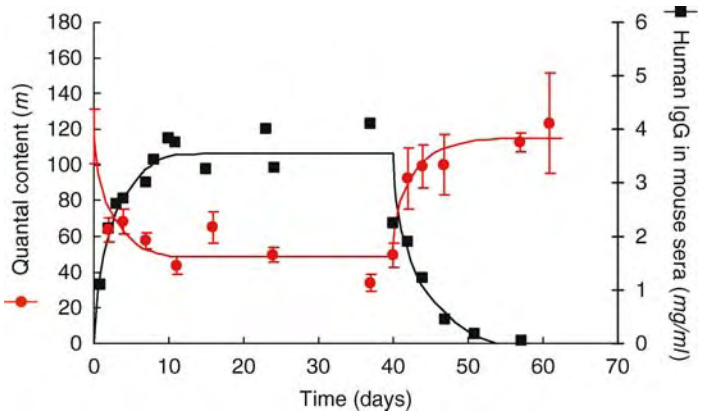
## Function

The quantal release of neurotransmitter provides unreliable processes in the neural network of brain. Although at first glance such unreliability seems detrimental to brain functions, it is hypothesized to be utilized by the brain for the purposes of learning, in analogy to the way in which unreliable genetic replication is used for evolution [9].

## Pathology

►Lambert-Eaton myasthenic syndrome (LEMS) is a disorder of neuromuscular transmission that is characterized by muscle weakness and autonomic dysfunction. The etiology of LEMS is unknown, but is often associated with small cell lung carcinoma, and is highly prevalent with autoantibodies, particularly to thyroid and stomach constituents. Neuromuscular transmission can be investigated by microelectrode methods in biopsied patients' skeletal muscles. The quantal analysis revealed that the quantal content ($m$) of the nerve-muscle transmission (the number of acetylcholine-containing quantal release per nerve impulse) was markedly reduced, so that *in vivo* the transmission-evoked depolarization would fail to exceed the threshold required for generating an action potential in the muscle membrane. Passive transfer of LEMS IgG to mice by daily intraperitoneal injection induced the reduction of quantal content of nerve-muscle transmission (Fig. 4).

Both quantal content and the human IgG level in the serum recovered in correlation after injections were terminated. These and other experiments support the hypothesis that the quantal content of nerve-muscle transmission is decreased by the reduction of $Ca^{2+}$ entry during presynaptic activation, probably through the increased degradation of voltage-dependent $Ca^{2+}$ channels in the presynaptic terminals [10].



**Quantal Transmission. Figure 4** Time course of the effect on quantal content of passively transferred Lambert-Eaton myasthenic syndrome (LEMS) IgG in mice. Daily injection of LEMS IgG increased the serum level of human IgG in the mice (black squares). IgG injection was stopped after 40 days administration. The quantal content was reduced with the increase of LEMS IgG and recovered with the reduction (red circles, mean and SEM). Modified after Prior et al. (1985).

# Quantitative Sensory Testing (QST)

## Definition

A sophisticated neurophysiological technique to test systems is quantitative sensory testing (QST). It uses a battery of standardized mechanical and thermal stimuli (graded v. Frey hairs, several pinprick stimuli, pressure algometers, quantitative thermotesting etc.). A standardized protocol for QST was recently proposed by the nationwide German Network on Neuropathic Pain including 13 parameters of sensory testing procedures for the analysis of the somatosensory phenotype. To judge plus or minus symptoms in patients an age- and gender-matched data-base for absolute and relative QST reference data in healthy human subjects was established. The QST data are then used to create zscore sensory profiles to judge altered somatosensation in patients.

## Rabies

### Definition

Rabies is an acute, usually fatal encephalomyelitis caused by Rhabdoviridae. Highly endemic in parts of Africa, Asia, and Central and South America, rabies is almost always transmitted by an infected animal bites.

Infected people first develop fever, headache and skin sensation abnormalities (paresthesias) followed by paralysis (“dumb” form), hydrophobia, delirium or psychosis (“furious” form), then coma and death.

Confirmatory diagnosis is made by PCR assay of skin or saliva, but a negative result does not exclude the diagnosis. Pre-exposure vaccination is recommended for people who work with wild animals, travelers who anticipate prolonged stays in rural areas with high levels of endemic rabies as well as for cave explorers (spelunkers).

## Radial Histogenetic Division

### Definition

A radially arranged region or territory of the brain, whose neurons primarily derive from a specific morphogenetic field (i.e. from a restricted ventricular sector of the neural plate/tube). The radial feature of brain histogenetic divisions is based on the predominant glial fiber-guided migration of immature neurons in

their way from the ventricular (proliferative) zone to the mantle during development. Nevertheless, radial histogenetic divisions can contain immigrant cells coming from other fields by tangential migration.

►Evolution and Embryological Development of the Forebrain

## Radial Migration

### Definition

Projection neurons are produced locally in the telencephalic wall and migrate to the overlying cortical plate perpendicular to the pial surface.

## Radiation Term

### Definition

The volumetric source or sink of non-mechanical power in the balance of energy.

►Mechanics

## Radiculopathy

### Definition

Radiculopathy refers to disease of the spinal nerve roots (from the Latin radix for root). Damage to the spinal nerve roots can lead e.g. to pain, numbness, weakness, and paresthesia (abnormal sensations in the absence of stimuli) in the limbs or trunk. Pain may be felt in a region corresponding to a dermatome, an area of skin innervated by the sensory fibers of a given spinal nerve.

►Neuropathic Pain

## Radioisotope

### Definition

A radioactive isotope of an element.

## Radioligand

### Definition

A radiolabeled molecular probe for the visualization of a particular receptor sub-type; see Positron Emission Tomography (PET).

►Positron Emission Tomography

## Radiopharmaceutical (Radiotracer)

### Definition

A specific pharmaceutical, labeled with radioactive isotope.

## Radiotracer Imaging

### Definition

Radiotracer imaging techniques involve intravenously injecting various short-lived radiolabelled molecules and then using positron emission tomography (PET) or single photon emission computed tomography (SPECT) to measure one or more biological functions of dopaminergic neurons in a resting state.

►Dopamine

## Raf

### Definition

A protein kinase and member of the MAPKK Kinase family. As a result of neurotrophic factor binding, MAPKKK is activated and phosphorylates MAPKK on its serine and threonine residues. The MAPKK then activates a MAPK through phosphorylation on its serine and tyrosine residues.

►Mitogen Activated Protein Kinase (MAPK)

## RAGs (Regeneration-Associated Genes)

### Definition

A series of changes in gene expression that occur in cell bodies (perikarya) of neurons with axon damage.

►Axon Degeneration and Regeneration of Peripheral Neurons

## Random Process

### Definition

The term "random process" denotes a series of uncorrelated events that are distributed either exponentially or in a Gaussian fashion.

►Circadian Rhythm

## Raphé Interpositus

### Definition

A collection of neurons lined up on either side of the midline ventral to the abducens nucleus. The neurons in raphé interpositus are the saccade-related omnipause neurons.

►Omnipause Neurons
►Saccade, Saccadic Eye Movement

## Raphé Nuclei

### Definition

The raphé nuclei are traditionally considered to be the medial portion of the reticular formation, and they appear as a ridge of cells in the center and most medial portion of the brain stem. The raphé nuclei have a vast impact upon the central nervous system. The raphé nuclei can be of particular interest to neurologists and psychologists since many of the neurons in the nuclei (but not the majority) are serotonergic, i.e. contain serotonin – a type of monoamine neurotransmitter.

Serotonin, also called 5-HT, seems to be the culprit in many of our modern psycho-pharmaceutical problems, such as anorexia, depression, and sleep disorders. It is not the sole culprit in the aforementioned disorders, but it is the area that the pharmacologists know how to affect in the best manner. It is important to note that pharmacology traditionally affects global serotonin levels, while the actions of the raphe nuclei are dependent on the complex interplay between nuclei.

►Serotonin

## Raphé Nuclei and Circadian Rhythm

### Definition

The midbrain dorsal and median raphé nuclei known for their widespread, extensively overlapping, ascending serotonergic projections. The projections of each nucleus, serotonergic or not, contribute to a great many different brain functions. In the context of the circadian rhythm system, the innervation by the dorsal and median raphé is somewhat unique because the raphé efferent projections of those two nuclei do not overlap in the two primary components of the system, the suprachiasmatic nucleus (SCN) and the intergeniculate leaflet (IGL). The SCN is very heavily innervated by neurons with cell bodies in the median raphé nucleus.

The majority of these contain the neurotransmitter, serotonin, but many median raphé neurons projecting to the SCN contain a different, currently unknown, neurotransmitter. Neurons of the median raphé do not project to the IGL. In contrast, both serotonergic and non-serotonergic neurons in the dorsal raphé nucleus project to IGL, but not to the SCN. In addition, the median and dorsal raphé nuclei reciprocally connect to one another via serotonergic and non-serotonergic connections. The direct serotonergic median raphé-SCN projection has been implicated as an inhibitor of retinohypothalamic tract transmission of photic input to the SCN, while the dorsal raphé serotonergic projection to the IGL has been implicated in the non-photic regulation of circadian rhythm phase.

## Rapid Eye Movement (REM) Sleep

### Definition
REM sleep (also called paradoxical sleep (PS) and activated sleep) is a distinctive sleep stage in mammals. Normally this stage of sleep appears after a period of non-REM (NREM) sleep and then alternates with episodes of NREM sleep throughout the sleep period. REM sleep is characterized by a constellation of events including the following: (i) low-amplitude synchronization of fast oscillations in the cortical electroencephalogram (EEG) (also called activated EEG); (ii) very low or absent muscle tone (atonia) in the electromyogram (EMG). The atonia is observed to be particularly strong on antigravity muscles, whereas the diaphragm and extra-ocular muscles retain substantial tone; (iii) singlets and clusters of rapid eye movements (REMs) in the electrooculogram (EOG); (iv) theta rhythm in the hippocampal EEG; and (v) spiky field potentials in the pons (P-wave), lateral geniculate nucleus, and occipital cortex (called ponto-geniculo-occipital (PGO) spikes). Supplemental to these polysomnographic signs, other REM sleep-specific physiological signs are: myoclonic twitches, most apparent in the facial and distal limb musculature; pronounced fluctuations in cardio-respiratory rhythms and core body temperature; penile erection in males and clitoral engorgement in females (tumescence). In humans, awakening from REM sleep typically yields detailed reports of hallucinoid dreaming, even in subjects who rarely or never recall dreams spontaneously.

REM sleep is critical for memory processing and improvement of learning. REM sleep is not identifiable in the fish, amphibian, or reptile classes. In birds REM sleep is seen only for brief periods of time, especially following hatching. Generally, REM sleep is considered to be a highly evolved behavioral stage of terrestrial mammals.

## Rate of Cross-Bridge Detachment

### Definition

In the cross-bridge theory, cross-bridge attachment and detachment to the actin filament are quantitatively described by position-dependent rate functions. The detachment rate describes the first order kinetics of cross-bridge detachment from actin, while the attachment rate describes the first order kinetics of cross-bridge attachment to actin. In order for force production and contraction to always be in the same direction (i.e. a muscle always tends to shorten upon contraction and to produce tensile forces), these rate functions have to be asymmetric relative to the equilibrium point of the cross-bridge.

## Rating Task

### Definition

A psychophysical task in which a subject is asked to state the magnitude of a stimulus either in absolute terms or relative to a reference.

## Ratiometric Dye

### Definition

Some dyes respond to a metabolic change with both increase and decrease of fluorescence, depending on how they are measured. For example, the fluorescence of the calcium sensitive dye fura increases with increasing calcium when excited at 340 nm, and decreases when excited at 380 nm. FRET-dyes (FRET means Fluorescence Resonance Energy Transfer) shift their emission spectrum, with the result that fluorescence decrease in one band, and increases in another.

These dyes can be evaluated by creating the ratio (hence the name ratiometric dye) of the two signals, creating a number that is independent of the absolute fluorescence strength.

►Functional Imaging

## Ray-finned Fishes

### Definition

Also known as actinopterygian fishes. So named because of the flexible rays that provide the structural support of their fins. They make up approximately 95% of all living fishes and about half of all living vertebrate species.

►Evolution of the Spinal Cord

## RC Circuit

### Definition

Electrical circuit consisting of a resistor and a capacitor.

## Reach to Grasp Postural Strategy

### Definition

A change in support reaction to postural perturbation in which a rapid reaching movement of the arm permits a stable object to be touched or grasped for support, in order to restore equilibrium.

►Postural Strategies
►Reaching Movements

## Reaching Behavior

### Definition

Goal-directed behavior of humans and animals that requires visual information for movement of arms and hands in reach for objects.

# Reaching Movements

Andrea d'Avella
Department of Neuromotor Physiology,
Santa Lucia Foundation, Rome, Italy

## Definition

The act of reaching, bringing a part of the body in contact with an object, is a crucial component of many animal behaviors. Several vertebrate species use the distal portions of their forelimbs to explore and feed. Reaching movements are particularly important for primates, whose hands are capable of grasping and manipulating objects, and consequently these movements have been extensively investigated in humans and monkeys.

## Characteristics

To reach for an object with the hand, the central nervous system (CNS) must map sensory input, which provides information about the object and hand locations in space, into motor output, comprising activations of shoulder and arm muscles that move the hand towards the target. Considering visually guided reaching, the location of a visual target is specified in retinal coordinates, proprioception gives information on the initial hand location in terms of arm muscle lengths, and muscle activations generate forces between arm segments. Thus, the CNS must transform sensory information into motor commands that are encoded in different ►frames of reference. It is usually assumed that the CNS performs these sensorimotor transformations in two stages. First, sensory information is used to define a kinematic plan. Target location and hand location are mapped into a common reference frame and a difference vector or motor error is computed. Second, the movement is executed by mapping the plan into muscle activations. This transformation may be performed using sensory signals for correcting the motor commands while they are generated (►Feedback control) or by pre-computing the appropriate commands (►Feedforward control). Since the delays involved in the conduction and processing of sensory signals may create instabilities in a feedback controller, the control of fast reaching movements requires feedforward control. Knowledge of the dynamical behavior of the musculoskeletal system necessary for pre-computing the appropriate motor commands is thought to be incorporated into the controller either explicitly as an ►internal model of the motor apparatus or implicitly as a collection of motor programs. The kinematic and dynamic characteristics as well as the muscle activation patterns observed during reaching movements have provided the experimental bases for the elaboration of these and other models of the computations involved in controlling reaching movements (►Motor control models).

### Kinematics

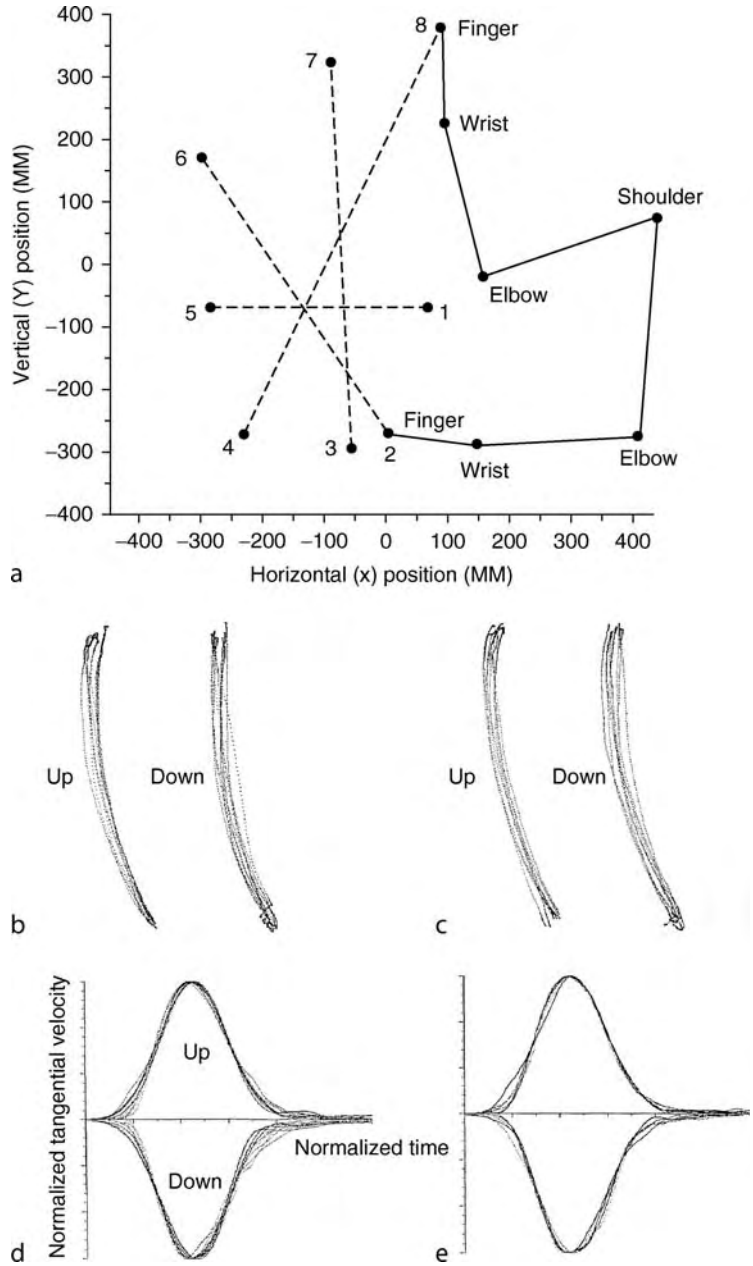
The motion of the arm during reaching, arm kinematics, is fully specified by the rotational motion of all the joints in the arm. Considering the wrist as the arm end-point to be positioned in space, three rotations at the shoulder (flexion-extension, adduction-abduction, internal-external rotation), and one at the elbow (flexion-extension) are required to characterize reaching kinematics. Since there are four joint angles, or degrees-of-freedom, for three spatial coordinates of the wrist, the system is redundant, i.e. the same spatial location can be reached with the arm in many different configurations. For example, it is possible to raise the elbow without moving the wrist. Moreover, there are infinite paths along which the wrist can be moved to reach a target location from a given start location. Thus, to plan a reaching movement the CNS has to select one out of infinite possible kinematics.

Simple invariant features have been observed in the kinematics of reaching movements and they have provided an indication of the strategy used by the CNS for the planning stage. When performing a point-to-point reaching movement between two points on a horizontal plane, the wrist paths are straight and the wrist tangential velocity has a "bell-shaped" profile with a single peak [1]. For unrestrained movements in a vertical plane, the hand path is not always straight but it is independent of the speed of the movement [2] and of the hand-held load [3] (Fig. 1b–c).

Moreover, the tangential velocity profiles for movement at different speeds have the same shape when normalized for speed (Fig. 1d). The existence of invariant kinematic features has been interpreted as evidence for kinematic planning of reaching movements. Moreover, the straightness of the wrist path has been interpreted as evidence for planning end-point trajectories or displacements. However, since movements are executed by changing joint angles, end-point planning also requires mapping desired end-point positions into joint angles (inverse kinematics).

### Dynamics

Arm movements are generated by the forces applied on the arm segments by the contraction of the muscles interconnecting them as well as by gravity. Since the arm is a chain of articulated segments, the motion of one joint depends not only on the forces directly applied to it but also on the motion of the other joints and the forces applied to them. For example, during a sagittal-plane reach to a target at shoulder level, from a starting posture with the forearm at waist level and the upper arm vertical along the trunk, the shoulder flexes and the



**Reaching Movements. Figure 1** Invariant wrist path and tangential velocity for point-to-point movements across speeds and loads. (a) The position in space of markers placed on the arm of subjects performing unrestrained reaching movements between two points in the sagittal plane is recorded. (b–c) The path, on the sagittal plane, of the wrist for upward and downward movements (between points 3 and 7) does not change with the speed (b, where 6 slow, 6 medium, and 6 fast movement paths are overlapped) and the hand-held load (c, where 6 unloaded, 6 with 2 lb load, and 6 with 4 lb load movement paths are overlapped). (d–e) Similarly, the tangential velocity profile for upward and downward (with inverted ordinates) movements between the same two points, once normalized for speed, does not change with speed (d) and load (e). Adapted from [3] copyright © 1985 by the Society of Neuroscience, with permission.

elbow extends. However, because of the intersegmental dynamics, the muscles generate a flexor torque at *both* shoulder and elbow joints. Thus, the transformation between kinematics and dynamics (inverse dynamics) is not trivial and how the CNS implements this transformation is still an open question.

The characteristics of the torque profiles generated by the muscle contractions suggest that the CNS uses

simple rules to find approximate yet adequate solutions to the inverse dynamic problem. The net torque generated at each joint by all muscles acting on it can be estimated from the arm kinematics using a simplified dynamic model of the arm based on the Newtonian equations of motion. For point-to-point movements in the sagittal plane, from one central location to several peripheral locations arranged on a circle, the dynamic muscle torque (expressed as the net muscle torque minus the torque required to counteract gravity) at the shoulder and at the elbow are related almost linearly to each other [4] (Fig. 2).

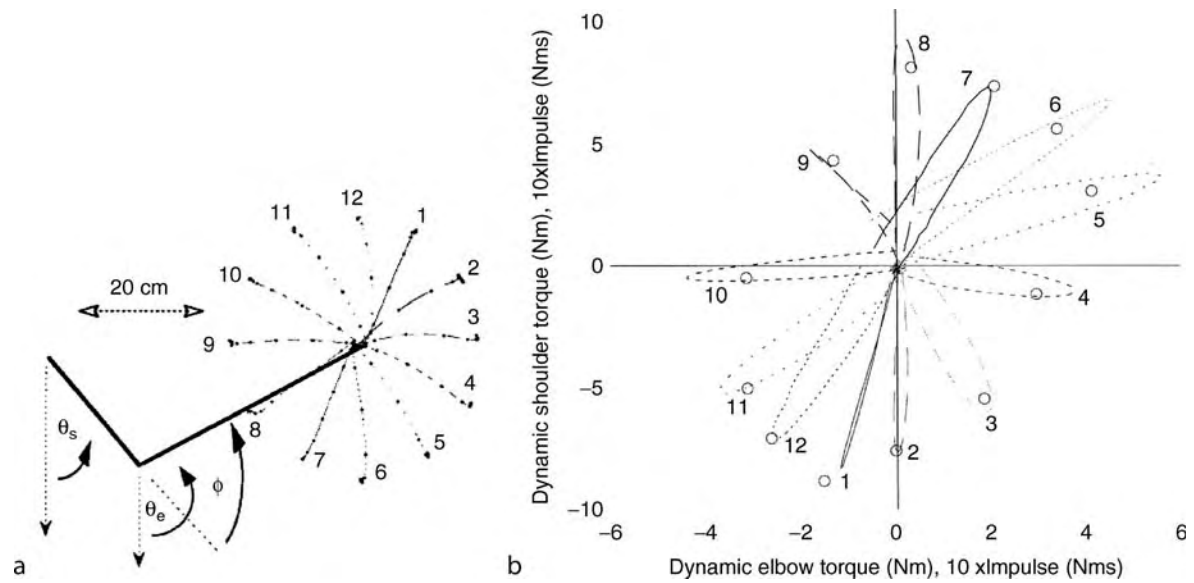
Both shoulder and elbow dynamic torque profiles have similar biphasic and synchronous shapes. Moreover, the relative amplitude of the two torque profiles changes with ▶movement direction, with the same biphasic torque profile scaled at each joint by a coefficient that varies as a linear function of the angular displacement at both joints. Simple torque scaling rules have also been proposed as a mechanism to generate movements with invariant paths and tangential velocity with different speeds and loads [3]. These rules derive from the observation that scaling in time the antigravity torque profiles and both in amplitude and in time the dynamic torque profiles generates invariant kinematics.

## Muscle Patterns

The patterns of muscle activation observed during reaching movements have a complex dependence on the movement direction and speed. For reaching in vertical planes, the electromyographic (EMG) waveforms are constructed by combining components related to both dynamic and gravitational torques [5]. The waveform components responsible for the dynamic torques (phasic activations) have an intensity and a timing that changes with the movement direction in a complex manner [6]. Each muscle has a distinct spatial and temporal pattern, with a recruitment intensity maximal in multiple directions and a recruitment timing changing gradually across directions. Moreover, the phasic activations scale in time with movement speed differently for different muscles.

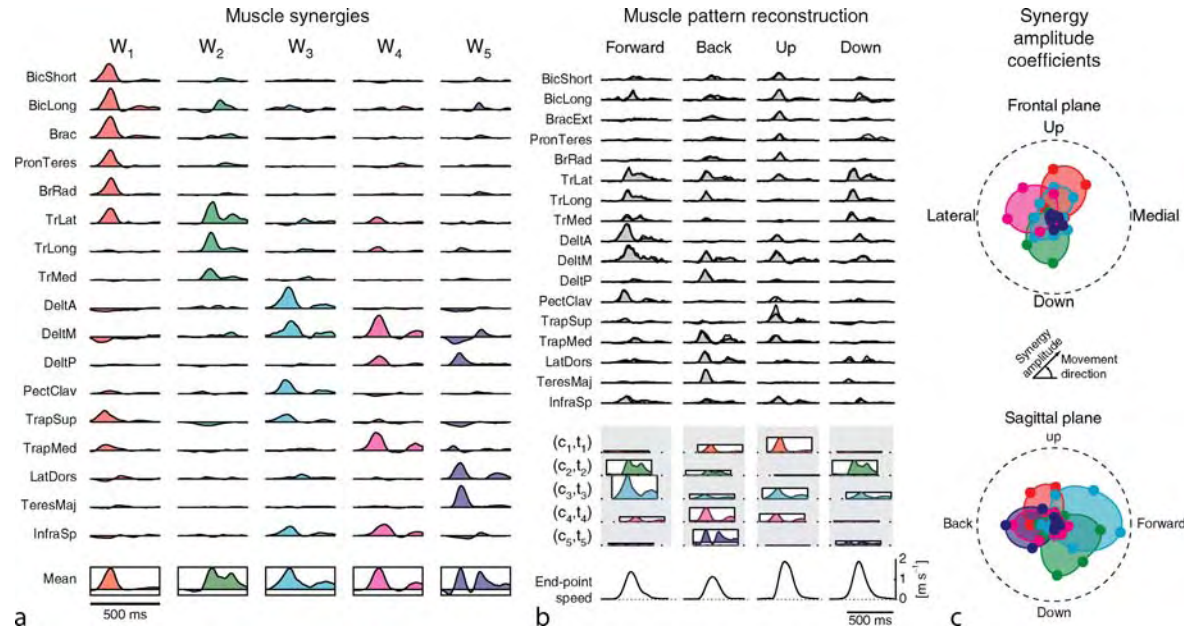
Despite their complex dependence on the movement parameters, the muscle patterns for reaching are generated according to relatively simple rules. The changes in the muscle patterns for fast reaching movements in different directions on vertical planes are well captured by the combinations of a few time-varying ▶muscle synergies [7] (Fig. 3).

A muscle synergy represents the coordinated activation of a group of muscle with specific activation profiles. Each synergy is modulated in intensity and



**Reaching Movements. Figure 2** Scaling of dynamic muscle torques as a function of movement direction. (a) The elbow and shoulder muscle torques necessary for performing center-out reaching movements to 12 targets in the sagittal plane are estimated from the movement kinematics. (b) The average dynamic torque at the elbow and at the shoulder, obtained removing the torque required for resisting gravity from the total muscle torque at each joint, are plotted against each other, during the initial accelerating phase, for the 12 different directions (*solid and dashed lines*; open symbols represent the integrated torque, or impulse, at elbow and shoulder). The dynamic elbow and shoulder torque are approximately linearly related for all movements with a slope depending on the movement direction. Adapted from [4] copyright © 1997 by the American Physiological Society, with permission.

R



**Reaching Movements. Figure 3** Muscle synergies for reaching. (a) A set of five time-varying synergies, identified from the muscle patterns recorded during point-to-point movements between one central location and eight peripheral locations in the frontal and sagittal planes. (b) The activation waveforms of 17 shoulder and arm muscles are reconstructed (*top*, where the gray area represents the averaged EMG activity and the solid black line the synergy reconstruction) by scaling in amplitude and shifting in time (*bottom*, where the amplitude scaling coefficient is represented by the height of a rectangle and the onset latency by its horizontal position) and combining, muscle by muscle, each one of the five synergies. Different movements are reconstructed with different synergy combination coefficients. (c) The amplitude scaling coefficients are directionally tuned (►Directional tuning), with a tuning in most cases well captured by a cosine function. Adapted from [7] copyright © 2006 by the Society of Neuroscience, with permission.

delayed in time differently across movement directions and multiple synergies are combined to generate the observed muscle patterns. Such a combination mechanism may simplify the sensorimotor transformations for reaching by allowing a direct, low-dimensional mapping between kinematic plans and muscle patterns, and, thus, an implicit implementation of approximate inverse kinematics and inverse dynamic computations.

## Neural Control

A distributed network of cortical areas in the parietal and frontal cortex and subcortical structures (spinal cord, cerebellum, basal ganglia) is involved in the neural control of reaching movements. This network functions in an integrated manner and it has not been possible to associate specific stages of the sensorimotor transformations to specific areas or neuronal populations. However, each area has a different degree of involvement into the different aspects of the control process. Spatial representation of limb position, target locations, and potential motor actions are highly expressed in the parietal cortex which is thought to be mainly involved in the early sensorimotor transformations. Selection and execution of motor actions are strongly expressed in the motor areas of the frontal cortex, from which most of the descending axons to the brain stem and the spinal cord originate, and which are believed to play a major role in transforming kinematic plans into descending commands closely related to the muscle patterns.

To understand the neural mechanisms underlying the sensorimotor transformations involved in reaching, the characteristics of the activity of individual neurons in many of the cortical areas involved have been investigated in monkeys. Recordings in the motor areas of the frontal cortex, composed by the primary motor cortex and six distinct premotor areas, have shown that the activity of most neurons is broadly tuned to the direction of movement [8]. The activity of each cell depends on the movement direction approximately as a cosine function, with a maximum in a ►preferred direction that varies from cell to cell. Thus, each cell is active for a broad range of movement directions. Conversely, each movement direction is associated by a pattern of graded activation of the entire neural population. In fact, the direction of movement, either during movement preparation or movement execution,

can be approximately estimated using a "►population vector," the sum of the preferred direction vector of each recorded cell weighted by its firing rate change from baseline. These observations have been interpreted as an indication that the motor cortex in mainly involved in high-level movement representation in terms of spatial location of the hand. However, the activity of most of the cells in the motor cortex is also modulated by the posture of the arm [9] and by the movement dynamics [10]. Thus, the representation of both kinematic and dynamic features are likely to coexist in the motor cortex, as expected in a neural network implementing a coordinate transformation from a kinematic motor plan to dynamic motor commands.

# Reaction Time Task

## Definition

A class of experimental paradigms in which a response (a movement) occurs reflexively in response to the appearance of a sensory stimulus. Movement onset is usually defined either as the time a threshold in speed is exceeded or as the beginning of a burst of electromyographic activity, the latter criterion yielding smaller values. The reaction time is shorter in contrast to voluntary tasks in which the response requires the selection of a response goal that is dependent on other cognitive factors.

# Reactive Astrocyte

## Definition

When the cebtral nervous system (CNS) is damaged, inflamed or infected the astrocytes undergo a characteristic set of changes known as reactive gliosis. The cells may proliferate.

Morphologically they hypertrophy and generally put out more and longer processes. There are characteristic changes in the cytoskeleton with upregulation of GFAP, vimentin and nestin. The cells may secrete a range of cytokines and may express class II major histocompatibility complex (MHC) receptors.

After injury the cells may be neuroprotective, play a part in controlling inflammation and in resealing the blood-brain barrier.

### Synonyms

Electrocommunication; Electrical communication

### Definition

Every motor act that an animal produces will elicit sensory input from its own receptors [1]. Termed ►reafference, this self-generated sensory input can be quite useful. For example, bats listen to the echoes of their own ultrasonic calls to navigate through the night, and sensory feedback from skeletal muscles can be used to improve motor control. On the other hand, reafferent input is often not informative, and it can even interfere with the detection of external sensory input. A major problem faced by all animals is distinguishing reafferent sensory input from external sensory input. This issue is particularly relevant to the subject of animal communication. A communicating animal must produce its own signal as well as detect the signals produced by other individuals. A central question in the neurobiology of communication behavior is how sensory systems are able to discriminate self-generated from externally produced signals.

Consider the problem of reafference for visual perception. Any movement of the eyes, either directly or indirectly, due to movements of the head or body, causes the visual input to the retina to shift dramatically. How does the visual system compensate for this shift and maintain sensitivity to external visual stimuli? Early experiments suggested that every time a motor command that induces eye movement is issued, a copy of that command is also sent to the visual system, which generates a negative image of the visual input expected to result from that movement [1,2]. Combining this negative image with actual visual input eliminates any self-induced changes. As a result, the perceived visual world maintains its stability and only externally generated visual inputs are detected.

This basic mechanism relies on two distinct features. First, the timing of motor output must be relayed to the sensory system through what is referred to as a ►corollary discharge [2]. Second, the corollary discharge must activate a negative image of the reafferent input, a so-called ►efference copy [1]. Research on weakly electric fish has provided insight into the neuronal implementation of these two features [3,4].

### Characteristics

#### Quantitative Description

African mormyrid fish possess an electromotor system that generates weak electric signals from a specialized ►electric organ, as well as an electrosensory system for detecting these signals (Fig. 1a). This unique sensorimotor system serves two functions. Through ►active electrolocation, mormyrids are able to detect distortions in their own electric field caused by nearby objects and thereby locate and identify various features of those objects, as well as navigate through their environment. By sensing the electric signals generated by other

individuals, mormyrids are also able to communicate within the electric modality.

Electric signals in mormyrids consist of a fixed ►electric organ discharge (EOD) separated by a variable ►sequence of pulse intervals (SPI) (Fig. 1b). The EOD waveform conveys several aspects of the sender's identity, such as its species, sex, dominance, and possibly even its individual identity [5]. The total duration of the EOD is a particularly salient variable across species, ranging from as little as 100 μs to over 10 ms, and it may also exhibit sex- and status-related differences, with dominant males having a two- to three-fold longer EOD than females. By contrast, the SPI is involved in communicating contextual information about the sender's behavioral state and motivation. A variety of different patterns in the SPI have been linked with behaviors such as courtship and aggression [5].

In order for mormyrids to utilize the information available to them in these electric signals, however, they must first be able to distinguish their own EODs from those of other individuals. This distinction is made possible by a corollary discharge pathway that relays the timing of EOD production to central electrosensory regions (Figs. 1a and 2). By comparing incoming electrosensory information with an internal copy of their electromotor commands, they are able to distinguish their own electric signals from those of other nearby fish [4].

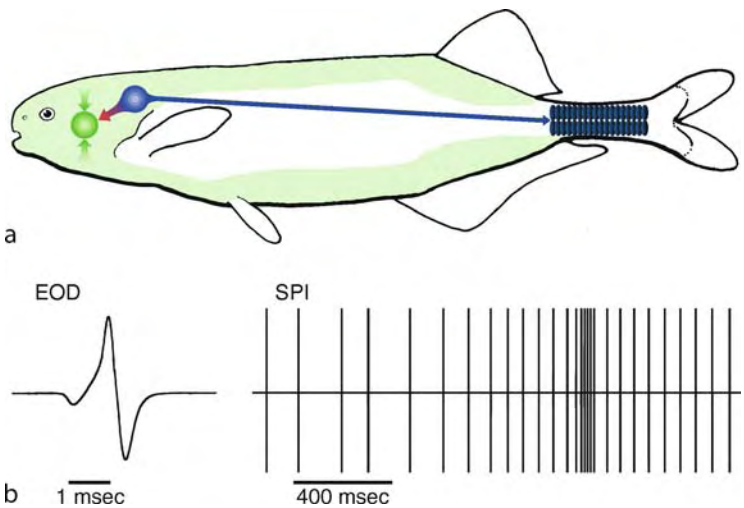
## Higher Level Structures

### *Electromotor Pathway*

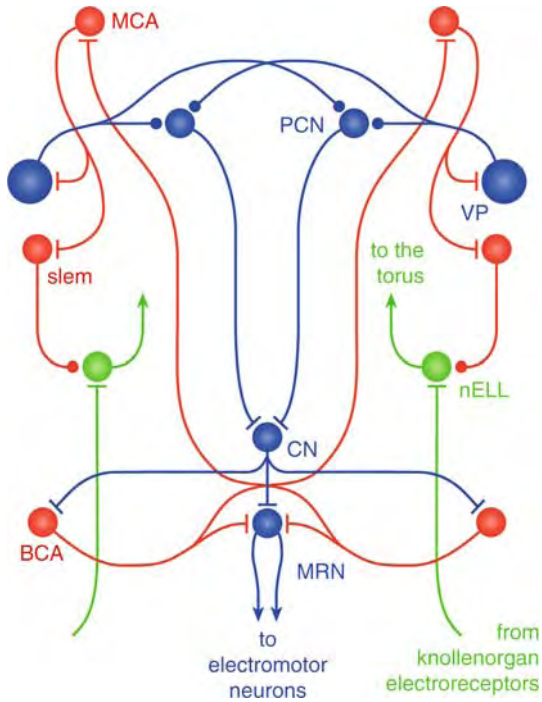
Each EOD is initiated by a group of neurons in the ventral hindbrain that together constitute the electric organ ►command nucleus (CN) [5]. The neurons in the CN project both directly and indirectly to an adjacent group of neurons that make up the medial relay nucleus (MRN). The neurons in the MRN receive the command from the CN and relay it down the spinal cord to electromotor neurons that drive the electric organ (Fig. 2). The activity in the CN, and therefore the SPI, is determined by a number of descending inputs, foremost of which is a precommand nuclear complex (PCN) consisting of two adjacent, but physiologically and anatomically distinct neuronal populations [5].

### *Electrosensory Pathway*

The electrosensory system of mormyrids consists of three distinct pathways, one of which is relevant for electric communication (Fig. 2). The primary sensory afferents in this pathway receive input from so-called ►knollenorgan electroreceptors, and project to a region of the dorsal hindbrain termed the nucleus of the electrosensory lateral line lobe (nELL) [6]. The neurons in the nELL relay this electrosensory input to a large midbrain structure termed the ►torus semicircularis, a sensory processing region considered homologous to the inferior colliculus of mammals.



**Reafferent Control in Electric Communication. Figure 1** (a) Schematic of the electric communication system in the mormyrid *Brienomyrus brachyistius*. The electric organ, shown in blue, is controlled by a command center in the hindbrain. Each descending command drives the production of a single electric organ discharge (EOD). External electric fields are detected by electroreceptors, whose distribution on the body surface is indicated by turquoise shading. Input from the electroreceptors converges onto an electrosensory region in the hindbrain, which also receives input from the electric organ command center. (b) Structure of electric signals in mormyrids. Head positive voltage is plotted upward. The electric organ discharge (EOD) has a fixed, characteristic waveform, while the pattern of EOD production, indicated by the sequence of pulse intervals (SPI), is variable.



**Reafferent Control in Electric Communication.**

### *Electric Organ Corollary Discharge Pathway*

The EOD command issued by the CN is relayed not just down the spinal cord to the electric organ, but also to higher brain centers that provide a precise timing reference of EOD production (Fig. 2) [3,5]. This electric organ corollary discharge (EOCD) pathway plays an important role in electric communication. For electrosensory processing in the knollenorgan pathway, it gives rise to an inhibitory input to the nELL that serves to block responses to reafferent electrosensory input (Fig. 2) [4]. In addition, the EOCD pathway helps regulate EOD production, as it projects to an electromotor region that provides inhibitory input to the PCN (Fig. 2). As a result, the region that drives the CN to fire is inhibited each time an EOD is generated. This negative feedback, referred to as recurrent inhibition, plays a critical role in controlling the SPI [5].

## Lower Level Components

### *Electric Organ*

The electric organ of mormyrids is located at the base of the tail and consists of a homogenous population of disc-shaped, modified muscle cells called ▶electrocytes (Fig. 1a) [7]. When they are activated in synchrony by input from spinal electromotor neurons, their individual electrical potentials summate and give rise to the EOD, the amplitude of which is typically a few volts. Differences in the EOD waveform across species and between the sexes are directly related to variations in electrocyte morphology [7].

### *Electroreceptors*

The knollenorgans involved in electric communication typically contain a few receptor cells that are housed together within a single large capsule [8]. Knollenorgan receptors are broadly tuned to the spectrum of the species-specific EOD and are extremely sensitive, with thresholds as low as 0.1 mV. In response to outside positive-going voltage steps, they fire a single spike at a short fixed latency. This phase-locked activity is relayed by primary sensory afferents to the nELL.

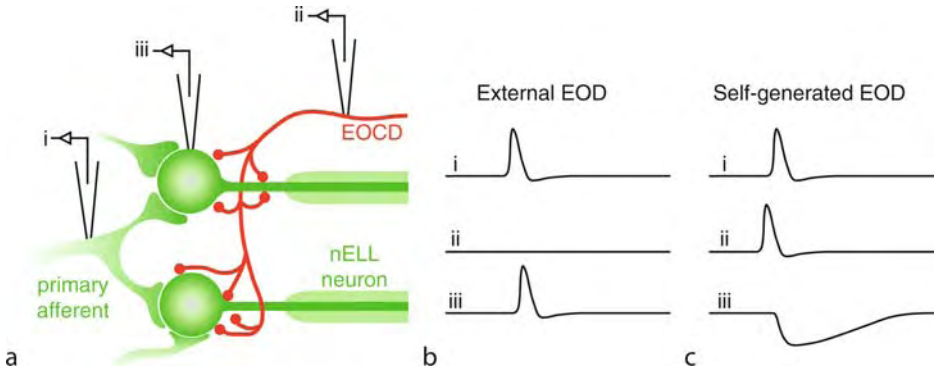
### *Specialized Features of Time-Coding Circuitry*

The electromotor and electrosensory pathways of mormyrids are characterized by several unique anatomical specializations. Both pathways contain high levels of calcium-binding protein and consist of large, spherical, adendritic cell bodies that give rise to thick, heavily myelinated axons. Synapses in both pathways are typically mixed chemical-electrical, and often form large terminals that envelope a significant portion of the postsynaptic soma. Unlike most brainstem nuclei that occur in bilateral pairs, the CN and MRN form unpaired, midline nuclei. All of these features have been associated with neural circuits in which spike timing precision is of the utmost importance [9]. For the electromotor system, this precision is critical for activating the electrocytes in synchrony and thereby maintaining a constant EOD waveform. For the electrosensory system, it is involved in accurate temporal coding of the EOD waveform.

## Higher Level Processes

### *Distinguishing Self-Generated EODs from External EODs*

Knollenorgan receptors respond equally to any EOD that is above threshold, whether it is generated by the fish's own electric organ or that of another fish. In both cases, primary knollenorgan afferents generate a single spike that gives rise to an excitatory input to nELL [4]. However, the neurons in nELL also receive inhibitory input from the EOCD pathway [4], which causes the nELL neurons to respond quite differently to self-generated and external EODs (Fig. 3).



**Reafferent Control in Electric Communication. Figure 3** Corollary discharge-mediated inhibition of reafferent electrosensory input in the nucleus of the electrosensory lateral line lobe (nELL). (a) Primary knollenorgan afferents form large, excitatory, mixed chemical-electrical synapses onto the soma of large, adendritic spherical nELL neurons. The electric organ corollary discharge (EOCD) pathway also provides inhibitory input onto the soma and initial segment of nELL neurons. (b) Patterns of activity recorded from the electrode locations shown in (a) in response to an external EOD. (c) Patterns of activity recorded from the electrode locations shown in (a) in response to a self-generated EOD.

When knollenorgan afferents respond to an external EOD, the EOCD pathway is not active. As a result, the nELL neurons only receive the excitatory afferent input, which they relay to the midbrain (Fig. 3b). By contrast, when the fish generates its own EOD, the EOCD pathway also becomes active, providing inhibitory input to nELL neurons. This inhibition blocks the response of nELL neurons to afferent electrosensory input (Fig. 3c), and the signal therefore does not get relayed to the midbrain [4]. As the reafferent input for this system is simply a brief excitation, the corollary discharge-driven efference copy is simply a brief inhibition.

### *Temporal Coding of the EOD Waveform*

The EOD of a neighboring fish will cause current to flow into one half of the body surface and out the other, meaning that knollenorgans on these two surfaces will be exposed to opposite stimulus polarities. As knollenorgans only respond to positive-going voltage steps, those located where current is entering the skin respond to the rising edge of the stimulus, while those located where current is exiting the skin respond to the falling edge. Thus, by comparing spike times from opposite sides of the body, a mormyrid can, in principle, determine the duration of the EOD waveform [6].

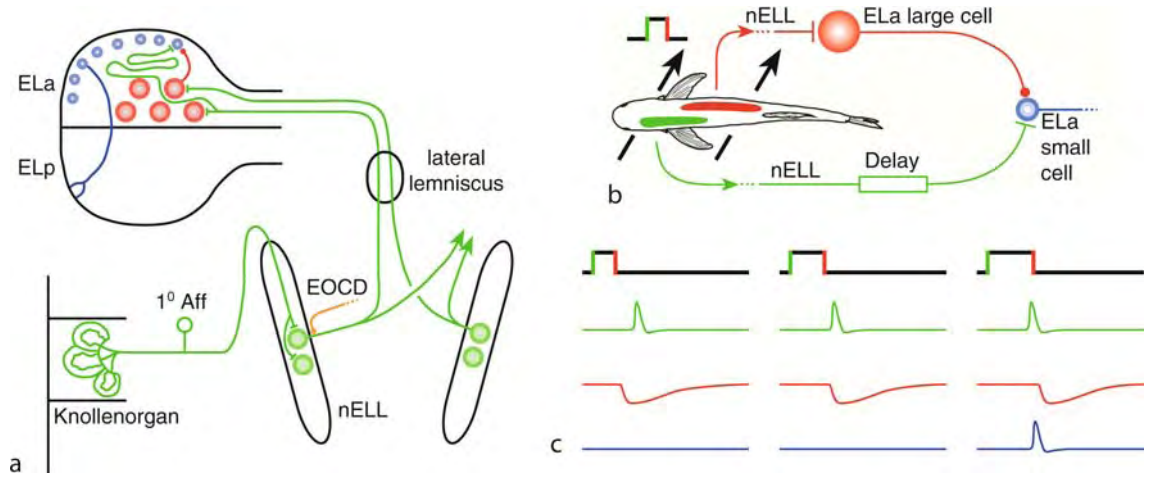
A primary projection site of nELL axons is the anterior exterolateral nucleus (ELa) in the torus semicircularis (Fig. 4a). Within the ELa, there are two distinct types of neurons, large cells and small cells, both of which receive excitatory input from nELL axons. Upon entering the ELa, the nELL axons immediately terminate onto 1 or 2 large cells, and then wind their way throughout the nucleus over distances of 3 to 4 mm before branching and terminating onto a large number of small cells [6]. The large cells project exclusively within the ELa, terminating on small cells with large inhibitory synapses [6]. Thus, the small cells receive phase-locked input from two different sources: excitatory input from nELL axons and inhibitory input from ELa large cells (Fig. 4b). However, the excitatory input is significantly delayed by the time it takes an action potential to propagate down the long, winding path of the nELL axon, suggesting an "anti-coincidence detection" model for comparing spike times from knollenorgans on opposite sides of the body [6].

As an example, the small cell shown in Fig. 4b receives delayed excitatory input in response to stimulus onset and inhibitory input in response to stimulus offset. For short duration stimuli, this delayed excitatory input will arrive during the inhibition, and the small cell will not fire (Fig. 4c). As stimulus duration increases, however, there will be a greater delay before the inhibitory input reaches the small cell. If the duration is long enough such that the delayed excitatory input arrives before the inhibitory input, then the small cell will fire (Fig. 4c). Thus, a given small cell will only respond to EODs that are longer than some threshold duration. Assuming that different small cells receive input from nELL axons of varying delays, each small cell will have a different threshold value, and EOD duration will be reflected in the total number of active small cells [6].

## Function

### *The Reafference Principle*

Dealing with reafferent sensory input is a problem faced by all animals [1]. In the communication system of mormyrid electric fish, this problem is solved by a very simple, yet effective solution: incoming sensory input is blocked by inhibition every time the fish produces a



**Reafferent Control in Electric Communication. Figure 4** Model of EOD waveform discrimination in mormyrids. (a) Neuroanatomy of the knollenorgan pathway. Excitatory connections are indicated by flat lines, inhibitory connections by solid circles. Primary afferents from knollenorgans project ipsilaterally onto the nucleus of the electrosensory lateral line lobe (nELL), which also receives inhibitory input from the electric organ corollary discharge pathway (EOCD). Axons from nELL ascend through the lateral lemniscus to project bilaterally to the anterior exterolateral nucleus (ELa) of the torus semicircularis, first onto large cells, then after winding throughout the nucleus, onto small cells. The large cells provide inhibitory input to the small cells. The small cells project ipsilaterally to the posterior exterolateral nucleus (ELp). (b) Schematic diagram showing the inputs to the small cell shown in (a) in response to a transverse square pulse. The ipsilateral side responds to the pulse onset, providing delayed excitatory input to the small cell, while the contralateral side responds to the pulse offset, providing inhibitory input to the small cell. c, Responses of the small cell shown in (b) to square pulses of varying duration. The green traces show the excitation provided by the nELL axon, while the red traces show the inhibition provided by the large cell. The blue traces show the resulting output of the small cell.

signal. Thus, the fish only senses the electric signals produced by other individuals. Recent studies have shown that this same strategy is used by singing crickets to block auditory responses to their own song [10]. Thus, corollary discharge-driven inhibition may be a widespread solution to dealing with the problem of reafference.

However, reafferent stimuli may often be much more complex, and the temporary blanking of responses afforded by simple inhibition may not be an effective solution. The earlier description of the effects of eye movement on visual processing is an illustrative example. Rather than brief excitation, the reafferent input in this case is a complex pattern of excitation and inhibition across many neurons over time, which is dependent on the specific eye movement undertaken. It is not sufficient to simply block incoming visual input during any movement, because this would result in complete blindness. In this case, rather than simple inhibition, the corollary discharge activates a spatiotemporally complex efference copy that cancels out the sensory input arriving from each portion of the visual field in response to the movement [1].

For active electrolocation in mormyrids, the fish's own EOD is the signal of interest, while those of other individuals constitute noise. Not surprisingly, then, the EOCD pathway provides excitatory, rather than inhibitory, input to the electrosensory pathway involved in active electrolocation and thereby facilitates reafferent sensory input [3]. However, much of this input is not informative, as it signals the presence of unchanging, or predictable, environmental features. In contrast to the hard-wired inhibition provided to the knollenorgan pathway, this corollary discharge-driven excitatory input can be altered through experience so that expected sensory input is nullified and only novel, informative input gets through [3]. This system provides an example of a modifiable efference copy, one that may be adjusted to compensate for changes in the sensory consequences of motor production.

### *Temporal Coding*

Early research on electric communication in mormyrids focused on the SPI, because it was assumed that the EOD acted simply as a carrier signal for information encoded in a temporal pattern. The reasoning behind this was that EODs must be too brief to transmit any information. However, field recordings from mormyrids in the field revealed incredible species-specific diversity in the EOD waveform, as well as sex differences in many species [5]. Playback experiments in the field later demonstrated that these differences

were behaviorally significant. In particular, EOD duration, or the relative timing of positive and negative voltage deflections were especially important [6]. These experiments therefore demonstrated that EOD recognition was mediated by a temporal code. In this chapter, we have seen a remarkable, yet simple, example of how the information contained within such a temporal code may be extracted through dedicated neuronal circuitry.

# Realism (Metaphysical, Internal, Common Sense, Naïve, Scientific)

Alexander Staudacher
Otto-von-Guericke-Universitaet Magdeburg, Institut für Philosophie, Magdeburg, Germany

## Definition

Realism is a metaphysical position concerning the status of objects, facts and properties which can be of the most different kinds. One may be a realist concerning objects in space and time like trees, rocks, and molecules, concerning abstract objects like numbers or values, properties like being red or facts like the fact that the earth is round. What does realism with respect to one or more of these types of items amount to? Unfortunately there is no shared view among the experts in the field as to how realism is best defined. The question is especially disputed among adherents of the various brands of realism and their critics, the so-called anti-realists. According to the definition shared by most (but not all) philosophers considering themselves realists, realism with respect to a certain item implies the following two claims: First, *the existence claim (EC):* The items in question exist. Secondly, *the independence claim (IC):* The items in question are neither themselves something mental (mere ▶ideas or representations) nor is their existence in any way dependent on whether we represent them (that is, perceive them or think of them) in a particular way or not. If you believe, for example, that the earth exists independently of whether there is a being with mental states able to represent it then you are a realist about the earth. Realism is often restricted to certain types of items: one may be a realist concerning physical objects in space and time without being a realist concerning moral values. According to the two defining claims one might dispute realism concerning a certain item in two ways: by denying either (EC) or (IC). For example, realism about moral values can be denied either by denying that there are any such values in the first place or by admitting their existence but taking it to be completely dependent on our ability to devise such values.

According to the alternative definition put forward by anti-realists realism is not so much a theory about the nature of objects, facts or properties but a doctrine concerning the question of how the truth of sentences is best understood. The relevant conception of truth implies that truth is verification-transcendent, that is, a sentence might be true although we don't have the slightest possibility to find out that it is true. Anti-realists use this definition to criticize realism, because they take the verification-transcendent conception of truth to be at odds with their preferred accounts concerning the question of what is implied when a speaker understands a proposition [1]. Realists have objected to this characterization of their position that they see no need to commit themselves to any substantial notion of truth whatsoever by endorsing (EC) and (IC) [2]. This essay will therefore follow the first definition.

## Description of the Theory

Realism cannot only be held with respect to different items, it can also be formulated with varying strength. These variations in strength are mainly due to the fact that (IC) can be interpreted in various ways. According

to the strongest reading, (IC1), the items in question exist independently whether *any* mind (not only human minds but also more powerful minds) has even the *ability* to represent them. It is then not only possible that there are items with nobody represented at a certain time but with could have been represented in principle, as was probably the case with the earth one billion years ago, but that there might even be items which lie completely outside of any representational power. A somewhat weaker reading, (IC2), would restrict this claim to human minds. Still, the world might contain many items we will not even have the possibility to form a conception of just as a chimpanzee is unable to form a conception of an electron [3]. In this sense our conception and a fortiori our knowledge of the world might always be limited and partial even if we lack the slightest evidence to suppose that they are limited and partial in that way. A considerably weaker reading, (IC3), would allow that there are many items we have never represented and we will never be able to discover but could at least form a conception of, so that we could at least speculate about their existence. A still weaker reading, (IC4), would allow that there are many items we have never represented but could have represented and would have been able to discover. The weakest reading, (IC5), only allows that the items in question can exist independently of whether someone actually represents them, but not independently of whether we can discover them or not.

The last three readings all make items in the world dependent in a certain way on our abiliy to represent them. Therefore, one might argue that they are too weak to convey the idea of independence which is inherent in realism. Realism is generally contrasted with ▶idealism which holds that everything is in some sense dependent on our minds. True enough, there are forms of idealism which even contradict the weakest reading as it is the case with the idealism of Bishop Berkeley (1685–1753), who identified the existence of things with their actually being perceived. But there are many less radical forms of idealism (laying their emphasis on different kinds of *dependence* of the world of our mind or our representational capacities) which are compatible with these two readings. Note also, that the last two readings atleast don't allow for a verification-transcendent notion of truth, because they imply that truths about the world have to be discoverable by us. Therefore, they would also fail to count as reconstructions of realism according to the second, anti-realist definition of realism. This explains why the term "realism" is generally associated with the stronger readings, but as will become clear below, Hilary Putnam's ▶internal realism forms a notable exception.

The first two readings allow for insurmountable ignorance about parts of the world and the first three allow for certain kinds of radical error concerning parts of the world we have a conception of. It is not only possible that we err simply in mistaking something green for something blue or something spherical for a flat disc, we might even err in ascribing whole classes of properties to things that don't possess. In this case, the concepts we make use of in our characterizations of the world (our "conceptual schemes") don't correspond to the internal structure of the world: we take the world to be coloured in the way it appears to our eyes, but it might be that in fact nothing is coloured in that sense. In fact, science tells us that the surfaces of tomatoes aren't red in the way they appear red to our eyes, but that this appearance is largely due to the structure of our perceptual apparatus [3]. If science is right about these matters that we can say that it gives a more adequate picture of the world as it is than our everyday view. Considerations like these lead to interesting consequences concerning the question of how to deal with competing conceptions of reality which are not compatible with each other: According to realism there is a fact of the matter, how the world is. Therefore, either one of them will get closer to the true story about the world or both will fail in this attempt. Consequently, realism is opposed to various forms of relativism according to which truth and knowledge have to be relativized to culture, historical epoch, conceptual schemes and the like. Competing claims concerning the shape of the earth might then be correct relative to their specific cultural, historical and conceptual context and there might be no fact of the matter beyond these contexts allowing us to ask whether a claim, a theory or a conceptual scheme is correct or not. In contrast with these claims realism allows us to hold that the replacement of one theory or conceptual scheme by another scheme may be interpreted as progress in our endeavour to gain a picture of the world as it is independently of any of our representations of it.

Furthermore, there might be possibilities of large-scale error which open the door for certain notorious sceptical scenarios: the stronger versions of (IC) seem to allow that we could even be wrong about reality as a whole. Accordingly, it might be the case that we are always dreaming or, to cite another famous example, we might be all brains in vat filled with a nutritient and supplied not with real information about the world but only with hallucinations induced by a super-computer connected to us by nefarious neuroscientists [2,3] And considering that our revisions of our former world views also have to be couched in our conceptions of the world we can ask again whether these tensions will tell us the true story about the world as it really is [3]. In this sense realism leads to the consequence that all our epistemic accomplishments are in different respects fallible. Therefore a sceptical position which puts into doubt whether we will ever be able to gain knowledge about the world could possibly be true. A strong enough

realism seems even to be one of the central presuppositions needed in order to make these kinds of sceptical hypotheses intelligible in the first place. Most philosophers supporting such a strong kind of realism don't embrace scepticism, however. The fact that we have to admit the possible truth of scepticism should not be confounded with the fact that we have to take it seriously [2]. To the contrary, realists typically hold that they have the best explanation of how knowledge and scientific progress are possible inthe first place.

"►Metaphysical realism" is often used as a name for the kind of realism based on stronger readings of (IC) like (IC1) and (IC2). The term was originally coined by Hilary Putnam who refuses this kind of realism, because he takes the idea that a conception or theory of the world might be wrong, although it fulfilling all our predictions and following all our methodological constraints (coherence, elegance, simplicity etc.) to be incoherent. Additionally he has argued that metaphysical realism has to give up a commitment not only metaphysical realists would like to subscribe to: the claim that our representations of items in the world are connected with these items in a way which gives them a definite reference (e.g., that the concept "cat" refers to cats and not to rats) [4].

Internal realism is Putnam's alternative to metaphysical realism and can be characterized roughly by following two claims: (IR1) A description of the world is true if it can be justified under epistemically ideal conditions. A description is justified if it is internally coherent and can be in principle verified, so that it is at least in principle possible for us to detect its truth. This implies that its truth does not consist of a kind of correspondence to facts in the world which are completely independent of our way of conceiving them and which might be completely inaccessible to us. (IR2) We have to acknowledge a certain kind of conceptual relativity according to which questions as to what kinds of objects there are or how many there are can't be answered independently of the choice of a certain conceptual framework. If someone asks for example "How many objects are in this room?" the right answer depends on certain decisions concerning our concept of "object." If we admit as objects only things which are not attached to other things my nose or a lampshade will not count as objects, if we do without this restriction, they will. In this sense there is no fact of the matter of how many objects are in the room which is independent of our concept of an object [4,5].

Conceptual relativity puts internal realism close to relativism. Putnam has emphasized, however, that internal realism is to be distinguished from relativism which he takes as holding a wrong conception of truth and considers even to be self-refuting. In his eyes, relativists typically their truth to mere rational acceptability. Therefore, according to relativism, the claim of the ancients that the earth was a flat disc was true at their time (although false today) because it was rationally acceptable in light of the available methods of investigation and evaluation at that time (but not in the light of the methods available today). However, the claim was not *ideally* rationally acceptable even at that time, because the conditions of verification were not ideal. A claim may lose its rational acceptability over time, but it can not lose its ideal rational acceptability. Relativism is self-refuting because in claiming its own absolute truth it exempts itself from the claim that all truths have to be relativized to certain historical conditions, conceptual schemes and so on [4].

Internal realism obviously only allows for weak readings of (IC) such as (IC4) and (IC5) because it takes the existence of the relevant items to be dependent on our conceptual resources and decisions and our ability in principle to verify what is the case. It can allow the existence of a certain rock in the desert even if it isn't represented by anybody at any time. But the existence of rocks remains relative to the fact that we have the concept of a rock. It can also admit that there might be facts (e.g., in the past) we are not able to verify. But it can't allow the possibility that reality might be a certain way if we can't verify this under ideal conditions. Therefore, one might ask whether internal realism should be seen as a form of realism at all. It is no wonder that many have seen internal realism as a form of anti-realism [2].

Critics of internal realism have questioned among other things (i) whether it can be successfully distinguished from relativism [6], (ii) whether the specific examples Putnam gives of conceptual relativity cannot be accommodated within metaphysical realism, so that they don't conflict with the claim that there are facts which are completely independent of our conceptual schemes [6], and (iii) whether ideal rational acceptability makes truth really accessible to us Putnam himself admitting that we can never tell whether we have reached ideal conditions and comparing this kind of idealization in question with unattainable idealizations such as frictionless surface. More recently Putnam himself has given up the claim that truth can be explained as idealized rational acceptability [7].

It is often assumed that realism with respect to spatio-temporal objects like rocks, chairs, etc., is a view dictated by common sense and held independently of any sophisticated knowledge about philosophical matters by "the plain man or woman on the street." Realism of this kind is therefore often called "►common sense realism." Since common sense isn't a developed philosophical doctrine it is not easy to decide to which reading of (IC) common sense realism is committed to. Arguably, common sense is not sophisticated enough to make the necessary distinctions required for any decision on these matters. Note,

however, that philosophers with wildly diverging views also use this label for their own account of realism [2,7].

►Naïve realism is often taken to be a position quite similar to common sense realism. In philosophical debates on perception Naïve realism is often taken to be a view according to which perception presents us the world by and large as it really is. For example, things not only appear to us as coloured (because of the specific nature of our perceptual apparatus) they really *are* coloured.

►Scientific realism is a theory concerning the correct understanding of theoretical terms in scientific theories. Scientific theories make intensive use of theoretical terms like "molecule" "atom," "electron" and the like which don't refer to observable phenomena but play an indispensable role in the scientific explanation of such phenomena. We may say that with the help of these terms respective theoretical entities have been introduced into the scientific theory in question: molecules, atoms, electrons and so on. The behaviour of the observable phenomena is explained with the help of certain claims about the behaviour or state of these theoretical entities. The fact that water begins to boil at sea-level at 100°C is for example explained with the help of claims concerning the properties and the behaviour of $H_2O$-Molecules. Because theoretical entities like molecules or atoms are not among the things which can be observed, the question arises as to whether we ever have any good reason to believe in their existence and to accept the respective claims about their properties and their behaviour as true. Scientific realism gives an affirmative answer to these questions. According to one of its classical formulations [8] we have to interpret theoretical terms as putatively referring expressions and we often have enough reason to accept claims containing such terms as at least approximately true. Furthermore, we can see scientific progress as a steady approximation toward the truth of the observable and the unobservable. The reality described by scientific theories is largely independent of our thoughts and theoretical commitments. Therefore, we can say that we not only introduce theoretical terms in order to facilitate empirical predictions and the organization of our observation-knowledge, we also discover that there are molecules and electrons etc. In this sense scientific realism clearly endorses (EC) and a strong version of (IC), although the precise strength is often left open because the discussion concentrates more on whether theoretical entities are claimed to exist at all. One of the main arguments put forward in favour of this position is based on the claim that we can only plausibly explain why scientific theories have the predictive success they have if we suppose that the theoretical claims referring to theoretical entities are approximately true [8,2]. A classical objection to this claim is the historical observation that theories can be predictively successful although they are largely wrong [9]. A further general objection to scientific realism is that it cannot deal with the fact that two successful theories with commitments to different theoretical entities might lead to the same empirical predictions. It is argued that in such cases there is no evidential basis allowing a decision between these theories. If theoretical statements can be literally true, however, as Scientific Realism would have it, such a decision must be possible in principle. Against this, Scientific Realists have argued that we should allow for a conception of evidential support that is not restricted to positive outcomes concerning prediction [8]. Sometimes scientific realism is and to imply a further claim which puts it into strong opposition to naïve realism or common sense realism. If there is, e.g., an irreconcilable collision between the common sense view of physical objects as continuous solids and the scientific view that they are swarms of molecules, the commitment to the existence of the theoretical entities of science demands that we give up our naïve and common sense views concerning the nature of reality [10].

# Reality Monitoring

## Definition

Reality monitoring is defined as the ability of distinguishing between external memories (e.g., those of events directly perceived or actions actually

performed) and internal memories (e.g., those of events imagined or actions planned or intended to perform).

►Metacognition

## Realization

### Definition

Mental properties, although not identical to physical properties, are still said to be physical properties in a broad sense in virtue of being realized by physical properties, just as a machine table, for instance, is implemented by but not identical to the states of its physical implementation. A central idea is that if property F realizes property G, then G is not something distinct from or something over and above F. Unlike identity, realization is asymmetric: F realizes G only if the instantiation of F in o necessitates or determines the instantiation of G in o but not vice versa, where the necessity in question is at least nomological necessity.

►Epiphenomenalism

## Reasoning

Markus Knauff
Center for Cognitive Science, University of Freiburg, Freiburg, Germany

### Definition

Reasoning is a process of drawing inferences from information that is taken for granted. Formal reasoning is within the scope of mathematics and philosophy. It is the study of inferences whose validity only derives from its formal structure. Mental reasoning is a function of the human brain. It comes into play whenever people go beyond what is explicitly given. It is the cognitive activity to infer that something must be true, or is likely to be true, given that the known information is true. The problem information is given by a number of statements which are called ►premises, and the task is to find a ►conclusion that follows from these premises. The following inference is a typical reasoning problem:

If a patient's left hemisphere is damaged, then he has impaired reasoning abilities.
Alan's left hemisphere is damaged.

- - - - - - - - - - - - - - - - - - - - - - - - - -

Therefore, Alan has impaired reasoning abilities.

Although the premises (above the line) do not say anything about Alan's reasoning abilities, most people immediately agree with what is stated in the conclusion (below the line). The conclusion necessarily – logically – follows from the premises. Another inference is given in the following example.

Mammals have a nervous system.
Birds have a nervous system.
Fishes have a nervous system.

- - - - - - - - - - - - - - - - - - - - - - - - - -

All animals have a nervous system.

Although a reasoner might form the belief that the conclusion could be true, the premises do not warrant the truth of the conclusion. The reasoner is generating the ►hypothesis that the conclusion is true. The former inference is an example of ►deductive reasoning, while the latter is an instance of ►inductive reasoning.

### Characteristics

#### Deductive and Inductive Reasoning

Mental deductive reasoning is strongly related to formal logic. The latter serves as the normative model for the former (a critical assessment of this account from a neuroscience perspective can be found in [1]). To explore deductive reasoning in the psychological laboratory, people are typically asked to draw conclusions from given premises and later their responses are evaluated for logical validity. This evaluation is based on logical correctness only and does not account for the content of the statements (the deductive inference above is logically valid, although the content concerning the role of the left hemisphere is probably wrong; see below). In ►conditional reasoning, the premises of the problem consist of an "if A then B" construct that posits B to be true if A is true. The two logically valid inferences are the Modus Ponens (if p then q; p; q, MP) and the Modus Tollens (if p then q; not-q; not-p, MT). Humans are pretty good in making inferences of the form MP, but they make many mistakes in the form MT [2], In ►syllogistic reasoning, the premises of the problem consist of quantified statements such as "All A are B," "Some A are B," "No A are B," and "Some A are not B." People often make many mistakes in syllogistic reasoning, in part because of the existence of a variety of biases [2]. The most frequently used sort of inferences in daily life (and in the psychological lab) are based on relations. In ►relational reasoning, at least two relational terms

A $r_1$ B and B $r_2$ C are given as premises and the goal is to find a conclusion A $r_3$ C that is consistent with the premises. The relations represent spatial (e.g., left of), temporal (e.g., earlier than), or more abstract information (e.g., is akin to). People are pretty good in making such inferences, but the difficulty depends on the number of premises, the order of terms and premises, the content, and the ease to envisage the content of the problem [3,4]. Moreover, in cases where a reasoning problem has multiple solutions, reasoners consistently prefer the same subset of possible answers – and often just a single solution [5].

Inductive reasoning has not as much to do with logic because the conclusion goes beyond the information given in the premises. The premises only provide good reasons for accepting the conclusion. Thus, inductive reasoning is not truth-preserving but it is the most important basis of our ability to create new knowledge. This new knowledge is often based on a limited number of observations from which we formulate a law recurring to a set of phenomenal experiences. Cognitive theories of induction typically describe it as a process in which hypotheses are generated, selected, and evaluated [6,7]. Although there is no generally accepted definition of the term "induction," the majority of psychologists adopt the very broad definition that mental inductions are "all inferential processes that expand knowledge in the face of uncertainty" [6, p. 1]. Given that almost nothing is known about the neural basis of inductive reasoning this review is restricted to deductive reasoning. An easily accessible summary of behavioral findings on inductive reasoning can be found in Manktelow [8]. The main problems of research on inductive reasoning are summarized in Sloman and Lagnado [9].

## Cognitive Theories of Reasoning

There are two main theories of deductive reasoning. They differ in the postulated underlying mental representations and the computational process that work on these representations. In one theory, it is believed that people think deductively by applying mental ►rules which are similar to rules in computer programs. In the other theory, deductive reasoning is conceived as a process in which the reasoner constructs, inspects, and manipulates ►mental models. The ►rule-based theory is a syntactic theory of reasoning, as it is based on the form of the argument only, whereas, the ►mental models theory is a semantic theory, because it is based on the meaning (the interpretation) of the premises.

The ►rule-based theories are primarily represented by the work of Rips [10] and Braine and O'Brian [11]. These theories claim that reasoners rely on formal rules of inference akin to those of formal logic, and that inference is a process of proof in which the rules are applied to mental sentences (but cf. Stenning and Oberlander [12]). The formal rules govern sentential connectives such as "if" and quantifiers such as "any," and they can account for relational inferences when they are supplemented with axioms governing transitivity, such as: For any a, b, and c, if a is taller than b and b is taller than c, then a is taller than c. The rules are represented in the human brain and the sequence of applied rules results in a mental proof, or derivation, which is seen as analogous to the proofs of formal logic [10].

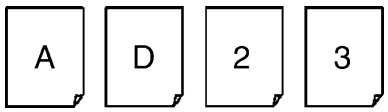
The ►theory of mental models has been developed by Johnson-Laird and colleagues [13–15]. According to the model theory, human reasoning relies on the construction of integrated mental representations of the information that is given in the reasoning problem's premises. These integrated representations are models in the strict logical sense. They capture what is common to all the different ways in which the premises can be interpreted. They represent in "small scale" how "reality" could be – according to what is stated in the premises of a reasoning problem. The model theory distinguishes between three different mental operations. In the construction phase, reasoners construct the mental model that reflects the information from the premises. In the inspection phase, this model is inspected to find new information that is not explicitly given in the premises. In the variation phase, reasoners try to construct alternative models from the premises that refute the putative conclusion. If no such model is found, the putative conclusion is considered true [14].

## Reasoning and the Brain

The two reasoning theories are related to different brain areas. The rule theory implies that reasoning is a linguistic and syntactic process, and so reasoning should depend on regions located in the left hemisphere. The model theory, in contrast, postulates that a major component of reasoning is not verbal, and so the theory predicts that the right cerebral hemisphere should play a significant role in reasoning [16]. More detailed predictions are related to specific brain areas. Here the rule theory assumes that the neural computations during reasoning are implemented in the language processing regions and here specifically in the temporal cortex, while the model theory predicts that the parietal and occipital cortical areas involved in spatial working memory, perception, and movement control are evoked by reasoning [17]. The lateralization of the reasoning process has been primarily investigated in patient studies, while brain imaging techniques allow for a more detailed localization of reasoning processes.

### *Patient Studies*

Early studies of patients with brain-damages seemed to support the rule-based theories of reasoning. Conditional reasoning has been studied by Golding [18]. The author used the Wason-Selection-Task, which is probably the most important paradigm in behavioral research on human reasoning [19]. In the task, four



**Reasoning. Figure 1** The Wason selection task.

cards are presented to the participants (see Fig. 1) and they are instructed to verify the rule "If there is a vowel on one side of the card, then there is an even number on the other side." The participants are allowed to turn over the cards in order to verify the rule. The visible letters and numbers on the card correspond to the four possible propositions p, not-p, q, and not-q. According to the propositional calculus of formal logic the only correct choices are p (according to the MP a q must be on the other side) and not-q (according to the MT a not-p must be on the other side). However, only one of the left-hemisphere-damaged patients but half of the right-hemisphere-damaged patients selected the two correct cards. Deglin and Kinsbourne [20] studied syllogistic reasoning with psychiatric patients while recovering from transitory ictal suppression of one hemisphere by electroconvulsive therapy (ECT; that simulates a short-term lesion). The premises were familiar or unfamiliar and true or false. When the right hemisphere was suppressed, the participants tended to perform deductive inferences even when the factual answer was obviously false. While their left hemisphere was suppressed, the same participants used their prior knowledge and if the content was unfamiliar they completely refused to answer. Patient studies on relational reasoning have been reported by Caramazza et al. [21] and Read [22]. Caramazza et al. [21] presented relational premises such as "Mike is taller than George" to brain-damaged patients. After reading the statements they had to answer either a congruent ("Who is taller?") or incongruent ("Who is shorter?") question. The left-hemispheric patients showed impaired performance in all problems no matter they were congruent or incongruent. Right-hemispheric patients, in contrast, showed impaired performance only in the incongruent problems. Read [22] used two relational premises and asked patients who suffered from temporal-lobectomy to generate a conclusion from these statements. Overall, the left-hemispheric patients again performed weaker than the patients with right-temporal-lobectomy, but the right-hemispheric patients were more impaired with the incongruent conclusions.

The reported findings have been frequently used by neuroscientists to support the idea that reasoning is mainly a linguistic and syntactic process, but this interpretation seems awkward to many cognitive oriented reasoning researchers. Although lesions to the left hemisphere might result in a deficit in the processing of the linguistic elements of the problem and, thus, impair overall performance, it does not necessarily follow that the damage will also affect the reasoning process. It is likely that left-hemisphere lesions lead to an inability to process the linguistic aspects of a reasoning problem, but that for the pure reasoning process the right hemisphere is important. This interpretation would also explain most of the findings. For instance, in the studies by Caramazza et al. [21] and Read [22] the patients had problems in logically deducing the converse of relations. Moreover, Whitaker et al. [23] examined conditional reasoning in patients that had undergone a unilateral anterior temporal lobectomy, one group to the right hemisphere and the other group to the left hemisphere. The content of the problems was related to the participants' prior knowledge of the world. Given the premises

If it rained, the streets will be dry.
It rained.

The right-hemisphere-damaged patients had a strong tendency to conclude "The streets will be wet" while the left-hemisphere-damaged patients concluded "The street will be dry." In other words, these right-hemispheric patients were unable to perform the deduction in isolation from their prior knowledge, while the left-hemisphere patients relied on the linguistic content of the problem.

### *Brain Imaging Studies*

Brain imaging studies have been conducted on all the main types of deductive inferences. As with the patient studies the early findings have been frequently interpreted in favor of the rule-based theories of reasoning, as they have shown that reasoning activates a fronto-temporal neural network often just in the left hemisphere [24,25]. However, more sophisticated experimental paradigms suggest this might be due to the confounding of linguistic processing and deductive reasoning. Knauff et al. [17] studied conditional reasoning problems by presenting premises such as "If the teacher is in love, then he likes pizza" to the participants. In half of the problems the second premise was "The teacher is in love" and the participants had to conclude (by MP) "The teacher likes pizza." In the other half of problems the second premises was "The teacher does not like pizza" and the participants had to conclude (by MT) "The teacher is not in love." Both types of problems activated a bilateral occipito-parietal-frontal network, including parts of the prefrontal cortex and the cingulate gyrus, the superior and inferior parietal cortex, the precuneus, and the visual association cortex. These finding are difficult to explain based on purely linguistic processes, as the activated brain areas are implicated in the processing of visual and spatial information and visuo-spatial working memory (→) (cf. [26–28]). Similar findings have been reported from a study on syllogistic reasoning. Goel et al. [29] used problems with semantic content (e.g., "All apples are red; all red fruit are sweet; therefore all apples are sweet") and

without semantic content (e.g., "All A are B; all B are C; therefore all A are C"). They found evidence for the engagement of both linguistic and spatial systems. The role of linguistic and spatial systems has been largely investigated by means of relational reasoning problems. In the study by Knauff et al. [30] such problems activated similar brain areas as the conditional problems did. However, the activity in visual association areas was even higher than during conditional reasoning. Goel and Dolan [31] addressed the question by using sentences with a spatial content. They again were either concrete (e.g., "The apples are in the barrel; the barrel is in the barn; therefore the apples are in the barn") or abstract (e.g., "A are in B; B is in C; therefore A is in C"). They reported that all problems activated a similar bilateral occipito-parietal network no matter if they were concert or abstract.

## Reasoning and Visual Mental Imagery

Many of the reported experiments seem to support the model theory of reasoning. However, it is essential not to confuse mental models with visual images (→) [32,33]. Visual images are structurally similar to real visual perceptions, and can represent objects, their colors and shapes, and the metrical distances between them. They have a limited resolution, but they can be scanned and mentally manipulated [34]. They are often accompanied by neural activity in visual association areas (→) and under certain conditions also activate the primary visual cortex (→) (e.g., [30,35,36]). In contrast, mental models are likely to exclude visual detail, to represent only the information relevant to inference and to take the form of multi-dimensional arrays that maintain ordinal and topological properties [33]. Visual images represent information in a modality-specific format, whereas spatial models are abstract and not restricted to a specific modality. To clarify the role of visual images in reasoning Knauff, et al. [37] conducted a combined behavioral and brain imaging study with four sorts of relations: (i) visuo-spatial relations that are easy to envisage visually and spatially, (ii) visual relations that are easy to envisage visually but hard to envisage spatially, (iii) spatial relations that are hard to envisage visually but easy to envisage spatially, and (iv) control relations that are hard to envisage either visually or spatially. This study highlighted two important findings: First, reasoners were significantly slower with the visual relations than with the other sorts of relations. This is called the visual-impedance effect [38]. And second: On the brain level, all types of reasoning problems evoked activity in the parietal cortices and this activity seems to be a "default mode" of brain functioning during reasoning. However, only the problems based on visual relations also activated areas of the visual cortices. Obviously, in the case of visual relations, reasoners cannot suppress a spontaneous visual image but its construction calls for additional activity in visual cortices and retards the construction of a mental model that is essential for the inferential process. Interestingly, congenitally totally blind people are immune to the visual-impedance effect, since they do not tend to construct disrupting visual images from the premises [39]. For a more detailed explanation on how visual images and mental models interact in reasoning the interested reader is directed to Knauff [4].

## Content Effects and Belief Biases

How easy it is to visualize is only one aspect of the content of a reasoning problem. Another aspect is how well the content agrees with the reasoners previous experiences and prior knowledge. Many behavioral studies have shown that prior knowledge can significantly influence how efficiently a reasoning problem is solved. Technically speaking, the abstract (logical) truth value of an inference can be the same as the truth value of our prior knowledge – in this case the inference is supported. Or, the formal truth value conflicts with the truth value of the prior knowledge – then the inference is more difficult, which means it results in more errors or takes significantly longer. If an inference generated by a person is biased towards the truth value of the prior knowledge or even overwritten by it, this is called belief bias [40]. Some patient studies, as described, have therefore explored the effects of brain injuries on reasoning with concrete and abstract materials. Their findings agree with the brain imaging study by Goel et al. [29] in which evidence for the engagement of both linguistic and spatial systems have been found. Reasoning with a semantic content activated a left-hemispheric temporal system, whereas problems without semantic content activated an occipito-parietal network distributed over both hemispheres. Goel and Dolan [41] brought logic and belief into conflict and found evidence for the engagement of a left temporal lobe system during belief-based reasoning and a bilateral parietal lobe system during belief-neutral reasoning. Activation of right prefrontal cortex was found when the participants inhibited a response associated with belief-bias and correctly completed a logical task. When logical reasoning, in contrast, was overwritten by a belief-bias, there was engagement of ventral medial prefrontal cortex, a region implicated in affective processing. In the dual-processing theory, Goel, et al. therefore suggests that deductive reasoning is implemented in two separate systems whose engagement is primarily a function of the presence or absence of semantic content. Content-free reasoning seems to be stronger related to visuo-spatial cortical areas in the right hemisphere, whereas content-based reasoning recruits language-related areas in the left temporal cortex. If the content of the reasoning problem results in a conflict between belief and logic,

this conflict recruits additional areas in the right prefrontal cortex.

## Evaluation of Reasoning Theories

For a long time the psychology of reasoning was strongly committed to the assumption that reasoning should be studied in term of computational processes. How these computations are biologically implemented in the human brain has been conceived to be not sufficient, because each computational function can be computed on each hardware (and, thus, also the brain) that is equivalent to a Turing machine (e.g., [42]). However, reasoning research is a good example of where the assumption of implementation-independency fails. As there are many mappings possible between cortical regions and cognitive functions, neuroscientific data alone are certainly too weak to test cognitive theories. But, if such data are consistent with behavioral findings this can provide strong support for a cognitive theory of human reasoning. An outstanding example is the field of relational reasoning, where hardly any researchers defend an approach based on inference rules (e.g., [3]). The behavioral and neuroscientific evidence showing that people use their visuospatial system to preserve the structural properties of the world are too overwhelming. In other fields of reasoning the situation is more complicated (cf. [43]). Many researchers will agree that mental models play a key role if humans perform inferences based on conditionals and quantifiers [8]. On the other hand, there is also evidence that verbal, linguistic, and syntactic processes are also involved. The most reasonable corollary from the field of research is that human think deductively by applying different mental algorithms and that these algorithms are implemented in different brain areas. Content-free inferences are "real logical" inferences and they seem to rely on neural computations in the right parietal cortices the precuneus, and the extrastriate and (sometimes) striate cortex. They are accompanied by executive functions and control processes in the prefrontal cortex. When the logical problem is embedded into a semantic content or related to the reasoners' beliefs additional linguistic and semantic processes in the left temporal cortex come into play. Another corollary from the neuro-cognitive research is that reasoning is a multi-component process and that the diverse components strongly overlap with the components of other cognitive functions. There is no single "cheater detection module" as proposed for reasoning about social contracts [44,45] much as there are no "pragmatic schemas" [46] that completely spare human to reason.

## Rebound Bursting

### Definition

Discharge of a burst of action potentials after the end of a hyperpolarizing influence, such as an inhibitory postsynaptic potential.

►Action Potential

## Recall

### Definition

Recall is the ability to not only recognize something as having been experienced in the past, but also to retrieve, on demand, spatiotemporal details of the context in which the stimulus or event was originally encountered.

►Recognition Memory

## Receiver

### Definition

In general an instrument that is able to register a signal. In communication theory, the receiver registers a signal, decodes it and reacts accordingly.

## Recency

### Definition

With respect to recognition, recency refers to the capacity to remember more accurately information which has just been experienced, as compared to events or items encountered further in time from retrieval.

►Recognition Memory

## Recent and Remote Memory

►Long-Term Memory

## Receptive Field

### Definition

The aspect (for example, a location or a temporal frequency) of the outer world that is represented by a given neuron in the brain is referred to as its receptive field.

## Receptive Field, Visual

### Definition

The receptive field of a "visual" neuron is the region of the visual field in which the presentation of a stimulus exerts a response of the neuron.

►Visual Cortical and Subcortical Receptive Fields

## Receptive Field of Retinal Ganglion Cell

### Definition

In physiological studies the visual field area over which a cell responds to light. The receptive field area corresponds roughly to the dendritic field area.

►Retinal Ganglion Cells

## Receptive Field Selectivity

►Contrast Enhancement

## Receptor

### Definition

The term receptor is an ambiguous term because, on the one hand, it is used as shorthand for sensory receptor cell. A sensory receptor (in physiology) is any structure which, on receiving environmental stimuli, produces an informative nerve impulse. The receptor recognizes a stimulus in the external or internal environment, initiates a transduction process by producing graded potentials (receptor potentials), from which all-or-none action potentials are elicited, that are conducted along afferent fibers originating in the same or adjacent cells. On the other hand, a membrane receptor, neurotransmitter receptor, etc. (in biochemistry/pharmacology) is a transmembrane glycoprotein, which is activated by ligands. Receptors to neurotransmitters are located at the plasma membrane. Upon binding by the specific transmitter, receptors can allow the passage of ions or activate enzymes, which ultimately modify the membrane potential. Ionotropic receptors are fast neurotransmitter-gated receptors formed by homomeric or heteromeric subunits outlining a channel, which allows influx or outflux of monovalent or divalent ions. Instead, metabotropic receptors are slow neurotransmitter-gated receptors, which are coupled to G proteins activating diverse effector mechanisms. Excitotoxicity is caused by ionotropic glutamate receptors of the AMPA, kainate and NMDA classes.

►Action Potential
►Glutamate Receptor Channels
►Sensory Systems

## Receptor Agonist

### Definition

A chemical substance that binds to a cell membrane receptor and mimics the regulatory effects of endogenous

signaling compounds such as neurotransmitters, neuromodulators and hormones.

►Membrane Components

## Receptor Cell

### Definition

►Sensory Receptor

►Sensory Systems

## Receptor Channel

►Ionotropic Receptor

## Receptor Current

### Definition

Receptor current denotes the transmembrane current evoked, at the receptor membrane of a sensory receptor cell, by an impinging sensory stimulus through opening or closing of specific ion channels.

►Sensory Systems

## Receptor Desensitization

### Definition

Receptor desensitization is a reduced response to a neurotransmitter or agonist drug due to a decrease in number of receptors available, or decreased activity of intracellular signaling pathways and ion channels, after prolonged exposure to the neurotransmitter or drug.

Desensitization also results from receptor internalization, the removal of receptors from a plasma membrane by endocytosis. Agonist-binding receptors are pinched off and drawn into the cytoplasm with membrane vesicles and either recycled to the cell surface or degraded.

►Ionotropic Receptor

## Receptor Membrane

### Definition

Receptor membrane denotes that region of a sensory receptor cell, where the transformed physico-chemical stimulus is converted, by a specific process called sensory transduction, into receptor current and receptor potential.

►Receptor Current
►Receptor Potential
►Sensory Receptor
►Sensory Systems

## Receptor Potential

### Definition

Receptor potential denotes the membrane potential change evoked, at the receptor membrane of a sensory receptor cell, by an impinging sensory stimulus through opening or closing of specific ion channels.

►Sensory Receptor
►Sensory Systems

## Receptor Regulation, Editing

### Definition

A novel channel regulation of the ionotropic glutamate receptors. It occurs at a specific CAG codon for glutamine which changes to a CGG codon for arginine in the pre-mRNAs for a specific subtype of glutamate receptor subunits. The edited codon determines the $Ca^{2+}$ permeability of the receptors containing the edited subunit.

►Ionotropic Receptor

## Receptor Regulation, Phosphorylation

### Definition

Certain types of neurotransmitter receptors, such as G protein-coupled receptors and ionotropic receptors, may be regulated by phosphorylation. These regulations are controlled by a combination of kinase and phosphatase, both of which are receptor-selective.

►Ionotropic Receptor

## Receptor Regulation, Splicing

### Definition

Alternative exon selection changes the receptor structure, modifying the property of the receptor. For example, the "flip/flop structures" of splice isoformes in the AMPA receptors determine the desensitization rate, and the C-terminal splice isoformes of many glutamate receptor subunits control their distribution in the subsynaptic membrane.

►Ionotropic Receptor

## Receptor Regulation, Subunit Change

### Definition

Almost all ionotropic receptors consist of different kinds of subunits. Their composition determines the functional properties and diversity of each receptor.

►Ionotropic Receptor

## Receptor Trafficking

Fiona K. Bedford
Department of Anatomy and Cell Biology, McGill University, Montreal, QC, Canada

### Synonyms

Post-synaptic receptor trafficking; Neurotransmitter receptor trafficking

### Definition

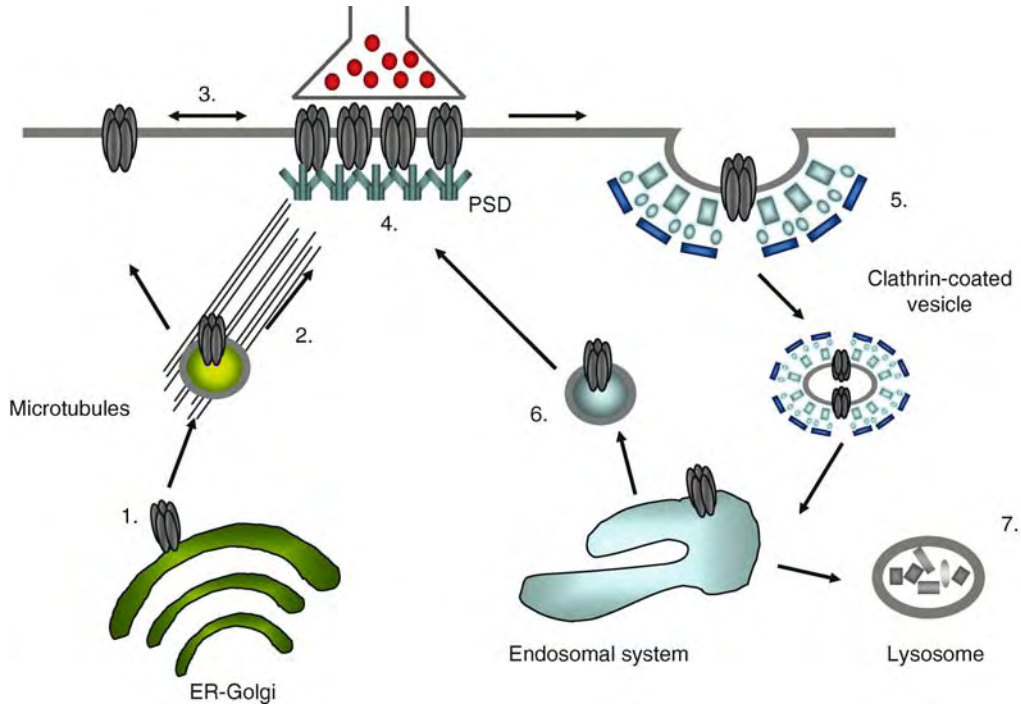
►Receptor trafficking is a term used to describe the movement of receptors within a neuron. It is used broadly to describe several distinct stages of receptor movement in neurons; the movement of newly synthesized receptors through the secretory pathway (Fig. 1), the movement of receptors into ►axons or ►dendrites and their targeting to the pre and postsynaptic domains of ►synapses respectively. In addition it is also used to describe the internalization of receptors from the plasma membrane as well as their subsequent intracellular trafficking. In all these incidents it should be noted receptor trafficking literally means the movement of receptors between distinct membrane and vesicular compartments of a neuron (Fig. 1).

### Characteristics

#### Description of the Process

In neurons, receptor trafficking is a process by which numerous neural functions, such as neuronal migration and ►synaptic transmission can be regulated. ►Receptor trafficking controls these functions by setting the capacity of a neuron to respond to an external cue. At the ►post-synaptic density for example, receptor trafficking can regulate the number of receptors available at any one time to respond to the ►presynaptic release of ►neurotransmitter molecules. As the amount of released neurotransmitter molecules often outweighs the number of available ►post-synaptic receptors, the process of receptor trafficking can control the efficiency and amplitude of the post-synaptic response. Over the past decade our understanding of the cellular mechanisms utilized by neurons to control postsynaptic receptor trafficking has increased significantly. We have discovered amongst other things that the basic mechanisms that control postsynaptic receptor trafficking are largely conserved with those controlling receptor trafficking in general. Therefore we have chosen to use examples of postsynaptic receptor trafficking below to illustrate the process and regulation of general ►receptor trafficking in neurons.

As ►receptor trafficking involves the movement of receptors between distinct membrane and vesicular compartments, it is intuitive that receptors must be recognized by components of these distinct compartments or by the trafficking machinery at each step. Simply put, receptor trafficking involves the recognition of discrete motifs within receptors by components of the different compartments. The motifs within receptors are defined as ►trafficking motifs and the components of the distinct compartments as ►trafficking adaptors. Hence if a receptor contains a specific trafficking motif, it has the potential to be recognized by a specific adaptor molecule of the compartment/ trafficking pathway defined by that motif and to be moved there. The



**Receptor Trafficking. Figure 1** Schematic of the cellular steps of post-synaptic receptor trafficking in neurons. (1) Post-synaptic receptors are generally synthesized and processed within the endoplasmic reticulum (ER) and Golgi of the neuronal cell body. (2) Receptors are then inserted locally into the plasma membrane or trafficked along dendritic microtubules to distal synapses. (3) In both cases receptors are either inserted directly at synapses or in the extra-synaptic membrane followed by later diffusion to the synapse. (4) Anchoring proteins within the post-synaptic density (PSD) then limit trafficking from the synapse. (5) Following release from the PSD anchoring proteins, receptors are internalized via clathrin-mediated endocytosis directly at the synapse or by lateral diffusion to designated endocytic zones. Internalized receptors then traffic within the endosome system and are either recycled back to the plasma membrane (6) or targeted for degradation within lysosomes (7). At each of these steps a specific protein-protein interaction between a trafficking adaptor(s) and a trafficking motif(s) within post-synaptic receptors dictate their trafficking itineraries.

physical movement in most cases is mediated by an indirect interaction with the cytoskeleton.

Postsynaptic receptors are multi subunit receptors frequently composed of different sub-classes of sub-units. Because of this heteromeric nature, it is common that different subunits within a single receptor may contain distinct trafficking motifs dictating specific movement to discrete compartments of the neuron. In the sections below I will describe examples that illustrate our present understanding of the motifs and adaptor molecules controling postsynaptic receptor trafficking.

### *Newly Synthesized Receptor Trafficking*

In the synthesis of heteromeric receptors, active retention in the ►endoplasmic reticulum (ER) is a commonly used process, whereby individual subunits are retained within the ER until they are correctly assembled into the mature receptor. This process acts primarily as a quality control measure ensuring the release of only functional molecules from the ER. The precise motifs and ER-proteins directing this retention are largely unknown for the vast majority of receptors. However it is thought and indeed the case in certain proteins that highly charged residues, which may be exposed in individual subunits but masked in the assembled receptor, play an important role in this retention process. In the case of the postsynaptic ►NMDA receptors, an additional layer of regulation in ER receptor trafficking exists [1].

The predominant NMDA-type glutamate receptor in the brain is composed of 2 NR1 and 2 NR2 type subunits and the trafficking of this NMDA receptor from the ER into the secretory pathway is controlled by differential splicing of the NR1 subunit. The NR1 subunit gene contains the splicing cassettes C1, C2, C2′ that produce different cytoplasmic C-termini of the NR1 subunit. The NR1–1 splice variant, which is the main splice variant in the brain, encodes a C2 cassette and a C1 cassette, which contains a triple

arginine (RRR) ER retention motif. If this NR1–1 splice variant assembles with NR2 subunits in the ER, mature assembled receptors will not exit the ER efficiently, due to the presence of this ER retention motif. However if the C1 cassette is expressed in combination with a C2′ cassette (NR1–3 splice variant) the assembled receptor successfully exits the ER. This is due to the presence of a specific trafficking motif within the C2′ cassette (Serine-Threonine-Valine-Valine, STVV) that overrides the RRR retention motif of the C1 cassette. This STVV trafficking motif is able to override the RRR retention motif, as it belongs to the family of ►PDZ domain interacting motifs and specifically binds to the PDZ domain containing protein Sec23. Sec23 is a component of the ►COPII coat complex that promotes ER exit via COPII vesicle formation. Differential expression of these different splice variants is in addition controlled via ►neuronal activity. For example, increased neuronal activity promotes the insertion of the C2 cassette. This favors the C1 retention mechanism; reducing NMDA receptor exit from the ER and thus lowering overall surface expression of NMDA receptors and neuronal activity. In contrast blocking neuronal activity promotes C2′ insertion over C2, which promotes ER exit, the secretory trafficking of NMDA receptors and increases neuronal activity. In essence, the above example neatly illustrates how a commonly used mechanism (ER retention) can be used to control receptor trafficking from the ER and how an additional process can be employed to override this retention in order to respond to the needs of the system.

### *Trafficking Along Dendrites and Targeting to Synapses*

Most postsynaptic receptors are synthesized in the ►soma and once they have passed through the ER and Golgi are either inserted locally within the plasma membrane or travel large distances within ►dendrites to reach the distal dendritic synapses. The latter is achieved predominantly via vesicular transport along ►microtubules within the dendrite. To traffic receptors in this manner, specific linker proteins that bind to trafficking motifs within the cytoplasmic domain of receptors and to ►microtubule motor proteins move the vesicle along the microtubule. The microtubule motor proteins controlling this distal direction of vesicle movement (anterograde trafficking) belong to the ►kinesin superfamily proteins. It is estimated that a large anterograde transport vesicle may be associated on average with between 100–200 kinesin molecules. Once the target of this vesicle is reached (the dendritic synapse) exocytosis of these receptors occurs and the kinesin molecules are either degraded or recycled back to the soma for future use.

With respect to the linker proteins involved, an obvious pre-requisite is their ability to interact with kinesins. Of the linker proteins identified thus far, many have the ability to bind only a single kinesin protein but to broadly bind a variety of receptor types. This occurs as these linker proteins generally contain multiple interaction domains that can bind distinct trafficking motifs within different proteins. Furthermore some receptors, such as the ►AMPA receptors, can bind multiple kinesins via different linker proteins. AMPA-receptors can bind convention kinesin via the linker protein the glutamate-receptor-interacting protein (GRIP1) and the kinesin family member, KIF1 via liprin-α [2]. Both interactions are mediated via carboxyl-terminal PDZ motifs in the cytoplasmic domains of the GluR2 and GluR3 AMPA receptor subunits. Thus a single postsynaptic receptor may encode multiple dendritic vesicular trafficking motifs, which can bind different linker proteins, which all participate in the anterograde movement of the receptor.

Under certain circumstances, postsynaptic receptors can also be trafficked in a retrograde fashion back to the soma. This involves a different set of linker proteins binding alternate trafficking motifs that have an affinity for retrograde microtubule motor proteins, such as the ►dynein superfamily of proteins. Finally exocytosis and insertion of receptors into the neuronal surface can occur at the synapse or at extra-synaptic sites followed by lateral diffusion of the receptors within the neuronal plasma membrane to the synaptic site. Once at the synapse, the binding of postsynaptic anchoring proteins subsequently retard further post-synaptic receptor trafficking and movement.

### *Endocytosis and Intracellular Trafficking*

The next and penultimate step in the journey of neurotransmitter receptor trafficking is ►endocytosis, where the receptor is targeted for internalization from the plasma membrane. The vast majority of postsynaptic receptors are internalized via ►clathrin-mediated endocytosis (CME). Endocytosis of postsynaptic receptors can occur at the synapse, but preferentially occurs at designated internalization sites lateral to the postsynaptic density. In which case, postsynaptic receptors need to disengage from their postsynaptic anchoring proteins prior to internalization. This occurs constitutively or in a signal-regulated manner, involving a post-translational modification that alters the association of the receptor with the postsynaptic density anchoring protein.

In general CME is mediated by endocytic trafficking motifs located in the cytoplasmic domains of postsynaptic receptors, which are recognized by the tetrameric clathrin-binding endocytic adaptor protein 2 complex (AP-2). Two classical endocytic motifs exist, a tyrosine (Y) based motif, YxxΦ, where –x- represents any amino acid and Φ is a hydrophobic amino acid and an acidic di-leucine motif, D/ExxxLL, (D = aspartic acid,

E = glutamic acid and L = Leucine). These motifs, which have been found in the cytosolic domains of many neurotransmitter receptors, are recognized by different subunits of the cytosolic AP-2 complex. AP-2 binding in both cases however promotes membrane invagination and the recruitment of the clathrin lattice, leading to the formation of endocytic vesicles and receptor internalization. Some postsynaptic receptors encode a single endocytic motif, which is recognized by the AP-2 complex whilst others contain multiple. The inhibitory ►$GABA_A$ receptor heteropentamer for example, is composed of subunits that contain both tyrosine and di-leucine endocytic trafficking motifs, which all may be relevant in mediating $GABA_A$ receptor ►endocytosis [3].

Once internalized these postsynaptic receptor containing endocytic vesicles quickly mature, losing their clathrin lattice to first form early endosomes, which then subsequently mature into late/sorting endosomes. It is in late/sorting endosomes that internalized receptors are targeted either to be recycled back to the plasma membrane or alternatively for degradation in lysosomes. Again, the interaction between trafficking motifs within the receptor and compartment specific adaptors plays an important role. In the vast majority of cases the recycling of receptors is the default pathway, while trafficking to the lysosomal pathway involves an additional sorting step. The di-leucine motif mentioned above has been implicated in this step, through the binding of a related lysosomal specific adaptor complex to AP-2, the AP-3 complex. In addition to these peptide specific endocytic sorting motifs, the modification of receptor subunits by the addition of a 7 kilodalton(kDa) protein called ►ubiquitin has been identified as a targeting signal for endosomal-lysosomal sorting, which is discussed in more detail below.

## Regulation of the Process

►Post-translation modifications, the addition of a molecule to a protein after it has been synthesized, provides an additional layer of regulation in receptor trafficking. Receptors can be modified by a number of different post-translational additions, such as lipids, inorganic ions or by the covalent attachment of small proteins. Listed below are some examples of how these different modifications can alter receptor trafficking itineraries.

### *Phosphorylation*

►Phosphorylation, the addition, or de-phosphorylation, the removal of an inorganic phosphate, are mediated by kinase or phosphatase enzymes respectively. This type of post-translational modification is used widely in neurons to regulate receptor trafficking, by altering the binding specificity of a trafficking adaptor to its linear trafficking motif. For example, the rate of $GABA_AR$ endocytosis is regulated by phosphorylation. All $GABA_AR$ heteropentamers contain a beta-type subunit, which encodes an atypical endocytic AP-2 binding motif that encompasses an established regulatory phosphorylation site [4]. Phosphorylation at this site results in the reduced affinity of the AP-2 complex for the endocytic motif, which interferes with the rate of $GABA_AR$ endocytosis. This example neatly demonstrates a phospho-dependent regulation of endocytosis via regulation of the endocytic adaptor protein AP-2 binding affinity.

### *Palmitoylation*

►Palmitoylation is the reversible post-translational attachment of a saturated fatty acid, palmitic acid, to cysteine residues in a membrane protein via a thiol-ester bond. Palmitoyl acyl transferase enzymes mediate this reaction and in neurons the action of one such enzyme, the Golgi-specific DHHC zinc finger protein GODZ directs the palmitoylation of two classes of postsynaptic neurotransmitter receptors. These are the AMPA-type glutamate receptor and the $GABA_AR$ [5,6]. Palmitoylation of these receptors can modulate their membrane trafficking, by enhancing their hydrophobicity, which leads to an enhanced rate of surface expression. Palmitoylation of post-synaptic receptors therefore facilitates enhanced secretion of newly synthesized receptors.

### *Ubiquitination and Sumoylation*

►Ubiquitin (Ub) is a highly conserved 76 amino acid polypeptide that is covalently conjugated to lysine residues on target proteins or to itself by a reaction involving three classes of enzymes: an E1 activating enzyme, an E2 conjugating enzyme and an E3 ligase that also determines substrate specificity. Protein ►ubiquitination is reversible and this is controlled by the action of de-ubiquitinating enzymes that cleave the Ub-protein bond. Modification of proteins by Ub chains ($Ub^n > 4$) primarily targets them for degradation by the multi-subunit proteolytic complex called the ►proteasome. In contrast, a single ubiquitin (mono-ubiquitination) as well as multi-site mono-ubiquitination, functions as a signal in the endocytic pathway controlling proteins internalization and lysosomal degradation. Mono-ubiquitination functions as an efficient endocytic-lysosomal trafficking signal, as several endocytic adaptor proteins encode ubiquitin-binding domains, which specifically recognize, bind to and traffic ubiquitinated membrane proteins.

There is now compelling evidence demonstrating a role for ubiquitination in regulating the abundance of glutamate receptors and synapse-associated proteins. Ubiquitin dependent proteasomal degradation of PSD95 for example, a glutamate receptor synaptic anchoring protein, enhances the endocytosis rate of AMPA receptors.

It does so by releasing AMPA receptors from the post-synaptic density and thereby enabling their interaction with the endocytic machinery [7]. This leads to a reduction in excitatory synaptic responses. With respect to the direct ubiquitination of glutamate receptors, a strong role for an E3 ligase complex of proteins called the Cullin E3 ligase (cul) complex has been discovered. The Cul3 adaptor protein actinfilin has been found to bind and mediate a Cul3 dependent ubiquitination of the GluR6 subunit of ►kainate receptors, controlling GluR6 levels and receptor accumulation at excitatory synapses [8]. The NR1 subunit of the NMDA-type of glutamate receptor is also targeted for ubiquitination by a cullin complex protein, the F-box protein Fbx2 [9]. Ubiquitination of NR1 by Fbx2 alternatively controls its retro translocation from the ER and ubiquitin-proteasome mediated degradation in an activity dependent manner, leading to a reduction in NMDA-dependent currents. Of the third class of mammalian glutamate receptors, the AMPA receptor, subunit ubiquitination has yet to be demonstrated, but is highly probable as the signal sequences targeting ubiquitination of the related *C. elegans* GLR-1 subunit, are conserved in all mammalian AMPA type glutamate receptors.

►Sumo (small ubiquitin-related modifier), also named "sentrin," is a 101-amino acid protein that can also be covalently attached to cytosolic lysine residues, in a process that is analogous to ubiquitination. ►Sumoylation was originally associated only with the functions of nuclear proteins, however more recently sumoylation of neurotransmitter receptors has been demonstrated and this modification on these proteins, like ubiquitination can regulate receptor trafficking. Sumoylation of the GluR6 kainate-type of glutamate receptor for example, regulates the rate of kainate receptor endocytosis and modifies the efficiency of synaptic transmission [10]. How precisely sumoylation facilitates this process is at present unknown, but it is likely it either release kainate receptors from an anchoring protein or alter the binding affinity of the receptor to endocytic adaptors. Sumoylation of the GluR6 subunit in neurons is rapidly enhanced in response to kainate treatment, which implies this modification is employed in an autoregulatory type of response to agonist application.

### *Closing Comments*

In this essay, I described the main cellular steps of neurotransmitter receptor trafficking that occur in a neuron (Fig. 1). Using specific examples of receptor trafficking for certain post-synaptic receptors, I have described how the different processes of receptor trafficking function at each step. In addition, I have outlined several post-translational modifications, which can regulate these processes of receptor trafficking and have explained how this regulation occurs and controls receptor trafficking.

# Receptor Tyrosine Kinase

## Definition

Receptor tyrosine kinase is a transmembrane receptor whose intracellular domain contains a kinase that is capable of transferring a phosphate group from ATP to a tyrosine of a protein. Many growth factors and extrinsic signaling molecules act through receptor tyrosine kinases.

►Growth Factor

## Reciprocal Activation

### Definition

Simultaneous activation of muscles with a mechanical action on a joint (agonist) and inhibition of muscles with the opposite mechanical action (antagonists).

Reciprocal activation may be of both central and peripheral origin and it is mediated by excitation of agonist motoneurons and reciprocal inhibition of antagonist motoneurons, via inhibitory spinal interneurons, by descending fibers (in voluntary movements) and by sensory afferents (in reflexive responses).

►Reaching Movements

## Reciprocal Dendrodendritic Synapse

### Definition

Principal synapse of the olfactory bulb. This is a synapse between mitral cell lateral dendrites and granule cell dendrites. Depolarization of a mitral cell releases glutamate, which excites the postsynaptic granule cell. This cell releases GABA at the same synapse and inhibits the mitral cell in a reciprocal fashion.

►Olfactory Bulb

## Reciprocal Inhibition

### Definition

A pattern of synaptic connection between neurons or groups of neurons where they each make an inhibitory synapse on the other neuron or group of neurons in a mutual or reciprocal fashion. This pattern of connectivity assures reciprocity/alternation in the activity of the two neurons/groups. The term also refers to inhibition of antagonist motoneurones when the agonist motoneurones are activated either as part of a stretch reflex or as part of a voluntary movement. Ia inhibitory interneurones play an important role in ensuring reciprocal inhibition, but other mechanisms also contribute.

►Integration of Spinal Reflexes
►Intersegmental Coordination
►Reciprocal Activation

## Recognition

### Definition

Recognition is the act during which a specific item or event is identified as having been experienced or encountered on a previous occasion. Variants of items or events that are not exactly like those previously experience can also be recognized by generalization or inference.

►Recognition Memory

## Recognition Memory

Luke Woloszyn, David Sheinberg
Department of Neuroscience, Brown University, Providence, RI, USA

### Synonyms

Familiarity; Recollection; Recency; Declarative memory; Explicit memory; Old/new recognition

### Definition

►Recognition memory refers to the ability of a system to classify a specific item or event as having been experienced or encountered on a previous occasion. Behavioral, neuropsychological, electrophysiological, and neuroimaging evidence indicate that recognition memory may be dissociable into the distinct processes of ►familiarity and recollection.

### Characteristics

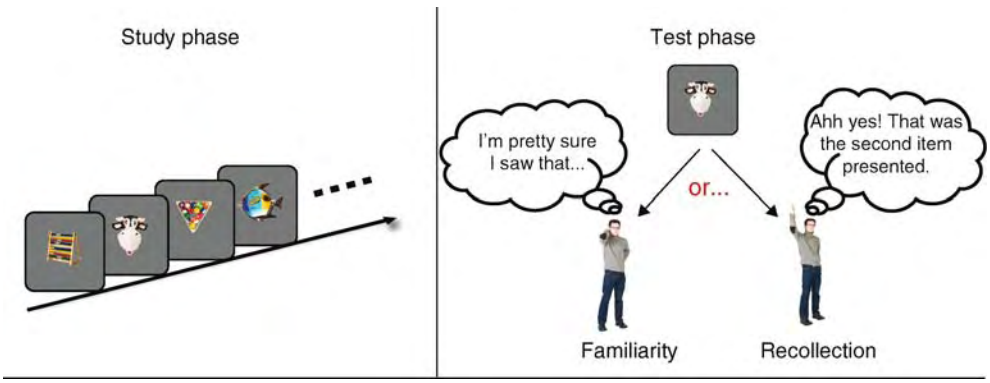
The ability to form, retain and manipulate memories is necessary for an organism to adapt to its environment. The broad concept of memory is generally divided into procedural and declarative branches. Whereas procedural, or implicit, memory underlies the unconscious learning of motor, perceptual and habitual tasks, declarative, or explicit, memory refers to the conscious memory for facts and events. Declarative memory has been regarded as critical for providing temporal contiguity to conscious experience. Subsumed under the umbrella of declarative memory is recognition memory – the psychological ability to judge a particular item or event as having been previously encountered in the past. A hallmark of recognition memory is that it can both lead to a distinct feeling of oldness, or familiarity, as well as evoke vivid spatiotemporal details associated with the prior experience of the item or event. For example,

imagine having a conversation with a stranger on a subway and then seeing that same stranger in a different setting a month later. Not only will you most likely have a strong sense of recognizing this person as familiar, but you also might be able to ▶recall the specific train your were on during your previous encounter. Most current theoretical models maintain that there is qualitative distinction between recognition memory that is or is not complemented by contextual recall [1].

Such dual-process models label recognition unembellished with episodic content as "familiarity" and recognition with accompanying contextual particulars as "recollection." This view can be contrasted with the less common single-process models which posit that the difference between familiarity and recollection is purely quantitative [2]. In this latter framework, familiarity and recollection vary along a continuum that captures how much background information is recalled at the time of recognition, with recollection obviously summoning more details than familiarity. Dual-process models also posit that memory traces can vary in strength, especially within the domain of familiarity, but there is a qualitative, as opposed to a quantitative, leap when one transitions from familiarity to recollection. Although dual-process models dominate the literature, and as we will show are supported by a wealth of converging evidence, the parsimony of single-process models makes them a viable alternative.

Several different experimental paradigms have been employed to independently assess the contribution of familiarity and recollection to recognition memory [3]. The remember/know procedure asks subjects to first study a list of words or pictures and then identify, within a list including both old and new items, those items which have been previously studied. If an item is judged as old, the subject further indicates whether he or she simply "knows" (K) this or can specifically "remember" (R) studying it (Fig. 1). Although the K judgment presumably reflects familiarity and the R judgment is analogous to recollection, it is difficult to tease these components apart because it is often the case that R judgments are preceded by implicit K judgments. Adding to the confound is the observation that the proportion of K and R judgments can be biased by manipulating the subjects' decision criteria. A similar procedure aimed at differentiating familiarity from recollection asks subjects to rate the confidence of their old judgments, with higher confidence ratings indicating recollection. Another common paradigm used to explore familiarity and recollection is a source judgment task. In this setup, subjects again encode items that the experimenter has specifically embedded in a specific context (e.g., a particular quadrant of the screen). In the test phase, subjects may be required to not only signal whether an item is new, but to also report some aspect of the context in which the item originally appeared. In this paradigm, the proportion of trials with incorrect or correct source judgments can provide indices of familiarity or recollection, respectively.

Through the application of the above-mentioned and other experimental manipulations, an emerging consensus is that familiarity and recollection are, to a certain degree, functionally distinct. So, for example, it has been shown that recollection benefits more than does familiarity from undivided attention at the time of encoding. Similarly recollection improves when subjects are given the opportunity to encode the initial list of items in more depth, which happens, for example, when subjects generate words instead of passively reading them. Conversely, familiarity judgements are



**Recognition Memory. Figure 1** A subject first encodes a set of words or pictures. Following a delay interval that is usually on the order of several minutes, subjects are presented with a list of words or pictures that include the initially studied items as well as new items. The subject's task is to indicate which items are old and which items are new. If the subject responds old, he or she is asked to elaborate if the old judgment is simply due to some intuitive sense of "knowing" or if it is due to "remembering" specific details associated with the original encoding of the item in question. A "know" response presumably reflects a familiarity-based judgment whereas a "remember" response reveals a recollection-based judgment.

more common when duration of encoding is limited. In addition, priming has been shown to have an effect on familiarity but not on recollection. While a full discourse on the relevant findings dissociating the two types of recognition memory is beyond the scope of this article, it is generally assumed that familiarity operates automatically and quickly whereas recollection requires voluntary control and time.

Given that these distinct cognitive phenomena must have neural correlates, a logical question is whether differences between familiarity and recollection are evident at the electrophysiological level. Event-related potentials (ERP) are one means to non-invasively measure the stimulus-locked neural activity of human subjects. Indeed, early ERP studies found that recognized items, at test, generated more positive ERPs than to unrecognized items. A series of studies then demonstrated a double dissociation between familiarity- and recollection-driven ERPs [1,4,5]. Specifically, recognition judgments based on familiarity elicit ERP effects that are more localized to frontal electrode sites and have a relatively short latency, starting around 300 ms and continuing for another 100–200 ms. Not surprisingly, frontally localized ERPs corresponding to familiar items have more positive amplitudes than the ERPs of correctly rejected new items. The hypothesized electrophysiological correlates of recollection, on the other hand, appears more localized to parietal sites. It, like the early frontal effect, is more positive for correctly recognized items than for correctly rejected items but is slower to develop, usually beginning at 400 ms post-stimulus onset and persisting for another 300–400 ms. The differential latencies of the ERPs parallel the behavioral observations that familiarity is more instinctive and thus quicker than the more effortful and slower recollection. Compellingly, old items receiving incorrect "new" classifications do not elicit the early frontal effect whereas false alarms do. This suggests that familiarity allows as to perceive oldness.

ERPs have relatively poor spatial resolution, which does not allow for a finer localization of the neural substrates of recognition. To overcome this particular limitation, investigators have turned to functional magnetic resonance imaging (fMRI). Making use of behavioral paradigms similar to the ones described above, several groups have started to delineate circumscribed areas of the brain responsible for familiarity and recollection [3,6]. These results have revealed distinctions between familiarity and recollection that parallel those obtained with ERPs. Familiarity has been shown to cause activity in a network of areas, including various frontal/prefrontal regions, medial temporal lobe (MTL) structures excluding the hippocampus, and the superior parietal lobule. The most convincing evidence centers on the MTL structures, which include the perirhinal, parahippocampal and entorhinal cortices. These structures not only exhibit reduced responses to old items, but this reduction correlates with the strength of the familiarity judgment, suggesting a neural substrate for the continuously scaled familiarity signal. Recollection-based judgments also tend also to activate several brain regions, most notably the hippocampus and a left lateral parietal cortex. These observations are consistent with the widely held belief that the hippocampus is critical for the recall of associations, which presumably constitutes a large component of the episodic retrieval inherent to recollection. Crucially for dual-process models, activity in the hippocampus does not increase for familiarity judgments. Intriguingly, the activity in the left lateral parietal region has been shown to increase even when items are mistakenly classified as old, again lending support to the existence of a brain network responsible for the subjective experience of oldness.

Another localization approach, complementing the fMRI studies, has been to examine patient groups with focal lesions. Because the hippocampus is particularly susceptible to hypoxia, patients suffering from lesions of the hippocampus are relatively easy to find. Investigations of these patients have revealed mixed results in that whereas some reveal significant impairment in tasks requiring recollection, others show equivalent deficits for both familiarity and recollection [3,7]. This has led some to postulate that while there may be important distinctions between the two kinds of recognition memory, all the structures within the MTL act as one integrated unit, which in turn contributes to both familiarity and recollection.

Notwithstanding the inconclusiveness of the human results, more controlled lesion studies in nonhuman primates have revealed that some division of labor is present within the classically defined MTL structures. Because we cannot ask monkeys to introspect about their recognition processes, it is difficult to tap into their different types of recognition memory; nevertheless, ►delayed match-to-sample (DMS) and ►delayed non-match-to-sample (DNMS) paradigms have been extensively used to explore familiarity judgments. The basic format for this task requires the animal to encode an object (generally, but not always, by looking at it), to retain its identity throughout a delay interval, which can range from seconds to minutes or longer, and to then recall its identity by selecting the matching (or non-matching) object from a choice array containing two or more possible alternatives.

A meta-analysis of primate lesion studies, with the lesions restricted either to the hippocampus or to the surrounding perirhinal cortex, showed ablation of the perirhinal cortex impairs DNMS performance more than lesions of the hippocampus. Additionally, a correlation analysis showed that the magnitude of the DNMS performance deficit scaled positively with the extent of the perirhinal damage. While hippocampal

damage also had a detrimental effect on the DNMS task, the size of the hippocampal lesion was negatively correlated with performance deficit, with the deficit becoming essentially negligible for monkeys totally lacking the hippocampus. This supports the view that the surrounding MTL structures play a more vital role in familiarity judgments than does the hippocampus itself.

The lesion studies described above are consistent with single cell recordings performed in the perirhinal cortex of nonhuman primates [8]. The monkeys in these experiments performed a serial recognition task in which the goal was to press one button if the stimulus was familiar (having been seen repeatedly on a daily basis or just recently presented) and to press another button if the stimulus was novel. Three distinct classes of neurons have been reported. ▶Recency neurons decrease their response when a displayed stimulus is one that was seen a few trials back, regardless of whether it is highly familiar or novel for that session. Familiarity neurons exhibit a reduced response to stimuli which are familiar to the monkey. Finally, novelty neurons show a marked enhanced response to the first presentation of a novel stimulus, with subsequent presentations of it or other familiar stimuli evoking much lower or shorter responses. Remarkably, some of these neurons appear to have memory spans of up to 24 h, providing persuasive evidence that they are involved in the extraordinary capacity of primates to remember stimuli for long periods of time, even following single exposures. Interestingly, the general tendency of these neurons to decrease their response to known stimuli mirrors results of fMRI studies in which the strength of the familiarity signal determines the amount of activity decrease observed in MTL structures. Additional studies have shown that the response of PFC neurons to familiar items is less affected by noise manipulations, suggesting that these items are more accurately and efficiently represented.

Recently, neurophysiologists have begun describing in more detail the properties of the neural activity underlying familiarity in primates. ERP studies have shown results similar to those obtained in humans, namely that the magnitude of the ERP differentiates between novel and familiar stimuli, with familiar stimuli eliciting a more positive ERP. These differences are present even in simple fixation conditions, which speaks to the fundamental contribution of familiarity to everyday behavior. Furthermore, as the monkey becomes more familiar with the novel set, the ERPs to the two sets of images become systematically more similar. Familiar and novel items also produce differences in the temporal dynamics of single cell responses. Specifically, both elicit a similar initial peak in the firing rate (~100 ms), but whereas the familiar response then quickly declines, the response to the novel images persists for an extended period of time. This suggests, again, that familiar items may be encoded more efficiently than novel ones, and that the prolonged response observed for novel images might contribute to the creation of new memories.

Although recollection is difficult to study in nonverbal animals, preliminary evidence does indicate that the hippocampus is essential [9,10]. Numerous studies have shown that removing the hippocampus in rats impairs their ability to use relational knowledge, particularly with regard to spatial relationships, which has been interpreted as reflecting deficits in associative recollection. Single cell recordings in monkeys have also demonstrated that the firing pattern of hippocampal neurons correlates with the simultaneous acquisition and immediate expression of arbitrary stimuli associations. It should be pointed out, however, that the long-term storage of associations is thought to rely on the surrounding MTL structures, particularly the perirhinal cortex. Hence, a precise and accurate account of the specific neural substrates of recollection will require more time and research.

In sum, there is strong evidence suggesting a dichotomy between familiarity- and recollection-based recognition memory. The precise nature of these differences is difficult to characterize given that the two processes interact extensively at the cognitive level; however, neurophysiological data obtained from both humans and primates has begun to elucidate possible neural substrates and processes that contribute to this distinction.

## Recognition Neurons

### Definition

Neurons that are able to signal by their response that a specific, generally complex stimulus has been recognized. Face neurons in the inferior temporal cortex are an example for recognition neurons (see also Grandmother Neuron).

## Recollection

►Recognition Memory

## Recruitment

### Definition

Abnormal increase in perceived loudness.

►Hearing Aids

## Recruitment in Acoustics

### Definition

Abnormal increase in perceived loudness.

►Hearing Aids

## Recruitment of Motor Units

### Definition

Central nervous system control of force output from a muscle by regulating the numbers and identities of motor units that are activated or de-activated (de-recruitment) during a movement.

►Motor Units

## Rectifying Gap Junctions

### Definition

Rectifying gap junctions conduct ionic current better in one direction than in the other. In contrast to electrical synapses comprised of non-rectifying gap junctions, electrical synapses comprised of rectifying gap junctions transmit electrical signals in a unidirectional fashion.

►Electrical Synapses

## Recurrent Brief Depression

### Definition

Depressive episodes lasting at least 2 days but less than 2 weeks occurring at least once a month for 12 consecutive months. They often occur unpredictably but frequently. An average of two attacks a month is typical. Although the episodes are brief, symptoms are severe. Intense suicidal ideation is common.

►Major Depressive Disorder

## Recurrent Facilitation

### Definition

►Recurrent Inhibition

## Recurrent Hypersomnia

### Definition

Also known as Kleine-Levin syndrome, this disorder is characterized by periods of excessive sleepiness and long sleep times lasting days to weeks. It is most commonly found in adolescent males. During symptomatic periods, there is often increased food intake as well as cognitive and emotional dysfunction.

►Sleep – Developmental Changes

## Recurrent Inhibition

### Definition

Recurrent inhibition is a basic type of neuronal circuit throughout the central nervous system. In the spinal cord, motoneurons give off axon collaterals to excite GABAergic/glycinergic Renshaw cells, which mediate recurrent inhibition of motoneurons, Ia inhibitory interneurons, Renshaw cells and some cells of origin of the ventral spinocerebellar tract. Since the Renshaw cells also inhibit Ia inhibitory interneurons, which inhibit antagonistic motoneurons, activation of the Renshaw cells leads to removal of the inhibition of the antagonist motoneurons, and this phenomenon is termed recurrent facilitation.

►Ia Inhibitory Interneuron
►Integration of Spinal Reflexes
►Renshaw Cell

## Recurrent Network

### Definition

A neural network architecture in which both feedforward and feed-back connections between neurons are present. In a fully recurrent architecture, the neurons are fully interconnected.

►Neural Networks

## Recurrent Processing

### Definition

Information is processed in a set of stages in which activation can propagate in feedback loops.

## Red Nucleus

### Definition

The red nucleus consists of two functionally entire separate divisions, the caudal magnocellular red nucleus and the more rostral parvocellular red nucleus. The magnocellular red nucleus is a large spherical nucleus in the midbrain containing very large neurons. It is the level of the oculomotor nucleus and the superior colliculus. It receives a very large input from the cerebellum by way of the superior cerebellar peduncle and also a small descending input from motor areas of the cerebral cortex. It projects to the contralateral facial and trigeminal nuclei in the brainstem and to the contralateral spinal cord, primarily to the cervical and lumbar enlargements that control the limbs. In fresh sections the magnocellular division of the red nucleus appears red or pinkish-yellow because of its marked vascularization, hence its name.

The parvocellular red nucleus, just rostral to the magnocellular division, consists of smaller neurons. In lower animals it is smaller than the magnocellular division but in primates, it is much larger. The parvocellular red nucleus receives a large input from the motor regions of the cerebral cortex and projects to the principle division of the ipsilateral inferior olive.

In summary, the magnocellular red nucleus is a premotor nucleus for muscles in the contralateral head and limb while the parvocellular red nucleus is a relay between the cerebral cortex and the inferior olive.

## Reductionism (Anti-Reductionism, Reductive Explanation)

Robert C. Richardson[1], Achim Stephan[2]
[1]Department of Philosophy, University of Cincinnati, Cincinnati, OH, USA
[2]Institute of Cognitive Science, University of Osnabrück, Lower Saxony, Germany

### Definition

In philosophy of science and in the sciences, reductionism is sometimes a methodological stance; sometimes it is a substantive position. As a methodological stance, it is committed to understanding a system's behavior analytically, i.e., in terms of the system parts and their interactions. As a substantive position, it anticipates the success of the reductionist methodology. Reduction sometimes is thought of in ontological terms; that is, as a commitment to the idea that, e.g., living systems consist of nothing other than physical constituents. This minimal commitment may be coupled with a claim that reduction holds *in principle*, even if not in practice, but does not require even this much. Reduction sometimes is an explanatory relation, either between theories or

between domains. The former is *theory reduction* while the latter is *reductive or mechanistic explanation*.

## Description of the Theory

Reductionism has been a persistent attractor for scientific thought. In physics, it led to some of the most striking successes of classical physics, such as the particle theory of light in the eighteenth century or ►statistical mechanics in the nineteenth century. In the biological sciences, the rapid growth of molecular genetics is a reductionistic triumph. In the ►cognitive sciences, reductionism has been no less attractive, as is evidenced by the rise of what is called "cognitive neuroscience" in the twentieth century, or the dramatic successes of the neurosciences more generally. Opposition to reductionist approaches also has been prominent, especially in cognitive psychology. The successes of cognitive psychology and of ►artificial intelligence in the middle decades of the twentieth century encouraged the idea that reductionist methods were not necessary in order to explain human psychological capacities. In opposition to rather brute reductionistic claims such as that there is nothing but elementary particles, or that mental states are nothing but brain processes, champions of the special sciences feared they would lose their particular subject matter. Vitalistic or dualistic alternatives are not fashionable any more, but there are a number of antireductionist positions that have been recently defended.

### Varieties of Reduction: Theory reduction

Theory reduction claims to deduce or "explain" one theory (the secondary or reduced theory) from another (the primary or reducing theory), perhaps as a limiting case. Theory reduction may involve theories at the same level of organization or at different levels of organization. A classical example for same level reduction, as discussed by Ernest Nagel [1], is the reduction of Newton's mechanics to Einstein's relativity theory; for reduction of theories at different levels Nagel refers to the relation of classical ►thermodynamics to statistical mechanics. The reducing theory is typically thought to be more general or more exact, or both. The reduced theory correspondingly is thought of as more restricted in its domain of application, or as an approximation, by comparison with the reducing theory. Thus, Newton's mechanics applies only to velocities far from the velocity of light. The classical gas laws in thermodynamics apply only to gases at intermediate temperatures and pressures. When reducing and reduced theories are on the same level, or cover the same domains, we have "homogeneous" reductions. If reduction is possible at all, it can be achieved relatively easily, because the theories at least appear to have the same concepts. For example, both Newton and Einstein appeal to *mass* and *velocity*, although they in fact may not be the same concepts (insofar as the theory defines its concepts). When reducing and reduced theories refer to different levels, or cover different domains, we have "heterogeneous" reductions. If reduction is possible at all, it is more difficult in these cases, since the theories do not share the same vocabulary. For example, statistical mechanics has neither the notion of temperature nor that of pressure, though these are the key concepts of classical thermodynamics. So, in these cases, connections between the two domains or levels have to be forged, in the form of "►bridge laws." These connections are usually thought to be identifications between levels; e.g., mean kinetic energy is identified with temperature, at least within the domain of classical thermodynamics.

These identifications often lead to so-called "nothing buttery," i.e., to the claim that the phenomena the upper level concepts originally referred to in fact are *nothing but* the entities the lower level concepts refer to. So, it is often said, temperature is *nothing but* mean molecular motion, and genes are *nothing but* nucleotide sequences. This sometimes leads to eliminativist claims concerning the reduced theory – that is, to denying the existence of things reduced [2]. In case there are suitable identifications available, reduction guarantees that the explanatory work done by the higher level theory can, at least in principle, be done by the lower level theory. The higher level theory can then, in principle, be eliminated without explanatory loss. In case the concepts of upper level theory are vaguer or more inexact, they cannot be identified with the more exact concepts of a lower level theory. Once again the original theory can be eliminated though in this case because it could *not* be reduced [3] ("phlogistaded").

To take an example closer to the neurosciences, the trichromatic theory was an important case historically. Newton's experiments with prisms revealed a visible spectrum ordered by wavelength. It was subsequently shown that any specific spectral hue could be matched by combining three different primary colors in different intensities. This led Thomas Young to propose, in 1801, that the retina contained exactly three different color-sensitive elements. This was subsequently confirmed and consolidated by the great physiologist, Hermann Helmholtz, with three classes of cones differing in their central sensitivities, though with substantial overlap of responses. This looked like a reduction of color theory to a trichromatic theory, which had broad acceptance into the middle of the last century. Unfortunately, not all the colors perceived by human subjects are represented in the physical spectrum. *Brown* is the most salient example of a color that is outside the physical spectrum. Hering eventually posited an "opponent process" theory which was aimed at more exactly describing the subjective phenomena of color perception. The existence of opponent processes

at the neural level was eventually confirmed in the macaque. We still lack a decisive direct test, but this sort of case also is suggestive of theory reduction.

To consider a more contemporary example, John Bickle [2] argues that contemporary neuroscience captures the phenomena on offer from psychology concerning memory. In particular, he observes that Eric Kandel's landmark work on ►aplysia has forged a link between the mechanisms of long term potentiation (►LTP) and ►memory consolidation. Memory consolidation is particularly important as the link between short-term and long-term memory. The key psychological phenomena include the importance of stimulus repetition, the time course relevant to fixation, and ►retrograde interference. The mechanisms, typically molecular, which characterize LTP capture these phenomena, at least to a first approximation. Bickle concludes that the "intended empirical applications of the two theories are virtually identical," even if the theories differ in substantial ways.

## Varieties of Reduction: Reductive or Mechanical Explanation

Reductive or mechanical explanations tell us *why* a certain entity instantiates a certain property, typically a property that is only attributed to the system as a whole [4,5]. So we might want to explain, e.g., how humans recognize faces, or how we acquire language. In trivial cases it suffices to simply add the corresponding properties of the system's components. So we get the weight of brains from the weight of its parts. However, the behavior of the brain in vision or perception – both definitely more interesting properties – cannot be deduced in an equally simple manner. Here we need to know the arrangement of the components, particularly those of the visual areas, what properties they have, and how they interact among each other and with the visual stimuli. The capacity to see would be reductively explained if it followed from the above-mentioned factors and the natural laws that hold generally. Of course, at the moment, we do not yet have such a reduction in place. That need not trouble reductionists, insofar as they are committed to what we will or (perhaps) could achieve.

So, the aim of each reductive explanation is to explain (or predict) a system's dispositions and properties solely by reference to its components, their properties, arrangement, and interactions. To be successful as a reductive or mechanistic explanation, several conditions must be met:

i. There must be a systemic property to be explained
ii. The property to be reduced must be functionally construable or reconstruable
iii. The specified functional role must be filled by the system's parts and their mutual interactions
iv. The behavior of the system's parts must follow from the behavior they show in isolation or in simpler systems than the system in question

These are demanding constraints, but without them no reductive explanation will be complete. What we are looking for, then, are functional characterizations of the properties to be reduced, and explanations of those functional properties in more fundamental terms. Usually we refer to these properties by concepts that classify properties at the system level, where specific patterns such as, e.g., learning a new person's face brings the instantiation of a capacity to our notice. The time course of memory consolidation is one such functional property. The functional analysis is a precondition for constructing appropriate explanatory connections between the components and systemic behavior. If, however, this conceptual "priming procedure" fails, as it may in the case of ►qualia, the corresponding reductive explanation fails, too [6].

Reductive or mechanistic explanations can be forged in two opposite directions. Given that we already know that some system $S$ has a systemic property $P$ one task is to provide a reductive explanation for $P$. For that we refer to the microstructure MS($S$) of $S$, to the behavior of the components, and to the interaction among the components $C_i$ of $S$. With these resources, we try to show that $S$ must have $P$ *given the analysis of its structure*. So, in the case described above, it was important to the trichromatic theory that humans had exactly three color sensitive cones, and that these had appropriate spectral sensitivities. We also knew that humans could, typically, discriminate among spectral hues. So there was a systemic property (human discriminatory abilities) and there were microstructural features (three types of cones) that were appropriate. All this depended on adequate conceptual preparations. That is, we needed to know the range of discriminable colors. When it turned out that the systemic properties were different from those predicted by the trichromatic theory, that required a change in the understanding of the physiology.

In converse cases, we might at first only know the microstructure MS($S$) of a system $S$ and be uncertain concerning its exact capacities. The task, then, is to verify theoretically, or to forecast whether or not $S$ has (a desired) systemic property $P$. To do so, we again must make use of adequate conceptual preparations and refer to the microstructure MS($S$) of $S$, to the capacities and interactions of the components $C_i$ of $S$. This is a difficult procedure, since the combinatorial possibilities are daunting. Experimental procedures that follow from imposing deficits, whether experimental or accidental, fall into this category. Ablation studies in nineteenth century physiology follow this simple approach, though there are more sophisticated methods (e.g., knock-out

genes) available to recent physiologists. So when Broca discovered a patient (Tan) that lacked the ability to produce coherent speech but who had normal comprehension, and who had damage to the left temporal lobe, he concluded that the temporal lobe was the location of articulate speech. Many fMRI experiments still follow this research strategy. They do not provide reductive explanations.

Of course, a system can be looked at from a "top down" perspective, a "bottom up" perspective, or from both simultaneously. In that case, we can stitch together the perspectives we garner from the bottom and the top.

### Anti-Reductionistic Positions

If it turns out that some purported phenomenon is not real, the property to be reduced is not accepted. In that case, condition (i) fails, and reductive explanation fails right at the outset. If telepathy is not real, there is nothing to explain or reduce. At the extreme, this becomes ►eliminative materialism, in which all psychological phenomena are rejected as real. Paul and Patricia Churchland [3], followed by John Bickle [2], defend largely eliminative positions, supported by an emphasis on theory reduction. If it turns out that one cannot functionalize a psychological property accepted for reductive explanation, even in principle, then condition (i) is satisfied, while (ii) is rejected. In this case, the systemic property is real but *irreducible*, and thereby it is *synchronically* (i.e., in a strong sense) *emergent*. Strong emergentism (►Emergence) is at least a type of property dualism [7]. The case in point is qualia. Commonly, it is held that, e.g., our sensation of red has an intrinsic character that cannot be captured in terms of function; and if this is so, then (ii) fails in this case [6]. If it turns out that the system components with their particular arrangement and interactions are not sufficient to account for the system's behavior, then there is a failure of condition (iii). Again, a mechanistic explanation fails. If this is a consequence of limitations on our knowledge, then this is not a principled limitation. If it is a principled limitation, as the great neurophysiologists Sherrington and Eccles [8] maintained, then that is a failure of the reductionist/mechanist program. We would be driven to substantive dualism, ►vitalism or Cartesianism (►Cartesian dualism). If the behavior of components, embedded in the appropriate context, is sufficient to explain the system behavior, but the behavior of the components in simpler constellations cannot account for their interactions within the more complex system, then condition (iv) fails, In that case, we are forced to a kind of ►holism; which establishes one type of emergentism. Irreducibility can coexist with mechanistic explanations [9].

Theory reduction also has its detractors, who usually contend that there will be a failure to provide appropriate bridge laws to connect the theories in heterogeneous reductions. Functionalists such as Jerry Fodor [10] and hold that psychological states are functional states (►Functionalism), which can be realized in multiple ways, and conclude that therefore there will not be appropriate identities available. They conclude that this supports a kind of autonomy for psychological explanations relative to physiological explanations. A more radical failure would be the absence of sufficient physical conditions to explain psychological capacities. In this case, we would be driven again to either dualism or eliminativism.

## Redundancy of Degrees of Freedom

### Definition

An excess of elemental variables (degrees –of freedom) within a system as compared to a number of constraints imposed on the system in typical tasks; this term assumes that redundant elemental variables need to be eliminated to make the system controllable.

►Coordination
►Degrees of Freedom

## Redundant Set, Redundancy Problem

### Definition

Also called Bernstein's problem, named after the scientist who has considered it as a major problem in motor control research; ambiguity in transforming a set of variables into a set of more numerous variables so that a unique solution of many possible solutions of the motor task must be chosen, for example, when it is necessary to distribute total torque acting on a joint into individual torques of muscles spanning this joint, or to choose one of many possible ways of combining different degrees of freedom of the body to reach the motor goal. See also the principle of neurological minimization.

►Equilibrium Point Control

## Reference

### Definition

Reference is the relation between an expression and what it refers to. A typical unambiguous concrete singular term like "the highest mountain" or "Gottlob Frege" refers to a certain concrete particular like a thing or a person. A [→] predicate like "is red" distributively refers to all those particulars to which it applies, i.e. to the red things. Sometimes the relation between a predicate and the set of things it applies to is also called "reference."

►Argument
►Logic

## Reference Frame

### Definition

►Sensory Systems

## Reference Model

### Definition

The Reference Model is used for a certain type of control design. It is a mathematical model that represents the desired behavior of the controlled physical system.

►Adaptive Control

## Referent Configuration

### Definition

A position of the body or its segments at which muscles are silent in the absence of co-activation or, otherwise, produce net zero joint torques but generate activity and resistive forces in response to deviations from it; modified by control levels to produce motor actions.

►Equilibrium Point Control

## Referent Trajectory of an Effector

### Definition

Comprised of the positions of the effector's associated with threshold configurations of the body at each instant of movement (see Threshold control).

►Equilibrium Point Control

## Referential

### Definition

Pointing to the meaning of an utterance.

►Cognitive Elements in Animal Behavior

## Referred Pain

### Definition

Referred pain is the phenomenon wherein nociceptive stimulation in one location results in the perception of

pain in another location. In clinical practice, this phenomenon is most often thought of as involving the projection of pain from a visceral structure to the body surface. However, nociceptive stimulation of muscle, and possibly other somatic tissues, can also lead to referred pain. A number of mechanisms have been proposed to explain referred pain. These include, most importantly, the convergence of afferent neurons from the site of insult and the site of perceived pain. This may occur through the dichotomization of afferent fibers such that one branch of an axon terminates on, for example, a visceral structure, while another branch of the same axon terminates in the skin. Alternatively, two distinct peripheral sensory neurons may both terminate on the same dorsal horn neuron. In either instance, it is proposed that the brain would have difficulty in determining the true source of nociceptive input, and would preferentially attribute pain to the more familiar source of sensory input – hence the body surface.

►Ascending Nociceptive Pathways
►Somatosensory Projections to the Central Nervous System

## Reflex

### Definition

Involuntary modification of activity in motoneurons in response to activation of sensory receptors.

►Motor Control
►Feedback Control of Movement

## Reflex Adaptation

### Definition

One of the simplest forms of motor learning. Inborn reflexes, such as an eyeblink reflex, are adaptable to new environmental conditions. For example, the force required for eyelid closure self-adjusts when the eyelid movement is impeded by an external load.

►Motor Learning

## Reflex Chain

### Definition

A sequence of reflexes where the action of the first reflex activates a set of receptors (e.g. proprioreceptors) that trigger a second reflex, and so on. The peripheral control hypothesis proposed that complex behaviours consist of simple reflexes that are linked together in a reflex chain. This hypothesis has been superseded by the central control hypothesis.

## Reflexes

Arthur Prochazka
Centre for Neuroscience, University of Alberta, Edmonton, AB, Canada

### Definition

(Taken from Dr. Wilfrid Jänig's essay on ►Autonomic reflexes) Reflexes are functionally defined by an efferent (motor) output system that generates a distinct effector response when activated and by the population of afferent neurons stimulated. Reflexes are fragments of more complex somatomotor behaviors and are used in the laboratory as tools to study experimentally the central organization of neural regulation of movement.

### Background

There is no universally accepted definition of reflexes that distinguishes them from voluntary responses to stimuli [1]. The Roman poet Ovid used the word *reflex* to describe "turning or bringing back." Substitute "feed" for "bring" and we have the word "feedback." In engineering, feedback refers to information about a process monitored by sensors and supplied to the controller of that process (see ►Feedback control of movement).

In biology, the first attempt at a definition of reflex is attributable to Georgiy Prochaska [2]: a behavior in response to an excitation, mediated by separate motor and sensory nerves. Prochaska saw the function of reflexes to be *conservation of the individual,* later called *homeostasis* by Claude Bernard [3]. The psychologist Herbert Spencer posited that reflexes were the atoms of the psyche; that the psyche was an assemblage of reflexes, and that instincts were reflex assemblies consolidated by repetition and transmitted in an hereditary manner [4]. The Russian clinical physiologist Ivan Sechenov went one step further, proposing that all motor acts in humans as well as animals were simply chains of elemental reflexes [5]. He argued that the appearance of spontaneity and volition was illusory and that all movements were in principle predicted by the history of prior events, sensory inputs and associated thoughts. His conception of reflexes included complex responses that involved choice, as well as learned responses that his successor Pavlov would later call conditioned reflexes. The ideas of Spencer and Sechenov were taken to their literal conclusion in the behaviorist theories of Watson and Skinner. These theories rejected all non-measurable explanations of behavior and replaced voluntary movement with operants: conscious arbitrary acts that have become associated with arbitrary stimuli through learning and arbitrary reinforcement.

Hughlings Jackson argued from clinical observations that movements ranged in a continuum from the most automatic or evolutionarily primitive to the least automatic or most evolutionarily advanced [6]. Primitive reflexes in humans were unmasked or released when the higher centers were damaged. The Jacksonian continuum from automatic to voluntary probably best encapsulates the current view of most neuroscientists. In this view, reflexes are brief, automatic and invariant responses to stimuli. But even this definition is problematic: Goldstein (1939) reviewed various responses called reflexes and found them all to be variable, state-dependent and mutable [1].

Jonathan Wolpaw recently argued that a single comprehensive hypothesis related to this question of distinguishing reflexes from voluntary actions developed in the nineteenth century, namely that the whole function of the nervous system is to convert sensory input into appropriate motor output [1]. Neuroscientists who say they are studying reflex behaviors are studying behaviors in which the connections from stimulus to response, from experience to behavior, are known to be, or at least believed to be, short and simple enough to be accessible to description with presently available methods, and they are excluding by one means or another voluntary behaviors, or behaviors involving connections so long and complex as to defy present-day analysis. Implicit in these definitions is the expectation that, as methodology and understanding advance, the class of reflex behaviors will grow larger and larger and the class of voluntary behaviors smaller and smaller.

When reading the essays on specific reflexes in this *Encyclopedia* it is useful to bear in mind the following comments of Francois Clarac [1]:

1. In normal behavior, reflexes are simple, fast reactions to the environment. The term should be confined to the simplest input-output reactions mediated by monosynaptic (or oligosynaptic) pathways at the lowest level, i.e. at the motoneuronal level. Reflexes should be viewed as elements of feedback control that each species possesses to react automatically to the environment.
2. The experimenter can induce a reflex artificially…. Reflexes then reduce to informative tests of CNS state. A reflex might be seen as a physiological "scalpel" permitting entrance into simple workings of the CNS, while not being a distinct and separable element when normal movements are considered. Thus although the understanding of motor behavior has benefited from reflex experiments, the normal functioning of the CNS, in which many afferent messages are integrated, should never be viewed as reflexive behavior even in the case of the "automatic" movements of invertebrates and lower vertebrates.

## Overview of the Essays Grouped within the Topic "Reflexes"

In the following synopsis, key points are extracted or paraphrased from each of the essays in this volume related to reflexes.

►*Autonomic Reflexes*. Reflexes related to autonomic regulation of pelvic organs, cardiovascular system, functions of skin, gastrointestinal tract, airways, eye and pineal gland are mediated by spinal cord, brain stem or hypothalamus and are functionally defined by their afferent input and efferent output. They are di- or polysynaptic, organized at the segmental propriospinal or propriobulbar level and form the building blocks of autonomic regulations. Interneurons are important for the integration and coordination of different autonomic and somatomotor systems. Command signals from higher centers act primarily via these interneurons rather than directly with the final autonomic pathways.

►*Conditioned Reflexes*. The fact that reflexes are affected by activity-dependent plasticity throughout life (and even in utero) implies that the traditional distinction between unconditioned and conditioned reflexes is merely an artificial distinction imposed by an experimenter. In reality, most and probably all reflexes are conditioned in the sense that they have been shaped by activity. Those traditionally designated as "unconditioned," such as the normal flexion withdrawal

reflex that withdraws a limb from a painful stimulus, are reflexes that have undergone standard conditioning in the course of earlier life, and thus are similar in most normal individuals. In essence, "unconditioned reflexes" are simply reflexes that were conditioned before the experimenter began to observe them.

►*Feedback control of movement*. The word feedback is used extensively in engineering. In neurophysiology, it is used to describe the sensory signals used by the CNS to control a large number of bodily functions to maintain constancy of the internal environment (homeostasis). Signals from mechanoreceptors in muscles, joints and skin are involved in the control of movement, as well those from the eyes, ears and vestibular apparatus. All levels of the CNS from the spinal cord to the cerebellum and cerebral cortex receive feedback from mechanoreceptors and all these levels are involved in controlling even the simplest movements.

►*Integration of reflexes*. Despite more than a hundred years of research, the integration of spinal reflex circuitries and descending motor commands remains a challenge. For example, there is still no consensus about the mechanism by which the much-studied monosynaptic stretch reflex contributes to the activation of muscles during walking, if it makes a meaningful contribution at all. An understanding of spinal reflex networks is a requirement for developing useful therapeutic strategies in the rehabilitation of neurological disorders.

►*Locomotor reflexes*. Locomotor reflexes play an essential role in the patterning of motor activity for walking. These reflexes have three major functions: (i) to regulate the timing of motor commands according to the mechanical state of the limbs and body, (ii) to control the magnitude of ongoing muscle activity, and (iii) to initiate corrective responses when the limbs or body are unexpectedly perturbed by events in the environment.

►*Long loop reflexes*. transcortical reflex. By definition, long loop reflexes occur at latencies longer than the simplest reflexes mediated by *segmental* circuits within the spinal cord yet the latencies are too short to be mediated volitionally. For muscles in the hand, the fastest (spinal) reflexes to muscle stretch occur at latencies ~35 ms; long loop reflexes occur at latencies ~60 ms, whereas volitional responses occur at ~140 ms. However, automatic motor responses of comparable latencies can also be generated by tactile (cutaneous) stimuli that do not involve muscle stretch, so the term "long loop reflex" should not be restricted to those generated by muscle stretch.

►*Presynaptic inhibition*. Presynaptic inhibition (PSI) refers to a decrease of transmitter release at central synapses. For example, activation of afferent fibers originating in flexor muscles attenuates monosynaptic ►EPSPs in extensor motoneurons without detectable changes in the time course of the EPSPs, membrane potential or motoneurone excitability. PSI occurs widely within the CNS of both vertebrates and invertebrates. Synaptic efficacy at axon terminals from sensory afferents, descending systems or interneurons can be subject to PSI control by a number of neurotransmitters and presynaptic receptors.

►*Respiratory reflexes*. Generating an optimal breathing pattern for $O_2$ and $CO_2$ homeostasis requires the integration of sensory information from a variety of receptors including central and peripheral chemoreceptors for adjusting the magnitude of alveolar ventilation and stretch receptors for regulating the depth and rate of breathing. Sensory input is also important in the coordination of breathing with other systems, such those required for speaking, eating, walking, running, and vomiting. Finally, sensory information is necessary for protection of the airways and lungs. Receptors in the nose, pharynx, larynx and lower airways elicit a variety of reflexes including coughs, sneezes and apnea that protect the airways from inhalation of noxious substances and increase mucous secretion that aids in their removal.

►*Sexual reflexes*. Spinal reflexes consisting of afferent and efferent components instigate the genital vasocongestion and neuromuscular tension responsible for sexual arousal (erection in men and vaginal lubrication and elongation in women), the triggering of ejaculation in men, and possibly orgasm in both sexes. While the spinal cord contains all the neural circuitry involved in the generation of genital arousal, many other body senses, emotions and cognitive processes mediating social awareness determine whether an individual person will orient towards sexual activity or lose interest.

►*Concluding thoughts*. The difficulty in classifying motor acts as either voluntary, involuntary or reflexive is the inevitable consequence of the overlap in the attributes that describe these categories as well as the brain mechanisms that control them. The various essays summarized above all demonstrate this overlap in one way or another. The Jacksonian continuum, "most automatic" to "most voluntary," should always be borne in mind when considering reflexive control of bodily functions.

## Reflexive Saccades

### Definition

These are also called reactive saccades, pro-saccades, or visual grasp reflex. A saccade elicited by visual, auditory and even tactile events, and direct gaze at the perceived location of these events. In freely behaving subjects they tend to be accompanied by head rotation when the eccentricity of this location exceeds 20° or so.

Depending on the modality and intensity of the stimuli, they occur at latencies of 150 to –350 ms. Considerable attentional effort is required if reflexive saccades are to be voluntarily suppressed.

## Refractory Period

### Definition

When, during an action potential, the membrane has undergone a full-blown depolarization (up to several tens of millivolts positive), the $Na^+$ system is subsequently in a state of reduced responsiveness, from which it recovers slowly over several milliseconds. This period is called refractory period. There is often an initial short period during which the $Na^+$ system cannot be activated at all, however strong the depolarization.

This is called the absolute refractory period. During the subsequent relative refractory period, the $Na^+$ system responds in part.

Regenerating axons grow well in the peripheral nervous system (PNS), but, in contrast, effective nerve regeneration rarely occurs in the central nervous system (CNS). Following ►axotomy, the distal segment of the injured axon degenerates (►Wallerian degeneration), whereas the proximal segment usually remains intact. The most prominent change of the neural cell body following axotomy is the disintegration of ►Nissl bodies [1]. This phenomenon is called ►chromatolysis (►Chromatolysis). Chromatolysis that can occur in neural cell bodies in both the PNS and CNS involves not degenerating, but regenerating reactions of neurons to axotomy. Though morphological changes of neurons in relation to chromatolysis have been extensively studied, the molecular basis behind this phenomenon has not yet been clarified. Chromatolysis is a sign for neurons, when their axons are injured, to shift from the normal condition to the regenerating phase, leading to axonal growth. In the normal condition, neurons are mainly involved in the synthesis and release of ►transmitters. However, following injury, neurons should change their machinery to produce molecules that contribute to regeneration. Molecular changes in association with axonal degeneration and regeneration have been studied, and gene expression involving in axonal elongation is crucial in understanding the molecular mechanism of nerve regeneration (►Neuronal changes in axonal degeneration and regeneration). The molecular changes of neurons responding to axonal injury have been studied [2].

In the PNS, ►Schwann cells and their basal laminae act as efficient scaffolds and sources of ►neurotrophic factors required for the growth of regenerating axons, and adhesion molecules present on the surface of Schwann cells contribute to nerve regeneration. On the other hand, glial cells including ►astrocytes and ►oligodendrocytes in the CNS play no supporting role in the growth of regenerating axons. In addition, there exist no extracellular matrices such as basal laminae in the CNS. Although axons in the CNS

have the ability to regenerate after injury, the microenvironment appropriate for the growth of regenerating axons is not provided in the CNS. Cell transplantation using Schwann cells, ►olfactory ensheathing cells, ►neural stem cells, ►choroid plexuses, and ►macrophages has been extensively studied to overcome this difficulty, as it could provide an efficient environment to enable regenerating axons to grow. Other studies have also been conducted on how to facilitate nerve regeneration via suppressing inhibitory factors using specific ►antibodies or via supplying trophic factors to the lesion using genetically altered cells to produce specific trophic factors.

## Nerve Regeneration in the PNS

Axons are ensheathed by Schwann cells in the PNS, where each cell forms a ►myelin sheath segment around the axon with ►nodes of Ranvier intervening between the neighboring myelin sheath segments. Schwann cells of myelinated and unmyelinated fibers possess basal laminae on the surface facing the connective tissue, which are continuous even at the nodes of Ranvier. Therefore, the axon and associated Schwann cells reside within a basal lamina tube along its entire length.

Peripheral nerve fibers are located in the connective tissue compartment, an essential difference from the central nerve fibers, which are tightly packed within the brain and spinal cord without any structural extracellular component present between the nerve fibers. During Wallerian degeneration following axonal injury, remaining Schwann cells temporally proliferate and form cell strands called "►Schwann cell columns" within the basal lamina tube. Axonal sprouts that emerge at the nodes of Ranvier adjacent to lesions of the proximal stump extend as regenerating axons through the connective tissue compartment to the distal stump, in which they further elongate along Schwann cell columns.

The tip of the regenerating axon is specialized as a ►growth cone [3]. Growth cones are formed at the growing tip of axons during development and regeneration. Growth cones emit filopodia and lamellipodia on the surface, which actively move in various directions to survey the surrounding environment. The structure of living growth cones and their impressive movement were first observed in the culture of single-dissociated neurons under cine-microscopy in Nakai's pioneering work [4]. He proposed that filopodia and lamellipodia might represent sensors searching for appropriate targets during their extension [5]. Numerous studies have been performed regarding the structure and function of growth cones ►Growth cone.

The growth of axonal sprouts is facilitated or suppressed depending on the conditions of myelin sheath degradation that occurs during Wallerian degeneration in the myelin sheath of the distal stump [6]. In the distal stump, regenerating axons come into contact with Schwann cell columns. Schwann cells play a critical role in nerve regeneration in the PNS; they provide cellular scaffolds for regenerating axons to grow through, and express trophic factors as well as adhesion molecules for promoting the extension and maintenance of regenerating axons. In Wallerian degeneration, Schwann cells disrupt myelin sheaths that have lost contact with axons into fragments called myelin balls that are subsequently transferred to and phagocytosed by macrophages. Thus, macrophages contribute to successful nerve regeneration. Schwann cells cooperate with macrophages not only in myelin sheath removal, but also in trophic factor production for promoting axon growth during nerve regeneration (►Schwann cells in nerve regeneration). Schwann cells that remain "quiescent" in Schwann cell columns during Wallerian degeneration become "active" by coming into contact with regenerating axons, following which they gradually ensheath axons and finally form myelin sheaths in myelinated fibers.

Schwann cells are primary sources of trophic factors for nerve regeneration. A large number of neurotrophic factors have been identified. A well-known neurotrophic factor is ►nerve growth factor (NGF), a member of the neurotrophins that include ►brain-derived nerve growth factor (BDNF), ►neurotrophin 3, and ►neurotrophin 4/5. ►Glial cell line-derived neurotrophic factors (GDNF) belong to another family that promotes the survival and neurite extension of neurons. ►Cytokines also have neurotrophic activity, which include ►ciliary neurotrophic factor (CNTF) and ►interleukin 6 (IL-6). Neurotrophic molecules have been studied in relation to their corresponding receptors, effects on axonal cytoskeletons, and gene expression to explore the regeneration mechanisms of injured axons in the PNS and CNS (►Neurotrophic factors in nerve regeneration).

On the other hand, in one experiment in which Schwann cells were killed by freeze-treatment, the damaged cells were removed by macrophages. Regenerating axons were then observed to vigorously grow through such basal lamina tubes in contact with the inner surface of the basal lamina [7]. This result indicates that peripheral nerve axons can grow through the acellular matrices (►Role of basal lamina in nerve regeneration). This is the theoretical basis for the use of artificial materials for nerve regeneration in the PNS. Basal laminae serve not only as the scaffold for growing axons, but also as a supply of trophic/nutritional factors that are adsorbed by heparan sulfate present on the outer surface of the basal laminae [8]. Thus, peripheral nerves are provided with dual structural insurance, Schwann cells and basal laminae, for successful nerve regeneration.

In a regular nerve suture, regenerating axons randomly enter distal Schwann cell columns. Therefore, it is not definite that regenerating axons can reach their original targets. The clinical estimation of functional recovery is important [9]. Several different methods of treatment have been developed and used clinically. In the case of crush injury, in which basal lamina tubes (endoneurial tubes) remain undisrupted, axonal sprouts can extend through the original Schwann cell tubes to the original targets. Therefore, nerve regeneration occurs readily, and the high correspondence in axon-target reinnervation is secured for accurate functional recovery. On the other hand, in the case of transection, the proximal and distal stump should be sutured by apposing directly, or using grafts including autologous nerve grafts and artificial tubes. In stump suturing, fascicular repair to connect the corresponding nerve fasciculi has been recommended to ensure that regenerating axons can reinnervate the original targets as accurately as possible (►Regeneration: clinical aspects).

Neural connections in the ►somatosensory area of the ►cerebral cortex can be reorganized depending on the input from the peripheral nervous system. The cortical neural organization including ►sensory cortex and ►motor cortex is not fixed, but can be modified subject to the functional demand. When the sensory inputs are lost due to peripheral nerve damage including the amputation of limbs or fingers, the corresponding areas of the somatosensory cortex are reorganized to receive inputs from the neighboring skin areas including the stump. A similar reorganization occurs in the motor cortex. Thus, motor and sensory representations of the cerebral cortex become remodeled following nerve injury and regeneration in the PNS. This means that patients should relearn how to appropriately perform an action through the remodeled cerebral cortex in rehabilitation. Reorganization of the cerebral cortex is a basis for the rehabilitation of limb activity (►Somatosensory reorganization; ►Regeneration: clinical aspects).

Artificial materials have been studied as guides for the growth of regenerating axons in the PNS. Collagen gel has been most commonly used. Other biodegradable polymers that have been utilized for nerve regeneration are polyglycolic acid, polylactic acid, poly-ε-caprolactone, alginate, and chitosan. Alginate is derived from brown seaweed, and chitosan is from the crustacian exoskeleton. These materials have been used as substrates for nerve regeneration in the PNS and CNS (►Transplantation of artificial materials for nerve regeneration). A polyglycolic acid-collagen tube has been developed with good results [10].

Blood supply is a critical point for successful nerve regeneration. Blood capillaries that readily regenerate in the connective tissue compartment greatly contribute to peripheral nerve regeneration. Blood vessels, once damaged, rarely regenerate in the CNS. This is probably because, unlike in the PNS, there is no extracellular matrix which can act as a scaffold for developing vessels in the CNS. The loss of blood supply results in severe ischemia, which in turn leads to the suppression of tissue repair and the promotion of cavity formation in the CNS.

## Motor Nerves: The Neuromuscular Junction

Motor nerves terminate at ►neuromuscular junctions, which consist of presynaptic axon terminals and postsynaptic folds of the muscle fiber plasma membrane. In addition, terminal Schwann cells cover the presynaptic axon terminals, and the basal lamina, a continuation of the ordinary basal lamina of muscle fibers, is present on the folds of the muscle fibers. Following Wallerian degeneration, the presynaptic terminal disappears, and the postsynaptic folds at the endplate become gradually less distinct, but remain as a remnant of small folds. At the same time, terminal Schwann cells persist in the preterminal region. Regenerating axons enter the empty endplate, and become presynaptic terminals, thus forming new neuromuscular junctions. The presynaptic terminal can be formed in the absence of terminal Schwann cells, such as in the acellular scaffold [11]. In addition, regenerating axons can develop a presynaptic structure when they come into contact with the basal lamina at the site of the original postsynaptic folds. This indicates that the basal lamina at the endplate contains molecules that induce the regeneration of axons and cause postsynaptic specialization.

When muscle is partially denervated, ►axonal sprouting occurs from the intact neuromuscular junction. Following motor neuron injury, axon terminals are lost from the endplates of muscle fibers belonging to injured motor neurons. Responding to the denervation of endplates, axonal sprouts emanate from axon terminals of neighboring intact endplates, reinnervating denervated endplates. Thus, the ►motor unit is enlarged, and the muscle activity can be kept almost unchanged. Terminal Schwann cells that have lost contact with axon terminals by denervation extend cell processes toward the neighboring intact endplates. Such Schwann cell processes act as guide tubes for axonal sprouts to elongate from the intact endplate to the denervated one (►Role of sprouting in sustaining neuromuscular function in health and disease).

## Sensory Nerves: Sensory Corpuscles in the Skin

Sensory nerve terminals occur as various types of organized corpuscles present in the skin. Representative sensory terminals include ►Pacinian corpuscles and ►Meissner corpuscles, which are composed of axon terminals and modified Schwann cells called lamellar cells. Following Wallerian degeneration, lamellar cells

in these corpuscles become atrophic owing to the loss of contact with axons, but continue to exist for a long period of time. Upon the arrival of regenerating axons, lamellar cells begin to proliferate and take on the same structures as those found in the original corpuscles. For the acellular corpuscle, corpuscular basal laminae deprived of lamellar cells can also serve as a scaffold that promotes the regeneration of the original corpuscle following reinnervation. However, no new corpuscle regeneration in regions other than at the original corpuscle in the skin occurs (►Meissner corpuscle Regeneration; ►Pacinian corpuscle Regeneration).

►Merkel cell-neurite complexes are different from Pacinian and Meissner corpuscles in that their axons make direct contact with Merkel cells. Merkel cells deprived of axon terminals tend to disappear, probably due to degeneration and/or movement to the surface of the epidermis. Upon reinnervation, Merkel cells reappear, partly due to the differentiation of keratinocytes, and then form Merkel-neurite complexes similar to the original ones present at the base of the epidermis (►Merkel cell-neurite complex Regeneration).

## Nerve Regeneration in the CNS

Nerve regeneration in the CNS, especially in the spinal cord, has been extensively studied for more than 100 years. No effective nerve regeneration or tissue repair occurs in lesions of the spinal cord, which usually results in cavity formation without distinct tissue repair. Following injury to the spinal cord, strong regenerative responses occur including the formation of growth cones and associated glial cell migration. However, such neural reactions do not develop as efficiently as they do in the PNS, and result in cavity formation without axonal extension into the lesion. As described above, the essential difference between the PNS and CNS is the presence of an extracellular matrix in the PNS, which is composed of basal laminae and collagen fibers. This means that there is no effective scaffold available for the growth of regenerating axons in the CNS. The same can be said for blood vessel regeneration, which requires an extracellular matrix scaffold to regenerate.

The ►glial scar is usually produced around the cystic cavity at a chronic stage after injury. If the ►pia mater is cut open, the fibroblast-like cells of the meningeal layer invade the lesion, contributing to the formation of dense glial scar of connective tissues composed of extracellular matrices including collagen fibers. In such cases, astrocytes form a barrier between the connective tissue and adjacent CNS tissue. Basal laminae are formed on the surface of astrocyte processes facing the connective tissues, and thus, the CNS tissue tends to segregate itself from the invading connective tissues using astrocytic scar tissue [12]. This kind of glial scar is regarded as the main obstacle preventing the growth of regenerating axons in the CNS. Connective tissue invasion followed by glial scarring is therefore an undesirable phenomenon for nerve regeneration in the CNS. On the other hand, in lesions in which the pia mater is not cut open, the tissue reaction is different. When the spinal cord is crush-injured, the pia mater is usually not damaged, with the pial basal lamina kept intact. Cavities of various sizes are usually formed in the lesion at chronic stages. In such cases, there is no cell invasion from the outside. Astrocytic proliferation is found along the margin of the cavity, and oligodendrocytes line the inner surface of the cavity margin.

Usually, astrocytes, oligodendrocytes, macrophages, and microglia all contribute to the formation of glial scars. The mechanisms for scar formation, roles of contributing cells, and expression of specific molecules including proteoglycans are complicated, and yet to be understood (►Glial scar). Glial scars are thought to be the main impediments to the growth of regenerating axons. Regenerating axons from the proximal stump have to surpass the glial scar at the distal stump to invade the host spinal cord tissue. The digestion of proteoglycans has been proposed to promote axonal growth through glial scar in the spinal cord.

Cavities resulting from the degeneration of impaired tissues hamper axonal extension through the lesion. The margin of the cavity is not as thick as the astrocytic scar tissue as previously thought in the crush-injured spinal cord. Using appropriate techniques including cell transplantation, it may be possible to induce regenerating axons to grow through a region with cavities.

Functional assessment is important for nerve regeneration in the CNS, for which BBB scoring and other types of estimation of behavioral recovery have been employed [13].

At present, cell transplantation is being extensively studied to facilitate nerve regeneration in the injured spinal cord. Several varieties of cells have been used for transplantation, among which the major cell types include: Schwann cells, bone marrow stromal cells, olfactory ensheathing cells, choroid plexus ependymal cells, neural stem cells, macrophages, and those found in embryonic spinal cord tissue. Other studies have also been carried out which focused on the suppression of inhibitory factors such as ►Nogo A by the specific antibody.

### Schwann Cells

Aguayo and colleagues showed that neurons within the CNS can induce the elongation of regenerating axons into peripheral nerves which were inserted at one end into the spinal cord and at the other end into the medulla oblongata [14]. This shows that regenerating axons from neurons in the CNS can extend if they are provided with an appropriate environment. Since this report, cell implantation aimed at CNS nerve regeneration has been extensively studied.

Schwann cells play a role in axonal elongation in grafted peripheral nerves, where regenerating axons come into contact with Schwann cells, which support the growth and maturation of regenerating axons, as in the case of the PNS. The utility of peripheral nerve grafts has prompted the use of cultured Schwann cells for transplantation in the CNS. Here, cultured Schwann cells mingle in matrigel, and are then placed into an artificial tube, after which the tube is subsequently grafted into the lesion of the spinal cord. Many regenerating axons extend through the tube, and some enter the distal stump. A few axons then form synapses with neurons present in the distal segment of the spinal cord, and behavioral improvement subsequently takes place [15].

Although Schwann cells also serve as effective conduits for regenerating axons in the CNS, extracellular matrices including basal laminae are inefficient as scaffolds for the growth of regenerating axons in the CNS, unlike in the PNS. Since Schwann cells possess basal laminae and the ability to produce collagen matrices, extracellular matrices can be brought into the lesion following Schwann cell transplantation. Therefore, astrocytes at the border of the lesion are apt to form barriers composed of cell processes with basal laminae on the surface facing the Schwann cell compartment, and regenerating axons cannot penetrate such astrocyte scar tissue. Studies have been concentrated to overcome this difficulty in Schwann cell transplantation (►Transplantation of Schwann cells).

The ►optic nerve is frequently used as an experimental model of nerve regeneration in the CNS. Since it is an isolated bundle composed of central nerve fibers, nerve regeneration can be more precisely evaluated than by using the spinal cord. Transplantation of peripheral nerves and Schwann cells into the optic nerve has been well studied [16]. A long peripheral nerve transplanted into the optic nerve can serve as a conduit for regenerating axons traveling from the optic nerve to the ►superior colliculus, in which some synaptic connections are formed. Some functional recovery of light sensation has also been reported using this technique.

Many ►retinal ganglion cells undergo retrograde degeneration after optic nerve injury, and this poses another major problem for optic nerve regeneration. The administration of trophic factors into the optic cup has been studied with the aim of promoting the survival of ganglion cells (►Regeneration of optic nerve).

## Bone Marrow Stromal Cells

Although they do not belong to the CNS, bone marrow stromal cells (BMSCs) have been used for transplantation into the spinal cord [17]. BMSCs are grafted by directly injecting them into the lesion or by infusing them through the cerebrospinal fluid (CSF) [18,19]. Some BMSCs then gather in the lesion and survive there for 2–3 weeks after grafting. BMSCs do not differentiate into neural cells after grafting into the spinal cord. In the rat, they tend to disappear from the spinal cord more than 4 weeks after grafting. Although BMSCs do not become integrated into lesions of the spinal cord, tissue repair including the suppression of cavity formation is facilitated. In addition, behavioral improvement is obvious in the spinal cord-injured rat. These findings imply that BMSCs can be used in transplants to treat ►spinal cord injury.

Since BMSCs can be obtained from the patients themselves and are not stem cells but ordinary functioning cells present in the bone marrow, they show promise for the clinical treatment of spinal cord injuries. Transplantation by infusing BMSCs into the CSF is more effective than direct injection into the lesion. Also, since BMSCs disappear several weeks after transplantation, they might release trophic factors that reverse the degeneration of damaged neural tissue. The clinical application of BMSCs by injecting them into the cerebrospinal fluid via lumbar puncture has progressed (►Transplantation of bone marrow stromal cells for spinal cord regeneration).

Bone marrow stromal cells can be trans-differentiated into Schwann cells and neurons, and the transplantation of trans-differentiated Schwann cells and neurons may be a promising technique for CNS as well as PNS regeneration [20].

## Neural Stem Cells

Neural stem cells (NSCs) have been regarded as appropriate for cell transplantation to treat spinal cord injuries. After transplantation, these cells survive, migrate, and become integrated into the host tissue. They also have the ability to differentiate into neurons, astrocytes, and oligodendrocytes after transplantation.

There is hope that NSCs can be used after differentiation into neurons, astrocytes, and oligodendrocytes in vitro. Although NSCs are attractive for use in clinical therapy, the source of these cells is the most critical problem. There are strict limitations regarding the use of human embryos as sources of NSCs. It is also difficult to obtain NSCs from adult tissues. However, it is possible that NSCs can be acquired from the brains of deceased human bodies within a short period after death [21].

Another difficulty in using NSCs is the potential for unlimited cell proliferation, and, thus, the formation of cancer. Even in cases for which NSCs are used after differentiation in vitro, it is possible that a few undifferentiated cells may remain, and cause undesirable cell proliferation. Neural stem cells have been transplanted for spinal cord regeneration (►Transplantation of neural stem cells for spinal cord regeneration).

### The Choroid Plexus

The choroid plexus is the main region where the cerebrospinal fluid (CSF) is produced. It consists of epithelial cells and associated connective tissue containing plenty of sinusoidal blood vessels, and few fibroblasts and macrophages in a scanty collagen matrix. Grafting of the choroid plexus into the injured spinal cord promotes tissue repair including the growth and regeneration of axons in lesions [22]. Other in vitro and in vivo studies have indicated that choroid plexus epithelial cells (modified ependymal cells) might have the ability to promote nerve regeneration by rescuing neural tissues from degeneration and facilitating axonal growth. Considering that the CSF plays an important role in maintaining normal brain function, it should contain a variety of factors that promote the survival and proper activity of neural cells including neurons and glial cells.

### Olfactory Ensheathing Cells

Recently, olfactory ensheathing cells (OECs) have been extensively studied for use in transplantation to promote nerve regeneration in the spinal cord. These cells possess the properties of Schwann cells and astrocytes, and grafted OECs become Schwann cells associated with axons and perineurial cells surrounding nerve fibers, as seen in the PNS [23]. Furthermore, functional recovery can be observed in accordance with histological improvement. It is obvious that OECs provide the guide for the extension of regenerating axons. OECs have had a great impact on the study of spinal cord regeneration; however, their effects have varied among such studies. In spite of the many studies performed so far, how OECs exert their effects in spinal cord regeneration has not yet been fully elucidated. Identification of OECs in in vivo experiments might be a crucial requisite for accurately understanding their roles in spinal cord regeneration. Genetically labeled OECs might be useful for long-term observation after transplantation (►Transplantation of olfactory ensheathing cells).

### Embryonic Spinal Cord Tissue

Satisfactory regeneration can be induced in the spinal cord in which a segment of the spinal cord obtained from an embryo has been transplanted in rats during the early postnatal period [24]. It has been proposed that embryonic tissue can overcome glial scaring of the cystic cavity in chronic injury of the spinal cord. Unfortunately, the use of embryonic tissues is greatly limited due to ethical problems.

### Genetically Modified Cells

Experiments in which cells that were genetically transformed to secrete trophic factors have been transplanted into the injured CNS tissue have been conducted. Fibroblasts and other kinds of cells including OECs have been used for such experiments [25]. However, at present, genetically modified cells involve problems of ethics and safety that should be overcome before clinical application.

### Immune System

Following injury to the CNS, microglia and macrophages invade the lesion. Microglia, macrophages, and T-cells have been demonstrated to play important roles in CNS protection and repair. Regulatory and autoimmune T-cells are contradictory regarding CNS protection. Autoimmune T-cells activate the microglia to secrete trophic factors for CNS repair (►Protective autoimmunity). Macrophages preincubated with sciatic nerve fragments or autologous skin promoted repair of the optic nerve and spinal cord. Microglia and bone marrow-derived macrophages with the property of antigen-presenting cells secrete trophic factors that contribute to neuroprotection in the CNS (►Autologous macrophages for central nervous system repair). Studies on the functions of immune cells such as microglia, macrophages, and T-cells provide insights into the CNS mechanisms of protection against injury, and contribute to achieve CNS regeneration.

### Inhibitory Molecules

It is believed that CNS regeneration cannot occur partly due to the presence of inhibitory molecules in the CNS. The main inhibitory molecules are associated with myelin sheaths and oligodendrocytes, including myelin-associated glycoprotein (MAG), oligodendrocyte-myelin glycoprotein (OMgp), and Nogo-A. Growth cones collapse when they encounter these inhibitory molecules. The administration of anti-Nogo A antibody promotes the growth of regenerating axons in the injured spinal cord and improves behavioral function in rats [26].

Another major inhibitor is chondroitin sulfate proteoglycan (CSPG) produced in the glial scar. CSPGs serve as barriers to growing axons. Regenerating axons are thought to be blocked at the boundary of the glial scar in the spinal cord injury (►Inhibitory molecules in regeneration).

Hand Surgery/Department of Clinical Sciences, Malmö University Hospital, Lund University, Lund, Sweden

### Definition

Outgrowth of ►axons following clinical nerve injury and repair, resulting in functional restoration in denervated body parts.

## Characteristics

### Background

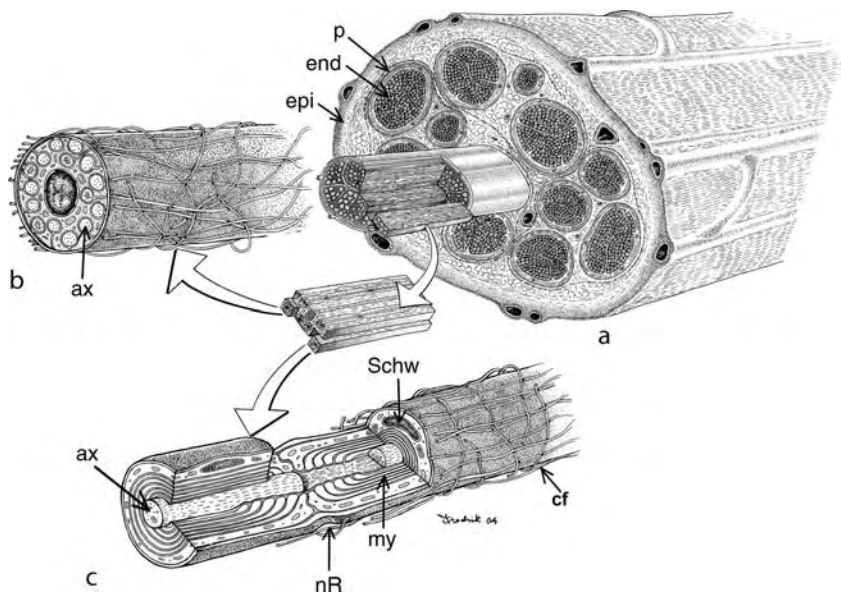
Injuries to peripheral nerve trunks constitute a major clinical problem [1,2]. Such injuries are most frequently seen in the upper extremity. The consequences are severe and the result is often permanent disturbances in sensory and motor functions of the hand. Normally, there is an interaction between the hand and the brain so that the hand is very well represented in the somatosensory cortex as well as the motor cortex [1,3,4]. A nerve injury implies a sudden de-afferentiation with arrest in inflow of sensory impulses to the brain. This results in a rapid cortical remodelling process where the "vacant" cortical area, previously representing the innervated area of the hand, is invaded by expanding adjacent cortical areas [1,3,4]. An analogous phenomenon occurs in the motor cortex.

If the nerve injury is surgically repaired, there is a regeneration of axons downstream of the distal nerve segment aiming at reinnervation of the denervated body part. To regain normal function, axons have to reinnervate their "correct" peripheral targets. However, there is always, in spite of meticulous surgical techniques, a large extent of misorientation of regenerating axons at the repair site and consequently an incorrect peripheral reinnervation [1]. With the reinnervation process, the cortical hand representation is again restored, however in a new and distorted pattern due to the peripheral mal-orientation. A relearning process is required that can be easily managed by the child's brain but usually not by the adult brain [5]. Therefore, fine tactile discriminative functions are seldom or never fully restored in an adult patient. The process of clinical regeneration is influenced by a number of intrinsic and extrinsic factors, some of them reviewed below.

### The Nerve Trunk and the Regeneration Process

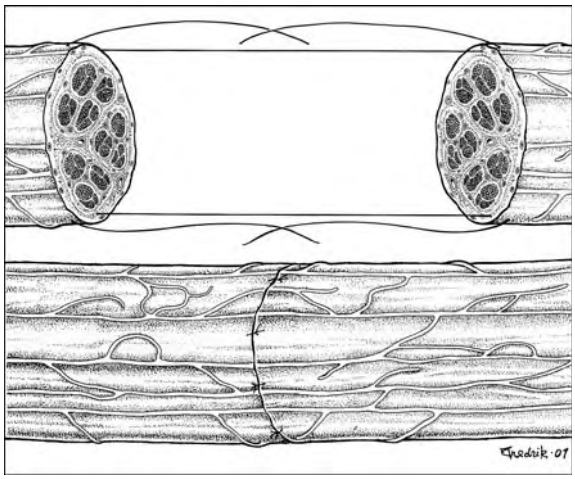
The nerve trunk represents a composite tissue structure constructed to maintain continuity, nutrition and protection of its basic elements – the axons (Fig. 1). An axon is a long tubular process of the nerve cell body, which may be situated in a dorsal root ganglion (sensory axons), or the anterior horn of the spinal cord (motor axons). The nerve cell and its processes is called a neuron. The axons are ensheathed by Schwann cells that may produce a myelin sheath. The Schwann cell basal lamina contributes to constitute an "endoneurial tube." The axons are closely packed within the endoneurial connective tissue inside ▶fascicles [1]. Each fascicle is surrounded by a perineurium, which is a multicellular laminated sheath of considerable mechanical strength, providing a diffusion barrier. The fascicles are embedded within an ▶epineurium, which is a supporting and protective connective tissue sheath carrying a longitudinal network of epineurial blood vessels.

Nerve injuries may be of several types and magnitudes. A severe compression or a crush lesion



**Regeneration: Clinical Aspects. Figure 1** Microanatomy of peripheral nerve trunk and its component. (a) Fascicles surrounded by a multi-laminated perineurium (p) are embedded in loose connective tissue, the epineurium (epi). The outer layers of the epineurium are condensed into a sheath. (b and c) The appearance of unmyelinated and myelinated fibres, respectively, is shown. Schw Schwann cell; my myelin sheath; ax axons; nR node of Ranvier; end endoneurium. Reproduced with permission from Lundborg 2004.

may disrupt axons while the ensheathing chain of Schwann cells and their basal lamina may be preserved. Disruption of axons results in degeneration of their distal segments, implying disintegration of the axonal elements and the myelin sheath. A regeneration process is then required where axons grow distally, following their original pathways, hereby reinnervating correct peripheral targets. The normal cortical representation of the body part is hereby re-established [3,4]. With transection of a nerve trunk, however, the situation is quite different: the "sprouts" that are formed by the transected proximal part of the axons may orient themselves into incorrect distal "Schwann cell tubes" that result in reinnervation of incorrect peripheral targets. Before the regeneration process is initiated, an "initial delay" may last for days or weeks. As a result of the injury a large number of nerve cell bodies in dorsal root ganglia may die, which excludes possibilities for regeneration of their corresponding axons [1]. Several physical, biochemical and other factors influence the course and functional outcome of the regeneration process [1].

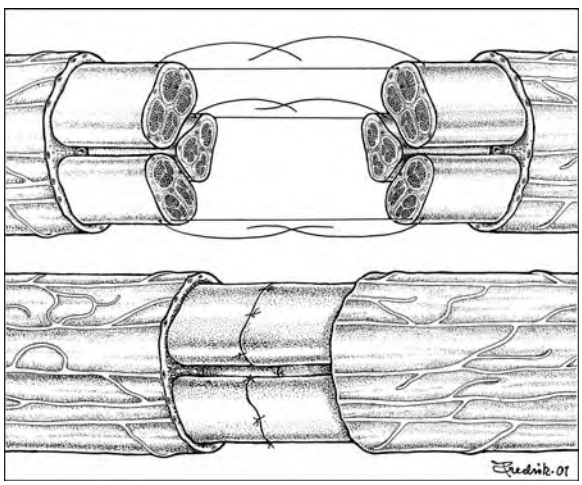


**Regeneration: Clinical Aspects. Figure 2** Epineurial suture. Adaptation of the nerve ends is achieved by single stitches in the superficial part of the epineurium along the circumference of the nerve. Reproduced with permission from Lundborg 2004.

## Clinical Nerve Repair and Reconstruction

Repair and reconstruction of injured peripheral nerves span over a variety of techniques such as direct repair, ►nerve grafting, use of conduits, ►nerve transfer and ►end-to-side (ETS) anastomosis [1,6,7,8].

With ►epineurial repair, the nerve stumps are approximated by suturing the epineurial sheath, using external landmarks like longitudinal blood vessels to ensure a correct rotational adaptation of the nerve ends. Although the external aspect of the repair site may look perfect, this technique does not, however, ensure an absolutely correct matching of the fascicular structures inside the nerve trunk. A more correct mechanical adaptation may be achieved by fascicular repair or ►group fascicular repair, which requires an internal dissection of the nerve so that separate bundles of fascicles are adapted towards each other. This technique may be justified in cases where sensory and motor fibres are running in separate, well-defined fascicles or fascicular groups, but otherwise the technique has no advantages over the epineurial technique. The various suture techniques may be combined and supplemented by fibrin glue. In ►tubular repair, a small distance is left between the nerve ends that are enclosed in a tubular structure of biological or synthetic type. Such tubes, which may be biodegradable or non-degradable, may give equally good results as direct sutures of the nerve ends (Figs. 2, 3).



**Regeneration: Clinical Aspects. Figure 3** Group fascicular suture. After resection of the epineurial tissue fascicular groups are approximated with single sutures in the connective tissue between separate fascicles or in the outer layer of the perineurium. Reproduced with permission from Lundborg 2004.

With more severe injury, there may be a defect in continuity of the nerve trunk. Such a situation may be seen in severe lacerations in the extremities or as a result of severe traction in the brachial plexus. Well-known examples are traction injuries occurring in difficult obstetrical situations or in adults involved in motorcycle or other types of traffic accidents. In such cases, the defect has to be bridged with a conduit to allow overgrowth of nerve fibres from the proximal to the distal nerve end. The most commonly used technique is to insert a nerve graft, usually harvested from the lower limb. Several cables of thin nerve grafts such as these are inserted between both of the nerve ends, using microsurgical techniques [7].

## Nerve Transfers

In severe nerve injuries, a proximal nerve segment may not always be available. An alternate "donor nerve" may then be required to provide the distal segment of the injured nerve with axonal input from a proximal nerve segment, a so-called nerve transfer. The situation requires sacrifice of the donor nerve, which can then be transferred to the distal segment of the injured nerve [6]. Such nerve transfers are widely used in brachial plexus surgery for restoring function in paralysed muscle by using adjacent intact nerves as donors, but can also be applied to more distal nerve injuries, for instance, to achieve motor or sensory functions in the hand by transferring an intact, nearby non-injured nerve.

## End-to Side (ETS) Nerve Repair

For more than 10 years it has been known that a distal nerve segment, when sutured in an end-to-side fashion to an adjacent intact nerve, can be reinnervated by sprouts from axons in the healthy donor nerve [8]. It was assumed that the intact axons in such cases may send out lateral sprouts that may reinnervate the sutured distal nerve segment. It was soon realised that this might be a new and promising possibility in clinical cases when routine nerve-grafting procedures where not possible, such as in root avulsions in brachial plexus injuries. The clinical results from these operations, as reported in the literature, are very variable.

## Functional Remodelling of Brain Cortex

A nerve transection represents an acute deafferentiation with immediate and longstanding influence on the cortical representation of the innervated body part. For instance, deafferentiation due to median nerve transection results in rapid expansion of adjacent cortical areas, which then occupy the former median nerve cortical territories. If no regeneration occurs, as after an amputation, the extensive cortical reorganisation persists so that the cortical area, previously receiving input from the median nerve, remains occupied by expanding adjacent cortical areas. In amputation, severe cortical reorganisations in such cases may result in persistent ►*phantom sensations* and *phantom* ►*pain*. After a ►*crush injury,* regenerating axons are guided by their original Schwann cell tubes so that they reach their original skin locations, and the corresponding cortical hand representation is normalised. However, after ►*transection and repair,* this scenario is quite different due to peripheral axonal misorientation. The previously well-organised cortical representation is changed to a mosaic-like pattern [1,3,4] and the nerve does not recapture all of its original cortical territory.

## Sensory Relearning and Sensory Re-Education

The outcome from nerve repair in adults is far from satisfactory and often disappointing, especially with respect to recovery of tactile discrimination [5]. One major factor is the new and distorted cortical hand representation – "the hand speaks a new language to the brain." A relearning process is required, and it can be a difficult task for adults to require their lost functional sensibility. In hand rehabilitation, ►*sensory relearning* is based on the use of ►sensory re-educational protocols [9,10]. According to these strategies, the brain is reprogrammed based on a relearning process. First, the perception of different touch modalities and the capacity to localise touch is trained, followed by touching and exploration of items, presenting shapes and textures of varying and increasing difficulty to the patient with eyes open or closed. In this way, an alternate sense (vision) trains and improves the deficient sense "sensation."

## Factors Influencing the Outcome from Nerve Repair

The functional outcome of nerve repair may vary considerably between patients although identical techniques may be used. There are several factors that are known to influence the outcome of nerve repair.

### *Age*

Although the functional recovery in adults is disappointing, especially with reference to recovering sensory functions, the situation is quite different among children who consistently show superior functional results after nerve repair [5]. This has usually been attributed to superior plasticity of the brain in children, with a better ability in central adaptation to the new pattern of afferent impulses presented by misdirected axons. A critical age period for recovery of functional sensibility in hands after nerve repair can be defined, the best results being seen in those younger than 10 years, followed by a rapid decline levelling out after late adolescence [5].

### *Cognitive Brain Capacities*

In adults, specific cognitive capacities of the brain such as verbal learning capacity and visuo-spatial logic capacity may help to explain variations in the recovery of functional sensibility after nerve repair [1].

### *Timing of Repair*

Nerve injuries should be repaired as soon as possible – if the condition allows. The posttraumatic nerve cell death, which usually occurs following nerve injury, can be reduced in this way. With early repair, the surgery is easier to perform since tissues may not yet be swollen, and the natural landmarks such as blood vessels can still be used to ensure a correct matching of the nerve ends. With increasing preoperative delay, there is a fibrosis of the distal nerve segment, atrophy of Schwann cells and there may be a progressive loss of neurons. After nerve transection the corresponding muscle atrophy rapidly,

and after two years the muscle fibres may fragment and disintegrate.

### *Type of Nerve*

The type of nerve that is injured considerably influences the functional outcome. If a pure motor nerve is injured, there is no risk of mismatch between motor and sensory cutaneous nerve fibres, thus optimising the accuracy in reinnervation. For pure sensory nerves, the situation is analogous. With mixed nerves, however, the situation is quite different with obvious risks for motor/sensory mismatch.

### *Level of Injury*

After nerve transection, there is an initial delay of days or weeks followed by sprouting and axonal outgrowth. The regeneration in humans has been reported to be non-linear, with a gradually decreased regeneration rate in distal parts. In humans the average outgrowth rate is at most 1–2 mm/day. When digital nerves in fingers are injured, there is only a short distance separating the regenerating axons from their distal target, while more proximal lesions may have a very substantial distance to grow. Lesions to the median nerve at wrist level may require 3–4 months before the first signs of reinnervation of the hand occur. In brachial plexus lesions reinnervation of the hand seldom or never occurs because of the long regeneration distance.

# Regeneration of Optic Nerve

Mari Dezawa[1], Kwok-Fai So[2]
[1]Department of Anatomy and Neurobiology, Kyoto University Graduate School of Medicine, Kyoto, Japan
[2]Department of Anatomy, The University of Hong Kong, Hong Kong, People's Republic of China

## Definition

Regeneration of retinal ganglion cell axons.

## Characteristics

### Higher Level Structure of Optic Nerve

The optic nerve is part of the central nervous system (CNS) and has a structure similar to other CNS tracts. The axons that form the optic nerve originate in the ►ganglion cell layer of the retina and extend through the ►optic tract. As a tissue, the optic nerve has the same organization as the white matter of the brain in regard to its glia. There are three types of glial cells: oligodendrocytes, astrocytes and microglia.

### Structural Regulation

Little structural and functional regeneration of the CNS takes place spontaneously following injury in adult mammals. In contrast, the ability of the mammalian peripheral nervous system (PNS) to regenerate axons after injury is well documented. A number of factors are involved in the lack of CNS regeneration, including: (i) the response of neuronal cell bodies against the damage, (ii) myelin-mediated inhibition by oligodendrocytes, (iii) glial scarring, by astrocytes, (iv) macrophage infiltration, and (v) insufficient trophic factor support.

### Higher Level Process

The fundamental difference in the regenerative capacity between CNS and PNS neuronal cell bodies has been the subject of intensive research. In the CNS, the target normally conveys a retrograde trophic signal to the cell body. CNS neurons die because of trophic deprivation. Damage to the optic nerve disconnects the neuronal cell body from its target-derived trophic peptides, leading to the death of retinal ganglion cells (RGCs). Furthermore, the axotomized neurons become less responsive to the peptide trophic signals they do receive. The survival of certain types of CNS neurons depends on physiological activation of electrical activity or elevation of intracellular ►cyclic AMP (cAMP). On the other hand, adult PNS neurons are intrinsically responsive to neurotrophic factors and do not lose trophic responsiveness after axotomy [1].

Oligodendrocytes, which represent the myelinating glia in the CNS, carry on their surface axon

growth-inhibiting molecules [2]. The hypothesis states that neurons in the CNS begin to lose their axonal regenerative capacity at roughly the period with the onset of myelination. Specific components of the myelin produced by the oligodendrocytes, such as ►Nogo A and ►myelin associated glycoprotein (MAG), have been shown to inhibit axonal growth, and antibodies against these proteins resulted in axonal regrowth in the CNS.

The glial scar at the injury site is a biochemical and physical barrier to successful regeneration. It contains large numbers of reactive astrocytes, oligodendrocyte precursor cells, and CNS meningeal cells. A recent study suggests that injury-upregulated ►bone morphogenetic protein 7 (BMP7) synthesized within the CNS induces differentiation of astrocytes from neural progenitors, which may also contribute to glial scar formation after CNS injury [3]. The expression of repulsive molecules such as ►semaphorin-3A, ►tenascin, ►NG2, ►neurocan, ►phosphacan, ►chondroitin and keratan sulfate proteoglycans are related to the repulsive nature of glial scars [4]. The reactive glial extracellular matrix is directly associated with the failure of axonal regeneration, whereas the myelinated white matter beyond the glial scar is rather permissive for regeneration. Nevertheless, Moon and Fawcett [5] have shown that despite the reduction of scar formation by treatment with antibodies to ►transforming growth factors (TGFs), sufficient enhancement of spontaneous CNS regeneration was not obtained. There is no doubt that glial scars have a negative impact on CNS regeneration, although their precise contribution to the inhibitory nature of the CNS environment needs to be ascertained.

The injury is very slowly and poorly infiltrated by macrophages. The importance of macrophage infiltration is illustrated by the observation that it stimulates regenerative responses in the transected rat optic nerve axons [6]. However, microglial activation is considered to be a double-edged response. The first stage of activation includes a non-phagocytic state, where microglia become hypertrophic and produce molecules that are cytotoxic to neuronal cells, such as ►tumor necrosis factor (TNF)-alpha. However, microglia also release cytokines to promote regeneration, for example ►TGF-beta, to promote tissue repair by reducing astrocytic scar formation. In addition, trophic factors including ►BDNF and ►GDNF, secreted by microglia, may also support regeneration.

## Process Regulation

The ability of the mammalian PNS to regenerate axons after injury is well documented. Studies in the past decade have shown that the Schwann cell, one of the most important myelin components of the peripheral glia, plays a key role in regeneration. The proliferation and activation of Schwann cells leads to the production of various kinds of factors and other related molecules, to enhance the axons of the proximal nerve stump to grow through the distal stump. Activated Schwann cells express a variety of cell adhesion molecules including ►neural cell adhesion molecules (NCAM), ►L1 and their close homologues ►CHL1, ►N-cadherin and integrins, represented by ►alpha1-beta1 and alpha6-beta1-integrin (α1β1 and α6β1-integrin), which mediate interactions between Schwann cells and axons, including growth cones. Besides these trophic factors and cell adhesion molecules, the Schwann cell supplies molecules to the extracellular matrix, such as ►fibronectin, ►laminin, ►J1/tenascin and ►merosin (laminin-2), to the injured axons, which then extend their processes. Among these extracellular molecules, ►laminin-alpha2 is known to play an important role in establishing remyelination, since its absence in mice led to reduced compactness and delay of myelination [7].

## Therapy

One strategy to elicit optic nerve regeneration is to provide a favorable environment by supplying neurotrophic factors and the transplantation of cells known to support axonal regeneration. Schwann cell is a strong candidate for transplantation, because optic nerve axons are known to regenerate, when the usual glial milieu is experimentally replaced by Schwann cells and/or peripheral nerve segments. Indeed, several experiments, involving CNS, have shown that exogenous supply of Schwann cells can improve axonal growth across the injured site [7].

Some cells such as gene-transfected astrocytes, ►olfactory ensheathing cells, ►ependymal cells, differentiated embryonic stem (ES) cells, and neuronal stem cells, can induce elongation of CNS nerve fibers, however, it has not been established that the elongated nerve fibers are remyelinated. Many CNS axons are myelinated by oligodendrocytes. The optic nerve tract is a typical example. Myelinating cells, either of Schwann cell or oligodendrocyte origin, mediate the spacing of sodium channel clusters at the nodes of Ranvier to enable saltatory conduction, which is a prerequisite for normal neuronal activity and function. Therefore, even if the CNS can elongate its axons, remyelination of regenerated axons is indispensable for the re-establishment of CNS function.

Schwann cells myelinate in peripheral axons, they also remyelinate CNS axons when transplanted. They are “cells with a purpose” and amongst the best candidates for implantation to support CNS regeneration. Thus, it is expected that transplantation of Schwann cells could become a feasible clinical treatment in the future if the technical and surgical issues can be overcome.

In addition to Schwann cell implantation, various other approaches have been attempted, as mentioned above, but a single approach alone does not appear to provide an optimal condition for optic nerve regeneration. Instead, recent studies using combined approaches, for example, ►CNTF with ►Nogo-neutralizing antibody IN-1 [8], and CNTF with cAMP [9] have shown a synergistic effect on RGC axon regeneration. It is therefore suggested that combining various experimental approaches including neutralizing inhibitory molecules (e.g. ►IN-1 or ►Nogo receptor blocker), blocking inhibitory signaling pathways (e.g. ►Rho pathway inhibitor), supplementing appropriate neurotrophic factors (e.g. BDNF, ►NT-4/5 or CNTF), providing a favorable environment for axon regeneration (e.g. peripheral nerve graft or Schwann cells/olfactory ensheathing glia transplantation), preventing scar tissue formation (e.g. ►Chondroitinase ABC), and elevating intrinsic regrowth capability (e.g. cAMP elevation), will help to provide the most favorable condition for optic nerve regeneration.

# Regeneration of the Central Nervous System

## Definition

Regeneration in general represents the replacement of lost body parts. Regeneration of the central nervous system (CNS) classically referred mainly to the regrowth of damaged neuronal axons. However, it has been realized that the replenishment of lost neural cells, and furthermore, the recovery of lost neural function, can be included in the concept of CNS regeneration. In fact, the attempt to recapitulate normal neural development has become a vital strategy for CNS regeneration.

►Regeneration

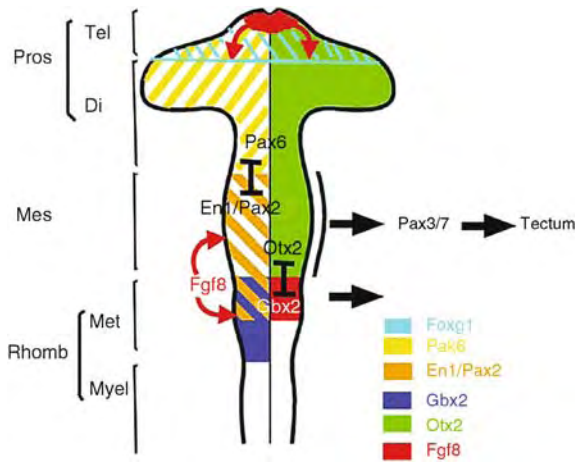
# Regionalization of the Vertebrate Central Nervous System

Harukazu Nakamura
Department of Molecular Neurobiology, Graduate School of Life Sciences and Institute of Development, Aging; Cancer, Tohoku University, Aoba-ku, Sendai, Japan

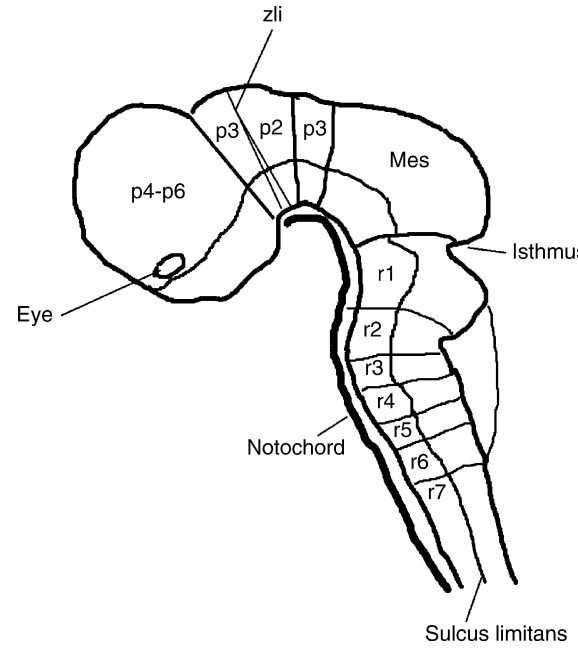
## Definition

The vertebrate central nervous system first arises as a simple neural plate, which then forms a neural tube. The neural tube is divided into functionally and morphologically distinct regions. The first sign of regionalization in the central nervous system is the appearance of primary brain vesicles such as the prosencephalon, mesencephalon and rhombencephalon (Fig. 1).

As a result of the subdivision of the prosencephalon into the telencephalon and diencephalon and the rhombencephalon into the metencephalon and myelencephalon, five secondary brain vesicles are formed, which are the fundamental brain plan. The telencephalon differentiates into the cerebral cortex and nuclei. The diencephalon differentiates into the thalamus and hypothalamus. The retina, neurohypophysis and pineal body are also derivatives of the diencephalon. The mesencephalon differentiates into the optic tectum and tegmentum. The metencephalon differentiates into the cerebellum and the pons. The myelencephalon differentiates into the medulla oblongata.



**Regionalization of the Vertebrate Central Nervous System. Figure 1** Brain vesicles The fundamental brain plan is in the brain vesicles. Primary brain vesicles (prosencephalon, mesencephalon and rhombencephalon) are transformed into secondary brain vesicles. The fate of the brain vesicles is determined by a combination of expression of transcription factors. The anterior neural ridge and mes-metencephalic boundary function as signaling centers. Otx2 is expressed down to the mes-metencephalic boundary. Foxg1 is expressed in the prospective telencephalon. The di-mesencephalic boundary is determined by repressive interaction between Pax6 and En1/Pax2 and the mes-metencephalic boundary is determined by repressive interaction between Otx2 and Gbx2. The region where Otx2, En1 and Pax2 are expressed is the mesencephalon. Additional expression of Pax3/7 in the mesencephalic alar plate confers differentiation into the optic tectum. *di* diencephalons; *mes* mesencephalon; *met* metencephalon; *pros* prosencephalon; *rhomb* rhombencephalon; *tel* telencephalon.



**Regionalization of the Vertebrate Central Nervous System. Figure 2** Neuromeres In the rhombencephalon, rhombomeres are formed, which are characterized by bulges and constrictions. Rhombomeres are compartments whose boundaries cells do not cross. In the prosencephalon, prosomere models are proposed. Zli is formed between p2 and p3 and functions as a signaling center. *p1-p6* prosomere 1–6; *r1-r6* rhombomere 1–6; *zli* zona limitans interthalamica.

The sulcus limitans divides the neural tube into the dorsal alar plate and the ventral basal plate (Fig. 2).

## Characteristics

### Description of the Process

The fate of the region is determined by a combination of transcription factors expressed in the region. For the antero-posterior (AP) axis, boundaries function as organizing centers. Signals from the organizing center regulate expression of the transcription factors, thus regulating the fate of the adjacent region. For the dorso-ventral axis (DV), signaling centers are in the outside of the neural tube, the notochord and the dorsal midline ectoderm. Transcription factors that are homologous to those of *Drosophila melanogaster* are expressed in the vertebrate brain anlage and define the fate of the brain region.

### Regionalization of the Prosencephalon

*Otx1* and *Otx2*, homologs of *orthodenticle* (*otd*) of *Drosophila*, are expressed in the prosencephalon and mesencephalon. Expression of these genes differs with time; *Otx2* is expressed from a very early stage whereas the *Otx1* expression window is later. *Otx2* plays a more important role in defining the region; *Otx2* null mutant mice lack prosencephalon, mesencephalon and anterior rhombencephalon, although *Otx1* null mutant mice show abnormality in the dorsal telencephalic cortex. Since *Otx1* could be replaced by *Otx2*, it was suggested that the difference in the phenotypes of *Otx1* and *Otx2* null mutant mice stems from differences in expression patterns [1–3].

*Emx1* and *Emx2*, homologues of *empty spiracle* (*ems*) are expressed in the telencephalon. These molecules may play a crucial role in arearization in the telencephalon, rather than defining the telencephalic region. *Emx2* is expressed in a gradient, posterior high and anterior low. Fgf8 signal from the anterior and Wnt signal from the posterior (cortical hem) determine the pattern of *Emx2* [1–3]. *Wnt* genes are homologs of *Drosophila wingless* (*wg*).

*Foxg1* (*BF1*) is expressed in the telencephalon and defines the telencephalic region (Fig. 1). *Six3* is expressed anterior to the zona limitans interthalamica (zli) and confers competence to express *Foxg1* in

response to Fgf8. *Irx3* is expressed posterior to the zli and confers competence to express *En1* and *En2* in response to Fgf8. *Six3*, *Irx* and *En* are homologs of *sine oculis, iroqois* and *engrailed* respectively [4].

Puelles and Rubenstein had proposed that the prosencephalon consisted of six prosomeres (p1-p6), but then reduced it to four prosomeres [5] (Fig. 2).

P1 corresponds to the synencephalon, which is a prospective pretectum. P2 and P3 correspond to the parencephalon and are prospectively thalamus and prethalamus respectively. P4-P6 are the secondary prosencephalon, which gives rise to the telencephalon and hypothalamus. The zli is formed between p2 and p3 and functions as a signaling center [4–6]. P1-P3 are the epichordal part and P4-P6 are the prechordal part.

## Regionalization of the Mesencephalon

The mesencephalon is characterized by a combinatorial expression of *Otx2*, *En1* and *Pax2* [7]. *Otx2* is expressed down to the mes-metencephalic boundary (Fig. 1). The posterior limit of the mesencephalon corresponds to that of the *Otx2* expression domain. Misexpression of *Otx2* in the metencephalon changes the fate of the metencephalon to that of mesencephalon, i.e. the metencephalon differentiates into the tectum instead of the cerebellum after misexpression of *Otx2*. *Otx2* knockout mice lack prosencephalon and mesencephalon. Misexpression of *Gbx2,* which is expressed in the metencephalon, causes an anterior shift in the posterior limit of the tectum. Fgf8, Pax2/5, En1/2 are in a positive feedback loop for their expression, so that misexpression of one of these molecules in the diencephalon activates the loop. Since *Otx2* is intrinsically expressed in the diencephalon, misexpression of one of these genes changes the fate of the diencephalon to that of the mesencephalon [3,7,8]. *Gbx2* is a vertebrate homolog of *Drosophila unplugged* and *Pax* genes contain a paired box, which was originally identified in the *Drosophila paired* gene.

## Regionalization of the Rhombencephalon

The rhombencephalon is characterized by seven or eight swellings called rhombomeres (r) (Fig. 2). It was shown that the ►neuromeres in the hindbrain are ►compartments [2,6]. The spinal cord also shows a metameric pattern, which is characterized by motor nerves and dorsal root ganglia. ►Metamerism in the spinal cord is not however intrinsically formed, but is a reflection of the ►segmentation of the somite [6]. It was shown that rhombomeres are true segments and form compartments whose boundaries are cell lineage restricting ones. Eph receptor tyrosine kinases and their ligands may be involved in lineage restriction. Receptors (EphA4, EphB2, EphB3) are expressed in odd-numbered rhombomeres (r3, r5) and their ephrin B ligands are expressed in the even numbered rhombomeres (r2, r4 and r6). The ephrin-Eph system is shown to produce repulsion, since the cells in the odd-numbered rhombomeres and those in the even-numbered rhombomeres do not intermingle [2]. Each rhombomere is characterized by a set of motor neurons. Orthologues of *Drosophila Hox* genes are expressed in an ordered and nested manner [2,6].

The identity of the rhombomere is determined by the combination of the expression of *Hox* genes [6]. Regulation of rhombomere identity by *Hox* genes has been shown by gain- and loss-of-function studies. *Hoxb1* is uniquely expressed in r4. Some of the facial motor neurons that are produced in r4 migrate to r6 and vestibuloacoustic neurons migrate to the contralateral side in wild type mice. In *Hoxb1*-knock out mice, neurons produced in r4 do not migrate either to r4 or to the contralateral side, which suggests that the r4 is transformed to r2 in the mutant mice. On the other hand, misexpression of *Hoxb1* in r2 changed its fate to that of r4.

## Regulation of the Process by Signaling Centers

The fate of the brain vesicles is determined by a combination of transcription factors. Signals from the boundary regulate expression of the transcriptionm factors. The mes-metencephalic boundary (isthmus) was first recognized to function as a secondary organizer for the tectum and cerebellum [2,7,8]. This was first shown by ectopic transplantation of the brain vesicles. The alar plate of the diencephalon changed its fate and differentiated into the tectum when it was transplanted to the posterior part of the mesencephalon. The fate change did not occur in the anterior part of the mesencephalon. Transplantation of the isthmus to the diencephalon induced the tectum around the transplant, showing that the isthmus functions as the organizer.

Implantation of an Fgf8-soaked bead into the diencephalon mimicked transplantation of the isthmus, i.e. tectum was induced ectopically in the diencephalon by Fgf8 [7,8]. Furthermore, *Fgf8* mutants in zebra fish and mice showed a disruption of the mes and r1. Later work all supported the idea that Fgf8 is a major organizing molecule in the isthmus (Fig. 1). Another secreted factor *Wnt1* is first expressed widely in the mesencephalon and restricted to the posterior margin of the mesencephalon. Wnt1 null mutant mice show a severe deficit in midbrain and hindbrain. But later studies indicated that *Wnt1* functions as a growth-accelerating factor. Fgf17 and Fgf18 have also been shown to function as growth promoting factors. *Wnt1* is a homolog of *Drosophila* wingless (wg).

Among eight splicing isoforms of *Fgf8, Fgf8a* and *Fgf8b* are expressed in the isthmus. Misexpression by *in ovo* electroporation in chick embryos showed that Fgf8a changed the fate of the diencephalon to

that of the mesencephalon and that Fgf8b changed the fate of the mesencephalon to that of the metencephalon. Since electroporation with a 1/100 dilution of Fgf8b expression vector exerted Fgf8a type effects, the difference in the effects of Fgf8a and Fgf8b may be due to difference in the intensity of the signal. A strong Fgf8 signal may activate the genes for cerebellar differentiation [7].

Signaling via FGF receptors, tyrosine kinase receptors (RTK), can activate the mitogen-activated protein kinase (MAPK) and the phosphatidylinositol 3-kinase (PI3K). Blocking of the Ras-ERK (MAPK) signaling pathway by the dominant negative form of Ras changed the fate of the metencephalon to that of the mesencephalon, i.e. the tectum developed instead of the cerebellum in the metencephalic region after misexpression of the dominant negative form of Ras. These results indicate that the strong Fgf8 signal activates the Ras-ERK pathway to cause differentiation into cerebellum [7]. Ras-ERK signaling is so strong that it may need negative regulators. Sprouty2, Sef (similar expression of Fgf8) and Mkp3 are induced by Fgf8, but regulate the pathway negatively. Sprouty2 is expressed overlappingly with Fgf8 and can be induced very rapidly by Fgf8 [7]. Repression of the Ras-ERK signaling pathway by misexpression of Sprouty2 changes the fate of the alar metencephalon to become the tectum. On the contrary, excess Ras-ERK signaling by application of dominant negative form of Sprouty2 results in an anterior shift in the mid-hindbrain boundary. Application of a specific inhibitor of the PI3K pathway indicated that this pathway is also activated by Fgf8 to induce Mkp3 and En2.

The anterior neural ridge also expresses Fgf8 and functions as a secondary organizer for the telencephalon. Fgf8 induces *Foxg1* in the telencephalon (anterior to the zli), but induces En in the region posterior to the zli. It was shown that the difference in competence is dependent on the transcription factors expressed in the region. *Six3* confers ability to express *Foxg1* in response to Fgf8, whereas *Irx3* confers ability to express *En2* in response to Fgf8 [4]. *Six3* is a homolog of *Drosophila sine oculis*.

The zli is another signaling center. There Shh is expressed and regulates the differentiation of the thalamic nuclei. *Sox14* and *Gbx2* are expressed in the young neurons of specific nuclei in the dorsal thalamus (*Sox14*: interstitial nucleus of the optic tract, perirotundic area; *Gbx2*: nucleus rotundus, posterior nucleus). High doses of Shh induce GliI, which in turn mediates expression of *Sox14*. On the other hand, low doses of Shh induce GliII, which in turn mediates expression of *Gbx2* [4]. *Shh* (*sonic hedgehog*) is one of vertebrate homologs of *Drosophila hedgehog,* and *Gli* is the homolog of *Drosophila Cubitus interuptus*.

## Regionalization Along Dorsoventral (DV) Axis

The floor plate and roof plate, which are situated at the ventral and dorsal midline respectively, segregate the bilateral halves of the neural tube. On each side, motor neurons differentiate in the ventral third, relay neurons in the middle third and smaller interneurons in the dorsal third. *Pax3/7* and *Pax6* are expressed in the dorsal and middle thirds respectively and *Nkx2.2* is expressed in the most ventral part. Class II homeodomain proteins such as Nkx2.2, Nkx6.1, Nkx6.2 and bHLH transcription factor Olig2 are expressed in the most ventral part of the neural tube and Class I homeodomain (HD) proteins such as Pax6, Dbx2, Irx3 and Dbx1 are expressed dorsal to the Class II HD protein. Combination of these transcription factors defines the cell types along the DV axis.

Notochord was shown to have ventralizing activity. Implantation of the notochord lateral to the neural tube could induce floor plate and motor neurons near the implant. On the other hand, removal of the notochord results in extension of the dorsal markers to the ventral and motor neurons and the floor plate disappear. When notochord formation is genetically perturbed in mouse and zebra fish, ventral cell types are absent. For the ventralizing signal, Shh signaling was shown to play a crucial role. Shh is first expressed in the notochord, then the floor plate expresses Shh. Shh could elicit floor plate and motor neuron development ectopically. Centrally, Shh null mutant mice lack floor plate and motor neurons. Shh induces expression of ventral markers and the motor neuron marker islet1, but represses the ventral markers.

BMP4 and BMP 7 emanate from the roof plate and the dorsal ectoderm and antagonize the Shh signal. Thus, cell fate along the DV axis is determined by these signals.

For the DV axis in the mesencephalon, Pax3/7 are expressed in the alar plate of the mesencephalon and force it to differentiate as a tectum [7]. Shh is expressed in the floor plate of the mesencephalon. Misexpression of Shh in the mesencephalon represses Pax3/7 expression and changes the fate of the alar plate of the mesencephalon to the tegmentum (Fig. 1). After misexpression of Shh, motor neurons and dopaminergic neurons differentiate in the dorsal part of the mesencephalon.

# Regulation of Neurotransmitter Release by Protein Phosphorylation

Robert D. Burgoyne, Alan Morgan
The Physiological Laboratory, School of Biomedical Sciences, University of Liverpool, Liverpool, UK

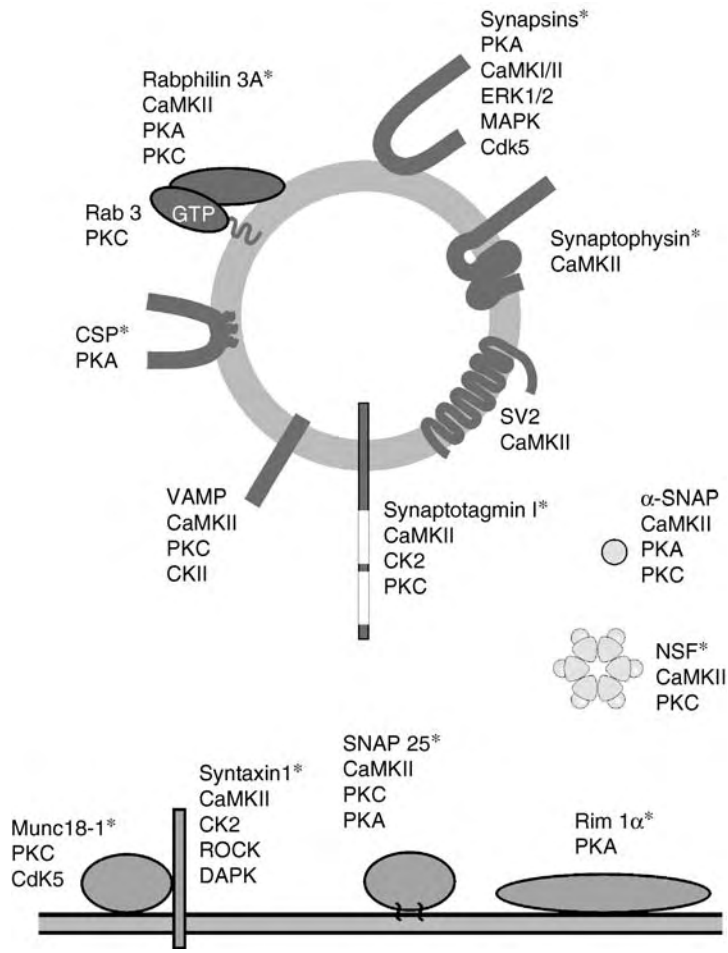
## Definition

The release of neurotransmitters at ►synapses is brought about by the process of regulated ►exocytosis, whereby a rise in the concentration of cytosolic $Ca^{2+}$ triggers the fusion of a ►synaptic vesicle with the plasma membrane and the release of the vesicle's neurotransmitter content into the extracellular space. The proteins responsible for the sensing of the $Ca^{2+}$ signal (synaptotagmin) and for vesicle docking and fusion (the SNARE proteins, SNAP-25, syntaxin and VAMP), have been identified and well characterized. In addition, several other proteins characterized through genetic approaches in flies, worms or mice are known to be either essential for neurotransmitter release (such as Munc13, Munc18-1 and NSF) or have important regulatory roles (such as cysteine string protein (CSP), Rabs and Rab effector proteins). In many neuronal cell types and various other kinds of secretory cells, exocytosis can be modulated through signalling pathways that result in phosphorylation of one or more of the key proteins involved in the exocytotic machinery [1]. The extent or kinetics of neurotransmitter release has been found to be modified by the action of several different ►protein kinases including PKA, PKC, Cdk5 and calmodulin-dependent protein kinase II (CaMKII). It has also been shown that ►protein phosphorylation by these, and other kinases, is required for various forms of ►synaptic plasticity. The changes in ►neurotransmission that underlie synaptic modification are in part post- and in part pre-synaptic. Regulation of protein phosphorylation is important for presynaptic changes in neurotransmitter release which is, therefore, likely to be involved in learning and memory formation. Neurotransmitter release could be modified via phosphorylation of channels or receptors, but it is clear that components of the release machinery are direct targets for protein phosphorylation and these will be the focus of this review. The protein targets for the various protein kinases, and the particular amino acids within these substrates that are phosphorylated, are increasingly being identified, and this is allowing the physiological roles of specific phosphorylation events to be established. The strategy that is being used and is most informative is the expression of mutated forms of the proteins, in which the identified phosphorylated amino acid is rendered non-phosphorylatable (e.g. by changing serine to alanine) or phosphomimetic, by mutation of serine to the acidic amino acid glutamate or aspartate. We have concentrated here on proteins known to be important, based on genetic manipulation, as part of the exocytotic machinery for neurotransmitter release, for which the mutation strategy has defined a significant functional role for protein phosphorylation on a defined amino acid. Other presynaptic proteins that are substrates for protein phosphorylation are known [1], but their importance for neurotransmission has not yet been validated genetically.

## Characteristics

Many aspects of neurotransmitter release can be modified following activation of protein kinases. These include an increase in release probability of vesicles, an increase in the size of the ►ready-releasable pool of synaptic vesicles, changes in $Ca^{2+}$-sensitivity of the release mechanism or changes in the kinetics of individual fusion and release events [1]. This has led to the search for the protein substrates involved. Several key exocytotic proteins have been shown to be substrates for protein kinases *in vitro*, and some of these have been confirmed to be phosphorylated in intact cells in response to physiological stimuli. In even fewer cases has the phosphorylation of a specific protein been convincingly linked to one of the known effects on neurotransmitter release of activation of a specific kinase. Nevertheless, a number of examples of well defined regulation by protein phosphorylation are now known. The key presynaptic proteins involved in neurotransmitter release, which have been shown to be protein kinase substrates, are shown in Fig. 1, and the identified phosphorylation sites that are known are listed in Table 1.

We will concentrate on those proteins that have been confirmed to be important for neurotransmission through genetic approaches, and whose phosphorylation has been shown to be physiologically significant for exocytosis. Phosphorylation of several proteins has been



**Regulation of Neurotransmitter Release by Protein Phosphorylation. Figure 1** Protein kinase substrates with established roles in the machinery for neurotransmitter release. Key synaptic proteins present on synaptic vesicles, the presynaptic membrane or the cytosol are shown, along with the protein kinases known to phosphorylate them *in vitro*. Only those proteins that have been confirmed through genetic approaches to be required for, or to regulate neurotransmitter release, are included. Proteins that are known to be phosphorylated in intact cells are indicated by asterisks.

linked to modification at various stages in the exocytotic process including vesicle mobilization (synapsins), vesicle recruitment into a releasable pool (RIM1), the maintenance of the ready-releasable pool size (SNAP-25) and late events during membrane fusion (CSP and Munc18-1).

The first presynaptic proteins whose phosphorylation was found to regulate neurotransmitter release were the synapsins, which have been extensively characterized both biochemically and functionally [1]. These proteins cross-link the reserve pool of synaptic vesicles to each other and to the cytoskeleton. Their phosphorylation by CaMKII following nerve terminal depolarization allows the release of the vesicles and, thereby, increases their availability for exocytosis. The functional significance of synapsins in the control of vesicle availability and recycling has been well established through the study of synapses from synapsin I and synapsin II knock-out mice.

A study using neurons from knock-out mice has shown that the Rab effector Rim1, which is localized on the presynaptic plasma membrane, is required to maintain the normal level of release probability in synapses and for ►long term potentiation (LTP) at parallel fibre/Purkinje cell synapses of the cerebellum [2]. LTP at these synapses is dependent on presynaptic PKA. RIM1 is phosphorylated both *in vitro* and *in vivo* by PKA on Ser-413. The ability of this residue to be phosphorylated is necessary for the recovery of the wild-type phenotype when expressed in neurons from null mutant mice, as expression of non-phosphorylatable mutants was ineffective. In contrast, mutation of another putative PKA phosphorylation site, Ser- 1548 was without effect on the recovery in knock-out mice. This study suggests that phosphorylation of Ser-413 of RIM1 is a significant mechanism for the PKA-dependent plasticity that

**Regulation of Neurotransmitter Release by Protein Phosphorylation. Table 1** Identified protein kinase substrates involved in exocytosis and the kinases that phosphorylate them

| Protein | *In vitro* phosphorylation sites | *In vivo* phosphorylation sites | Functional significance tested? |
|---|---|---|---|
| CSP | PKA: S10 | S10 | Yes |

Key synaptic proteins are listed that have been shown to be phosphorylated *in vitro* and whose phosphorylation sites have been identified. Only those proteins that have been confirmed through genetic approaches to be required for, or to regulate neurotransmitter release, are included.

exists in certain types of synapses and that involves changes in neurotransmitter release. The mechanistic basis for the effect of RIM1 phosphorylation is, however, unknown.

SNAP-25 is one of the key SNARE proteins that associates with syntaxin and VAMP and mediates vesicle docking/fusion at the plasma membrane. Phosphorylation of SNAP-25 has been suggested to regulate the size of the ready-releasable pool of vesicles, based on data from studies on ►adrenal chromaffin cells [3,4]. SNAP-25 [5] can be phosphorylated both *in vitro* and *in vivo* by PKA and PKC on identified sites (Table 1), and this has been implicated in the functional effects of PKA and PKC activation on exocytosis. Activation of PKC has multiple effects on exocytosis, one of which is an increase in the rate of refilling of the ready releasable pool of vesicles. SNAP-25 is phosphorylated by PKC on Ser-187 and this reduces its association with other SNARE proteins. Expression of SNAP-25 in adrenal chromaffin cells with mutations in this residue either increased (phosphomimetic mutant) or impaired (non-phosphorylatable mutant) the rate of refilling of the ►vesicle pools [3]. This suggests that this effect of PKC activation could be through phosphorylation of Ser-187 of SNAP-25. In contrast, a study on hippocampal pyramidal neurons did not find any effect of mutating Ser-187 of SNAP-25 on neurotransmitter release, suggesting the existence of other functionally important PKC substrates that increase neurotransmitter release in hippocampal synapses. Neurotransmitter release can also be increased by activation of PKA. In addition, the tonic activity of PKA is linked to the maintenance of the pool of ready releasable vesicles in adrenal chromaffin cells, and this was revealed by the use of PKA inhibitors [4]. Expression of SNAP-25 mutated at Thr138, the identified PKA phosphorylation site, to produce a non-phosphorylatable mutant reduced the size of the initial fast burst of exocytosis in chromaffin cells, suggesting that this might be the target for PKA's action on the ready releasable pool size. Phosphorylation of Thr138 has no effect on SNAP-25 binding to other SNAREs, although the effect on other protein interactions made by SNAP-25 is unknown.

CSP is a synaptic and secretory vesicle protein that has a chaperone role in the synapse. The phosphorylation status of CSP has been shown to affect late events in exocytosis that lead to changes in vesicle release kinetics and quantal size [6]. Overexpression of CSP in adrenal chromaffin cells was found to reduce the number of exocytotic events and also slowed vesicle release kinetics. CSP is phosphorylated *in vitro* on Ser-10 and this site was found to be phosphorylated *in vivo*. CSP phosphorylated on Ser-10 shows a reduced affinity for the syntaxin 1A and synaptotagmin I [6]. Expression of CSP with a mutation in Ser-10 (a non-phosphorylatable mutant) still reduced exocytosis but no longer modified the release kinetics. This suggests that Ser-10 is a target for protein phosphorylation, and that its phosphorylation

can regulate neurotransmitter release through an effect on the time course of release from individual vesicles. It is currently unclear, however, whether the regulation of CSP is a consequence of PKA-mediated phosphorylation or phosphorylation by some other kinase that recognizes the motif at Ser-10.

Munc18-1 is a member of the Munc18/Sec1 family of proteins that function in essentially all intracellular membrane fusion events. It is essential for neurotransmission in mice and knock-out animals are paralysed and die *in utero*. Munc18-1 and its orthologues in other species appears to have both negative and positive functions exerted in part through its interaction with syntaxin. Munc18-1 is phosphorylated *in vitro* by PKC on Ser-306 and Ser-313, and by Cdk5 on Thr-574. Only phosphorylation on Ser-313 has so far been confirmed to occur *in vivo* [7]. Phosphorylation of Munc18-1 by PKC or mutation of Ser-306 and Ser-313 to glutamates reduces the affinity of Munc18-1 for binding syntaxin 1A. Significantly, expression of Munc18-1 with the phosphomimetic mutations in Ser-306 and Ser-313 mimics the effects of PKC in increasing the speed of single vesicle release events in chromaffin cells [8]. Another effect of PKC, to increase the number of exocytotic events was not observed as a consequence of expressing phosphomimetic Munc18-1, suggesting that another PKC substrate (SNAP-25?) must be involved in this effect of PKC. In contrast, expression of a phosphomimetic mutation of Munc18-1 at Thr574 only partially reproduced the effect of Cdk5 activation. The evidence suggests that Munc18-1 may be a physiological substrate for PKC, but the significance of the putative phosphorylation by Cdk5 is still unclear.

Phosphorylation of syntaxin 1A *in vivo* has been demonstrated and recently implicated in the exocytotic events that are involved in the insertion of new membrane in growing neuronal processes [9]. Syntaxin 1A was found to be the substrate for both casein kinase II [10] and the Rho-associated serine/threonine kinase (ROCK) [9], and was phosphorylated on Ser-14 by both kinases. This phosphorylation site was demonstrated to be functionally important as its phosphorylation increased the affinity of binding of tomosyn to syntaxin, and thereby inhibited its ability to form productive SNARE complexes. It was suggested that this would provide a mechanism for the spatial regulation of exocytosis. Other work has shown, however, that phosphorylation of Ser-14 of syntaxin increases its binding to synaptotagmin and its recovery in complexes with SNAP-25, which would be more consistent with a stimulatory effect on exocytosis. It is not known whether phosphorylation of syntaxin 1 does regulate neurotransmitter release.

The changes in neurotransmitter release that occur following phosphorylation of synapsin, RIM1, SNAP-25, CSP and Munc18-1 are also believed to be due to modifications in specific protein-protein interactions between these proteins and others in the exocytotic machinery. The molecular basis for the effects of phosphorylation, are in general still to be resolved. In particular, the effect of PKA phosphorylation of RIM1 and SNAP-25 on their protein-protein interactions is unknown. As noted above, more information is available on the molecular effects of other phosphorylation events. It is also possible that other substrate proteins could be crucial for mediating the protein kinase effects. We still have only limited knowledge of the significance of the phosphorylation of other exocytotic proteins, and the physiological conditions under which specific protein phosphorylation events occur and become relevant for changes in neurotransmission and synaptic plasticity. It is clear, however, that these are important mechanisms that contribute to learning and memory.

## Regulatory Region

### Definition

Regulatory region is a promoter, enhancer or other DNA sequence of a gene that is bound by transactivating factors that control gene expression. The best-studied regulatory regions are in DNA, but they also exist in RNA where they can be bound for example by micro RNA.

## Regulatory Route

### Definition

Regulatory route refers to the pathway whereby after synthesis in the rough endoplasmic reticulum, proteins are transported via the Golgi apparatus to be stored in granules, and exocytosed from granular storage.

## Regulatory T Cells

### Definition

A sub-population of T cells, which in their resting state bear markers, e.g. CD25, characteristic of activated T lymphocytes. These cells, which originate in the thymus, ensure peripheral tolerance of autoimmune T cells by a mechanism known to be characterized by cell-cell contact and cytokine secretion, but are not yet fully understood.

►Protective Autoimmunity

## Reinforcement

### Definition

This term was first used in classical conditioning by Pavlov to describe the process by which a conditioned stimulus (CS) came to substitute for the unconditioned stimulus (US) and thus elicit a conditioned response. Its current use in the classical conditioning literature is rather casual and denotes trials on which the CS is followed by the US in contrast to the term non-reinforcement which denotes trials where the CS is presented without the US.

Reinforcement is a core concept in operant conditioning. It has traditionally been used to refer to the process of strengthening a response or behavior. Positive reinforcement is often used to describe situations in which the occurrence of an instrumental response leads to a desirable outcome (or reward). Its counterpart, negative reinforcement, is used to refer to situations in which the occurrence of an instrumental response leads to either the removal or the postponement of an undesirable event, although, depending on the particular theoretical orientation, the terms escape and avoidance learning, respectively, are more likely to be employed.

## Reinforcement Learning in Neural Networks

### Definition

An approach for training noisy networks based on increasing the likelihood of outputs that yield greater reward on average.

►Neural Networks for Control

## Reinforcement Learning in Animals

### Definition

Reinforcement learning is a learning rule to search optimal value based on a reward signal, signifying to the organism which conditions are desirable and which are the undesirable ones.

►Reinforcement

## Reinforcer

### Definition

In associative conditioning theory, a reinforcer is an event that modifies the frequency of the behavior that preceded it. The term refers to operant learning (also called Skinnerian or instrumental learning), a form of associative

learning in which animals learn to associate a behavioral action (for instance pressing a lever) to an outcome, either positive (a food reward) or negative (a punishment with an electric shock). Typically, the probability of the bar pressing response would increase if it is associated to the reward, but would decrease if it is associated to the punishment, a principle termed "the Law of Effect" by Edward Thorndike at the end of the 19th century. Note however, that the removal of a punishment can also act as a reinforcer: for instance, if bar pressing induces the end of a very loud noise, this behavior can increase because the end of the loud noise acts as a positive reinforcer.

►Reinforcement

## Reinnervation

### Definition

Return of lost nerve fibers (innervation) to a cell, tissue, organ.

►Neuronal Changes in Axonal Degeneration and Regeneration
►Regeneration

## Reinnervation of Muscle

### Definition

The nerve supply to denervated muscle fibers can be restored by reinnervation; injured nerve fibers regrow their axons to reach and resupply or reinnervate the denervated muscle fibers.

►Axonal Sprouting in Health and Disease

## Reinstatement

### Definition

The return of a conditioned response following re-exposure to the unconditioned stimulus after extinction training.

►Learning and Extinction

## Relation

### Definition

In the basic binary case, a relation R is a rule specifying when an object a is related by R to b. In an abstract mathematical sense, a binary relation is simply the set of ordered pairs (a,b) upon which it holds. The domain of the relation is the set of a which are related to some b.

The range of the relation is the set of b which are related to by some a. The relation is reflexive if every object a is related to itself. The relation is symmetric if whenever a is related to b, then b is also related to a. The relation is transitive if whenever a is related to b, and b is related to c, then a is related to c. An equivalence relation is a relation that is reflexive, symmetric and transitive.

A relation f is a function if to each a in its domain, there is exactly one b to which a is related, and this b is said to be the value of the function at a, written b = f(a).

A function is one-to-one if whenever a1 and a2 are distinct, then so also are f(a1) and f(a2). The function is onto B if every object in B is in the range of the function.

A one-to-one correspondence between A and B is a oneto- one onto function with domain A and range B. That is, a one-to-one correspondence provides a way of matching objects in A to objects in B in such a way that every object in A corresponds to a unique object in B and every object in B is corresponded to by a unique object in A.

The concept of binary relation can be generalized to trinary relations, which holds of triples (a,b,c), and so on to any dimension, even to infinite dimensions.

## Relative Pain Unpleasantness

### Definition

The amount of pain unpleasantness associated with a specific intensity of a pain sensation. It is a measure of how much a specific pain sensation bothers an individual. Equivalent intensities of pain may vary in unpleasantness, such as laboratory pain versus the pain of childbirth, or the pain of childbirth versus late stage cancer pain.

►Emotional/Affective Aspects of Pain

## Releasing Values

### Definition

Each stimulus has a certain attractiveness and may elicit a certain behavior. The attractiveness is measured by the releasing value. The natural, adequate stimulus has a releasing value of 100. Many stimulus have a lower releasing value, but some may have higher or supernormal releasing values.

## Releasing-Hormone and Release-Inhibiting Hormone

### Definition

These chemicals (mostly peptides) are produced by specific cells (neurosecretory cells) situated mainly in the hypothalamus and transported to the anterior pituitary gland. There they stimulate or inhibit a release of various anterior pituitary hormones. They include thyrotropin (TSH)-releasing hormone (TRH), which also acts as prolactin-releasing factor (PRF); adrenocorticotropin (ACTH) – releasing hormone (CRH); growth hormone (GH) – releasing hormone, (GHRH); growth hormone release-inhibiting hormone (somatostatin); gonadotropin (GnH) – releasing hormone (GnRH), sometimes called luteinizing-hormone (LH)- releasing hormone (LHRH), and prolactin release-inhibiting factor, now considered to be dopamine.

## REM-off Cells

### Definition

Extracellular single-unit-recording studies show that many neurons discharge at their highest rates (<5 spikes/sec) during waking, diminish their activity during non-REM (NREM) sleep, and become silent during REM sleep. Since these cells stop firing during REM sleep, they are called REM-off cells (also called PS-off cells). The majority of these REM-off cells are located in the locus coeruleus (LC) and raphé nuclei (RN). REM-off cells located in the LC contain the neurotransmitter noradrenaline and REM-off cells located in the RN contain the neurotransmitter serotonin. Although few in number, this type of cell is also

present in the caudal part of the pedunculopontine tegmentum (PPT) and laterodorsal tegmentum (LDT).

►Locus Coeruleus
►Non-REM Sleep
►Noradrenaline
►Raphé nuclei
►Rapid Eye Movement (REM) Sleep
►Serotonin

## REM-on Cells

### Definition

Neurons that exhibit increases in extracellularly recorded discharge rate during ►rapid eye movement (REM) sleep, rather than during waking and non-REM (NREM) sleep. This population of neurons is characterized by a progressively increasing mean tonic discharge rate as the animal moves from wake to NREM sleep and finally to REM sleep. This type of cell is mostly located in the pontine reticular formation, pedunculopontine tegmentum (PPT) and laterodorsal tegmentum (LDT). REM-on cells located within the pontine reticular formation contain the neurotransmitter glutamate and REM-on cells located in the PPT and LDT contain the neurotransmitter acetylcholine.

►Acetylcholine

## Renshaw Cell

### Definition

Renshaw cells are inhibitory interneurons (using glycine and GABA as transmitters), which are located in the ventral horn of the spinal cord, receive their main excitatory inputs from collaterals of motoneurons and mediate recurrent inhibition of motoneurons, Ia inhibitory interneurons, Renshaw cells and cells of origin of the ventral spinocerebellar tract. Other inputs to Renshaw cells arise from sensory afferent fibers and tracts descending from supraspinal structures.

►Ia Inhibitory Interneuron
►Recurrent Inhibition

## Repetition Maximum (RM)

### Definition

Repetition Maximum represents the load used in resistance training. Performing sets of ten repetition maximum (RM) loads or less are typically used for resistance training, with one RM being the maximum weight an individual can lift once, and ten RM being the weight an individual can lift exactly ten times. These values represent 100% and ~70% of maximum capability for one RM and ten RM, respectively.

►Muscle – Age-Related Changes

## Replacement Neuromast

### Definition

A superficial neuromast (hair cell of the lateral line system) having phylogenetic continuity with a neuromast found inside a canal in other taxa. This superficial configuration is most likely due to retarded development of canals in that taxon.

## Representation (Mental)

Michael Schütte
Institut für Philosophie, Universität Magdeburg, Magdeburg, Germany

### Definition

The term “mental representation” is sometimes used to cover any mental item which is semantically evaluable,

i.e. which has content, ►truth-value, refers to something, possesses ►truth-conditions, or is about something. Under this broad construal its extension includes beliefs, thoughts, memories, desires, perceptions and all other mental phenomena exhibiting the feature of intentionality.

But there also is a narrower construal of "mental representation" closely associated with the agenda of cognitive science. Under this narrower construal, mental representations are certain theoretical entities, i.e., semantically evaluable particulars which are postulated by classical or other types of cognitive architectures in order to explain processes and states which count as mental representations only in the broad sense.

## Description of the Theory

Mental representations as theoretical entities postulated by cognitive scientists come in very different shapes. Think of a cognitive scientist working in the paradigm of classical architectures. Insofar as she tries to understand the mind as a complex system that receives, transforms and stores information, that is, as a complex symbol-manipulating system, her approach is based on the idea that mental phenomena should be explained by postulating mental representations (symbols). Or think of a cognitive scientist working in the paradigm of ►connectionist architectures. Insofar as he tries to understand human behavior and mentality as based on the activity of neural networks, his approach, too, is based on the idea that mental phenomena should be explained by postulating mental representations, although these are notably different from those of classical architectures.

Mental representations as theoretical entities postulated by cognitive scientists come in great variety including, e.g., activity vectors in connectionist networks, Marr's 2½ -D sketches in his theory of vision, Kosslyn's mental images, the mental models of Johnson-Laird, or Fodor's "sentences in the language of thought" [1]. Ironically, most mental representations are misleadingly labeled "mental" representations, for they are explicitly understood as certain neuronal or other physical structures. But certainly, they all qualify as mental in the weak sense that they are postulated in order to explain mental features. The mental features to be explained range from pattern recognition to intentional behavior, but in the following we will concentrate on the so called propositional attitudes like believing or desiring that something is the case. Generally speaking, propositional attitudes are mental states which can be ascribed with the help of "that"-clauses.

## Representation

Representations are, of course, ubiquitous: There are words, photographs, paintings, maps, traffic signs, diagrams, graphs, music notes, X-ray photographs, digital images, and much more. They are not bound to a specific medium or syntax, and there are virtually no limits as to which things can represent which. A representation, as a self-representation, can represent itself, and two different things can represent each other. Representation should be distinguished from mere information, at least if the latter is taken to include things like the universe containing information about the big bang or the smoky sky containing the information that there is a fire. The idea behind distinguishing representation from information is that information cannot be false (otherwise it would not be information at all), whereas misrepresentation is possible. If this is correct, smoke does not represent fire, although it "indicates" or "means" fire [2]. It is notoriously hard to spell out precisely the necessary and together sufficient conditions which make something a representation, but there is a kind of consensus that every representation purports to stand for, denote, refer to, or be about something. Another important aim of philosophical thinking about representation is to build a useful classification of the many different forms of representation (see [3] and [4] for two very influential classificatory schemes).

## Representational Theory of Mind

The best-known representational theory of propositional attitudes is developed by Fodor [1]. It is a paradigm instance of a ►classical architecture in cognitive science, and is best seen as an attempt to explain how propositional attitudes and reasoning processes can be physically realized. Strictly speaking, this is a two-step enterprise: The first step is concerned with the question how propositional attitudes and cognitive processes can be realized by computational relations and processes in which symbols are manipulated. The second step consists in explaining how these computational relations and processes can in principle be physically implemented. Fodor thinks that the second step is already established by the theoretical work of Turing and others and, of course, by the actual development of computers. Therefore, he sees his main task in making intelligible how propositional attitudes can be realized by computational relations. The central features of propositional attitudes which are to be explained include the following: They are (i) semantically evaluable, (ii) causally efficacious, and (iii) opaque.

In order to account for these features, Fodor does several things. First, he assumes that there are mental representations. These are held to be sentence-like physical structures in a "language of thought." This means four things: Like sentences mental representations have propositional content; like sentences they are structured entities which have parts that themselves possess meaning; like sentences they have a compositional semantics, i.e., their meaning is a function of the

meanings of their parts and the order of these parts; and these parts are "transportable" which means that the same parts can appear in many mental formulas (Fodor [1]: 137). Fodor calls the conjunction of these claims the Language of Thought Hypothesis. Second, Fodor then uses these views to formulate the representational thesis according to which propositional attitudes are relations between organisms and mental representations. For example, to believe that grass is green means, according to the representational thesis, to stand in a certain relation (the belief-relation) to a mental representation which means that grass is green. More generally, for any organism O, and any attitude A toward the proposition P, there is a computational relation R and a mental representation M such that (i) M means that P, and (ii) O has A if and only if O bears R to M (Fodor [1]: 17). That an organism bears a certain computational relation to a mental representation M is spelled out in the following way: The representation M occupies a certain causal or functional role in the organism; i.e. it is tokened in a special functionally defined area (e.g. the "belief-box" or the "desire-box") and will be manipulated in a specific way. Third, Fodor claims that mental processes are causal sequences of tokenings of mental representations. This is best conceived as the view that causal relations between propositional states rely on computational processes that are sensitive to the structure of the involved mental representations.

This theory neatly explains the central features of propositional attitudes mentioned above as follows. (i) That propositional attitudes are semantically evaluable is accounted for by the fact that they are realized with the help of mental representations which are semantically evaluable. (ii) The deeper point in connection with second feature (causal efficacy) is this: Often causal relations between propositional attitudes contrive to respect their relations of content. For example, my thoughts that p and that (if p, then q) often cause me to think that q. This is explained by the fact that cognitive processes are computational processes which are structure-sensitive. This sensitivity to the syntax of mental representations is enough to explain the possibility of the parallel structure of logical and causal relations, because, as is well-known from logic, logical relations can be characterized syntactically. (iii) The belief that p and the belief that p* can be different beliefs, such that it is possible to believe that p without at the same time believing that p* (and vice versa), even when p and p* are both true or both false (or even possess the same truth-conditions). This feature of ▶opacity can be explained by the representational theory under the assumption that the mental representations of p and p* are syntactically different. Because syntactically different representations are typically manipulated in different ways, it is no mystery how at a certain time, there can be the mental representation p, but not the mental representation p* in someone's belief-box.

Main objections to Fodor's representational theory concern two issues. The first is the issue whether there is empirical evidence against its implication that causally efficacious attitudes require actual tokenings of mental representations. The second is the issue whether the assumption that there are physical structures which have semantic content can be made plausible at all. This is the topic of the next section.

## Physical Structures as Mental Representations

The representational theory as outlined above simply assumes that mental representations have a semantic content. Therefore, it remains another task for its proponents to explain how these representations being neural or physical entities can be semantically evaluable at all: How can physical or neuronal structures actually represent some state of affairs? This matter is not only of interest to the proponents of the representational theory, but is also of crucial interest for anyone else who takes a realistic stance on mental representations. Over the last two and a half decades, philosophers have developed several approaches to answer this question [1,5,6].

1. Dretske's information-theoretic approach is rendered in terms of information, and analyzes the property of having semantic content as a form of carrying information: A certain structure S (e.g. a representation) has the semantic content that p if and only if S carries the information that p and the information that p is the most specific piece of information which S carries, i.e. S carries no other piece of information in which the information that p is nested (see Dretske [5]: 177). That S carries information about something X at all basically means that there is a certain causal correlation between S and X. The attractiveness of this approach lies in the fact that in principle it is no mystery how physical structures (rocks, clouds, or brains) can carry information. In order to explain how misrepresentation is possible, Dretske appeals to the learning period in which a representation is acquired. In a nutshell, the explanation is that only causal correlations during the learning period determine what S represents, whereas after the learning period S can be caused by different things which, then, are misrepresented by S. This information-theoretic account faces two major problems: (i) it only works for representations which are acquired through an individual learning history, and (ii) it cannot deal with the ▶disjunction problem (Fodor [1]: 101f). The latter problem is a fundamental problem for every broadly causal account of meaning or content: If the contents of A-representations are determined by their being caused by

C-states, but sometimes A's are brought about by some other cause C*, then how can the causal theory account for the difference between the case in which A's represent C, but sometimes are caused by C*-states, and the case in which A's represent the disjunction C-or-C*? Dretske's appeal to a learning period would only be of help here if it were guaranteed that during this period all and only those factors cause A's which should enter into the semantic content of A's. But this seems to be false for empirical reasons.

2. Teleological accounts try to solve the disjunction problem by appeal to the biological function or purpose of representational states [6]. According to them, the mental representation R, although sometimes caused by dogs, represents wolfs and not wolfs-or-dogs, because it is the biological function of R-type representations to indicate wolfs and not wolfs-or-dogs. A major difficulty for this type of accounts is to explicate the notion of biological function in a non-semantic way. This is typically tried to be accomplished by an appeal to the (evolutionary) history of the organism. But it has turned out over the years that this is by far no easy task. Another problem lies in the fact that teleological accounts which appeal to evolution have counterintuitive consequences. For example, most people have the intuition that a perfect physical and behavioral duplicate of a human being would also have beliefs and desires. But if this duplicate has the wrong kind of history (or literally no history at all), it is thereby precluded from having mental representations. This arguably leads to an epistemological difficulty as well: If it is the evolutionary history of an organism which determines whether and which things are represented by its inner states, we can only know whether someone believes something if we know enough about its evolution.
3. Fodor [1] developed a third type of account which is based on the notion of asymmetric dependence. It runs along the following lines: A-states (of an organism O) represent C if and only if (i) under optimal conditions all C's cause an A-token, and (ii) all A-tokens which are caused by a state C* are asymmetrically dependent on the causation of A-tokens by C's. The idea behind Fodor's notion of dependence can be caught by a question: Would the C*-state also have caused A-tokens if C-states did not cause A-tokens? If not, the causal relation between C*-states and A-tokens is dependent on the relation between C-states and A-tokens. This dependence is asymmetrical if it is not the other way round, i.e. if it is not true that the relation between C-states and A-tokens is dependent on the relation between C*-states and A-tokens. Although this is an ingenious proposal, as some philosophers have pointed out, it might be entirely misguided. Let us assume that tokens of A in an organism O mean "bird," but sometimes are caused by big insects. According to Fodor's proposal, this is the case because big insects would not cause A's if birds did not cause A's in O. But, now, what is it that precludes big insects to cause A's in O even if there were no birds around? Why, in other words, should there be an asymmetric dependence relation at all? Certainly, if A were to mean "bird" in the first place, it would be quite plausible that some big insects cause A's in O only because normally birds cause A's in O. But that A means "bird" is exactly what Fodor's theory tries to explain and, therefore, cannot be assumed by it.

## Intentional Realism Versus Eliminativism

The representational theory of propositional attitudes and the project of naturalizing mental representations as sketched in the last section are committed to ►Intentional Realism. Intentional Realism is the view that humans have intentional states which (i) more or less obey the laws of folk psychology and which (ii) have a semantic content that is (iii) causally efficacious. But these assumptions can, of course, be denied. Most prominently some philosophers favor an eliminative stance towards propositional attitudes. Churchland [7] argues that folk psychology is a rather unsuccessful theory which in the long run will be substituted by a much better explanation of human behavior developed by scientific psychology or neuroscience which is incompatible with the folk assumptions. But because intentional states like beliefs and desires are only theoretical entities postulated by folk psychology, Churchland argues, they will be eliminated when folk psychology is abandoned.

Intentional Realism and Eliminative Materialism are opposing views on the ends of a spectrum and there are positions in-between. A very prominent one is Dennett's [8]. On the one hand, Dennett agrees with the Eliminative Materialists that there are in principle neuroscientific explanations of human behavior which are superior and incompatible with ►intentional explanations. On the other hand, he stresses that we cannot abandon intentional explanations altogether, because there are certain patterns in human behavior which can only be discovered from the intentional stance. Whether this or other "in-between" positions (as [9,10]) can be coherently defended is difficult to evaluate. What they all try to show is that the semantic contents of intentional states are real enough to underpin the autonomy of intentional explanations, but at the same time are not real enough to require their physical implementation. This can be put it in another way which perhaps is an exaggeration: These approaches aim to preserve mental representations in the broad sense (intentional states) without committing themselves to

the existence of mental representations in the narrow sense. Faced with the empirical and conceptual problems of Intentional Realism and the smell of absurdity of eliminativism, this may be an attractive direction of inquiry for further theories of mental representation.

## Rescorla-Wagner Model

### Definition

This model of classical conditioning attributes variations in the effectiveness of conditioned stimulus-unconditioned stimulus (CS-US) pairings to variations in US processing. The model asserts that an US must be surprising for learning to occur. An US is defined as surprising if the discrepancy term ($\lambda - V_T$) is different from zero. This discrepancy reflects the difference between the maximum conditioning the US can support ($\lambda$) and the associative strength of all the stimuli on the trial ($V_T$). The equation for calculating a change in the associative strength of a CS is:

$$\Delta V_{CS} = \alpha_{CS}\beta_{US}(\lambda - V_T)$$

where $V_T$ represents the total or sum of the individual associative strengths of all CSs present on that trial; $\alpha$ and $\beta$ are fixed rate parameters (values from 0 to1) determined by the salience (physical properties) of the CS and US, respectively; $\lambda$ is the maximum conditioning that the US can support.

## Respiration – Neural Control

Peter M. Lalley
Department of Physiology, Medical Sciences Center, University of Wisconsin School of Medicine and Public Health, University Avenue, Madison, WI, USA

### Synonyms

Respiratory system neurophysiology; Neuroanatomy and neurotransmitter/neuromodulator control

### Definition

The neural control of respiration refers to functional interactions between networks of neurons that regulate movements of the lungs, airways and chest wall and abdomen, in order to accomplish (i) effective organismal uptake of oxygen and expulsion of carbon dioxide, airway liquids and irritants, (ii) regulation of blood pH.

### Introduction

The neural control of respiration is still not completely understood, although remarkable progress has been made as instrumentation, technology and analytical procedures continue to improve at an accelerated pace. (Many excellent reviews are available that have followed progress in the field, and the interested reader is encouraged to consult them for particular areas of interest [1–14,16–18,20,21,23–26,28–31,33].)

It is axiomatic that biological cells are dependent on respiration for survival, proper function and ►homeostasis. They require an efficient transport system that provides oxygen ($O_2$) for aerobic metabolism and energy production and for extrusion of its end products, carbon dioxide ($CO_2$) and water.

In mammals respiration takes on an additional, organismal meaning and significance, synonymous with ventilation; i.e., the act of breathing ambient air in and out to deliver $O_2$ from the mouth and nasal passages to the lungs, and to transport $CO_2$ from lungs to atmosphere.

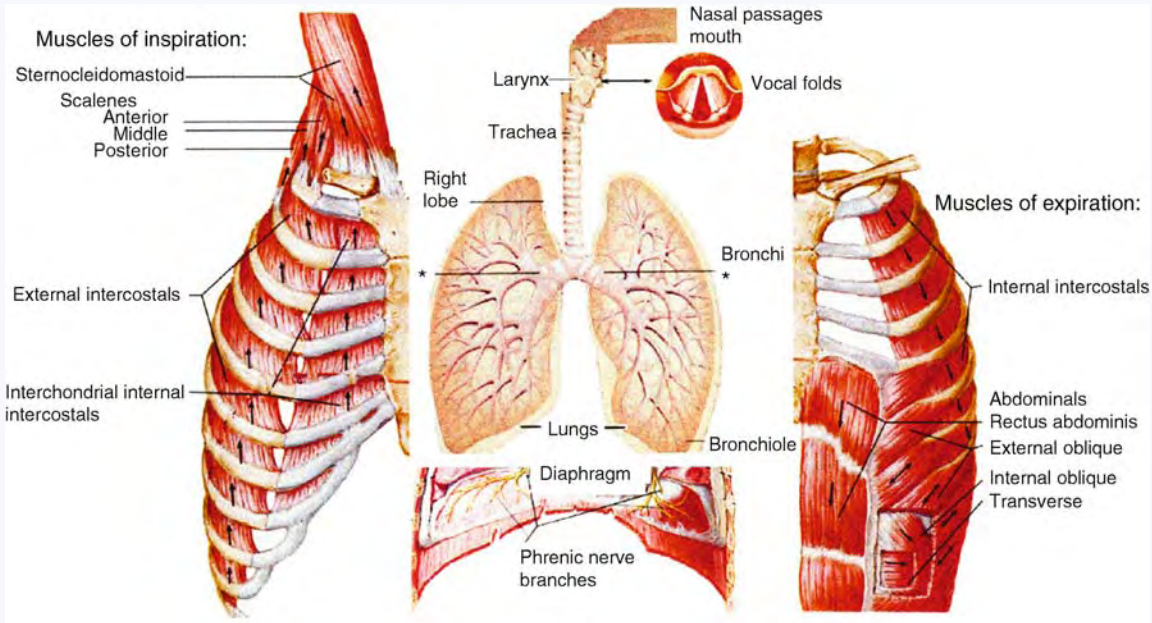
### The Respiratory Apparatus in Mammals

Effective organismal exchange of $O_2$ and $CO_2$ in mammals requires finely coordinated interactions between the organs of breathing and the ►cardiovascular system. The latter consists of the heart acting as the pump for blood in which $O_2$ and $CO_2$ are dissolved and the vascular network, from capillaries to major arteries and veins, which serves as the transport line between the lungs and other $O_2$-consuming, $CO_2$-producing organs. A system of valves in the heart and in the sphincters surrounding arterioles regulates the flow of blood.

The organs of breathing (Fig. 1) can also be subdivided into pump and flow components. The pump machinery consists of the diaphragm, chest wall and abdominal muscles, while the transport system involves the mouth, nasal passages, bronchi, bronchioles and lungs. In the lungs, the alveoli, a vast network of air-filled sacs, are in intimate contact with blood capillaries where exchange of $O_2$ and $CO_2$ takes place. Airway resistance and airflow in and out of the lungs is affected by altering the tone of bronchiole smooth muscle, pharyngeal skeletal muscle, nasal musculature, as well as tongue position and the tone of the laryngeal (vocal fold) abductor and adductor muscles.

### Performance of the Respiratory Apparatus During Inspiration and Expiration

During inspiration, airflow into the lungs and alveoli is produced as the diaphragm contracts during periodic discharges of the phrenic and inspiratory intercostal nerves (Fig. 2); the discharges are activated by excitatory synaptic drive within the ►brainstem-spinal cord respiratory network. Contraction of the diaphragm changes its configuration from dome shaped to relatively flat. This increases the intrathoracic volume, resulting in an increase of negative intrapleural pressure that promotes lung inflation and inward airflow from the mouth to the lungs. Discharges in intercostal nerves contract the inspiratory muscles of the rib cage,



**Respiration – Neural Control. Figure 1** The respiratory apparatus. Left side, muscles that expand the chest for lung inflation during inspiration are illustrated. Arrows show the upward direction of rib movement. The middle upper segment illustrates the airways, from nasal passages to lungs. A cross section through the larynx shows the laryngeal folds in an open (abducted) state during inspiration. The middle lower segment shows the diaphragm, which contracts downward to inflate the lungs during inspiration. Phrenic nerve branches that innervate the diaphragm and cause the musculature to contract are also seen. Right, muscles of the chest wall and abdomen that contract to aid lung deflation during active expiration. Arrows show the direction of rib and abdominal muscle movements. Modified from [19].

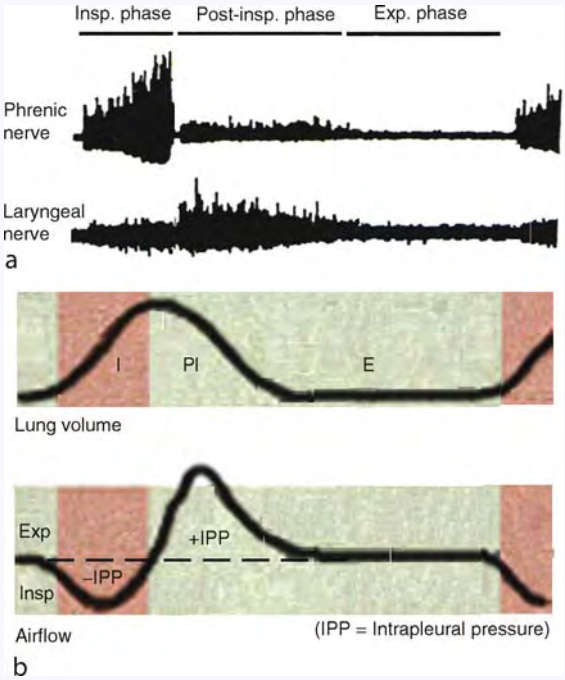
moving the ribs upward and outward to further increase intrathoracic volume and inward airflow. (►Spinal respiratory neurons) Movement of air into the lungs is further supported by cranial ►motoneuron discharges (►Action potential) that reduce upper airway resistance by contracting the muscles of the nasal passages and pharynx, move the tongue forward in the mouth (►Respiratory control of hypoglossal motoneurons during sleep and wakefulness) and dilate the vocal folds by contracting abductor laryngeal muscles.

Until the end of the inspiratory phase, phrenic and inspiratory intercostal nerve discharges progressively increase, causing a gradual flattening of the diaphragm and expansion of the chest wall.

At the end of the inspiratory phase, phrenic, inspiratory intercostal and abductor laryngeal motoneurons stop discharging. A very brief silent period is followed by resumption of discharges that is less intense and declining as it progresses. During this transitional stage, referred to as either the postinspiratory or early expiratory phase, adductor motoneurons of the superior laryngeal nerve also discharge with declining intensity. The decrementing phrenic and laryngeal nerve discharge patterns result in a more gradual relaxation of the diaphragm, a reduced rate of outward airflow and thus a slowing in the rate of lung deflation. Alveolar collapse is opposed and ►functional residual capacity (FRC) is maintained, which has beneficial pulmonary consequences. Normally, only about 15% of air in the lungs is replaced by new air during each normal inspiration, and about the same amount of old air is expired. The slow replacement of air prevents sudden changes in blood gases that would destabilize respiratory control. Excessive increases and decreases of blood $pO_2$, $pCO_2$ and pH are also prevented when respiration is temporarily interrupted, for example during swallowing or phonation. Partial inflation during a normal FRC also maintains surfactant release and thus lung compliance, because the principal stimulus for liberation of surfactant appears to be direct mechanical distortion of type II alveolar cells [35].

Expiration during quiet breathing is mainly passive. Discharges of inspiratory cranial, phrenic and inspiratory intercostal nerves are silenced by synaptic inhibition in the brainstem and spinal cord. The chest wall and diaphragm return to their resting configurations and airway patency is maintained to allow passive outward airflow from the lungs to the atmosphere.

During active expiration, for example during exercise or coughing, discharges of the internal (expiratory) intercostal nerves move the lower ribs downward and inward. In addition, lumbar motoneuron discharges



**Respiration – Neural Control. Figure 2** Discharges of the phrenic and laryngeal nerves (A) and changes in lung volume and airflow (B) during one respiratory cycle. In part B, I = inspiration, PI = post-inspiration, E = expiration. Part A adapted from Bianchi et al. 1995 [2]. Part B adapted from [24].

contract the abdominal muscles and compress the abdominal contents, pushing up the diaphragm and actively expelling air from the lungs. Upper airway patency is maintained by discharges of laryngeal abductor nerves and pharyngeal constrictor nerves.

The cycle of inspiration, postinspiration and expiration in the adult human is repeated, on average, about 15 times during quiet breathing.

## Respiratory Muscles Contract in an Ordered Sequence that Optimizes Mechanical Advantage

The inspiratory pump muscles in both humans and quadrupeds discharge with a set temporal order that optimizes the mechanical advantage, or leverage of the muscles, and reduces the work of breathing [8]. Electromyographic studies in humans show that, relative to the onset of airflow into the airways, the diaphragm and the third dorsal external intercostal muscles are the first to contract, followed by the second parasternal intercostal and scalene muscles and lastly by the fifth dorsal external intercostal muscles. The order of recruitment is consistent with the relative inspiratory mechanical advantage that each of the muscles has, and the degree of inspiratory opening pressure exerted on the airways by each. The intensity and duration of unit discharges are greater for the diaphragm and third dorsal external intercostal ►motor units than for the other pump muscles. The pattern of recruitment of intercostal muscles not only expands the rib cage, but also applies stretch to the diaphragm to increase contractile strength.

Several factors have been posited for the recruitment and discharge patterns of the different pump muscles, including: (i) recruitment order of bulbospinal and spinal interneurons, (ii) different degrees of persistent and rhythmic inward currents and (iii) their spatial distribution over the soma and dendrites of motoneurons and (iv) graded distribution of inhibitory central respiratory drive potentials.

## Central Nervous Control of the Respiratory Apparatus

Aggregates of neurons that discharge periodically during inspiration, post-inspiration or expiration are distributed bilaterally in the bulbar brainstem, from the rostral ►pons (►Pontine control of respiration) to the caudal border of the ►medulla (►Anatomy and function in the respiratory network). Synaptic interactions among the neurons establish the network respiratory rhythm, and their connections with cranial and spinal motoneurons and interneurons set up the timing and patterns of contraction in the muscles of respiration. Three regions of the medulla in particular have been studied for their roles in respiratory rhythmogenesis: the Pre►Bötzinger Complex (►PreBötzinger Complex Inspiratory Neurons and Rhythm Generation) and the para-facial and retrotrapezoid regions (►Respiratory network analysis and isolated respiratory centre functions; [12]). Their functional integrity is essential for a normal respiratory rhythm, and in the PreBötzinger and para-facial areas neurons with autorhythmic pacemaker properties have been identified (►Respiratory network analysis, isolated respiratory centre functions; ►Pacemaker neurons and respiratory control).

Respiratory neurons of the brainstem receive modulatory synaptic input from non-respiratory regions such as the ►motor cortex, pontine and medullary ►reticular formation, ►cerebellum, ►hypothalamus, other ►limbic and cardiovascular regions of the brainstem as well as from extrapyramidal motor areas (►Anatomy and function in the respiratory network). These non-respiratory modulatory inputs adapt breathing rhythm and pattern to accommodate activities such as phonation, swallowing, coughing, physical exertion, defecation and postural change.

## Rhythm Formation in Bulbar Respiratory Neurons

The ►membrane potential of medullary respiratory neurons normally oscillates between cycles of depolarization and hyperpolarization. The pattern of depolarization or hyperpolarization may be augmenting (increasing in intensity from onset to termination), decrementing

(declining in intensity) or plateau (constant from onset to termination). In association with the patterns of depolarization, periodic discharges can be augmenting, decrementing or of constant intensity [9,25].

The rhythm and pattern of discharge in bulbar respiratory neurons result from a combination of intrinsic membrane ion ►conductances, synaptic interactions among the neurons, and input from other CNS neurons and peripheral sensory afferents.

Intrinsic membrane ion conductances initiate membrane depolarization that triggers action potential discharge, control the rate of depolarization and hyperpolarization, and terminate action potential discharge [25,26] (►PreBötzinger Complex Inspiratory Neurons and Rhythm Generation). Tonic excitatory drive comes from at least two sources. One is from $CO_2$-sensitive neurons in the medulla (►Central nervous chemoreceptors and respiratory drive; ►Medullary raphe nuclei and respiratory control). A second is from non-respiratory reticular activating neurons. These excitatory inputs can be suppressed or reinforced by feedback synaptic input from medullary and pontine respiratory neurons. ►Chemoreceptor and ►mechanoreceptor afferents from the ►carotid bodies (►Carotid body chemoreceptors and respiratory drive), heart, lungs, chest wall and upper airways also influence discharge properties of bulbar respiratory neurons.

All afferent inputs and synaptic interactions among the respiratory and non-respiratory neurons are regulated chemically by ►neurotransmitters and neuromodulators, including excitatory and inhibitory amino acids, acetylcholine, peptides, monoamines and adenosine (►Respiratory neurotransmitters and neuromodulators).

## Rhythmic Properties, Connections and Functions of Respiratory Neurons in the Pons and Medulla

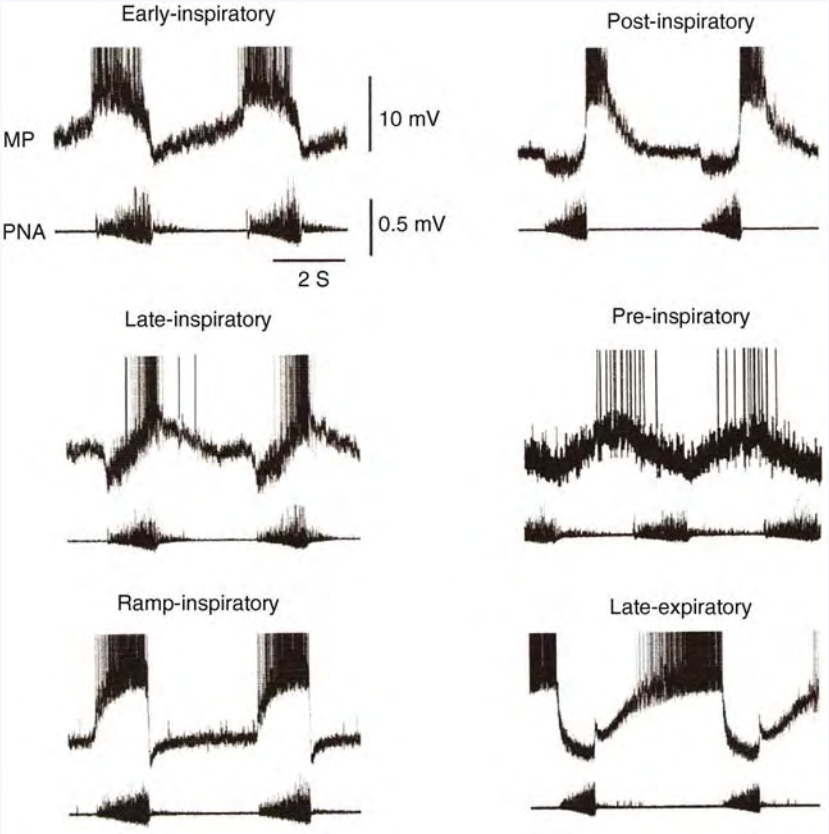
The roles that various types of bulbar neurons play in respiratory control have been investigated by: (i) measuring membrane potential and discharge properties during various phases of the respiratory cycle, (ii) identifying synaptic connections among them and (iii) observing their responses to changes in respiratory rhythm and ventilation. From such studies, theories of how the neurons interact as a network to generate rhythm have been proposed [2,16,25] (►Anatomy and function in the respiratory network). Elegant computer modeling studies based on the experimental findings have tested and support many of the proposed connections and predict additional ones (►Computational modeling of the respiratory network).

*Neurons in the respiratory-related regions of the rostral pons* discharge with waves of excitatory and inhibitory postsynaptic potentials and intermittent bursts of action potentials and that are coincident with one of the three phases of the respiratory cycle, and some discharge more intensely at the transitions between phases (►Pontine control of respiration). In unanesthetized cats prepared for chronic studies, respiratory rhythm is not obvious during sleep [2], and rhythmicity is diminished when nervous input from the lungs is intact. The pontine network of neurons modulates amplitude and timing of the respiratory muscles, and seems to promote inspiratory termination if pulmonary afferent feedback is impaired.

*In respiratory regions of the medulla*, six different types of medullary respiratory neurons differentiated by membrane potential and discharge properties have been identified: (i) Early-Inspiratory, (ii) Ramp-Inspiratory, (iii) Late-Inspiratory, (iv) Post-Inspiratory, (v) Late-Expiratory, (vi) Pre-Inspiratory (Fig. 3).

*Early-Inspiratory neurons* are propriobulbar, that is, their cell bodies, dendrites and axons are restricted to bulbar regions. They depolarize suddenly to threshold shortly before phrenic nerve discharge begins at the onset of inspiration. One type of Early-Inspiratory neuron exhibits a discharge that is intense but decrementing, in association with a declining pattern of depolarization, until it terminates late in inspiration, before the phrenic nerve inspiratory discharge ceases [25]. The other type exhibits a constant, or plateau pattern of depolarization and discharge that begins and ends with the phrenic nerve inspiratory discharge [9]. In either case, two processes seem to be responsible for discharge termination. One is weak synaptic inhibition, possibly from Late-Inspiratory neurons, but a more prominent source is the development of a ►$Ca^{2+}$-activated $K^+$ conductance that builds up as $Ca^{2+}$ enters during cell discharge through high voltage-regulated channels. Thereafter, membrane potential is hyperpolarized by synaptic inhibition produced by the discharge of Post-Inspiratory and Late-Expiratory neurons. The proposed role of Early-Inspiratory neurons of the decrementing type is to impose synaptic inhibition on Late-Inspiratory and Post-Inspiratory neurons, which prevents premature termination of phrenic motoneuron discharges [25]. As for the plateau type, they seem to augment inspiratory phase excitatory synaptic drive, because input to Ramp-Inspiratory neurons has been demonstrated electrophysiologically [9].

*Ramp-Inspiratory neurons* are either propriobulbar and/or bulbospinal and provide excitatory synaptic drive to phrenic and intercostal inspiratory motoneurons and interneurons. They depolarize and discharge with an augmenting pattern at the beginning of inspiration, in parallel with phrenic nerve discharges. The pattern of depolarization and discharge in Ramp-I neurons is attributed to a combination of mutual recurrent excitation among the neurons and declining inhibitory synaptic input from Early-I neurons. Discharge is terminated by inhibitory synaptic input from Late-Inspiratory and Post-Inspiratory neurons.



**Respiration – Neural Control. Figure 3** Medullary respiratory neurons thought to be involved in respiratory rhythmogenesis. The six types of neurons were recorded intracellulary in adult cats *in vivo* in studies performed by A. Haji and coworkers. Each pair of tracings shows neuron membrane potential (MP) and phrenic nerve activity (PNA). Figure courtesy of Prof. Dr. Akira Haji, Laboratory of Neuropharmacology, School of Pharmacy, Aichi Gakuin University, Nagoya.

*Late-Inspiratory neurons* are propriobulbar. During most of the inspiratory phase, their discharges are prevented by declining synaptic inhibition, probably set up by Early-Inspiratory neurons. They discharge coincident with the termination of Ramp-Inspiratory and phrenic nerve discharges and cease firing due to synaptic inhibition that seems to derive from discharges of Post-Inspiratory and Late-Expiratory neurons. Their proposed function is to initiate inspiratory phase termination [2,25] and mediate reflex inspiratory inhibition by slowly adapting ►lung stretch afferents (Respiratory Neurotransmitters and Neuromodulators).

*Post-Inspiratory neurons* are of two types. Some are cranial motoneurons that contract the pharyngeal constrictor and laryngeal adductor muscles. Others are propriobulbar and are thought to contribute to rhythm formation by securing termination of the inspiratory phase, and imposing a delay to the onset of expiratory neuron discharges. According to the network theory of rhythmogenesis, reciprocal inhibitory interactions between propriobulbar Post-I and Early-I neurons constitute the primary rhythm generator, and contribute to shaping the discharge patterns of inspiratory and expiratory neurons [25]. Post-Inspiratory neurons depolarize abruptly and discharge action potentials coincident with the termination of firing in Ramp-I neurons and with the arrest of phrenic nerve inspiratory phase discharges. Membrane depolarization and discharges in Post-I neurons exhibit declining patterns, which seem to be activity-dependent and mediated by a $Ca^{2+}$-activated $K^+$ conductance. Throughout the inspiratory phase, the neurons receive a declining wave of inhibitory postsynaptic potentials, evidently set up by Early-Inspiratory neurons. The rapid onset of depolarization and discharge in Post-I neurons is attributed to release from Early-I neuron inhibition and reactivation of low ►voltage-dependent $Ca^{2+}$ currents and ►non-selective cationic currents that bring the membrane to threshold for action potential discharge. Throughout the expiratory phase, Post-I neurons receive synaptic inhibition set up by the discharge of Late-Expiratory neurons.

*Late-Expiratory neurons* are of two types, according to location and function. One group is located in the Bötzinger region of the rostral ventrolateral respiratory

column (VRC) of the medulla, the other in the caudal region of the VRC (►Alheid and McCrimmon: anatomy and function in the respiratory network). Late-E neurons in both regions have similar membrane potential and discharge properties but play different roles in respiratory control. Late-E neurons located in the caudal VRC are bulbospinal and provide excitatory synaptic drive to expiratory intercostal and lumbar motoneurons and interneurons. During inspiration and postinspiration, synaptic inhibition set up by Early-Inspiratory and Post-Inspiratory neurons prevents Late-E neuron discharge. The expiratory neurons depolarize gradually to threshold during the post-inspiratory phase and then discharge steadily during the expiratory phase. The Late-E neurons in the Bötzinger region of the VRC are both propriobulbar and bulbospinal. Their discharges result in inhibition of medullary, phrenic and intercostal inspiratory neurons during the expiratory phase.

*Pre-Inspiratory neurons* are propriobulbar. They discharge in short bursts at the end of expiration and sometimes at the end of inspiration. They are subject to augmenting synaptic inhibition during the inspiratory phase and declining inhibition during the postinspiratory phase. Based on these time-intensity profiles, they are thought to receive inhibitory synaptic input from Ramp-Inspiratory and Post-Inspiratory neurons. One function they might have is to initiate termination of discharge in Late-Expiratory neurons [15].

## Network Hypothesis: How Bulbar Respiratory Neurons Express a Three-phase Rhythm that Controls Respiration in the Mature Respiratory Network [2,9,25] (Computational Modeling of the Respiratory Network)

According to the network model, bulbar respiratory neurons receive tonic excitatory drive from pH/$CO_2$-sensitive chemoreceptor neurons and from neurons of the brainstem reticular activating system. Inspiration begins when Ramp-I neurons are released from inhibition and low-voltage activated (LVA) $Ca^{2+}$ currents and non-selective cationic currents are activated. Ramp-like inspiratory discharges begin, driven by mutual recurrent excitation and by declining inhibition from Early-I neurons. Early-I discharges are terminated by $Ca^{2+}$-activated $K^+$ conductances, allowing disinhibition of Late-I and Post-I neurons that terminate discharge of Ramp-I neurons and arrest inspiration. Buildup of $Ca^{2+}$-activated $K^+$ conductances ends Post-I neuron inhibitory discharges, allowing discharge of Late-E neurons. Arrest of Late-E neuron discharge is initiated by Pre-I neurons and sustained by Early-I and Post-I neurons.

A key element in the cyclic regeneration of the inspiratory and expiratory phases is the termination of Early-I and Post-I discharges by activity-dependent $Ca^{2+}$-activated $K^+$ conductances.

## Post-Inspiratory Discharges in Phrenic and Intercostal Inspiratory Motoneurons

The origin of postinspiratory discharge activity in inspiratory spinal motoneurons is not firmly established, but it does not arise from intrinsic membrane currents. Hypoxia increases its duration and hypercapnea shortens it. ►Pulmonary irritant receptors and stretch receptors inhibit it, whereas withholding of lung inflation prolongs it.

Bulbospinal neurons have been identified in the medulla of the cat that discharge with two bursts; one beginning simultaneously with the onset of phrenic nerve inspiratory discharges and, a second that begins after a very brief pause and declines in synchrony with the postinspiratory discharge of phrenic nerve activity The discharge of these *Inspiratory-Post-I* (*IPI*) *neurons* and that of the phrenic nerve respond identically to activation of tracheal and pulmonary afferents. Thus, the postinspiratory discharge component in spinal inspiratory motoneurons may be linked to excitatory synaptic input from the medullary IPI neurons. The slow decline of the postinspiratory discharge in IPI neurons is attributed to integration of excitatory and inhibitory synaptic inputs coming from two populations of postinspiratory neurons within the medulla, one excitatory and the other inhibitory [27].

## Cranial Motoneurons and Control of Flow in the Upper Airways

Cranial motoneurons with respiratory periodicity in the ventrolateral medulla have axons in the trigeminal (5th), facial (7th), glossopharnygeal (9th), vagal (10th) and hypoglossal (12th) cranial nerves. They innervate the muscles of the nostrils, pharynx, tongue and larynx, coordinating their positions and movements with those of the diaphragm, chest wall and abdominal muscles during breathing. Trigeminal motoneuron discharges open the mouth during breathing, whereas facial motoneurons flare the nostrils. Glossopharyngeal motoneurons discharge with an augmenting pattern during inspiration and contract the muscles of the pharynx and palate. Laryngeal motoneurons with an augmenting inspiratory discharge pattern contract the abductor muscles, those with a decrementing postinspiratory discharge contract and narrow the opening of the glottis and slow outward airflow as the lungs gradually deflate. Vagal motoneurons with an augmenting expiratory discharge contract the pharyngeal constrictor muscles during expiration to lower upper airway resistance. Hypoglossal motoneurons (►Respiratory control of hypoglossal neurons during sleep and wakefulness) also regulate airway resistance and flow patterns by controlling tongue position.

Respiratory rhythm and pattern is derived from periodic excitatory and inhibitory synaptic input from the propriobulbar respiratory neurons described above.

For laryngeal and hypoglossal motoneurons, at least, important sources of synaptic excitation and inhibition are respiratory neurons of the preBötzinger Complex and surrounding ventrolateral medulla [20,32].

The motoneurons are assigned other duties related to sneezing, coughing, movements of the mouth, swallowing, vomiting, etc., during which their discharge properties are appropriate for the movements they promote.

## Spinal Motoneurons and Contraction of the Pump Muscles

The location, synaptic connections and electrophysiological properties of spinal respiratory neurons are described in detail elsewhere, with special emphasis on α-motoneurons that innervate the extrafusal muscles of respiration (►Spinal respiratory neurons and respiratory control). Interested readers can also consult an earlier review [17].

*Phrenic motoneurons* innervating the diaphragm are located in the ventral horns of the lower cervical spinal segments, and receive bilateral excitatory synaptic drive from medullary bulbospinal Ramp-I neurons and inhibitory synaptic input from bulbospinal Late-E neurons of the Bötzinger Complex. The neurons depolarize and fire with an augmenting discharge pattern during inspiration and hyperpolarize with an augmenting pattern during expiration. Not all phrenic motoneurons reach threshold simultaneously, rather, there is a scatter in the discharge latencies (recruitment times) with respect to the onset of the population discharge in the phrenic nerve. It appears that the order of recruitment derives, at least in part, from similar temporal properties of the bulbospinal neurons that provide excitatory synaptic input. Some of the excitatory drive also comes from interneurons located in the phrenic motoneuron pool and at higher cervical levels, which are driven by excitatory input from bulbospinal inspiratory neurons [34].

*Intercostal motoneurons* that contract the scalene, sternocleidomastoid and intercostal muscles are located in the ventral horn at all levels of the thoracic spinal cord. Medullary bulbospinal neurons that control phrenic motoneurons are also responsible for the periodic depolarization, discharge and hyperpolarization of intercostal motoneurons. Some of the synaptic connections are direct and others are made through interneurons located in the same segment as the motoneuron pool and in other cervical and thoracic segments.

*Lumbar spinal motoneurons* innervate the rectus abdominis, external and internal oblique and transverse abdominal muscles of the abdomen, and produce contraction during active expiration.

*Recurrent Inhibitory Interneurons* with a very high frequency of action potential firing are found near to phrenic and intercostal motoneurons. They are activated to discharge by motor axon collaterals and in turn suppress motoneuron discharges [17]. The high-frequency discharge and the resulting feedback suppression of motoneuron discharges are reminiscent of the ►Renshaw inhibition that modulates discharge properties of limb motoneurons.

## The Effects of Hypoxia on the Respiratory Apparatus: A Multiphase Reaction Involving the Carotid Bodies and the CNS Respiratory Network

Hypoxia produces dramatic disturbances of respiration. The initial response to acute hypoxia is increased breathing in an attempt to replenish $O_2$. The immediate source of respiratory augmentation is stimulation of type 1 (glomus) cells of the carotid bodies (CB) located bilaterally in the bifurcation of the common carotid arteries, which leads to activation of CB afferents and reflex stimulation of the CNS respiratory network. (►Carotid Body Chemoreceptors and Respiratory Drive).

If hypoxia is maintained, disturbances of synaptic function within the CNS convert breathing rhythm to gasping and apnea. (►Neural respiratory control during acute hypoxia). The CNS-derived hypoxic ventilatory response is a 5-component process, consisting of augmentation, apneusis or breath holding, protective apnea, gasping and terminal apnea. For each component, there are related changes in endogenous neurotransmitter and neuromodulator release and alterations in ion channel permeabilities.

Here, metabolic, enzymatic, ion channel and chemical neuromodulatory mechanisms that control the carotid body oxygen sensor and trigger the respiratory response to acute hypoxia are presented. The role of the CB in $CO_2$/pH sensing and its importance in health and disease are also discussed (Carotid Body Chemoreceptors and Respiratory Drive). Sites and mechanisms within the CNS respiratory network that engender ventilatory disturbances and ultimate apnea are described. In one essay (►Respiratory network responses to hypoxia) the hypoxic response is defined in terms of two phases and a comprehensive description of neural pathways, neurotransmitters and neuromodulators that mediate respiratory depression during the late hypoxic ventilatory response (HVR) is presented. In another essay (►Neural respiratory control during acute hypoxia), the energy cost of hypoxia to cells and its effects on ionic homeostasis are discussed. In addition, the HVR is presented as a 5-component process: augmentation, apneusis or breath holding, protective apnea, gasping and terminal apnea. For each component, accompanying changes in endogenous neurotransmitter and neuromodulator release and ion channel changes are described.

## Concluding Comments

This overview has focused on respiratory control mechanisms in the adult mammal. Other contributions will show how the respiratory network develops before and shortly after birth (►Development of the respiratory network) and how autorhythmic pacemaker neurons in the rodent medulla regulate respiration in the postnatal period (►Respiratory pacemakers). Disturbances of respiratory control that are gene-related are also reviewed elsewhere (►Gene-related respiratory control disturbance).

Other important aspects of respiratory control not considered in this overview include: (i) neuroplasticity in the respiratory network, which allows readjustments of network responsiveness to injury and other environmental challenges (►Respiratory neuroplasticity), (ii) ►laryngeal chemoreflexes responding to liquid and chemical stimulation of laryngeal receptors, and (iii) respiratory control during sleep (►obstructive sleep apnea), (►Respiratory control of hypoglossal neurons during sleep and wakefulness).

Hopefully, the reader will appreciate the valuable insights of the contributing authors into how respiration is controlled, and the innovative methods they utilize, including imaging techniques, (►Respiratory network analysis, functional imaging) computer modeling (►Computational modeling of the respiratory network) and the use of novel preparations to study integrated cardio-respiratory regulation (►Central integration of cardiovascular and respiratory activity studied in situ).

## Synonyms

Respiratory control of the tongue and airway

## Definition

Hypoglossal ►motoneurons control the tongue muscles; genioglossus muscle (tongue protrudor), hyoglossus and styloglossus (tongue retractors) and intrinsic muscles. Because the genioglossus as well as other tongue muscles participate in a range a motor acts (e.g., drinking, licking, swallowing and breathing), the hypoglossal motoneurons that innervate them receive numerous inputs from a variety of relevant brain areas. Since the tongue position affects airway patency and resistance, respiratory control is essential to coordinate respiratory muscle effort and airway resistance, minimizing resistance during inspiration and using the control of resistance during expiration to modify expiratory flow patterns. The hypoglossal control of the tongue assumes a greater importance during sleep when relaxation of the tongue can occlude the airway; a condition of ►obstructive sleep apnoea (OSA).

## Characteristics

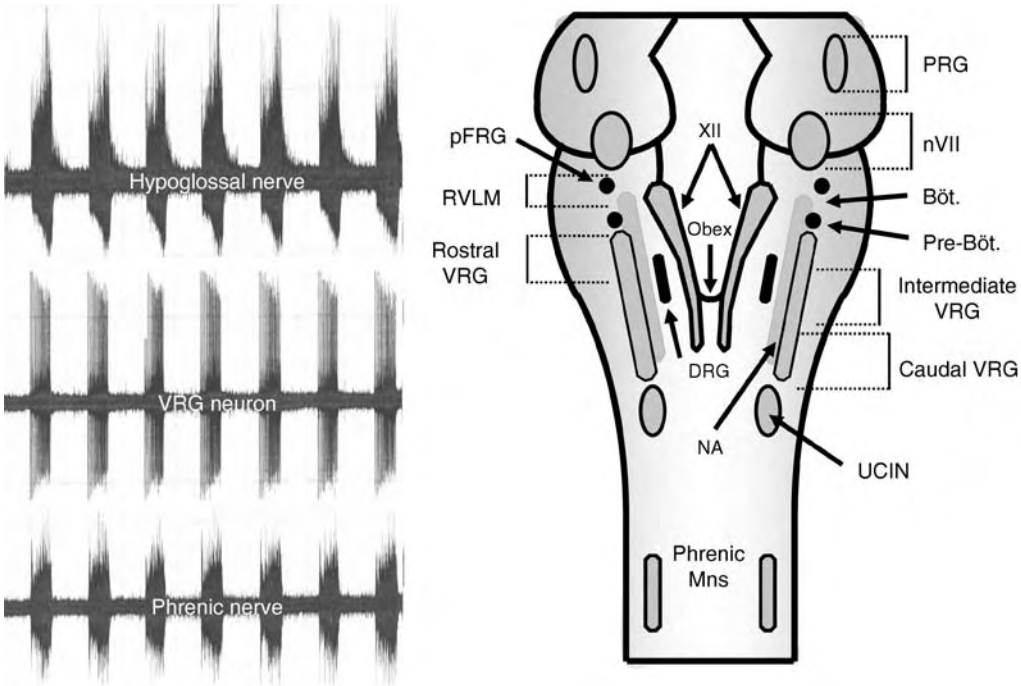
### Hypoglossal Motoneurons Anatomical Location

Hypoglossal ►motoneurons are ►somatotopically organized bilaterally in compact columns extending along the midline of the brainstem above and below the obex. For example a recent study in dogs [1] showed that the nuclei extend from 0.75 mm caudal to 3.45 mm rostral to the obex, with cells 0.37–2.12 mm below the dorsal surface, and symmetrically centered between 0.66 and 1.33 mm from the midline. There are a number of detailed locations studies including those in rats, cats, rabbits, frogs and monkeys as well as dogs. The hypoglossal motoneurons have varied and extensive dendritic arborizations that provide the potential for a wide range of afferent contacts. (Fig. 1) shows a schematic of the medullary respiratory neurons illustrating their general location and pattern of respiratory activity.

### Projections of Hypoglossal Motoneurons

The axons of these motoneurons course ventrally and slightly laterally to emerge from the medulla in the preolivary sulcus separating the olive and the pyramid, and form the twelfth cranial nerve (XII). The hypoglossal nerve innervates all the muscles of the tongue except for the palatoglossus muscle which is innervated by the vagus nerve (X) and the accessory nerve (XI). The tongue is a complex muscle, and the hypoglossal nerve bifurcates to form medial and lateral branches, with the medial branch innervating the protrusor tongue muscles, and the lateral branch innervating the retractor tongue muscles [2].

The ventrolateral and ventromedial subnuclei contain motoneurons that innervate the geniohyoid and genioglossus muscles respectively, and the dorsal subnucleus motoneurons innervate the hyoglossus and styloglossus muscles. The genioglossus muscle is of particular importance clinically because it is considered the main protruder and depressor muscle of the tongue.



**Respiratory Control of Hypoglossal Neurons During Sleep and Wakefulness. Figure 1** A schematic showing the location of hypoglossal motoneurons relative to medullary respiratory neuron groups with representative recordings from the hypoglossal nerve, a ventral respiratory group inspiratory neuron and the phrenic nerve in an adult decerebrate rat. Abbreviations: PRG = pontine respiratory group, nVII = Facial nucleus, pFRG = parafacial respiratory group, XII = hypoglossal motor nucleus, RVLM = rostro ventrolateral medulla, Böt = Bötzinger complex, Pre-Böt = preBötzinger complex, VRG = ventral respiratory group, DRG = dorsal respiratory group, NA = nucleus ambiguus, UCIN = upper cervical inspiratory neurons.

It is co-activated during inspiration with tongue retractor muscles [3] so that airway compliance is reduced, and upper airway patency increased during inspiration.

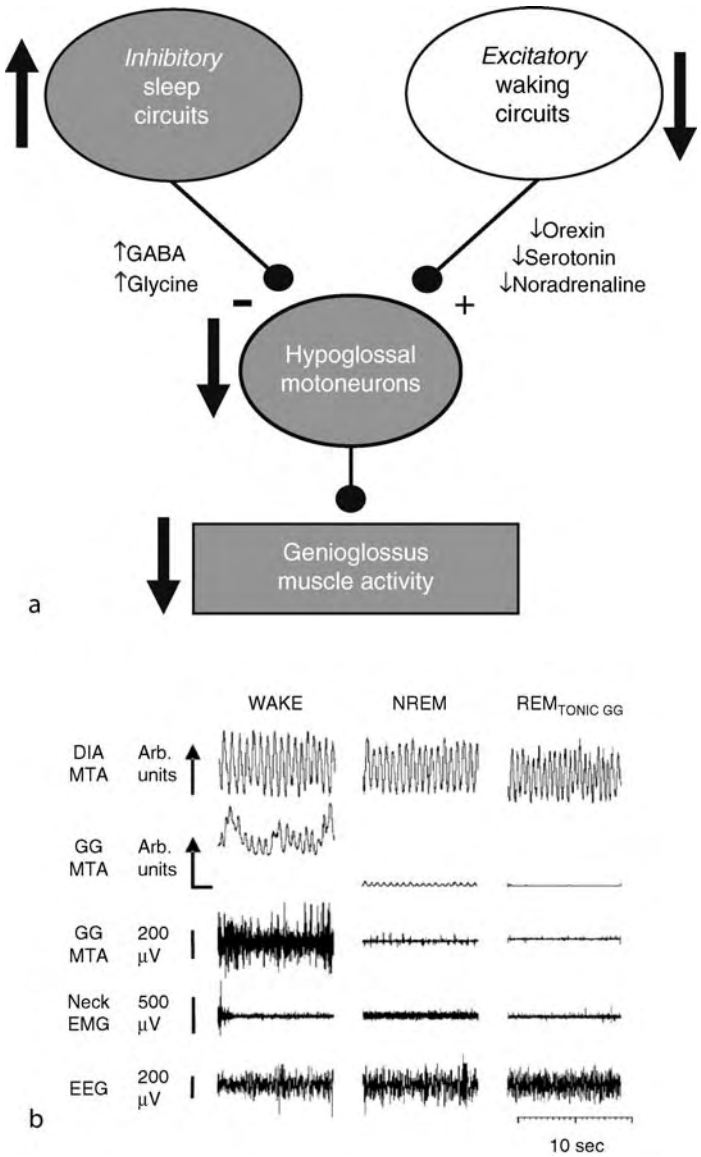
## Respiratory Inputs to Hypoglossal Motoneurons

Hypoglossal motoneurons participate in rhythmic oro-facial motor acts such as mastication, licking, swallowing and breathing; receiving neural inputs from the brainstem rhythm-generating networks that generate these behaviors. They play a major role in respiratory airway control and the following focuses on the neural mechanisms by which respiratory drive is communicated to them.

A major function of the genioglossus muscle is to stiffen the pharyngeal airspace during inspiration so that it does not collapse during diaphragmatic contraction. Therefore, hypoglossal motoneurons are synaptically excited during inspiration (i.e., discharge action potential during inhalation); however, they are activated 200–300 ms before the ►phrenic motoneurons that innervate the ►diaphragm [3]. This pre-activation of hypoglossal motoneurons ensures that the airway is stiffened before the diaphragm contracts.

Although both the hypoglossal and phrenic motoneurons receive inspiratory signals from the medullary network that generates breathing, they receive their respective inspiratory commands from separate premotor populations. Inspiratory drive is transmitted to phrenic motoneurons by premotor neurons located in the ventral respiratory group (parallel to the nucleus ambiguus), while hypoglossal motoneurons receive respiratory drive from premotor neurons located in the medullary lateral tegmental field, lateral to the hypoglossal motor nucleus (Fig. 2) [4].

Although separate premotor populations relay inspiratory drive to phrenic and hypoglossal motoneurons, both release glutamate to activate post-synaptic non-NMDA receptors to induce inspiratory activation [5]. Unlike phrenic motoneurons, which are silenced during expiration by GABAergic and glycinergic inhibition, hypoglossal motoneurons receive no such inhibitory drive; instead, they are passively disfacilitated (withdrawal of excitation) during expiration [4]. Because the genioglossus is not only involved in the control of breathing, but is also in the control of speech, the lack of inhibition during expiration enables more effective modulation of their activity and thereby tongue muscles because motoneurons are more easily excited by other non-respiratory inputs.



**Respiratory Control of Hypoglossal Neurons During Sleep and Wakefulness. Figure 2** A schematic representation of the neural mechanisms responsible for suppression of genioglossus muscle activity in sleep. (a) It is hypothesized that active inhibition and passive disfacilitation reduce hypoglossal (airway) motoneuron activity and hence genioglossus muscle tone in sleep. Several lines of evidence indicate that inhibitory processes play a predominant role in controlling airway motoneuron and muscle activity in sleep, particularly in REM sleep. There is also evidence indicating that withdrawal of excitatory sleep-related inputs (e.g., serotonin, orexin, noradrenaline) in sleep may reduce airway motoneuron excitability. (b) A typical example from a naturally behaving rat demonstrating that genioglossus (and neck) muscle activity is depressed in sleep, and particularly REM sleep. This figure was modified (with permission) from Morrison et al. Journal of Physiology, 2003, 552.3, pp. 975–991.

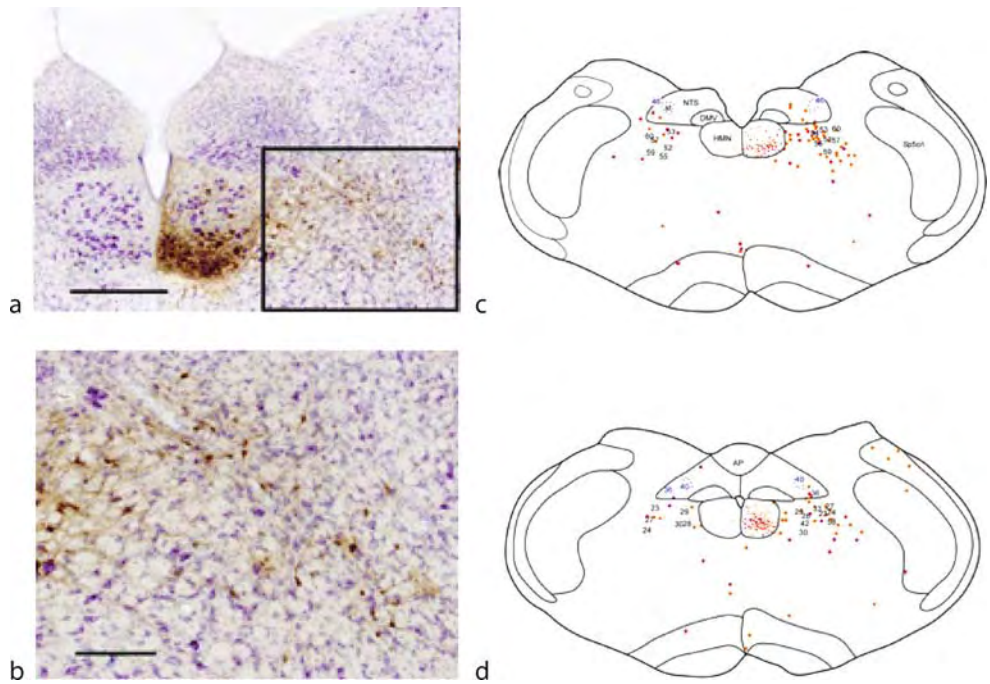
Hypoglossal motoneurons are not only controlled by premotor neurons in the lateral tegmental field, they also receive respiratory signals from a population of interneurons located directly within the hypoglossal motor nuclei [4]. Hypoglossal interneurons are significantly smaller than motoneurons, they are active only during inspiration and they make inhibitory (e.g., GABA) connections with hypoglossal motoneurons. The precise role that interneurons play in transmitting inspiratory drive to hypoglossal motoneurons is unclear; however, it is hypothesized that they gate or filter presynaptic inputs.

## Impact of Sleep on Hypoglossal Motoneuron Activity

►Sleep suppresses the excitability of hypoglossal motoneurons. Although this review focuses on hypoglossal motoneurons, it should be made clear that the excitability of all somatic motoneurons including other airway motoneurons (e.g., trigeminal and facial) are also affected by sleep [6]. Understanding how hypoglossal motoneuron activity is regulated in sleep is clinically important because sleep-related reductions in their activity lead to reduced airway motor tone, airway narrowing and collapse in predisposed individuals (e.g., small airway). The suppression of airway motoneuron activity in sleep, and particularly during rapid-eye-movement (►REM) sleep, is the primary cause of OSA.

The root cause of hypoglossal motoneuron suppression in sleep is unknown; however, recent work from our laboratory and others has begun to shed light on potential mechanisms. It is hypothesized that the neurocircuitry generating sleep (e.g., REM and ►non-REM) also innervates and regulates hypoglossal motoneuron activity. Although multiple neural circuits are involved in sleep generation, they can be subdivided into two categories – those that are excitatory and promote wakefulness and those that are inhibitory and promote sleep. Excitatory circuits are active during waking and project to both the cortex and motoneurons to promote behavioural arousal and high levels of motor tone [7]. Inhibitory circuits are active in sleep and project to and switch-off both the wake-promoting circuits as well as inhibiting airway motoneurons. Therefore, it is hypothesized that hypoglossal motoneurons are both actively inhibited and passively disfacilitated (withdrawal of excitatory inputs) during sleep (Fig. 3).

The primary wake-promoting circuits consist of excitatory neurons located in the noradrenergic locus coeruleus, the ►serotonergic dorsal ►raphe, the ►orexinergic (also called hypocretin) lateral hypothalamus, the histaminergic tuberomammillary nucleus and the ►dopaminergic ►periaquaductal grey and ventral tegmental area. The activity of these neural populations is highest in waking and minimal or silent in sleep. Because they project to motoneurons, it is hypothesized that withdrawal of noradrenergic, orexinergic, and serotonergic inputs may be a contributing factor to the reduction of motoneuron excitatory and hence muscle activity in sleep [6]. The major sleep-promoting



**Respiratory Control of Hypoglossal Neurons During Sleep and Wakefulness. Figure 3** Location of the premotor neurons that relay inspiratory drive to hypoglossal motoneurons. (a) Photograph of the premotor neurons in lateral tegmental field that are hypothesized to relay inspiratory drive to hypoglossal motoneurons. Premotor neurons were identified by visualizing the location of pseudorabies virus that was retrogradely transported from the genioglossus muscle where it had been injected. (b) Higher magnification of the black box in (a); brown cells represent hypoglossal premotor neurons. C and D, represent the anatomical distribution of hypoglossal premotor neurons (*small dots*) and hypoglossal motoneurons (*small dots*) plotted on schematic cross-sections of rat brainstem at 0–500 μm rostral to obex (c) and −100 to −600 μm caudal to obex (d). This figure was modified (with permission) from Chamberlin et al., J. Physiology, 579.2, 2007, pp 515–526.

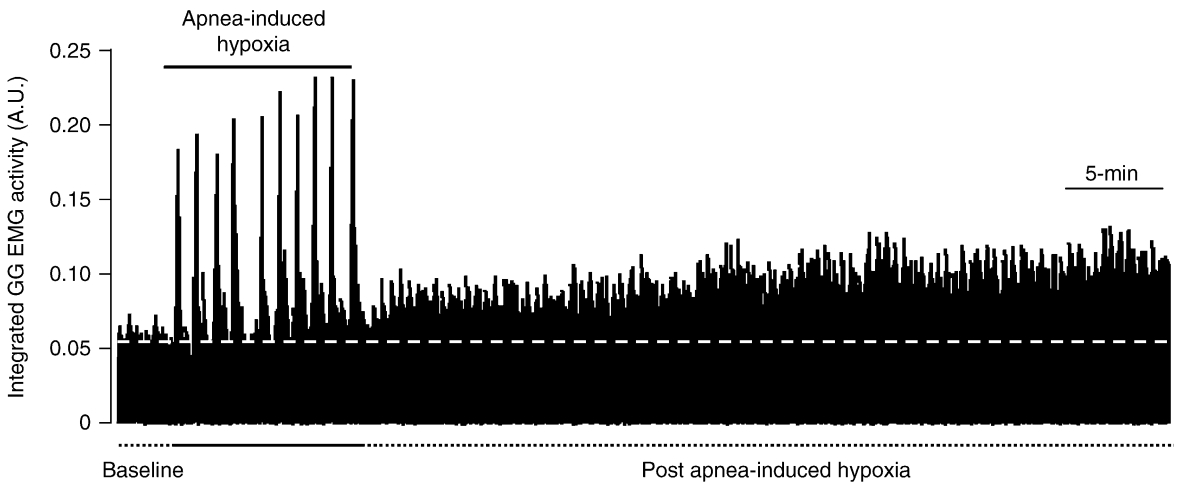
system consists of inhibitory neurons located in the GABAergic ventrolateral and median preoptic areas of the anterior hypothalamus. The activity of these neurons is lowest in waking and highest in sleep (particularly non-REM sleep). Because they project to motoneurons, it is hypothesized that they actively inhibit (via GABA) hypoglossal motoneuron activity and thereby suppress airway motor tone in non-REM sleep.

Another source of motoneuron inhibition comes from the medial medullary reticular formation. Unlike neurons in the ventrolateral and median preoptic areas, these neurons contain both GABA and glycine, and are maximally active in REM sleep when genioglossus muscle tone is minimal or absent [7]. It therefore appears that together GABA and glycine play a role in regulating hypoglossal motoneuron activity in both non-REM and REM sleep. Although GABAergic and glycinergic neurons in the medial medullary reticular formation project to hypoglossal motoneurons and are active in REM sleep, they are not responsible for the ►muscle atonia that typifies this state. Rather GABAergic and glycinergic inhibition are responsible for suppressing the phasic muscle twitches that characterize REM sleep [8]. The muscle atonia of REM sleep can not be explained by disfacilitation of excitatory because application of glutamate or glutamatergic receptor agonists (e.g., AMPA or NMDA) directly into airway (e.g., trigeminal) motoneurons can not reverse REM sleep atonia. Therefore, the cause of airway motoneuron inactivity and hence airway muscle atonia in REM sleep has yet to be identified. Identification of the neurochemical responsible for REM atonia requires attention because OSA is most common and severe during REM sleep.

## Plasticity of Hypoglossal Motoneurons

Somatic motoneurons are generally considered to be passive neural relays that monotonically respond to pre-synaptic inputs; however, they are able to undergo remarkable degrees of plasticity. One type of motoneuron plasticity (►neural plasticity) that is particularly relevant to hypoglossal control is respiratory ►long-term facilitation (LTF). LTF is characterized by a progressive increase in the inspiratory amplitude of the hypoglossal nerve (or genioglossus muscle) activity following exposure to ►intermittent hypoxia (an example is shown in Fig. 4) [9].

LTF can only be evoked by intermittent hypoxia; exposure to continuous hypoxia does not evoke LTF. The central serotonergic system is required for LTF because blocking either serotonin release or serotonin receptors nullifies LTF. It is hypothesized that LTF is induced because intermittent hypoxia activates the serotonergic medullary raphe nuclei to release serotonin onto hypoglossal motoneurons. Intermittent serotonin receptor activation subsequently causes plastic changes in the excitability of hypoglossal motoneurons perhaps via group-I ►metabotropic glutamate receptors [10].



**Respiratory Control of Hypoglossal Neurons During Sleep and Wakefulness. Figure 4** A typical example of apnea-induced long-term facilitation (LTF) of genioglossus motor outflow in an anaesthetized rat. Basal levels of inspiratory genioglossus muscle activity were recorded 5-min before (*baseline*) and for 60-min after obstructive apneas (ten 15-s apneas each separated by 45 s). Each obstructive apnea caused a reflexive increase in the inspiratory activity of the genioglossus muscle (see under apnea-induced hypoxia). The cluster of ten apneas induced a persistent and progressive increase in peak inspiratory genioglossus muscle activity that lasted for over 60-min (i.e., LTF). The *dotted line* represents the average magnitude of genioglossus inspiratory efforts before apnea-induced LTF; note that genioglossus activity returned to *baseline* levels after apneas and then progressively increased to reach maximal levels at 60-min post-apnea.

Since intermittent hypoxia causes persistent increases in hypoglossal motoneuron excitability and hence genioglossus motor output, and since hypoglossal motoneuron activity is lost in sleep and contributes to airway obstructions, then inducing LTF of during sleep may be an effective method for minimizing or reversing the root cause of obstructive sleep apnea. Therefore understanding the cellular mechanisms of LTF may provide the basis for rationale development of therapeutics for treating this prevalent (it affects about 5% of adults) sleep disorder.

Visualization of respiratory centers; Microscopy of structure-function relationships in mammalian respiratory networks

## Definition

Functional imaging of ►respiratory networks means optical analysis, with (►Confocal microscopy), ►multiphoton microscopy (two-photon microscopy) or cameras (e.g. CCD- or CMOS-type) of structure-function relationships in rhythmically active neuronal brainstem networks involved in the control of breathing in mammals. Such imaging has so far only been carried out *in vitro*, specifically in (*i*) respiratory active slices, (*ii*) *en bloc* brainstem preparations from perinatal rodents and (*iii*) arterially-perfused "working-heart-brainstem" preparations of both newborn and adult rodents. ►Voltage-sensitive dye imaging of the activity of neuronal populations is feasible in the latter three *in situ* models. In contrast, simultaneous ►$Ca^{2+}$ imaging of both the activity and basic morphology of single respiratory neurons, or clusters of such cells, has not been reported so far in the perfused preparation, and only in one case for *en bloc* medullas. In rhythmic slices, ►$Ca^{2+}$ imaging is primarily done in inspiratory active interneurons and hypoglossal (XII) motoneurons. The latter neuron populations are also being used for optical analyses of subcellular processes such as activity- or metabolism-related changes of mitochondrial membrane potential, $Ca^{2+}$ or redox state. Finally, expression of fluorescent proteins in transgenic mice and ►fluorescence labeling of neurotransmitter receptors are currently used for targeted electrophysiological recording from respiratory neurons in the slices. As outlined below, these approaches have provided important insights into both the structural organization and functional properties of respiratory centers. The following (yet mostly hypothetical scenario) would likely answer, with imaging techniques, most relevant questions regarding the neural control of breathing: Subpopulations of respiratory interneurons or output cells will be identified via a specific pattern of intrinsically-expressed fluorescent proteins and acutely fluorescence-labeled ion channels, receptors and/or transporters. Populations of these identified cells will then be loaded with cell-permeant fluorescent dyes for, e.g., simultaneous imaging of dynamic changes of signaling factors such as $Ca^{2+}$ or pH in the cytosol and cellular organelles. At the same time, one or few of these cells will be whole-cell recorded (with further functional or morphological dyes in the patch electrode solution) for a correlation of dynamic changes of (sub) cellular activities with respiratory-related membrane potential oscillations or underlying membrane currents. Further improvement of computerized data processing and of the spatiotemporal resolution of fluorescent microscopy will enable simultaneous 4D-imaging of all these events for a thorough structure-function relationship of interactions between respiratory centers and (pre) motor circuits.

## Characteristics

### Medullary Respiratory Networks

Three major bilaterally-organized respiratory groups have been identified in the lower brainstem of mammals [1]. The dorsal respiratory group is primarily involved in the transmission of (chemosensory and mechanosensory) inputs to the medullary respiratory control system. The pontine respiratory group plays a major role in orchestrating the highly complex (pre/post)inspiratory-expiratory synaptic neuronal activity pattern for the innervation of diverse groups of respiratory muscles that are active during one or several of these phases. The ventral respiratory column contains various aggregations of respiratory neurons, among which some are capable of generating primary ►respiratory rhythms. Specifically, the ►pre-Bötzinger complex (preBötC) appears to be pivotal for the generation of inspiratory-related interneuronal and motor activities. Conversely, the ►parafacial respiratory group (pFRG), located between the pons and the more caudal preBötC, generates preinspiratory (and postinspiratory) activities that drive, e.g., expiratory abdominal muscles [1,2]. Both, the preBötC and pFRG remain active in distinct transverse brainstem slices from newborn rodents (see ►isolated respiratory centers). In more intact preparations, the pFRG and preBötC constitute presumably a dual respiratory center that may interact with the pontine and dorsal respiratory groups for generation of the full spectrum of respiratory activities [1]. As described below, voltage-sensitive dye imaging has been used for characterization of all three respiratory groups, whereas other imaging approaches were so far primarily used for studying the ventral respiratory column, in fact mostly presumptive or histologically-identified preBötC interneurons and inspiratory XII motoneurons.

## Voltage-Sensitive Dye Imaging of Spatiotemporal Respiratory Patterns

Voltage-sensitive dye imaging is principally suitable to measure the activity of single cells. Though, this technique has been applied yet only to monitor, at low optical magnification, spatiotemporal activity patterns in large populations of respiratory neurons. In most studies, fluorescence signals were collected from the intact ventral brainstem surface. Two dyes are preferentially used for this approach. The agent Di-4-ANEPPS stains primarily superficial tissue layers, whereas the less lipophilic Di-2-ANEPEQ stains deeper brainstem structures in addition. Bath-application of these agents for time periods of 0.5 h to sometimes >1 h is necessary for effective staining of respiratory active regions in newborn rodent brainstems [2,3]. Decreases and increases in fluorescence intensity of the above voltage-sensitive dyes correlate with enhanced and attenuated neuronal activity, respectively, due to the fact that the fluorescence of Di-2-ANEPEQ and Di-4-ANEPPS is proportional to (neuronal) membrane potential [2]. Accordingly, in an area corresponding to the *locus coeruleus*, which is located between the pontine respiratory group and the pFRG, initial inspiratory-related voltage-sensitive dye imaged activity is followed by a pronounced period of decreased activity [3]. The time course of these optical signals is similar to that of the inspiratory depolarization and the subsequent postinspiratory hyperpolarization of single neurons in this area. In contrast, optical activity in the main area of the pFRG is primarily preinspiratory-related, with less pronounced postinspiratory activity compared to that observed with whole-cell recording from single pFRG neurons [2]. In the latter study, inspiratory-related activity was in particular pronounced in the region of cervical spinal motoneurons, and in an area located ~0.4–0.6 mm caudal to the caudal end of the facial motor nucleus [2]. The latter region corresponds well with the presumptive rostrocaudal extension of the preBötC [4]. Most areas of the ventral respiratory column, including the pFRG and preBötC, contain different classes of respiratory neurons. It is not clear at present, why no prominent respiratory-related optical activity is revealed in regions of the ventral respiratory column other than the pFRG and preBötC.

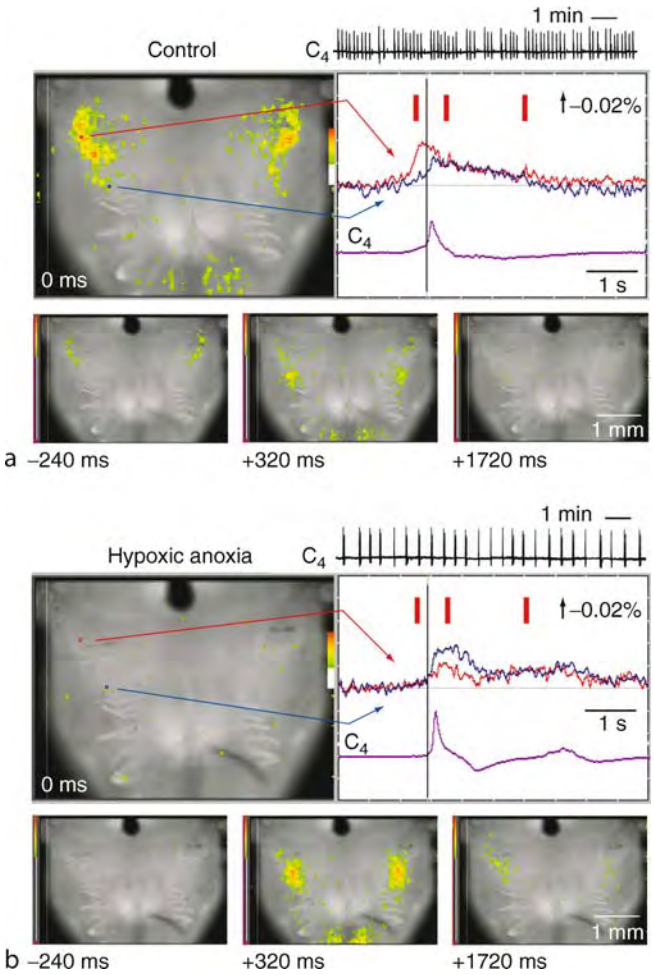
Despite these caveats, respiratory voltage-sensitive dye imaging provided important information regarding the structural organization and function of respiratory networks. In *en bloc* medullas from newborn rodents, voltage-sensitive dye imaging revealed that both the dorsal and pontine respiratory groups are active in regions similar to those previously identified in adult mammals with combined electrophysiological and histological techniques [3]. The seminal imaging study on the discovery of the pFRG [2] suggested that the area of the location of these rhythmogenic preinspiratory neurons may extend further rostrally than previously assumed. Regarding respiratory functions, voltage-sensitive dye imaging showed that anoxia-induced slowing of ►respiratory rhythm in newborn rat brainstems is accompanied by depressed preinspiratory and augmented postinspiratory medullary optical activities that coincide with the occurrence of inspiratory-related cervical nerve burst doublets (Fig. 1).

The latter findings suggest that anoxia synchronizes the dual respiratory rhythm generators. This may result in enhanced postinspiratory medullary activity that triggers repetitive inspiratory motor bursts. All this shows that voltage-sensitive dye imaging is a potent tool for the analysis of normal and pathologically disturbed spatiotemporal patterns of respiratory activities, in particular when this technique is combined with electrophysiological recording of cellular respiratory bursting.

## Imaging of Respiratory $Ca^{2+}$ Oscillations and (Sub) Cellular Signaling Factors

In excitable cells, a notable rise of the free cytosolic [$Ca^{2+}$] is associated with the $Ca^{2+}$ influx caused by activity-related depolarization. Accordingly, $Ca^{2+}$ imaging is a widely used tool for monitoring neuronal activity (see ►neuron-glia imaging). The vast majority of $Ca^{2+}$ imaging studies of the respiratory system has focused on preBötC neurons or preBötC-driven interneurons and XII motoneurons in rhythmic slices from perinatal rodents. In most of these reports, clusters of preBötC neurons were loaded with the membrane-permeant acetoxy-methyl (AM) form of ►$Ca^{2+}$-sensitive dyes, in particular Fluo-4-AM, Calcium-Green-1-AM and Fura-2-AM [4–8].

In the first respiratory $Ca^{2+}$ imaging study, cytosolic $Ca^{2+}$ oscillations in preBötC neurons occurred synchronously with inspiratory-related XII activity [7]. Following pharmacological blockade of glutamatergic synaptic transmission, asynchronous $Ca^{2+}$ oscillations persisted in a subpopulation of these cells, in line with the hypothesis that preBötC neurons have intrinsic bursting ("pacemaker") properties [1,7]. For this CCD camera imaging study, Calcium-Green-1-AM was microinjected near the midline contralateral to the preBötC side to be imaged. This ensured that only cells were imaged that project their axons to the contralateral preBötC. As a caveat, such loading of cells via diffusion of dye from their axon to the cell bodies required "overnight," i.e. >10 h, incubation times. This substantial delay between the generation of the acute slice and the start of recording may affect functional properties of rhythmogenic preBötC networks although basic inspiratory activity was preserved, at least in solution of artificially-elevated (7–8 mM) [$K^+$] [7]. Alternatively, inspiratory $Ca^{2+}$ oscillations can be monitored within <20 min after the injection of AM $Ca^{2+}$ dye into the "online histologically-identified" preBötC [4] (Fig. 1).



**Respiratory Network Analysis, Functional Imaging. Figure 1** Anoxic respiratory pattern shifts in newborn rat brainstem-spinal cords. (a) traces in box (50 averaged optical signals) show that pFRG activity (red dot) preceded preBötC activity (blue dot) in control. Images below box show fluorescence signals of the voltage-sensitive dye Di-2-ANEPEQ during time periods indicated by vertical red bars. (b) Hypoxic anoxia due to $N_2$-gassed solution decreased inspiratory-related cervical nerve ($C_4$) burst rate and induced double bursts (compare integrated $C_4$ activities in (a) and (b)). Anoxia also suppressed preinspiratory optical pFRG activity (50 averages) and elicited a second optical peak in the pFRG, preBötC and intermittent regions. The latter activity appeared in the postinspiratory phase after the augmented $C_4$ peak and coincided with secondary $C_4$ activity. In original $C_4$ traces, the amplitude of the second $C_4$ peak was similar to that of initial activity, but was attenuated by averaging due to variation in the time of burst onset. Scale bar indicates percentage change in fluorescence. (From K. Ballanyi & H. Onimaru, unpublished).

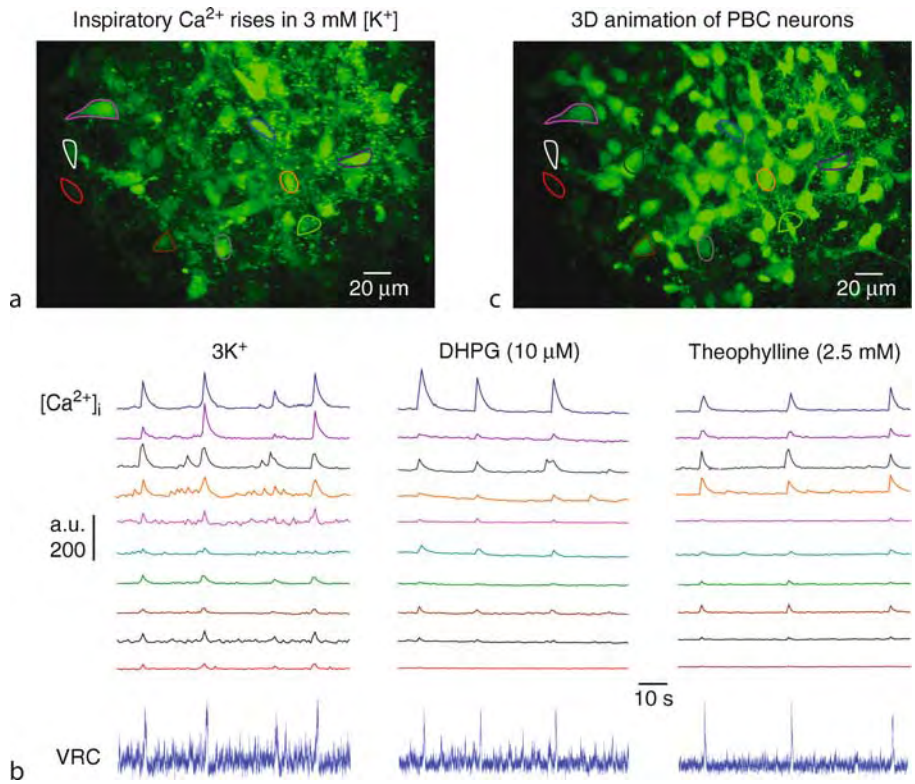
As a major advantage of this approach, preBötC rhythms can be studied for several hours in physiological (3 mM) $K^+$ which ensures a higher sensitivity of preBötC rhythms to clinically-relevant agents such as opioids [4]. Although multiphoton microscopy was used in that report, neither the activity nor the gross morphology of preBötC neurons could be imaged at high spatial resolution at depths >80 µm into the tissue for yet unknown reasons. Similarly, CCD camera imaging and confocal laser scan microscopy are restricted to recording depths <70 µm [4–8]. Focal injection of $Ca^{2+}$ dye limits the monitored area of active respiratory neurons to a circular spot with a diameter of 150–300 µm [4]. This limitation is overcome by loading cells unspecifically in the entire slice via bath-application of the AM $Ca^{2+}$ dye which, however, penetrates <50 µm into the tissue. As further caveats, $Ca^{2+}$ imaging may induce phototoxic effects (▶Phototoxicity) on (respiratory) neurons and is subjected to bleaching of dye (▶Photobleaching). The extent of these effects increases at both higher sampling rates and enhanced optical magnification for visualizations of (sub)cellular structures. Though, at scan rates of 1.5–3 scans/s most of the peak of respiratory-related $Ca^{2+}$ oscillations is captured and continuous multiphoton or confocal imaging is possible for time periods >30 min

[4] (Fig. 2), similar to CCD camera imaging (Fig. 3) (B.U. Keller, unpublished observations).

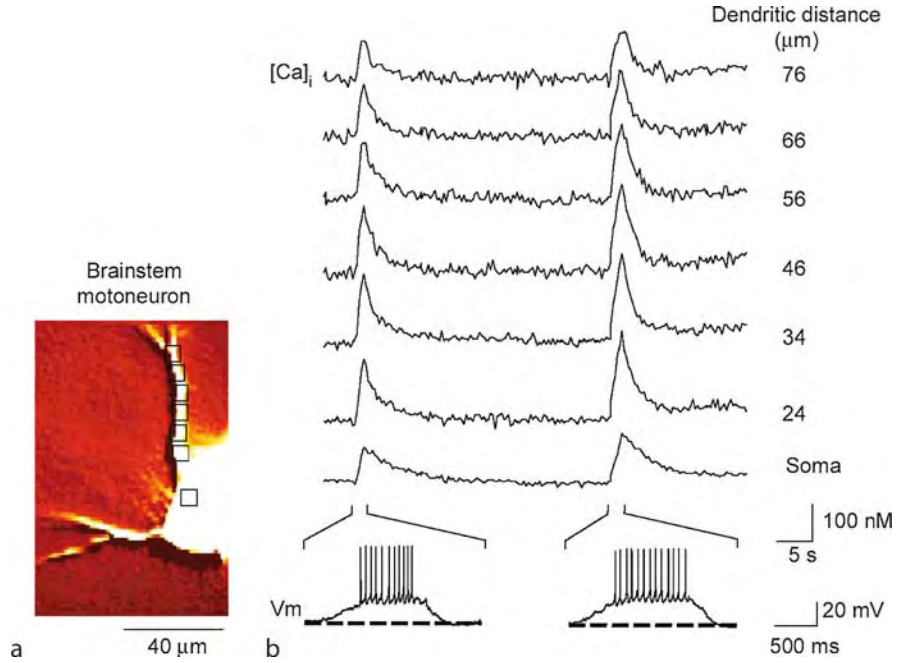
The correlation between inspiratory-related membrane potential oscillations (or underlying membrane currents) and intracellular $Ca^{2+}$ can be analyzed during whole-cell recording of respiratory neurons that are loaded with $Ca^{2+}$ dye via the recording patch-electrode (Fig. 3). The first study in that regard showed with photomultiplier-based "point" imaging in presumptive preBötC neurons that somatic $Ca^{2+}$ rises with a magnitude of maximally 300 nM occur during the inspiratory drive potential, and that a major portion of this signal is due to $Ca^{2+}$ influx via high voltage-gated $Ca^{2+}$ channels [5]. The relation of membrane excitability with cytosolic $Ca^{2+}$ transients and their buffering, or with other cellular signaling factors, has been studied thoroughly in inspiratory active XII cells [8] (Fig. 3). These cells are not only a potent model to study the inspiratory drive from the preBötC to motor networks, but also for analysis of the selective vulnerability of particular motoneurons in amyotrophic lateral sclerosis [8]. Disturbances of (sub)cellular signaling processes such as (respiratory-related oscillations of) mitochondrial $Ca^{2+}$ and membrane potential or redox processes are studied in XII motoneurons with regard to the latter disease [8]. Rhythmic changes of (sub)cellular signaling factors have also been optically monitored in presumptive inspiratory preBötC neurons, e.g., in the context of anoxic respiratory depression [9].

## Targeted Recording from Fluorescence-Tagged Respiratory Neurons

It is not clear, whether yet unidentified rhythmogenic respiratory neurons, in particular of the preBötC and pFRG, have specific morphological features such as a particular size and shape of the soma or the number and



**Respiratory Network Analysis, Functional Imaging. Figure 2** Multiphoton/confocal imaging of the activity and morphology of inspiratory preBötC neurons. (a) cells located 0.59 mm caudal to the caudal end of facial nucleus in the preBötC of a 600 µm thick newborn rat brainstem slice were stained by pressure-injection (0.7–1.0 psi, 10 min) with $Ca^{2+}$ sensitive dye, Fluo-4-AM. Movie (*supplemental material*) shows 90 s recording in 3 mM $[K^+]$ of $Ca^{2+}$ oscillations in these neurons that were in phase with inspiratory population activity recorded from the contralateral PBC; bottom left trace in (b). Fluo-4-AM fluorescence intensity is plotted in arbitrary units (a.u.) against time. After washout of rhythm in 3 mM $[K^+]$, preBötC bursting and $Ca^{2+}$ oscillations were restored by low concentrations of the metabotropic glutamate receptor agonist dihydroxyphenylglycine (DHPG) and the clinically used respiratory stimulant theophylline. (c) 3D animation (*supplemental material*) showing gross morphology of preBötC neurons and neighboring non-rhythmic cells obtained from z-stack (0.5 µm single step) image series encompassing areas starting 7.5 µm above to 7.5 µm below image plane of (a) (reproduced from [4] with permission).



**Respiratory Network Analysis, Functional Imaging. Figure 3** Whole-cell patch-clamp recording and simultaneous $Ca^{2+}$ imaging of a rhythmically active hypoglossal motoneuron. (a) Fluorescence image of the soma and proximal dendrite of a patch-clamped hypoglossal motoneuron in a 700 µm thick mouse brainstem slice. (b) Whole-cell recording in current-clamp mode and simultaneous ratiometric CCD camera imaging of cytosolic $Ca^{2+}$ concentrations. Rhythmic electrical discharges are paralleled by notable $Ca^{2+}$ transients in the soma and six dendritic compartments, selected for analysis at distances of 24–76 µm from the soma (compartment positions are represented by boxes in (a)). Spontaneous bursts of action potentials, shown in the bottom trace as changes in membrane voltage (Vm) are accompanied by cytosolic $Ca^{2+}$ rises up to 200 nM (reproduced from [8] with permission).

array of (primary) dendrites. If this were the case, such cells could be selectively targeted after fluorescence labeling for intracellular electrophysiological recording in the rhythmic slices. The above mentioned $Ca^{2+}$-sensitive fluorescent dyes, and also other functional dyes such as the marker for mitochondrial potential Rhodamine-123, can principally be used as morphological markers (Fig. 2–4) (see neuron-glia imaging).

Regarding $Ca^{2+}$ dyes, Fura-2 provides a robust fluorescence signal at low (resting) cytosolic [$Ca^{2+}$], whereas both Fluo-4 and Calcium-Green-1 fluoresce during rises of cytosolic $Ca^{2+}$ (Fig. 2–4) [4–7]. Although recording from inspiratory (preBötC) interneurons in the rhythmic slices is routinely done under visual control, these superficial cells are surprisingly not routinely labeled during recording with high resolution morphological dyes, e.g., of the "Alexa" family.

Alternatively, subpopulations of respiratory neurons in acute medullary slices can be labeled with fluorescent markers for proteins in the plasma membrane or cytosol. In that context, it was assumed that rhythmogenic preBötC neurons are characterized by postsynaptic neurokinin-1 receptors that are normally activated by substance P [1,6]. Accordingly, fluorescence-tagging of substance P uptake via these receptors revealed that preBötC neurons can indeed be targeted [6] (Fig. 4). However, as shown in the latter study, the labeling was not specific and included various other types of (respiratory) brainstem neurons. In addition, respiratory neurons can be targeted in acute slices from transgenic mice that express a fluorescent protein coupled to a promoter such as glutamic acid decarboxylase [10]. Also this approach is yet not specific enough for identifying one particular population of candidate rhythmogenic respiratory neurons. Currently, fluorescence-tagged transcription factors that may be specific for rhythmogenic respiratory neurons, are being constructed in transgenic mice. However, it may turn out that such cells are not characterized by a single characteristic feature that can be visualized in the *in vitro* models, but rather by a unique pattern of transcription factors, (pacemaker) ion channels plus neurotransmitter receptors and/or transporters.

## Synonyms

Dual respiratory center organization; Mammalian respiratory rhythm generators

## Definition

Analysis of isolated respiratory centers means a reductionistic approach for studying the neural control of breathing using *in vitro* brainstem preparations (mostly from ►perinatal rodents) in which rhythmogenic respiratory networks remain active. The ►pre-Bötzinger complex (preBötC) has been identified as a brainstem region that generates respiratory rhythm in mammals and remains active in a transverse medullary slice preparation. In a more rostral transverse medullary slice without the preBötC, the pre/postinspiratory active ►parafacial respiratory group (pFRG) continues to drive facial (VII) motoneurons rhythmically. Although both groups of rhythmogenic neurons operate autonomously in the distinct brainstem slices, they appear to constitute a ►dual respiratory center, at least in less reduced " ►*en bloc*" brainstem-spinal cord preparations from perinatal rodents and juvenile rats *in vivo*. This hypothesis is based on a differential action of opioids on functionally inspiratory (preBötC-driven) or expiratory (pFRG-driven) motor activities *in vivo* and *in vitro* suggesting that the pFRG provides a pivotal excitatory drive to the preBötC. Conversely, anoxia appears to synchronize and enhance the activities of both rhythm generators, resulting in pronounced postinspiratory medullary activities and lumbar/facial motor bursting that are accompanied by inspiratory-related nerve burst doublets. The latter findings suggest that the preBötC and pFRG are capable of adjusting their interactions to cope in particular with pathological disturbances of breathing.

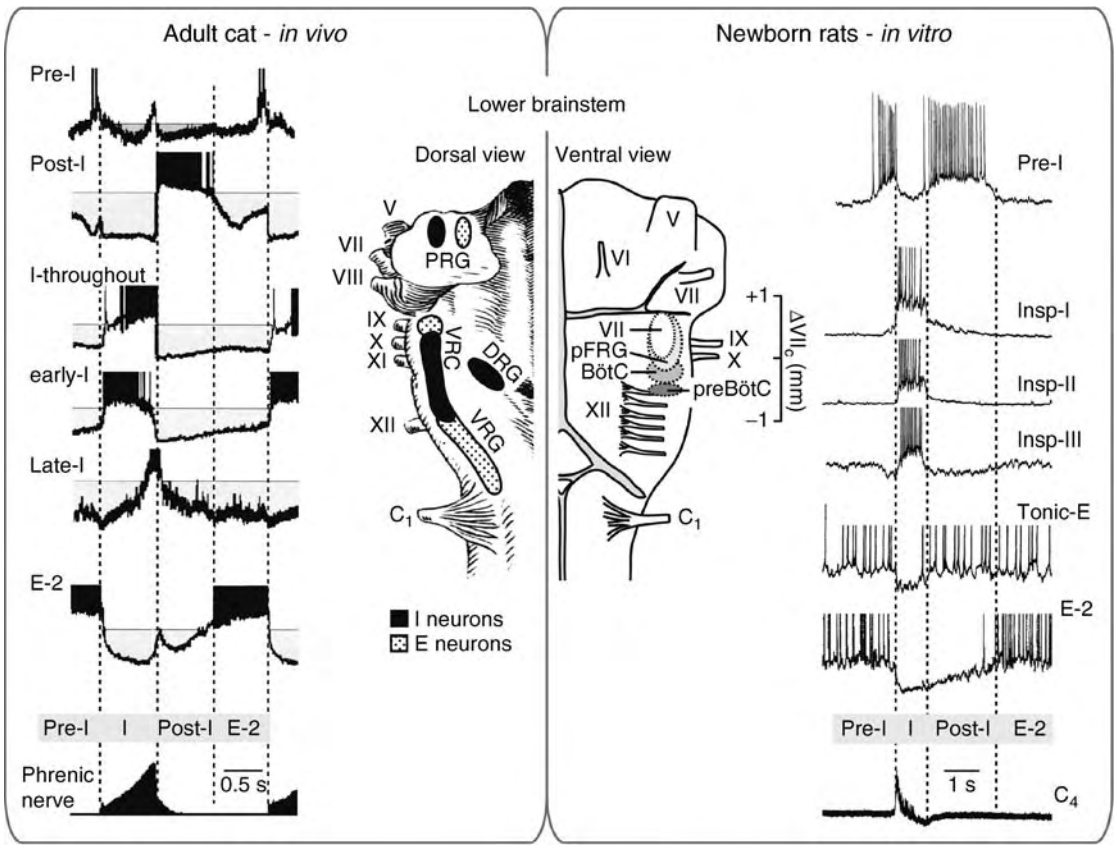
## Characteristics

### Respiratory Network Organization *in vitro* and *in vivo*

Three major anatomically defined respiratory groups have been identified in the lower brainstem of mature mammals *in vivo* by microelectrode analysis of respiratory-related extra- or intracellular activities and subsequent histological identification of the recording sites [1] (Fig. 1). The ►dorsal respiratory group is a relay site of peripheral mechano- and chemoreceptor inputs to primary respiratory networks, whereas the pontine respiratory group is important for the generation of the multiphase neuronal activity pattern, which is projected to the respiratory muscles [1]. The ►ventral respiratory group (or rather column) contains arrays of interneurons, which are involved in the generation of the basic rhythm [1,3,4] (Fig. 1). In 1984, Suzue reported that respiratory activity in mammals is retained *in vitro*, specifically in isolated brainstem-spinal cord preparations from newborn rats [3] (Fig. 1). Extra- and intracellular electrophysiological recording of rhythmic drive potentials and/or action potential discharge in histologically-identified brainstem sites established that different classes of respiratory neurons are active in this *en bloc* model in areas corresponding to those in adult mammals *in vivo* [1,3,4] (Fig. 1). Neonatal rat ventral respiratory column neurons have been classified according to the phase relation of their cellular bursting with inspiratory-related cervical nerve bursting. This revealed that such neurons are active during one or several phases of the *in vitro* respiratory rhythm, which is comprised of a preinspiratory, inspiratory, postinspiratory and an active expiratory ("E-2") component in brainstem-spinal cord preparations [3,4–7] (Fig. 1).

### Isolation of Respiratory Centers

The findings from a large number of studies using the *en bloc* brainstem model greatly advanced the understanding of cellular mechanisms involved in the neural control of breathing [3,4]. In that regard, findings from one seminal study [8] supported in 1991 the long-standing hypothesis that breathing movements originate from a limited area, a "*noeud vitale*," in the "upper neck" [1]. Specifically, microsection of the newborn

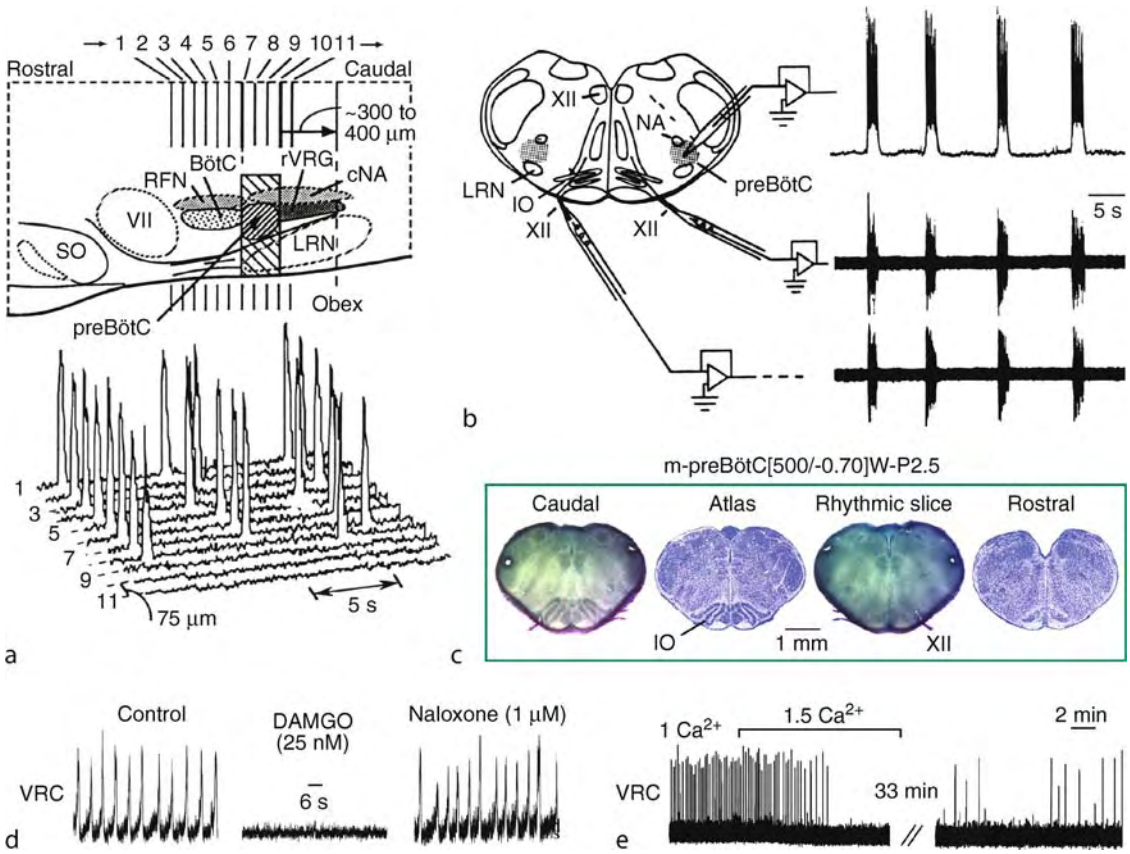


**Respiratory Network Analysis, Isolated Respiratory Center Functions. Figure 1** Respiratory groups, centers and neuron classes in mammals. Sharp microelectrode membrane potential recordings in the left part of the figure revealed rhythmic depolarizations in six classes of adult cat medullary respiratory neurons. These cells discharge action potentials (black bars) in a specific phase relation with the inspiratory (I) plus postinspiratory (post-I) activities of the phrenic nerve which activates the diaphragm, i.e. the main inspiratory muscle. Grey areas indicate periods of inhibition via $GABA_A$ and glycine receptors. Modified with permission from D.W. Richter (in Comprehensive Human Physiology, eds. R. Greger, U. Windhorst; Springer-Verlag, Berlin Heidelberg, 1996). The dorsal schematic view on an adult cat brainstem shows the simplified distribution of I neurons (black areas) and expiratory (E, dotted areas) neurons in the pontine, dorsal and ventral respiratory groups (PRG, DRG, VRG). Note that the rostral portion of the VRG is named ventral respiratory column (VRC). Modified with permission from [1]. The attached ventral view on a newborn rat brainstem shows the locations and rostrocaudal extensions of the parafacial respiratory group (pFRG) and pre-Bötzinger Complex (preBötC) rhythmogenic respiratory centers with reference to the caudal end of the facial (VII) motonucleus, $VII_c$. The constancy of the rostrocaudal extensions of respiratory marker nuclei such as the VII nucleus and the inferior olive allowed the generation of "calibrated" newborn rat brainstem-spinal cord ("*en bloc*") preparations with a defined content of (respiratory) brainstem tissue [2]. The ventral brainstem view also shows the location of cranial nerves and blood vessels, which are used as landmarks for insertion of "patch-clamp" electrodes in the *en bloc* model for "whole-cell" recordings of membrane potentials from different types of newborn rat VRC neurons. In the right part of the figure, the activity patterns of such neurons are aligned with reference to inspiratory-related activity of ventral cervical nerve roots ($C_{3–6}$) forming the phrenic nerve. Specifically, these neurons are I neurons (sublabeled Insp-I, Insp-II, Insp-III after [3]), two types of E neurons, and preinspiratory (plus postinspiratory) active "Pre-I"-type pFRG neurons. Modified with permission from H. Onimaru, A. Arata, I. Homma (Respiration & Circulation 46, 773–782, 1998). Abbreviations: *E-2*, active expiratory phase; *BötC*, Bötzinger Complex; *V-XII*, cranial nerves, specifically *V*, trigeminus; *VI*, abducens; *VIII*, vestibulocochleat; *IX*, glossopharyngeus; *X*, vagus; *XI*, accessorius; *XII*, hypoglossus; $C_1$, 1st ventral cervical nerve.

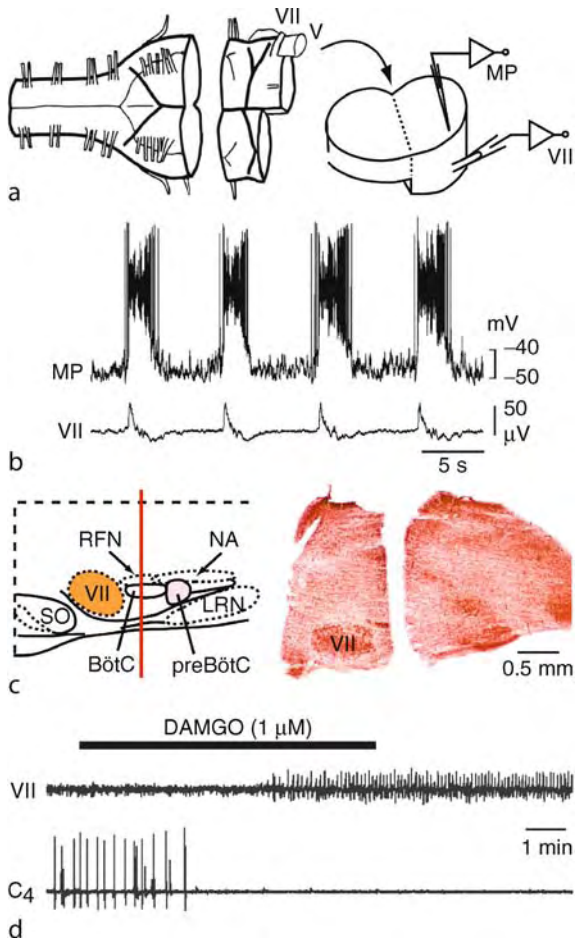
rat brainstem-spinal cord preparation was combined with suction electrode recording of cranial and spinal nerve activities to consolidate first the conclusion from previous findings on that model [3] that neither the pontine nor the dorsal respiratory group are necessary for fictive inspiratory-related rhythm [8]. Instead, inspiratory rhythm was irreversibly blocked when microsection affected a medullary area, named the

preBötC, which extended ~200 µm in rostrocaudal direction (Fig. 2). Finally, this study demonstrated that the preBötC remains inspiratory active after isolation in a transverse brainstem slice (Fig. 2).

The view that the preBötC constitutes an essential respiratory center is supported since its discovery by numerous *in vivo* and *in vitro* studies [3,4]. However, the preBötC is not the only autonomous respiratory



**Respiratory Network Analysis, Isolated Respiratory Center Functions. Figure 2** Isolation of the inspiratory center. (a) the upper panel shows a schematic lateral sagittal section through the ventral aspect of the newborn rat brainstem. The numbers correspond to consecutive 75 µm transverse sections through the brainstem-spinal cord model (Fig. 1). The sections were carried out in rostral to caudal direction, while recording with suction electrodes inspiratory-related cervical nerve bursts which are displayed, after integration, in the lower panel. Such experiments revealed an irreversible block of rhythmic discharge following section 8. These findings were complemented by results from corresponding recordings from inspiratory active cranial nerves during sectioning in caudorostral direction. This identified the preBötC as a brainstem region with a rostrocaudal extension by ~200 µm (see box) which is important for generation of respiratory rhythm. Abbreviations others than those in Fig. 1: *LRN*, lateral reticular nucleus; *RFN*, retrofacial nucleus; *SO*, superior olive; *rVRG*, rostral ventral respiratory group; *cNA*, caudal nucleus ambiguus. (b) The preBötC remains inspiratory active in a newborn rat brainstem slice with a thickness >175 µm. Rhythmically active neurons in the area of the ventrolateral medulla rhythmically drive XII motoneurons which innervate via the XII nerve genioglossal tongue muscles for patency of the upper airways during inspiration. (a and b modified with permission from [8].) (c) The constancy of respiratory marker nuclei such as the inferior olive enables the generation of preBötC slices with rostrocaudal boundaries which are "calibrated" by comparison with a newborn rat brainstem atlas [9]. The latter study introduced a terminology for such slices. In this example the "m-preBötC[500/-0.70]W-P2.5" slice contains the preBötC in the middle ("m-preBötC"), is 500 µm thick with the caudal boundary 0.70 mm caudal to $VII_c$, and was produced from a 2.5 days-old (P2.5) Wistar (W) rat. (d) calibrated preBötC slices generate robust inspiratory-related rhythm in the area of the VRC in superfusate with physiological (3 mM) instead of routinely used 7–11 mM [$K^+$]. This rhythm is very sensitive to low concentrations of the µ-opioid receptor agonist DAMGO. Note that the 3 mM $K^+$ rhythm is effectively restored within few minutes of application of the opioid receptor antagonist naloxone (1 µM). c and d modified with permission from [9]. (e) in a different preBötC slice, 3 mM $K^+$ rhythm was abolished shortly after raising superfusate $Ca^{2+}$ from 1 mM (the lower limit of the proposed physiological range) to 1.5 mM (the upper limit). Note the incomplete recovery of inspiratory rhythm following washout of raised $Ca^{2+}$. Modified with permission from [2].



**Respiratory Network Analysis, Isolated Respiratory Center Functions. Figure 3** Rhythmic pFRG activity in a transverse slice of brainstem tissue rostral to the preBötC. (a) the newborn rat *en bloc* model was transected slightly rostral to the most rostral XII root to obtain a transverse slice for simultaneous suction electrode recording from the VII nerve and whole-cell recording of membrane potential (MP) from neurons within the ventrolateral medulla. (b) membrane potential oscillations of putative Pre-I neuron in the rostral block were synchronous with VII nerve activity in "Suzue-type" solution with 6.2 mM $K^+$ and 2.4 mM $Ca^{2+}$. Shortly before the recording, the preparation was treated for 10–15 min with DAMGO (1 μM) for enhancement of such bursting. (c) histological reconstruction revealed that the transection was between $VII_c$ and the rostral boundary of the preBötC, thus in the region corresponding to the BötC in adult mammals (compare Fig. 1). (d) in a preparation transected at a level similar to that in the experiment of a–c, but without removing the rostral block, DAMGO in 6.2 mM $K^+$ and 2.4 mM $Ca^{2+}$ abolished inspiratory-related $C_4$ activity in the caudal aspect of the transected preparation, but restored VII nerve rhythm, which was transiently depressed due to the transection procedure. These findings suggest that pFRG neurons in rostral medullary slices, not including the preBötC, produce rhythmic bursting which is facilitated by opioids, in contrast to a strong depressing action of such drugs on more caudal preBötC-driven rhythms. Modified with permission from [7,8].

center in mammals. Already more than 20 years ago, the hypothesis has been proposed that pre/postinspiratory active "Pre-I" neurons are important for maintenance of the rhythmic activity of inspiratory medullary networks in the newborn rat *en bloc* preparation [3]. More recent findings from voltage-sensitive dye imaging of spatiotemporal respiratory patterns and concomitant electrophysiological recording of membrane potential indicated that Pre-I neurons form the pFRG, a functionally and anatomically defined respiratory group [6] (Fig. 1). The pFRG remains rhythmically active and drives VII motoneurons in a transverse slice of brainstem tissue that rostrally neighbors the preBötC [7] (Fig. 3). Most pFRG neurons are active during both the preinspiratory and postinspiratory phase, but are subject to pronounced inhibition via hyperpolarizing $GABA_A$ and glycine receptor-mediated inhibitory postsynaptic potentials during the inspiratory phase [3,5–7] (Fig. 1). In contrast, pFRG neurons are continuously active for a time period of several seconds in the slices with rhythmic VII nerve activity [7] (Fig. 3). This supports earlier assumptions that the preBötC is responsible for inspiratory inhibition of Pre-I cells in the *en bloc* medullas [3]. Although "reference" inspiratory motor activity is missing in the rhythmic pFRG slices, it is likely that the sustained neuronal and VII nerve activities (Fig. 3) span the preinspiratory, inspiratory plus postinspiratory phases.

Bursting of pFRG neurons during these phases is in accordance with the finding that branches of the VII nerve innervate muscles of the *alae nasi* that decrease the nasal airway resistance in cats and dogs before, during and after inspiration [7]. Conversely, the finding that interneurons in the ventrolateral aspect of preBötC slices induce rhythmic activity of XII motoneurons (Fig. 2) strongly suggests that the rhythm in that model is inspiratory-related [8], because subgroups of XII motoneurons innervate the tongue during inspiration for patency of the upper airways [1,4].

## Determinants of Isolated Respiratory Center Activities

The rhythmic activities of the isolated respiratory centers are not identical with those in intact animals or less reduced *in vitro* preparations such as the "working heart brainstem preparation" of rodents [see corresponding chapters]. Though, activities in the rhythmic slices share several features with respiratory behaviors *in vivo*. For example, in juvenile rats preBötC-driven inspiratory activity is blocked by opioids, whereas rhythmic contractions of pFRG-driven expiratory abdominal muscles are not inhibited [4,5]. Similar to these *in vivo* findings,

opioids depress preBötC-driven (motor) rhythms *in vitro*, whereas pFRG-driven cellular and nerve activities are not inhibited [4,5,7]. The effects of various neuromodulators on the *in vitro* respiratory-related rhythms are influenced by the experimental conditions, which differ notably between laboratories. In particular the superfusate concentrations of $K^+$ and $Ca^{2+}$ vary between 3–11 mM and 0.8–2.4 mM, respectively, despite the notion that these cations strongly modulate neuronal excitability [2]. Regarding the action of opioids, preBötC slice rhythms in physiological $K^+$ (3 mM) and 1 mM $Ca^{2+}$ are blocked by low nanomolar concentrations of opioids (Fig. 2), whereas close to micromolar concentrations are needed to depress rhythms in preBötC slices or *en bloc* medullas in superfusate with elevated $K^+$ (Fig. 3) [7,9]. Furthermore, preBötC slices generate long-term and robust rhythm in 3 mM $K^+$ and 1 mM $Ca^{2+}$ (corresponding to the lower range of the physiological spectrum), whereas rhythm is depressed by elevation of $Ca^{2+}$ to 1.5 mM (the proposed upper limit of the physiological range) [2,9] (Fig. 2). In 1.5 mM $Ca^{2+}$, preBötC slice rhythm is reactivated by raised $K^+$ leading to the view that isolated inspiratory center activity is determined by an extracellular "$Ca^{2+}$/$K^+$ antagonism" [2].

Respiratory center rhythms depend also critically on the physical dimensions of the *in vitro* models. For example, findings in the newborn rat *en bloc* model indicated that the pFRG drives pre/postinspiratory bursting of lumbar motoneurons in spinal $L_{1-2}$ segments via premotoneurons which are located caudal to the preBötC [5]. This view was substantiated by the observation in juvenile rats *in vivo* that brainstem transection at the caudal end of the VII nucleus, which partially overlaps with the pFRG [6] (Figs. 1 and 3), abolished pre/postinspiratory bursting of expiratory abdominal muscles innervated by $L_{1-2}$ lumbar motoneurons [4]. Similar transection experiments in the newborn rat *en bloc* model revealed that the transection level critical for blocking pre/postinspiratory lumbar bursting is quite close to the rostral instead of the caudal end of the VII nucleus [2]. The absence of respiratory lumbar bursting in such transected preparations suggests that pFRG neurons responsible for this motor behavior are located in the most rostral aspect of the pFRG [2] (Fig. 1). However, it is for example also possible that axons from more caudal pFRG neurons inducing lumbar respiratory bursting project first rostrally and may thus have been transected [2,10]. This indicates that results from transection experiments need to be considered with caution. Furthermore, Pre-I neurons are not only found in the main area of the pFRG, but also within the preBötC, and even in regions caudal to the preBötC. In addition to Pre-I and expiratory cells, the preBötC in both perinatal rodent *en bloc* medullas and *in vivo* contains various subclasses of inspiratory neurons [3] (Fig. 1). Conversely, inspiratory (and expiratory) neurons are also active in the main area of the pFRG. While the rostral portion of the pFRG co-locates with the VII nucleus, the caudal part of the pFRG partially covers an area corresponding to the Bötzinger Complex in mature mammals. Finally, the pFRG also more or less overlaps medially with the Retrotrapezoid nucleus, which is one presumptive site of central respiratory chemosensitivity [4].

Due to the overlap of primary (rhythmogenic) areas and secondary (chemosensitive) respiratory drive regions, in concert with a rostrocaudally dispersed distribution of distinct classes of respiratory neurons, the respiratory centers can not be isolated without portions of functionally and/or anatomically different structures that may interact with these centers. Despite these caveats, the reductionistic approach has already, and will further, provide important information on the neural control of breathing. For example, ►multiphoton/confocal $Ca^{2+}$ imaging has been adapted to study the activity and gross morphological features such as soma size or shape of preBötC neurons, located in a histologically defined rostrocaudal area of "calibrated" preBötC slices that operate in physiological cation solution [9] (Fig. 2) [see ►Respiratory network analysis, Functional imaging]. A structure-function relationship of the isolated respiratory centers may be feasible by using the calibrated *in vitro* models in combination with nerve and intracellular electrophysiological recording plus $Ca^{2+}$ and voltage-sensitive dye imaging, which was crucial for identification of the pFRG [6] [see ►Respiratory network analysis, Functional imaging].

## A Dual pFRG-preBötC Respiratory Center

Findings in the *en bloc* brainstem model and juvenile rats *in vivo* suggest that the pFRG and the preBötC constitute a dual respiratory center. This hypothesis has been first proposed according to the above described distinct effects of opioids on inspiratory and pre/postinspiratory motor behaviors. These findings led to the conclusion that opioids inhibit breathing, at least partly, due to depression of synaptic excitatory transmission between the pFRG and the preBötC [4,5]. This view that excitatory drive from the pFRG to the preBötC is necessary for robust activity of the preBötC has already been proposed much earlier based on the finding in the *en bloc* model that focal lesion of the area including the pFRG impairs inspiratory cervical motor output [3]. However, as stated above the preBötC slices are capable of generating robust rhythm in physiological ion solution for several hours in the absence of structures corresponding to the main location of the pFRG [2,9]. The finding that rhythmic VII nerve activity in the pFRG slices is not depressed, but rather stimulated, by μ-opioid receptor agonists [7] (Fig. 3) supports the view that this respiratory center may be in particular important for breathing during the

perinatal period, when the brainstem is presumably subject to a surge by endogenous opioids [4].

Anoxia represents a further approach for analyzing the cooperativity of the pFRG and the preBötC. In the *en bloc* model, both hypoxic and chemical anoxia synchronize and enhance the activities of the pFRG and preBötC rhythm generators. This results in pronounced and persistent (>20 min) postinspiratory medullary activities and lumbar/facial motor nerve bursting during anoxia which is accompanied by inspiratory-related nerve burst doublets [10]. A causal relation between the latter anoxia-related phenomena is suggested by the finding that control pre/postinspiratory lumbar bursting is absent (similar to anoxia-induced enhancement of postinspiratory lumbar bursting and inspiratory-related nerve burst doublets) upon transection of the newborn rat *en bloc* preparation between the preBötC and the caudal end of the VII nucleus [10]. These results suggest that the anoxic postinspiratory augmentation of medullary interneuronal and lumbar/facial nerve bursting as well as inspiratory motor burst doublets require an interaction between the preBötC and the pFRG [10].

In summary, the rhythmogenic preBötC and pFRG appear to constitute a dual respiratory center, which adjusts its activity to cope with pathological disturbances of breathing. Under the influence of opioids, boosted pFRG activity may partly compensate for the depressed intrinsic preBötC interneuronal activity and provide enhanced drive for breathing efforts. During oxygen depletion, a functional reorganization of the preBötC and pFRG for synchronized and augmented bursting may optimize uptake of oxygen by enhancing single breaths. However, the extent of cooperativity between these respiratory centers during normal breathing is not clear yet. In particular, it remains to be shown that the pFRG has a similarly important role for breathing in mature mammals compared to newborns. That the pFRG is active *in vivo* after birth is indicated by the above finding of pre/postinspiratory abdominal muscle activity in juvenile rats [4,5]. It may be important to study whether the pFRG in mature mammals is closely related to the chemosensitive ►Retrotrapezoid nucleus [4]. That this may be the case is suggested by the anatomical overlap of these brainstem regions and by the findings that neurons in both regions are excited by raised levels of $CO_2$ and $H^+$ and project to other respiratory areas including the preBötC [3,4].

# Respiratory Network Responses to Hypoxia

Narong Simakajornboon[1], David Gozal[2]

[2]Kosair Children's Hospital Research Institute, Department of Pediatrics, University of Louisville, Louisville, KY, USA

## Definition

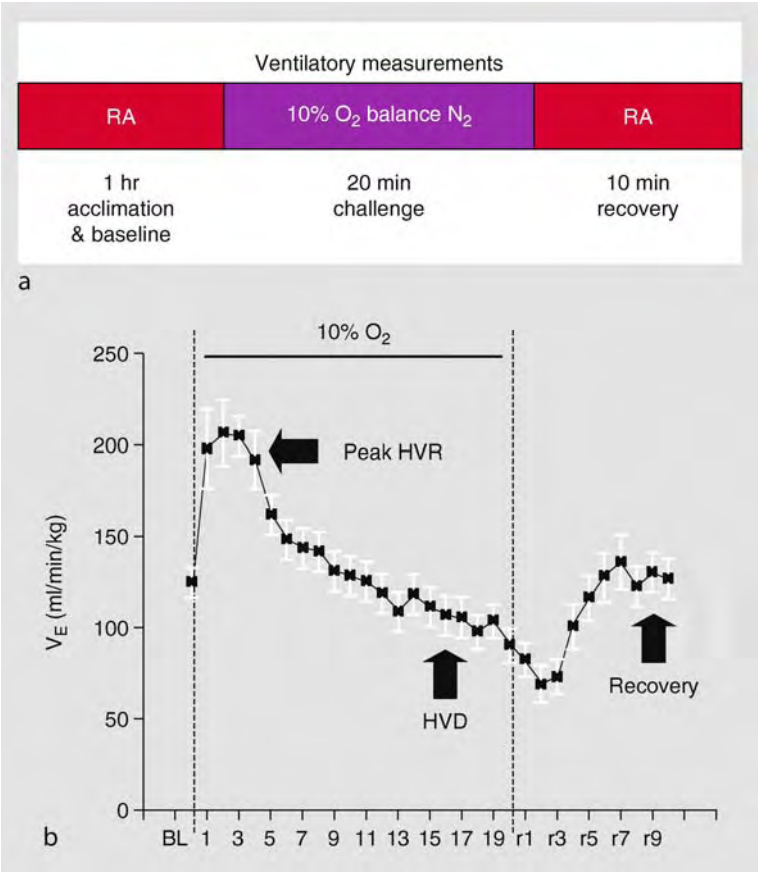
Respiratory network responses to ►hypoxia refer to the complex interactions between groups of neurons located mainly in the medulla, pons and midbrain that are responsible for control of ventilation during hypoxia. The physiologic mechanisms underlying these processes involve intricate interplay of ►neuromodulators released from respiratory neurons and glial cells.

The ventilatory response to hypoxia is precisely controlled and distinctive patterns emerge during postnatal development. The functional role of this process is not only to adapt the respiration during hypoxic conditions, but also to ensure cell survival, especially during the vulnerable period of development.

## Characteristics

The mammalian ventilatory response to hypoxia is biphasic. It consists of an initial increase in ►minute ventilation, followed by a later decline in ventilation which is termed hypoxic ventilatory depression (Fig. 1).

In developing mammals, the magnitude of hypoxic ventilatory depression is particularly prominent such that minute ventilation decreases below normoxic level [1]. The early component of hypoxic ventilatory response is mediated mainly through the ►peripheral chemoreceptor in the ►carotid body. The type I glomus cells in the carotid body are the primary site of oxygen sensing signal. The afferent signal is then transmitted to sensory terminals of the carotid sinus nerve and is subsequently projected to the nucleus of solitary tract (nTS). The nTS is located in the brainstem region and provides the first central synaptic relay to peripheral chemoreceptor afferent inputs. Other nuclei at this level of brainstem that play a role in respiratory control and the HVR include the nucleus ambiguus, the area postrema, the dorsal motor nucleus of vagus, the hypoglossal nucleus and the pre-Botzinger complex. A variety of neuromodulators in these areas play a crucial role in the central mediated hypoxic ventilatory response. Several studies have shown that the early response to hypoxia is mediated through platelet activating factor receptor pre-synaptically [2,3] and post-synaptically by N-methyl-D-aspartate (NMDA) glutamate receptors [4,5], which then activate downstream signaling pathways such as protein kinase C, tyrosine kinases, and calcium calmodulin kinase [6]. The hypoxic ventilatory depression is mediated through several complex mechanisms. In addition to hypoxia-induced reductions in metabolism, several neuromodulators have been thus far identified as playing a role in the hypoxic ventilatory depression, namely adenosine, γ-aminobutyric acid (GABA), serotonin (5-HT), opioids, and platelet derived growth factor (PDGF-β) receptors.



**Respiratory Network Responses to Hypoxia. Figure 1** Representative recording of minute ventilation during a 20-min hypoxic challenge followed by 10 min recovery in normoxia in a 14-day old rat pup. Please note initial increase in minute ventilation (HVR) followed by progressive time-dependent reduction in ventilatory output (HVD).

In this section, we will discuss the respiratory neuronal network with particular emphasis in the caudal brainstem, and will delineate specific neuromodulators mediating each component of hypoxic ventilatory response from a developmental perspective.

## Respiratory Neuronal Network

The peripheral chemoreceptors are located in carotid bodies and aortic bodies. These areas contain glomus cells of 2 types. The type I glomus cells in the carotid bodies is oxygen sensing cells of the peripheral chemoreceptor. The hypoxic stimulus is then transmitted to the sensory terminal of the carotid sinus nerve (CSN). From CSN, the signal projects to the several regions of the nucleus of solitary tract (nTS), the first synapses for primary afferents originating from peripheral chemoreceptors. Retrograde tracer studies reveal that the medial, dorsomedial, lateral and commissural regions of the nTS receive dense innervations from peripheral chemoreceptor afferent fibers. The nTS, the main neuronal nucelus of the ►dorsal respiratory group, has interconnections to other respiratory neurons including the pontine respiratory and the ►ventral respiratory group. The pontine respiratory group is composed of the lateral and medial parabrachial and Kollicker-Fuse nucleus, which play a role in diaphragmatic motor control and respiratory rhythm modulation. The ventral respiratory group is divided into the rostral and the caudal group. The rostral part of ventral respiratory group includes the Botzinger complex, the pre-Botzinger complex, and the parafacial respiratory group. The pre-Botzinger complex and the parafacial respiratory group are believed to encompass the kernel for ►respiratory rhythmogenesis. In addition, there are influences from many rostral brain areas to the respiratory neurons including the suprapontine nuclei, midbrain, diencephalons, hypothalamus, cerebellum, and regions of the cerebral cortex.

## Neuromodulators

### *Early HVR*

#### *Platelet Activating Factor Receptors*

Platelet activating factor and its cognate receptor (PAFR) are proposed to modulate glutamatergic signaling presynaptically, thereby influencing the release of glutamate into the synaptic cleft. PAFR activity has now been conclusively implicated in the acute ventilatory response to hypoxia [2,3].

#### *NMDA Glutamate Receptors*

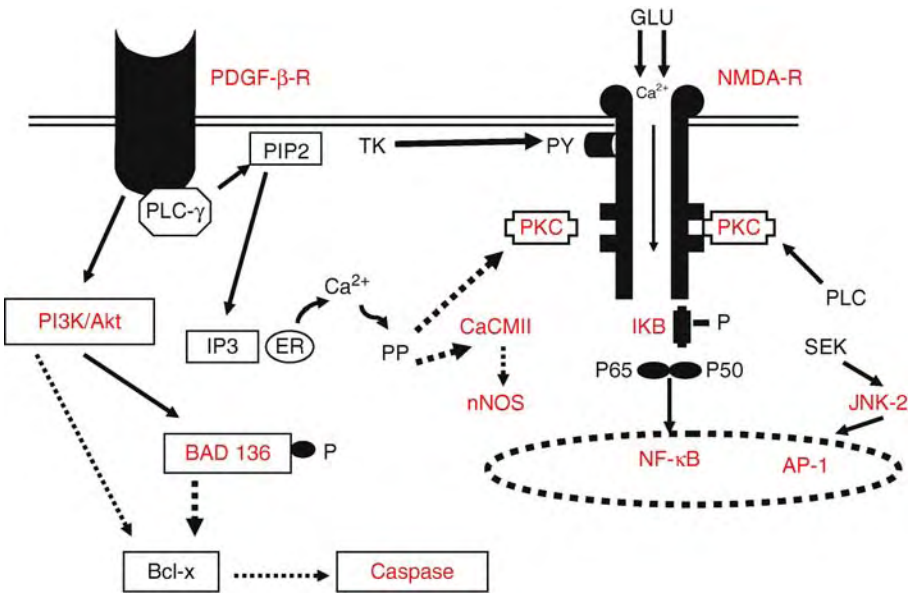
In the cardiorespiratory control regions, N-methyl-D-aspartate glutamate (NMDA) receptors mediate critical components of the respiratory pattern generation, cardiovascular regulation and HVR. The early response to hypoxia is mediated through NMDA glutamate receptors [4,5]. NMDA receptors are widely expressed throughout the brain, including the respiratory control areas such as nTS. Previous studies have demonstrated that systemic and targeted brainstem administration of NMDA glutamate receptor antagonists is associated with attenuation of HVR in adult and developing animals. In addition, hypoxia induces an increase in glutamate concentration within the nTS of conscious rats, which is associated with an increase in minute ventilation. However, the hypercapneic (►hypercapnia) ventilatory response is not affected by NMDA glutamate receptors [5]. The structure of NMDA glutamate receptors consists of heterodimeric, mandatory subunits that include one or more of the splice variants of the NMDA NR1 subunit and additional NR2 and NR3 subunits. Activation of NMDA receptors in the caudal brainstem of conscious rats involves tyrosine phosphorylation of both NR1 and NR2A/B subunits. In addition, the role of NMDA receptor in HVR is developmentally regulated such that an increasing dependency on NMDA glutamate receptor emerges over time and transition from an immature to a more mature hypoxic response requires NMDA receptor-bearing neurons within the nTS.

#### *Non-NMDA Receptors*

Previous studies have indicated the potential role of AMPA glutamate receptors in the ventilatory control and the HVR. Administration of NBQX (a selective non-NMDA receptor antagonist) did not affect ventilatory output in adult conscious mice and cats, but led to marked respiratory depression in neonatal animals. Microinjection of the AMPA glutamate receptor blocker NBQX within the nTS of anesthetized adult rats resulted in attenuation of ventilatory responses following carotid body stimulation. However, NBQX failed to modulate hypoxia-induced c-Fos activation in the adult rat. AMPA receptors appear to influence the respiratory pattern in the immature animal. The respiratory rhythm generation in neurons within the pre-Botzinger complex of neonatal rats is dependent on AMPA receptor activity. Notwithstanding, the role of AMPA glutamate receptors in the developmental of respiratory control may be limited to the regulation of timing mechanisms during normoxia, but not in mediating the hypoxic ventilatory responses [7].

#### *Intracellular Downstream Signaling Pathways Underlying the early HVR*

During the early HVR, NMDA receptors (NMDA-R) activation elicits calcium influx, and subsequent activation of phospholipase C (PLC), mitogen-activated protein kinase kinase (SEK) and calcium calmodulin kinase 2 (CaCmII). Our previously proposed model suggests that activation of PLC leads to translocation of protein kinase C, and phosphorylation of serine/threonine residues in the intracellular domain of NMDA receptors. SEK phosphorylates stress activated protein kinase 2 (JNK-2) leading to activation of the activator



**Respiratory Network Responses to Hypoxia. Figure 2** Schematic diagram of signaling pathways that are operational in respiratory neurons within the nucleus of the solitary tract during hypoxia. Signal transduction proteins for which there is definitive evidence are shown in red. (See text for more details).

protein-1 complex (AP-1). CaCmII activates neuronal nitric oxide (NO) synthase resulting in NO formation. NMDA receptor activation will also lead to phosphorylation of IκB with subsequent activation of nuclear kappa B (NF-κB) and activation of tyrosine kinase (TK) by tyrosine phosphorylation (PY) (Fig. 2).

Of all the downstream signaling pathways, the functional role of PKC on respiratory control neurons has been studied extensively. PKC activation within the respiratory neurons of the ventral medullary group is associated with increased respiratory drive potentials. Endogenous PKC activity modulates tonic activity and excitability of the expiratory neurons in the cat. PKC within the caudal brainstem underlies critical components of both tonic respiratory drive and the HVR [6]. Most of the known PKC isoforms are expressed with in the dorsocaudal brainstem, and activation of both $Ca^{2+}$-dependent and $Ca^{2+}$- independent PKC isoforms occurs in the nTS during hypoxia [6]. PKC exerts a significant influence on respiratory timing during normoxia in the early postnatal period, and the effect decreases with advancing age. In contrast, hypoxia-induced PKC activation is absent in the immature animal and emerges concomitantly with the appearance of NMDA dependency. Nitric oxide (NO) is another important neuromodulator with a dual role in hypoxic chemotransduction. While NO derived from endothelial nitric oxide synthase (eNOS) exerts an inhibitory effect at the carotid body level, NO derived from neuronal nitric oxide synthase (nNOS) in the caudal brainstem plays a significant role in sustaining ventilation during the second phase of the HVR. Activation of NMDA receptors will lead to opening of a voltage-dependent calcium channel, calcium calmodulin binding and subsequent nNOS activation. The intracellular NO will in turn modulate glutamate release, either through activation of cGMP-dependent protein phosphorylation cascades, or by retrograde activation of the pre-synaptic neuron. Therefore, nNOS acts an excitatory neurotransmitter during the HVR and may prevent the early onset of hypoxia-induced ventilatory depression. In addition, we have recently identified a mechanism whereby deoxyhemoglobin elicited by the presence of environmental hypoxia activates the formation of S-nitrosothiols through a very tightly regulated process, and that these compounds lead to excitation of respiratory-related neurons within the nTS, and thus contribute to the early phase of HVR [8].

### Late HVR

As the duration of hypoxia is extended, some degree of ventilatory depression will develop. This component of HVR is extremely prominent in developing animals. Several neuromodulators including γ-amino-butyric acid (GABA), serotonin (5-HT), adenosine, opioid receptors, and platelet-derived growth factor (PDGF)-β receptors have all been shown to play contributory roles to the emergence of the hypoxic ventilatory depression associated with prolonged hypoxia. We will briefly delineate the role of each neuromodulator in the late phase of HVR. GABA acts through two GABA receptor subtypes, GABA-A and GABA-B. GABA-A receptors modulate tidal volume, whereas GABA-B receptors

modulate respiratory frequency and pattern of breathing. It is postulated that the hypoxic ventilatory depression is the result of imbalance between the excitatory glutamate and the inhibitory GABA [4]. In addition, hypoxic ventilatory depression of developing animals is partly mediated through the neuro-depressant effect of GABA. Another neuromodulator, adenosine plays an important role in hypoxic ventilatory depression during the early postnatal period, and the effect decreases with maturation. Among the major 4 adenosine receptors ($A_1$, $A_{2A}$, $A_{2B}$ and $A_3$), adenosine $A_1$ and $A_{2A}$ receptors are postulated to play a role in the hypoxic ventilatory depression. The inhibitory effect of adenosine $A_1$ receptors may involve postsynaptic hyperpolarization, presynaptic depression of synaptic transmission, modulation of cAMP mediated pathway and activation of potassium channels. While adenosine $A_1$ receptors are involved in cardiorespiratory control during normoxia, adenosine $A_{2A}$ receptors play a critical role in the hypoxic ventilatory depression. Serotonin (5-HT) has been shown to play a role in hypoxic ventilatory depression in both adult and developing animals. This neurotransmitter exerts multiple effects on respiratory control, and modulates both the respiratory rhythm generator and the respiratory motoneurons. Among the myriad of 5-HT receptor subtypes, 5-$HT_{1A}$ and 5-$HT_2$ receptors have been shown to play a role in respiratory control. While 5-HT exerts an excitatory effect on the central respiratory rhythm generator within the rostral medulla area, it inhibits the hypoglossal inspiratory output in developing animals, possibly through activation of 5-$HT_2$ receptors. The release of endogenous 5-HT may signal the termination of the early hypoxic augmentation, possibly through activation of 5-$HT_{1A}$ receptors. 5-$HT_{1A}$ receptors are present in the hypoglossal nucleus of developing rats. Their density is high in the newborn and decreases with increasing postnatal age. Since the use of morphine led to occasional onset of respiratory depression, it became apparent that opioids are involved in respiratory functions within the CNS. Interestingly, endogenous opioids have been shown to play a role in the late phase of hypoxic ventilatory response, whereby ventilatory depression may be partly mediated through opioid-mediated neuronal inhibition. Opioids modulate the respiratory frequency and tidal volume through activation of μ- and δ-opioid receptors respectively. The caudal brainstem, especially the nTS and the nucleus ambiguus, seem to be important sites for opioid-induced inhibition of respiration. Opioid receptors display a distinct maturation pattern during the early postnatal period. The μ-opioid receptor binding sites are present during the mid-fetal period and are located in the cardiorespiratory-related brainstem nuclei, whereas the δ-opioid receptors primarily appear during the postnatal period. Both μ(1) and μ(2) opioid receptors are involved in opioid-induced respiratory depression in early postnatal period.

Finally, we have shown that hypoxia specifically triggers the release of the PDGF polypeptide isoform called PDGF-BB from glial cells, which in turn leads to subsequent activation of PDGF-β receptor in the nTS, where it reduces ventilatory output [9]. Both PDGF-B chains and PDGF-β receptors are abundantly expressed in nTS neurons of adult rats [9], and activation of the receptors leads to down-regulation of ligand-gated ion channels, such as NMDA glutamate receptors. PDGF-β receptor activation is an important contributor to the hypoxic ventilatory depression at all postnatal ages, but is more critical in the immature animals. The increased expression of PDGF-β receptors in the caudal brainstem of immature animals may provide additional protection against hypoxia-induced ▶apoptosis. In fact, PDGF-β receptors exert their role in promoting neuronal cells survival via two major signaling pathways, namely the phosphoinositide 3 kinase (PI3K)/Akt and the MEK/MAPK pathways. Activation of PDGF-β receptors leads to tyrosine phosphorylation of sites that will activate Ras kinase. Ras can activate PI3K, which in turn may phosphorylate PI3K, which in turn may phosphorylate the serine-threonine protein kinase called Akt, the latter phosphorylating BAD at serine 136. Phosphorylated BAD binds to cytosolic 14-3-3 protein, whereas dephosphorylated BAD binds elements of the Bcl-2 complex such as Bcl-x to promote apoptosis (Fig. 2). In fact, hypoxia-induced phosphorylation of PDGF-β receptors in the caudal brainstem of adult rats is temporally associated with activation of an anti-apoptotic mechanism via the PI3 kinase-dependent phosphorylation of both Akt and BAD pathways [10]. This mechanism may prevent induction of apoptosis in the respiratory neurons during hypoxia, and may contribute to the well known increased hypoxic tolerance of the brainstem neurons.

# Respiratory Neuroplasticity

Kendall F Morris[1], Donald C. Bolser[2]
[1]Department of Molecular Pharmacology and Physiology, Neuroscience, University of South Florida College of Medicine, Tampa, FL, USA
[2]Department of Physiological Sciences, University of Florida College of Veterinary Medicine, Gainesville, FL, USA

## Synonyms

Respiratory memory; Respiratory recovery from injury; Lasting alteration of breathing reflexes

## Definition

Respiratory Neuroplasticity has been defined as "a persistent change in the neural control system (morphology and/or function) based on prior experience" [1]. Plasticity exists in various forms in all of the segments of the respiratory network; the afferent, central control and efferent segments. The plasticity may be classed as recovery from injury, respiratory memory, and lasting alterations of protective reflexes such as cough.

## Characteristics

The basic respiratory rhythm and pattern is generated by neural networks in what is called the ►ventral respiratory column (VRC) of the medulla. The column spans several groupings of cells, called nuclei, in the ventral lateral medulla from nearly the beginning of the cervical spinal cord almost to the pons. However, breathing is modulated by many other regions of the medulla, such as the midline raphe, the main source of the neurotransmitter serotonin. Neural networks in the pons, cerebellum and cerebrum can also affect breathing and play roles in breathing plasticity.

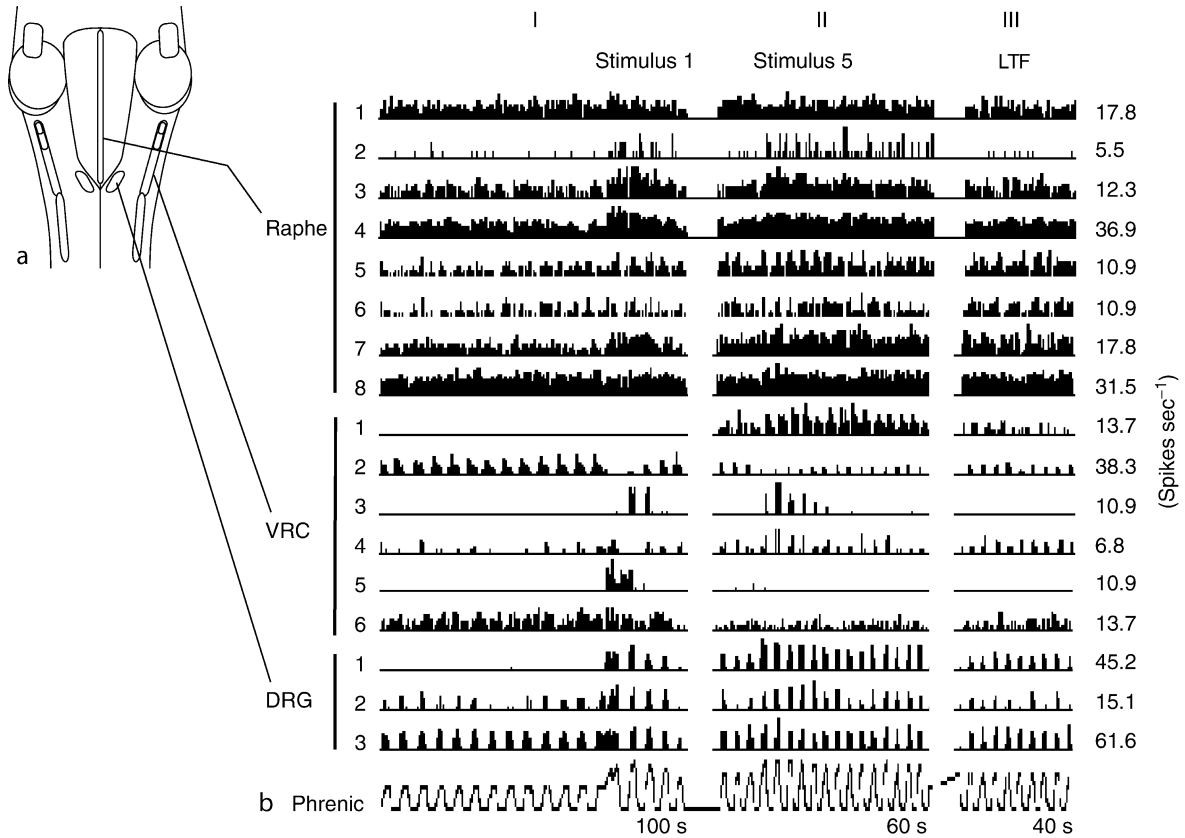
The central respiratory neural networks use information, or afferent input, from various sensors. Important examples include the carotid and ►aortic bodies that sense carbon dioxide concentrations, as well as acidity (pH) but are the predominant sensors of oxygen in the blood. There are also sensors in the lung that transmit information about lung distension, irritation and excess fluid. Sensors within the medulla itself feedback pH of the brain tissue. Since carbon dioxide and pH are in chemical balance in the body, and brain tissue only functions well in a narrow range of pH, it is important that the respiratory control system tightly control elimination of carbon dioxide produced by metabolism as well as provide oxygen.

Neurons that connect with muscles are called motor neurons. Two important groups of such neurons that reside in each side of the spinal cord are known as phrenic motor neurons. Phrenic motor neurons receive drive, or efferent input, from the VRC directly and in many species indirectly from another group of medullary cells called the dorsal respiratory group (Fig. 1a) Phrenic motor neurons send axons through the phrenic nerves to provide drive to the diaphragm, the major muscle that expands the lungs and produces inspiration of air.

### Recovery from Injury

In response to loss of partial function, such as removal of important afferent input, the respiratory neural networks can recover significant normal function. This plasticity varies among species and with age. After surgical removal of ►carotid bodies, normal response to low oxygen, hypoxia, is temporarily lost, but can be recovered in some species, such as cats or rats. Human asthmatics who have had carotid bodies removed show little or no recovery of function. Dogs, ponies and goats recover much less of this function while one-day-old goats that have carotid bodies removed completely recover normal responses to hypoxia. Mechanisms of recovery include up-regulation of alternative input, in this case that from the aortic bodies and perhaps other tissues as well as up-regulation of the efferent limb so that phrenic motor neurons become more responsive to drive.

In response to spinal cord injury, pathways that have little or no activity normally can become active. If one half of the spinal cord is cut, the diaphragm on that side becomes paralyzed because the efferent output of the VRC for phrenic motor neurons is interrupted.



**Respiratory Neuroplasticity. Figure 1** Firing rate histograms from multi-site recordings during induction of long-term facilitation (LTF). a, schematic dorsal view of the cat brainstem showing midline raphe, Ventral Respiratory Column (VRC), and the Dorsal Respiratory Group (DRG) b, Data segments show firing rate histograms of 17 neurones and integrated phrenic nerve activity, recorded simultaneously at the indicated sites during the first (I) and fifth (II) period of carotid chemoreceptor stimulation and 6 min following the fifth and final stimulus and induction of LTF (III). Numbers on the right are the firing rates that correspond to the highest "bin." This demonstrates that phrenic amplitude has nearly doubled, while the rate of cycling has increase. Note that some cells have persistent greater peak activity with concomitant shorter durations of activity corresponding to the shorter respiratory phases. Other cells that may be inhibitory to inspiratory activity have persistent decreases in activity (adapted from Fig. 2 of [4] with permission).

However, under increased respiratory drive, alternate, usually inactive pathways from the uninjured side can be activated resulting in partial recovery of function. This is known as the "crossed phrenic phenomenon" [1,2].

## Memory

There is a transient plasticity associated with the offset of a respiratory response to a stimulus; e.g., hypoxia, hypercapnia, or many other stimuli with an excitatory effect on breathing. This transient effect is termed short-term potentiation (STP) a slow decay of breathing back to baseline after stimulation. The exact mechanism that produces STP, although neural, remains unknown.

In many rodent strains, there is a short-term decline in respiratory cycle frequency (STFD) following an episode of hypoxia, but not other stimuli, that coincides with STP. STFD results entirely from prolongation of time in expiration. Both post-hypoxic STFD and STP have a similar time course. These changes in pattern have been referred to as "activity-dependent" plasticity [1].

Damage or chemical blockade of regions of the pons removes the prolongation of time in expiration and the short-term decline in respiratory frequency after hypoxia, with no effect on the response to hypoxia. STFD may be mediated by changes in network connections between the medullary and pontine respiratory networks [2].

Long-term facilitation (LTF, Fig. 1b), an increase in respiratory motor output that persists more than 1 h, is another type of plasticity and a robust type of memory. Induction and expression of this memory can be blocked by serotonin and brain derived neurotrophic

factor antagonists [3]. LTF is induced by repeated brief, intermittent, but not extended, hypoxia, chemical stimulation of carotid chemoreceptors, or electrical stimulation of the carotid sinus nerve or brain stem midline but not by hypercapnia. In some experiments with cats, rats, dogs and goats, LTF can increase measures of phrenic nerve activity to approximately twice that of baseline.

Altered activity and connectivity among neurons in the VRC and raphe neurons have been identified in spike train data sets in which; (i) the constituent neurons had respiratory-modulated firing patterns, (ii) significant changes in firing rate during carotid chemoreceptor stimulation were correlated with altered respiratory efferent activity, (iii) persistent firing rate changes were expressed during LTF, (iv) there was evidence of effective connectivity between the recorded neurons appropriate to contribute to LTF, and (v) changes in measures of effective connectivity between these neurons after induction of LTF were greater than those during different control periods [2,4].

LTF has been demonstrated in rats in both the activity of the phrenic nerve and in sympathetic nerve activity that is involved in control of blood pressure [9]. Human beings who have sleep apnea are exposed to brief periods of hypoxia each night, similar to many protocols that produce LTF in animal experiments. These people have increased sympathetic nerve activity during the day when they are not hypoxic, and that activity has increased modulation with their breathing. The increased sympathetic nerve activity probably contributes to their increased incidence of high blood pressure, cardiovascular disease and stroke. Normal awake human subjects experimentally exposed to brief, intermittent hypoxia show persistent changes in breathing pattern, they breathe more shallowly and faster as well as with less variability [5]. However, they do not have an over-all increase in breathing similar to LTF in some animals. In contrast, subjects with sleep apnea have a persistent increase in breathing in response experimental intermittent hypoxia during sleep [3].

The plasticity of the neural network expressed as LTF can therefore be both adaptive and maladaptive. It may act to stabilize upper airways and prevent further hypoxia. However, if the intermittent hypoxia persists it may contribute to hypertension and attendant illness.

Sudden infant death syndrome (SIDS) is the most common cause of death in infants between 2 weeks and 1 year of age. Some SIDS cases appear to result from fetal neural damage that later compromises responses to breathing or blood pressure challenges during sleep. A major risk factor is pre- or post-natal tobacco smoke exposure. The deficits appear to involve alterations in neural network function within regions involved in oxygen-sensing and cardiovascular control. A developmental abnormality in serotonergic neurons in the caudal raphe, i.e., a major part of the network implicated in LTF, may result in a failure of protective responses to life-threatening stressors during sleep [6].

Finally, the respiratory networks demonstrate a "metaplasticity" in that early exposure to hypoxia or hyperoxia can produce life long changes in respiratory behaviors, responses and plasticity [1]. Neonatal hyperoxia produces plastic changes that lead to blunted responses to hypoxia in later life, whereas hypoxia in infancy produces greater adult hypoxic ventilatory response and increased expression of LTF [1].

## Airway Defensive Reflexes

Cough is an essential component of pulmonary defense and is the most common manifestation of pulmonary disease. Cough is the single most common reason why sick patients visit physicians in the United States. The function of cough is to remove fluids, mucus, and/or foreign bodies from the respiratory tract by the generation of high velocity airflows. These airflows during cough are generated by a complex motor pattern involving three phases: inspiration, compression, and expulsion. The inspiratory phase of cough is generated by a large burst of activity in inspiratory muscles, such as the diaphragm. The compressive phase of cough is produced by laryngeal closure caused by a burst in expiratory laryngeal muscles during rapidly increasing expiratory thoracic and abdominal muscle activity. The resulting large increase in lung air pressure produces very high airflows (up to 12 L $s^{-1}$ in humans) when the larynx opens and the expulsive phase begins. The expulsive phase is characterized by extremely large bursts of activity in expiratory thoracic and abdominal muscles.

In the lower airways, slowly adapting receptors (SARs), rapidly adapting receptors (RARs), and pulmonary C-fibers all can influence the production of cough. There is little doubt that RARs can elicit cough. SARs have a permissive role in the production of cough. The exact role of C-fibers in the production of cough is more controversial, with some groups supporting an excitatory role and others supporting an inhibitory role. Sensory information is processed in the ►brainstem, where the basic elements responsible for the production of cough are located. Pulmonary afferent information is processed by second order interneurons located near to and in various subnuclei of the nucleus of the tractus solitarius.

It was once thought that neural networks separate from those controlling normal breathing, eupnea, controlled other reflexes that defend the upper airways and lungs, such as cough. Recent research has revealed that the brainstem neural networks that produce eupnea

also are involved in coughing and sneezing as well as other less well known reflexes. The process by which the brainstem neural network for breathing can be involved in the production of other behaviors is known as *reconfiguration*. That is, the breathing network changes its "circuit diagram" to allow for the generation of a non-breathing behavior [2]. This process involves alteration of the discharge patterns and effective connectivity of neurons in the respiratory network. The reconfiguration process may also involve "conscription" of neurons that have little to do with breathing but have activity patterns that are selective for certain behaviors, such as cough. This conscription may include recruitment of previously silent neurons and significant modification of the activities of neurons during cough that were not modulated during breathing. There is good evidence that these processes take place and that, in addition to the network that controls breathing, coughing is also controlled by another brainstem control mechanism known as a gate. In essence, the system can be functionally subdivided into a controller (the gate) and an effector (the brainstem respiratory network). The controller regulates the excitability of the behavior and the effector is responsible for the coordination of motor drive to respiratory muscles for cough. During breathing the gate, or controller, is functionally quiescent and the respiratory network is primarily involved in the production of breathing. When RARs are stimulated, the gate becomes active and the brainstem respiratory network reconfigures to produce coughing [7].

## Plasticity of the Cough Reflex

There is considerable evidence that cough can undergo significant plasticity in both humans and animals, especially during induced or naturally occurring airway disease. This plasticity is usually manifest in the form of an increased number of coughs in response to a given stimulus and/or increased sensitivity to inhaled irritants. The relative role of central and peripheral mechanisms in this plasticity is less well understood.

In humans, chronic spontaneous cough lasting for years is well documented and can occur in a variety of conditions, such as smoking, asthma, chronic obstructive pulmonary disease, upper airway disorders, and gastro-esophageal reflux. In many of these conditions, the sensitivity of humans to inhaled irritants is elevated but this enhanced cough sensitivity resolves with successful treatment of the underlying disorder. However, tobacco smoke exposure during childhood is associated with cough in adulthood, suggesting that there is a permanent alteration of some important part of the cough reflex [8]. The increased sensitivity of the cough reflex in these patients is consistent with plasticity. It is presumed that hyperexcitable peripheral afferents are responsible for the enhanced coughing in these patients, but the potential contribution of central mechanisms has been difficult to address in humans.

Very similar observations have been made in animal models of airway disease and it is well established that airway sensory afferents responsible for cough undergo significant plasticity in many of these conditions. It also has been shown in an animal model that inflammation of one region of the airway will elicit an enhanced cough response to stimulation of a non-inflamed region of the airway. Presumably the sensory afferent responsiveness in the non-inflamed region of the airway was normal. This suggests that plasticity can occur in the central cough neural networks.

Cough can undergo hypoexcitability during neurological diseases. Stroke, Parkinson's Disease and Multiple Sclerosis are all associated with cough weakness or an inability to cough at all. This cough impairment can contribute to an increased susceptibility to aspiration in these patient groups. In stroke, cough impairment can occur even if the lesion does not include the brainstem. This fact, in combination with the knowledge that cough can be produced voluntarily suggest that suprapontine mechanisms can be important in the regulation of cough excitability in awake humans. The extent to which these mechanisms can be subject to plasticity is unknown. More research must be performed to gain a greater understanding of these mechanisms.

# Respiratory Neurotransmitters and Neuromodulators

Akira Haji
Laboratory of Neuropharmacology, School of Pharmacy, Aichi Gakuin University, Chikusa, Nagoya, Japan

## Synonyms

Neurochemicals; Endogenous receptor agonists

## Definition

Chemicals synthesized by neurons involved in generating rhythm and pattern in the ►respiratory network, and in transmitting input signals from central and peripheral chemoreceptors and mechanoreceptors to respiratory interneurons and motoneurons (Fig. 1).

## Active Phase

The period of the ►respiratory cycle (phase) in neurons characterized by membrane depolarization to threshold for the generation of action potentials [2,9].

## Silent Phase

The period of the respiratory cycle characterized by membrane hyperpolarization that prevents action potential generation [2,9].

## Characteristics

### Neurotransmitter Functions in the Respiratory Network

Rhythmic fluctuations of membrane potential in respiratory neurons evolve from neurotransmitter- and membrane conductance-dependent, periodic barrages of ►IPSPs and ►EPSPs that occur with precise timing during the respiratory cycle. Neurotransmitter-dependent excitatory synaptic connections between synchronously active neurons evoke bursts of action potential discharge, while discharges of reciprocally activated neurons periodically release inhibitory ►neurotransmitters that hyperpolarize membrane potential away from firing threshold. Tonic neurotransmitter release provides a continual excitatory bias on what appears to be all types of respiratory neurons, whereas tonic release of inhibitory neurotransmitter can have a stabilizing effect on membrane potential.

#### *Inhibitory Amino Acids (GABA and glycine)*

There are three types of phasic inhibition in respiratory neuron activities; reciprocal inhibition, recurrent inhibition and phase-transition inhibition, as well as tonic inhibition. All four types are characterized by membrane hyperpolarization and lowered input resistance [1,3,4,7].

#### *Phasic inhibition during the inactive phase*

GABA initiates IPSPs during the inactive phase by binding to a $GABA_A$-type of receptor in respiratory neurons. During the inactive phase, temporal summation of IPSPs hyperpolarizes membrane potential near to the equilibrium potential for chloride ions ($Cl^-$).

#### *Inhibition during Phase Transitions*

The $GABA_A$ receptor-mediated mechanism plays an essential role during transition from one respiratory phase to another. During transition from the inspiratory to the expiratory phase, postinspiratory (early expiratory) IPSPs occur in augmenting inspiratory (aug -I) neurons. During transition from late expiration to inspiration, inspiratory IPSPs are observed in augmenting expiratory (aug-E) neurons. In the latter case, activation of $GABA_B$ receptors is partially involved, leading to increased potassium ($K^+$) conductances.

#### *Inhibition during the Active Phase*

Glycine mediates IPSPs during the later part of stage 2 expiration in aug-E neurons, and IPSPs during late inspiration in aug-I neurons. Aug-I neurons also show IPSPs during early part of inspiration, but whether GABA, glycine or both are involved is unclear.

#### *Tonic Inhibition*

$GABA_A$, $GABA_B$ and glycine receptor-mediated postsynaptic inhibitions are active in respiratory neurons to help stabilize membrane potential level.

#### *Inhibition of Spinal Motoneurons*

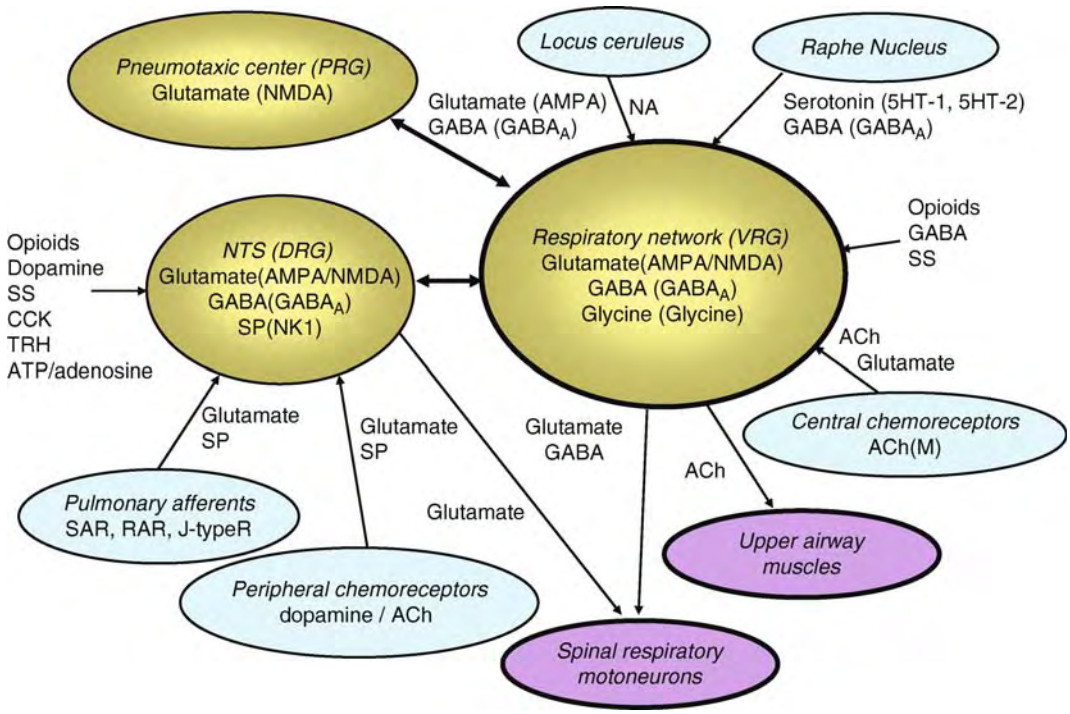
GABA mediates the inhibition of phrenic motoneurons during expiration through $GABA_A$ receptors [6,8]. This inhibition comes from aug-E neurons of the Bötzinger complex. $GABA_A$ mechanisms are also involved in the raphe-stimulated inhibition of the respiratory neuronal activity. The $GABA_B$ mechanism decreases transmitter release by acting at presynaptic site and hyperpolarizing phrenic motoneurons through activation of $K^+$ conductances at postsynaptic sites [6].

#### *Excitatory Amino Acid (Glutamate)*

All types of respiratory neurons exhibit glutamate-activated EPSPs, in association with lowered input resistance and induction of action potential discharge. They summate temporally to bring membrane potential to discharge threshold [1,3,4,7].

#### *Phasic Excitation during the Active Phase*

Glutamate initiates EPSPs during the active phase in most types of respiratory neurons by activating both AMPA- and NMDA-type glutamate receptors. The sequential activation of the two types of postsynaptic receptor is required for production of respiratory-related



**Respiratory Neurotransmitters and Neuromodulators. Figure 1** A schematic diagram of the neuronal interactions between the respiratory center and other modulatory structures, and of putative neurotransmitters and neuromodulators involved in the neuronal control of respiratory rhythm and pattern generation. The main neurotransmitters of respiratory neurons are glutamate, GABA and glycine. Glutamate mediates excitatory transmissions through AMPA and NMDA receptors and GABA mediates inhibitory transmissions through $GABA_A$ receptors. They are also utilized in the phase-switching process which is regulated by the pneumotaxic descending inputs and pulmonary SAR afferents. Transduction of hypoxic signals within the peripheral chemoreceptors depends primarily on $O_2$-sensitive $K^+$ channels associated with neuroactive substances such as ACh and dopamine. These signals are transmitted to relay neurons in the NTS by glutamate through AMPA receptors. Hypercapnia stimulates preferentially the central chemosensitive area near the ventral surface of the medulla, where ACh acts as a mediator of such signals. Many neuroactive substances other than amino acids have been implicated in modulating the respiratory rhythm. Serotonergic, noradrenergic and dopaminergic inputs modulate the respiratory neuronal discharge and respiratory rhythm. Muscarinic and nicotinic cholinergic modulations are also apparent. Several neuroactive peptides including SP, SS, CCK and opioids affect respiration. They act either presynaptically or postsynaptically to modulate synaptic transmission within the primary neuronal network as well as at the input and output relay nuclei. These substances are not involved in generation of a basic eupnea. Interactions among various neuroactive substances are essential for precise control of the normal functioning and adaptive processes in the central organization of respiratory rhythm and pattern.

bursts of discharge. In aug-E neurons, depolarization and discharge are due to AMPA receptor activation, as is phasic recurrent excitation in aug-I neurons. Metabotropic glutamate receptor-mediated mechanisms have no significant effect on membrane potential of ►bulbar respiratory neurons.

### *Inspiratory Off-Switch (►IOS) Mechanism*

The NMDA mechanism plays an important role in IOS of pontine as well as medullary respiratory neurons. IOS is accomplished by a sequential activation of late inspiratory (late-I) and postinspiratory (post-I) neurons to produce barrages of IPSPs in aug-I neurons. During ►apneusis caused by NMDA blockade, active phase depolarization of late-I and post-I neurons and their firing activity are decreased. The discharge activity of aug-I neurons is also decreased during apneusis.

### *Tonic Excitation*

Respiratory neurons receive glutamatergic tonic inputs that activate both NMDA and AMPA receptors.

### *Pneumotaxic Descending Inputs*

Termination of the IOS can be produced by afferents originating from the ►PRG. Glutamate through the NMDA mechanism responsible for IOS is present in the pontine structure. However, the pontine descending inputs generating fast EPSPs in bulbar respiratory

neurons are not mediated by NMDA receptors, but by AMPA receptors.

#### *Pulmonary Mechanoreceptor Afferent Inputs*

Glutamate mediates the primary afferent excitation of the NTS neurons in the ►Hering-Breuer reflex pathways, primarily through the activation of AMPA receptors. The Hering-Breuer inspiratory promotion reflex induced by application of lung deflation during expiration is mediated by NMDA receptors.

#### *Excitatory Drive to Bulbospinal Motoneurons*

Glutamate mediates the bulbospinal transmission of respiratory drive acting on both AMPA and NMDA receptors [6,8]. Contribution of the former is greater than that of the latter to motor outputs. AP4 receptors are located at the presynaptic sites of the inspiratory bulbospinal terminals. Short term potentiation is mediated by NMDA receptors, which augment EPSPs and prolong depolarization of phrenic motoneurons. Activation of metabotropic glutamate receptors affects the inspiratory-modulated activity of phrenic motoneurons via distinct mechanisms at pre- and postsynaptic sites.

#### *Excitatory Drive to Spinal Motoneurons*

The major glutamatergic excitatory drives to phrenic, intercostal and abdominal motoneurons come from bulbospinal neurons that activate AMPA/Kainate- and NMDA-types of receptors

### Neurotransmitters, Neuromodulators and Responsiveness to Hypercapnea and Hypoxia

Carbon dioxide and its acid byproduct, $H^+$ ion, constitute the primary respiratory stimulus within the central nervous system. Sensitivity to $CO_2$/pH is up-regulated or down-regulated by several different neurotransmitters and ►neuromodulators [5,7]. Acetylcholine (ACh) activation of muscarinic receptors on neurons close to the ventrolateral surface of the medulla increases respiratory responsiveness to $CO_2/pH^+$. Adrenergic cell groups have also been reported to increase respiratory responsiveness to hypercapnea/acidosis in the rostral ventrolateral medulla. Glutamate is also a neurotransmitter candidate for tonic excitation of respiratory neurons mediated by central $CO_2/pH^+$ sensitive neurons. A GABAergic mechanism in the caudal hypothalamus dampens respiratory responsiveness to hypercapnea/acidosis.

Respiratory responsiveness to hypoxia is modulated peripherally by neuromodulators in the carotid bodies and within the central respiratory network. Generally, excitatory transmission is cholinergic, whereas dopamine (DA) plays an inhibitory role in carotid body chemoreceptors. Hypoxic release of ACh activates nicotinic receptors, leading to augmentation of hypoxia-induced depolarization and further release of ACh and other neurotransmitters. DA release, on the other hand, suppresses carotid body discharges by activating $D_2$-type receptors. Glomus cells contain other compounds that are released during hypoxia, including serotonin (5-HT), enkephalins, prostaglandins, ATP, adenosine, substance P (SP), cholecystokinins (CCK), nitric oxide and atrial natriuretic peptide.

SP localized within vagal afferent fibers appears to act as a neurotransmitter or modulator of chemo- and baroreceptor fibers. Central dopaminergic mechanisms are also involved in modulating the chemoreflex respiratory control.

In the central respiratory network, glutamate release from the afferent glossopharyngeal terminals in the nucleus of the solitary tract (NTS) activates AMPA receptors on relay neurons in response to hypoxia. Release and local accumulation of GABA and/or neuromodulators, including catecholamines and opioids, are important factors leading to late hypoxic depression. GABA mediates inhibition in the NTS neurons that respond to stimulation of the carotid sinus nerve. Accumulation of metabolic byproducts such as adenosine may increase $K_{ATP}$ channel currents in postsynaptic neurons. Hypoxia also increases endogenous 5-HT levels and increases $K^+$ currents via $5\text{-HT}_{1A}$ receptors in respiratory neurons, resulting in depression of respiratory neurons.

### Respiratory Neuromodulation by Monoamines and Peptides

It has been more difficult to assess the neuromodulatory roles of serotonin, catecholamines and peptides in the central respiratory network. Their actions are generally slow in onset, discreet, state-variable, and dependent on a vast array of receptor subtypes. Assessment of function is often assumed from the effects of exogenous receptor agonists and antagonists, not all of which are suitably selective [1,4,7].

#### *Serotonergic Agents*

5-HT has diverse effects on respiratory neurons. Respiratory neuron excitability is increased postsynaptically by $5\text{-HT}_2$, $5\text{-HT}_{1C}$ and $5HT_4$ receptor agonists, and decreased postsynaptically via $5\text{-HT}_{1A}$ and $5HT_7$ agonists. Activation of $5\text{-HT}_{1A}$ and $5HT_7$ receptors depresses the cAMP-protein kinase A pathway, $5HT_4$ receptors activate it, and $5\text{-HT}_2$ receptor activation stimulates the PLC/PLA- protein kinase C pathway.

#### *Catecholaminergic Inputs*

The effects of catecholamines (noradrenaline, adrenaline, DA) are also diverse and dependent on which subtypes of receptor are affected. Noradrenaline and adrenaline have a predominantly depressant effect on bulbar respiratory neurons. Dopaminergic mechanisms exert a tonic inhibitory influence in the central pathways involving in the hypoxic ventilatory responses through

$D_2$ receptors, and increase central respiratory responsiveness to $CO_2$ via $D_1$ receptors.

### Peptides and Hormones

SP and thyrotropin-releasing hormone (TRH) have excitatory, and somatostatin (SS) and ►opioid peptides have depressant effects on respiration. CCK produces either excitatory or inhibitory effects, depending on its receptor types activated. Individual neuropeptides often coexist and interact with classical neurotransmitters in respiratory neurons. They play some roles in the central control of respiratory activity including the chemoreflex [1,4,7].

#### *Substance P*

SP mediates excitatory neurotransmission and integration of the peripheral chemoreflex in the NTS through $NK_1$ receptors. SP reverses the respiratory neuronal depression induced by SS or opioids. Hypoxia induces desensitization of $NK_1$ receptors to SP in the NTS neurons, leading to a decline of hyperventilation during hypoxia. SP is a transmitter of the pulmonary C fiber-mediated reflex which induces a rapid shallow breathing and/or apnea.

#### *Thyrotropin-Releasing Hormone*

TRH had postsynaptic excitatory effects on neurons in the NTS, nucleus ambiguus and pre-Bötzinger complex. TRH enhances glutamatergic transmissions and counteracts the inhibitory effects of opioids. TRH also seems to be involved in central ($CO_2$/$pH^+$) chemoreception (►central chemoreception).

#### *Somatostatin*

SS has an inhibitory effect on respiratory neurons. Anesthesia or sleep enhances the effects of SS. SS metabolites potentiate the voltage-dependent, non-inactivating outward $K^+$ currents ($I_M$ current) in the NTS neurons.

#### *Opioid Peptides*

Opioid peptides may be the most important peptides endogenously involved in respiratory modulation in the brainstem. Opioid peptides depress respiratory neuron activity by increasing $K^+$ conductances through μ receptors. Endogenous opioids negatively interact with the $CO_2$-sensitive cholinergic transmission, and with the glutamatergic transmission of respiratory neuronal activity.

#### *Cholecystokinin*

CCK octapeptide ($CCK_8$) causes various effects on respiration; It stimulates respiration by stimulating either the forebrain or the medullary region and depresses ventilation by stimulating vagal afferents. The activation of $CCK_A$ receptors causes inhibition of respiratory neurons due to an increase of $K^+$ conductances, while that of $CCK_B$ receptors produces excitation due to a decrease in $K^+$ conductances. Further, activation of $CCK_B$ receptors by endogenous CCK reduces the GABA-mediated fast inhibitory responses in the NTS neurons.

#### *Progesterone*

Endogenous progesterone is a respiratory stimulant [10]. It increases ventilatory responsiveness to $CO_2$. In pregnancy and during the luteal phase of the menstrual cycle, it accounts for hyperventilation and low $CO_2$. Endogenous progesterone also has a beneficial effect on the upper airways. It increases tonic and phasic geneoglossus activities.

## Respiratory Pacemaker Neuron

### Definition

Neuron with an intrinsic ability to generate rhythmic bursts.

►Respiratory Pacemakers

# Respiratory Pacemakers

Jan-Marino Ramirez
Department of Organismal Biology and Anatomy, Committees on Neurobiology, Computational Neuroscience and Molecular Medicine, The University of Chicago, Chicago, IL, USA

## Synonyms

Respiratory bursting neurons; Respiratory pacemaker neurons

## Definition

A respiratory pacemaker is a neuron with the intrinsic ability to generate rhythmic ►bursts that emerge through voltage-, time- and calcium- dependent ion fluxes [1]. These ion fluxes give rise to rhythmic membrane fluctuations that are defined as "►drive potentials" or "pacemaker potentials." The ion fluxes leading to drive potentials are carried by sodium, calcium, and/or non-specific cations, but many ionic conductances contribute to shape and frequency of these potentials. The drive potentials can, but do not always give rise to a series of action potentials. A drive potential that gives rise to action potentials is called a "burst". Bursts that are generated by ionic conductances intrinsic to the neuron are often referred to as "►intrinsic bursting." Two types of pacemaker neurons have been described in the respiratory network: (i) Pacemakers that depend on CAN current and are blocked by cadmium are referred to as "►Cadmium-sensitive pacemakers" [2]. (ii) Pacemakers dependent on the persistent sodium current burst even in the presence of cadmium. These neurons are referred to as "►Cadmium-insensitive pacemakers" [2].

A neuron that generates pacemaker activity only in the presence of a neuromodulator is generally called a "►conditional pacemaker." As described in the next paragraph, the dynamic regulation of pacemaker neurons is the rule, and not the exception. Hence, it is conceivable that all respiratory pacemakers are "conditional".

## Characteristics

### Quantitative Description

The identity of a respiratory pacemaker is not fixed, but dynamically regulated. Non-pacemakers can be turned into respiratory pacemakers, and conversely respiratory pacemakers can become non-pacemakers [1]. This dynamic process is not all-or-none. A non-pacemaker can turn into a weakly bursting or strongly bursting pacemaker, and weak pacemakers can turn into strong pacemakers. Weak pacemakers are characterized by small amplitude, intrinsically generated ►drive potentials that give rise to one or two action potentials. Bursts can occur irregularly in some, while regularly in other neurons. Thus, the discharge properties of respiratory neurons cover a wide range from non-bursting, to weak-irregular bursting to strong-regular bursting [1,3]. Transformation of pacemakers and non-pacemakers and their dynamic regulation are not unique for the respiratory system. For example the discharge patterns of neocortical and thalamic neurons change dramatically during the transition from wake to sleep [1,4,5] and there are numerous other examples in which neurons can loose or attain pacemaker properties.

Mechanistically, this is not surprising as the pacemaker property emerges through a complex, and modifiable ratio of different ionic currents in which inward currents (typically carried by $Na^+$ or $Ca^{++}$) are larger than outward currents (typically carried by $K^+$ or $Cl^-$ currents).

In the functional network the ratio of these ion channels is continuously modulated by endogenously released neuromodulators, such as amines and peptides. In the respiratory system, induction of pacemaker properties has been demonstrated for serotonin, acetylcholine, norepinephrine, TRH (►TRH: thyrotropin releasing hormone) and substance P [1,3,6]. It is likely that many still unexamined neuromodulators can induce and suppress pacemaker properties in respiratory neurons.

In the functional network intrinsically generated drive potentials are also dynamically regulated by synaptic transmission: Intrinsically generated bursts can be activated by excitatory synaptic inputs, and thus function as a mechanism to boost or amplify synaptic inputs. But the boosting mechanism must also be considered dynamically, since concurrently occurring synaptic inhibitory mechanisms can also suppress these intrinsically generated drive potentials. Thus, in the functional network concurrent inhibitory synaptic mechanisms can regulate the bursting mechanism to the extent that excitatory synaptic drive is necessary to activate bursting in a pacemaker neuron. Synaptic mechanisms play also critical role in timing the onset of a burst, even in pacemakers that have strong intrinsic bursting properties. Thus, the bursting property must be considered as a dynamic property that is highly influenced by fine balance of synaptic as well as neuromodulatory mechanisms.

Due to the tight interaction between synaptic and intrinsic membrane properties, demonstrating pacemaker properties is challenging. It must be shown that the rhythmicity recorded in a neuron is generated intrinsically and is not the result of rhythmic synaptic input that emerges through network interactions. In the respiratory network pharmacological approaches are typically used to isolate pacemaker neurons [6,7]. Exogenously applied neurotransmitter antagonists can

block inhibitory and excitatory neurotransmission which eliminates rhythmic synaptic population inputs. The pharmacological approaches are usually combined with electrophysiological approaches that take advantage of the voltage-dependency of ion channels [7]. Brief de- or hyperpolarizing current injections can reset ongoing pacemaker activity by advancing or delaying the generation of a pacemaker burst. Long-lasting de- or hyperpolarizing current injections can accelerate or slow the frequency of pacemaker activity. Brief depolarizing current pulses can prematurely trigger, while hyperpolarizing current pulses can prematurely terminate ongoing pacemaker bursts. It is important to be aware that pharmacological approaches can be misleading. For example low concentrations of extracellular calcium can block synaptic transmission, but at the same time, this manipulation can induce pacemaker properties in non-pacemakers by blocking ►calcium-dependent potassium currents [2]. Conversely, low calcium concentrations could block the activation of the CAN current, which plays a major role in evoking bursts in some respiratory neurons [2]. Bicucculline, is a substance that blocks ►GABAergic synaptic transmission, but at higher concentration it can also block potassium channels which could induce pacemaker properties.

An even greater challenge is the interpretation of lesion experiments in a functional network. Pacemaker, synaptic and modulatory properties are highly integrated elements of the functional network and provide the respiratory network with the necessary adaptability and flexibility for survival. The removal of any of these elements will change the overall network property, and whether its removal abolishes rhythmicity is neither an indicator for its importance nor its specific role in respiratory rhythm generation [1].

## Higher Level Structures

The majority of neuronal networks in the brain generate rhythmic activity, and pacemakers are found in the majority of these networks including networks within the spinal cord, medulla, ►neocortex, ► basal ganglia, thalamus, ►locus coeruleus, ventral tegmentum area (VTA), ►hippocampus and ►amygdala [1,8]. In many cases it is unclear how the rhythmicity in general and how pacemakers in particular contribute to these network functions, and the respiratory network is no exception. Pacemaker neurons have been identified in various areas that belong to the respiratory network, including the NTS [6], the pre-Bötzinger complex [1] and the ►parafacial nucleus [9]. Pacemakers are also found in areas that are driven by the respiratory network including the locus coeruleus [10]. While most pacemakers were identified in vitro slices, it is likely that recordings in more intact networks reveal that pacemaker neurons are more abundant than generally expected. Intact networks have more active modulatory systems that can promote pacemaker properties, such as norepinephrine and serotonin.

## Lower Level Components

In general terms, the ionic mechanisms that give rise to pacemaker activity are very heterogeneous. These mechanisms typically involve a complex interaction between voltage-dependent and voltage-independent components of ion channels within their intra- and extracellular environment [1]. In general, a neuron depolarizes and ultimately bursts either in response to the activation of inward currents that are carried by sodium and/or calcium ions, or in response to the cessation of outward currents that are carried by potassium ions. The inward currents include the hyperpolarization-activated current (Ih current), the persistent sodium current, various low- and high-voltage activated calcium currents and the calcium-activated non-specific cation (CAN) current [1]. The ongoing burst is commonly terminated by either of two principal ionic mechanisms. (i) The channels responsible for the inward current inactivate. Such properties may play a major role in determining bursting in neurons dependent on persistent sodium current. (ii) The calcium or sodium influx during the ongoing burst can activate calcium- or sodium-dependent potassium currents that hyperpolarize the membrane and thereby terminate the burst. Possible mechanisms that cause a repolarization can include voltage-independent intracellular signals, and slow activation or inactivation properties of inward or outward currents.

## Structural Regulation

There is currently no characteristic anatomical structure that defines a ►respiratory pacemaker neuron. Similarly there are many different discharge patterns that characterize a respiratory pacemaker neuron. “Irregular-” and “regular-bursting” neurons are differentiated by the regularity of the burst periodicity. Given that rhythmic drive potentials can arise through a variety of ionic mechanisms, it is not surprising that the same anatomical region may contain different types of pacemaker neurons. The fact that the same anatomical region contains more than one type of pacemaker neuron is not the exception, but presumably the rule [1]. It is assumed that different types of pacemaker neurons play different roles in the generation of network activity, an issue of much ongoing research [1,2,3,8,9]. This complexity is not unique to the nervous system: cardiac pacemakers for example are also very diverse.

## Higher Level Processes

Pacemaker neurons are embedded in complex neuronal networks. Hence there are many synaptic and modulatory processes that govern the activity of a pacemaker neuron [1,3]. Many principle insights into

the interactions between pacemaker neurons, synaptic transmission and ►neuromodulators were gained from studying small neuronal networks of invertebrates. It can be expected that medullary pacemakers are modulated by various inputs from networks outside the ►medulla, and vice versa that pacemakers influence networks outside the medulla. Unfortunately, recordings from pacemakers in more intact networks are sparse. Thus very little is known about these potential network interactions.

## Lower Level Processes

Neuromodulators play a critical role in modulating the cellular events that govern the discharge pattern of a pacemaker neuron. Endogenously released neuromodulators can phosphorylate voltage-dependent ion channels, or alter second messenger pathways and intracellular calcium thereby changing ion channel properties. This complex interplay between neuromodulators, the intracellular milieu and voltage-dependent ion fluxes will significantly alter pacemaker activity. In doing so, neuromodulators can determine the burst frequency, the amplitude and shape of the drive potential [3]. Neuromodulators are also responsible for the fact that the pacemaker property itself is not a fixed property as described above.

## Function

As described above, pacemakers are embedded in synaptically organized networks and therefore pacemaker activity itself is influenced by synaptic inputs [1]. Thus, in general pacemaker activity can not be regarded as a "driver" of network activity. Thus assigning a specific function to a pacemaker neuron becomes difficult if not impossible, since this property can not be separated from the other properties that determine its discharge. Tonic excitatory or inhibitory synaptic inputs can determine the frequency of pacemaker activity. Excitatory synaptic input can prematurely trigger pacemaker activity, which means that synaptic inputs can determine the timing of pacemaker activity. A pacemaker burst can act as a non-linear amplifier of synaptic excitatory inputs, while synaptic inhibitory inputs can act as leak currents that will greatly suppress pacemaker activity.

Various functions have been ascribed to pacemaker neurons. It is thought that pacemakers can influence regularity, burst amplitude and frequency of respiratory activity. Due to differences in their voltage-dependence cadmium-sensitive and insensitive pacemakers may assume different roles in regulating frequency versus amplitude of respiratory bursts [3].

## Process Regulation

The number, the types of pacemakers, and the degree of their bursting properties in a functional neuronal network will be continuously regulated by neuromodulators and synaptic interactions. Consequently, the contribution of pacemaker properties to the overall network output will not be fixed [1,2]. By altering for example the number of active pacemaker neurons a network can assume different configurations that can lead to different network outputs. These complex modulatory interactions imbue neuronal networks with a high degree of plasticity. This is an essential prerequisite for generating a rhythmic behavior that has to continuously adapt to changes in behavioral, environmental and metabolic conditions.

## Pathology

It has been hypothesized that the suppression of pacemaker properties may lead to the failure of gasping and possibly Sudden Infant Death Syndrome [1,2].

## Therapy

In vitro studies suggest that pacemaker neurons are important in regulating regularity of respiratory rhythmic activity. Hence, a better understanding of the ionic basis of pacemaker activity and their modulation may be an important step towards developing rational therapies or strategies to prevent neurological disorders associated with erratic breathing.

### Definition

Respiratory reflexes encompass a significant repertoire of responses to a variety of sensory receptors regulating the depth and frequency of individual breaths and participating in the protection of airways from potentially damaging inhaled substances. Specifically, receptors in the airways and lungs sense the relative inflation or deflation of the lungs as well as the presence of inhaled irritants, and elicit appropriate responses via brainstem respiratory circuits to maintain the integrity and efficient function of the lungs and airways. Central (brain) chemoreceptors and peripheral chemoreceptors in contact with arterial blood, evoke changes in breathing to maintain appropriate levels of oxygen and carbon dioxide as well as pH.

### Characteristics

Continuous, rhythmic breathing movements are essential for the homeostatic regulation of arterial blood gases, acid-base balance and, ultimately, for the maintenance of life itself. Neurons responsible for generating respiratory rhythm and shaping it into the detailed pattern of activity evident on respiratory motor output are located predominantly in two brainstem regions (see Alheid & McCrimmon this volume). One group forms a long column of cells in the ventrolateral medulla in close proximity to the nucleus ambiguus. Termed the ventral respiratory column (VRC), this group extends rostrally from the spinal-medullary junction to a region ventral to facial nucleus. A second group, termed the dorsal respiratory group, is localized in the dorsomedial medulla, mainly within the ventrolateral nucleus of the solitary tract (NTS). These neurons fire in bursts phase locked to the breathing rhythm. Most fire either during inspiration (inspiratory neurons) or expiration (expiratory neurons) although some fire in bursts that span phase transitions between inspiration and expiration.

The magnitude and rate of respiratory efforts generated by brainstem respiratory neurons are regulated to maintain brain and arterial tensions of oxygen ($O_2$), carbon dioxide ($CO_2$), and pH within narrow limits despite large variations in metabolic requirements. A variety of chemical and mechanical receptors located in the airways, lungs, and chest-wall provide the sensory feedback essential to optimization of the breathing pattern. Sensory feedback from arterial and central (brain) chemoreceptors as well as lung mechanoreceptors modulates the breathing pattern, e.g., tidal volume and breathing frequency.

Receptors distributed throughout the airways also help defend the respiratory system. Afferent-evoked protective reflexes include apnea (a transient cessation of breathing), shallow rapid breathing, coughing, sneezing, mucus secretion, and airway constriction. These reflexes protect the airways from irritants and facilitate the removal of inhaled substances potentially harmful to the lungs and airways.

### Chemoreceptors

Regulating the level of the metabolic product $CO_2$ and maintenance of tissue oxygenation are principal roles of the respiratory system. In performing these tasks, the

central circuitry generating respiratory pattern receives sensory input from chemoreceptors located in the brain (central chemoreceptors) and the arterial system (peripheral chemoreceptors). Through the regulation of $CO_2$, the respiratory system also adjusts pH and hence contributes importantly to acid-base balance.

Central chemoreceptors have a relatively greater role than peripheral receptors in regulating $CO_2$ and pH and they have been identified in several regions of the brain [1]. Most are in the medulla and pons including: (i) regions at the ventral surface of the medulla, particularly in the retrotrapezoid nucleus, (ii) midline raphe serotonergic neurons, (iii) the NTS, (iv) the preBötzinger complex [a subregion of the VRC] and (v) noradrenergic neurons in the locus coeruleus. Additional chemosensitive sites have been identified in: (vi) the fastigial nucleus of the cerebellum, and (vii) the posterior hypothalamus. The relative importance of several sites including the NTS, retrotrapezoid nucleus and caudal raphe may vary with physiological conditions such as the sleep–wake state. Central $O_2$ chemoreceptors appear to exist but little ventilatory response to hypoxia is observed after peripheral deafferentation when $CO_2$ levels are held constant.

Peripheral chemoreceptors have a dominant role in eliciting the ventilatory increases in response to hypoxia [2]. Peripheral chemoreceptors are located in both the carotid and aortic bodies but the carotid bodies are quantitatively much more important in regulating breathing. The aortic bodies contribute relatively more to cardiovascular adjustments. Afferent fibers emanating from the carotid bodies have a low discharge rate at normal resting levels of arterial $O_2$ and $CO_2$ but increase their discharge in response to a decrease in the partial pressure of arterial $O_2$ ($PO_2$) or to an increase in the partial pressure of arterial $CO_2$ ($PCO_2$) or to decreases in pH.

Overall, chemoreceptors are remarkably sensitive to $PCO_2$. Increasing arterial $PCO_2$ by 1–3 mm Hg from a normal resting value of about 40 mm Hg can cause a doubling of ventilation. About 60% of this response is contributed by central chemoreceptors. In contrast, there is little ventilatory response to hypoxia until arterial $PO_2$ decreases below 60 mm Hg from a normal resting value of 80–100 mm Hg.

Chemoafferent fibers from the carotid body are contained in the carotid sinus nerve (CSN), a branch of the glossopharyngeal nerve, with the cell bodies of (first order) CSN chemoafferent neurons found mainly within the petrosal ganglia. CSN chemoreceptor afferent fibers are a mixture of unmyelinated C-fiber axons and myelinated A-fibers. The principal fast transmitter in these afferents appears to be glutamate, however, dopamine appears to be present in about 40% of the C-fibers. Other potential chemoafferent transmitters include substance P and ATP.

Carotid body afferents target 2nd-order caudal NTS neurons [3], specifically within its commissural division (SolC; Fig. 1).

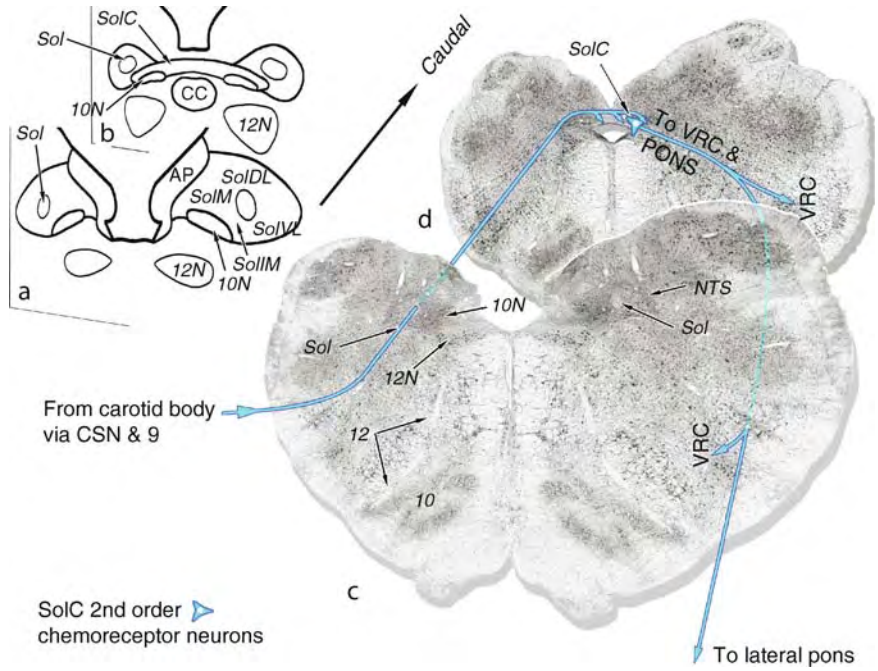
Within the NTS, intrinsic polysynaptic pathways provide recurrent excitatory feedback that can initially increase the excitability of 2nd- and higher-order NTS chemoafferent interneurons. Inhibitory GABAergic neurons in SolC are also activated during hypoxic stimulation of breathing and the initial activation of NTS neurons is followed by local inhibition that ultimately limits the excitatory responses of the NTS 2nd and higher order neurons.

Multiple pathways emanating from the NTS are involved in processing carotid chemoreceptor afferent activity. Both second and higher order neurons in SolC are the source of extrinsic projections to the brainstem and forebrain. Among brainstem targets are VRC respiratory neurons. Additionally, SolC neurons relay chemoafferent input to the rostral dorsolateral pons in the region of the parabrachial and Kölliker-Fuse nuclei. These nuclei contain respiratory neurons and are collectively referred to as the pontine respiratory group (PRG). Some neurons in the PRG are likely relays for chemoafferent (and other visceral) inputs to higher brain structures (in addition to the direct forebrain projections from the NTS). PRG neurons also provide descending inputs that coordinate respiratory activity with other systems such as cardiovascular control as well as with nociceptive afferent input.

### Plasticity in Chemoreceptor Breathing Responses

Short and long-term modifications (plasticity) occur in the breathing response to chemoreceptor activation. Respiratory plasticity accommodates the changing demands of development as well as environmental demands such as changing $PO_2$ levels at varying altitudes, and physiological demands created by pathological changes in the efficiency of the airways and lungs.

Plasticity of the hypoxia reflex is evident in changes in respiratory pattern occurring in multiple stages. The acute response to hypoxia is characterized by increases in both respiratory frequency and the volume of each breath (tidal volume). There is a progressive increase in tidal volume (termed short-termed potentiation) over a period of seconds to minutes. Upon returning to normal oxygen levels there is a slow return to the normal tidal volume. There is also a post-hypoxic decline in breathing frequency lasting several minutes in which respiratory frequency declines below pre-hypoxic levels. While the mechanisms underlying these changes are not well understood, short term potentiation may involve recurrent excitation within the chemoreceptor pathway in the NTS as well as pre-synaptic changes (e.g. calcium accumulation) in NTS or downstream neurons. Post hypoxic frequency decline, on the other hand, may require participation of neurons in the ventrolateral pons.



**Respiratory Reflexes. Figure 1** Carotid body chemoreceptor afferent terminations within the nucleus of the solitary tract (NTS). (a & b) NTS subnuclei at two rostrocaudal levels. (c & d) Central pathways of carotid chemoreceptors projected onto Nissl-stained coronal sections of the medulla at the levels approximating those diagramed in A & B. The axons of these sensory fibers are carried by the carotid sinus nerve (CSN), a branch of the glossopharyngeal nerve [9]. They enter the medulla near the level of the facial nucleus and run caudally within the solitary tract (sol) terminating predominantly within the commissural subregion (SolC) in the caudal aspect of the NTS. NTS 2nd-order neurons relay this afferent input directly (or indirectly via NTS higher-order neurons) to respiratory regions in the ventrolateral medulla and pons. Compare with the distribution of lung mechanoreceptor afferents in Fig. 3. Abbreviations: *10N* dorsal motor nucleus of the vagus; *12* hypoglossal nerve; *12N* hypoglossal nucleus; *AP* area postrema; *CC* central canal; *IO* inferior olive; *sol* solitary tract; *SolDL* dorsolateral subnucleus; *SolIM* intermediate subnucleus; *SolM* medial subnucleus; *SolVL* ventrolateral subnucleus; *VRC* ventral respiratory column of the ventrolateral medulla.

As illustrated in Fig. 2, repeated episodes of hypoxia lasting from seconds to minutes result in an additional form of plasticity consisting of a long-term facilitation (LTF) of respiratory motor output that can persist for several hours [1].

LTF is observed at motoneurons innervating respiratory pump muscles (e.g. phrenic and external intercostal motoneurons in the cervical and thoracic spinal cord) and upper airway muscles (e.g. hypoglossal motoneurons) and has been related to brainstem serotonergic afferents to these cells (via 5HT-2A receptors) as well as to up-regulation of the peptide, brain derived neurotrophic factor (BDNF), and the molecular signalling proteins activated by BDNF receptors (e.g. TrkB).

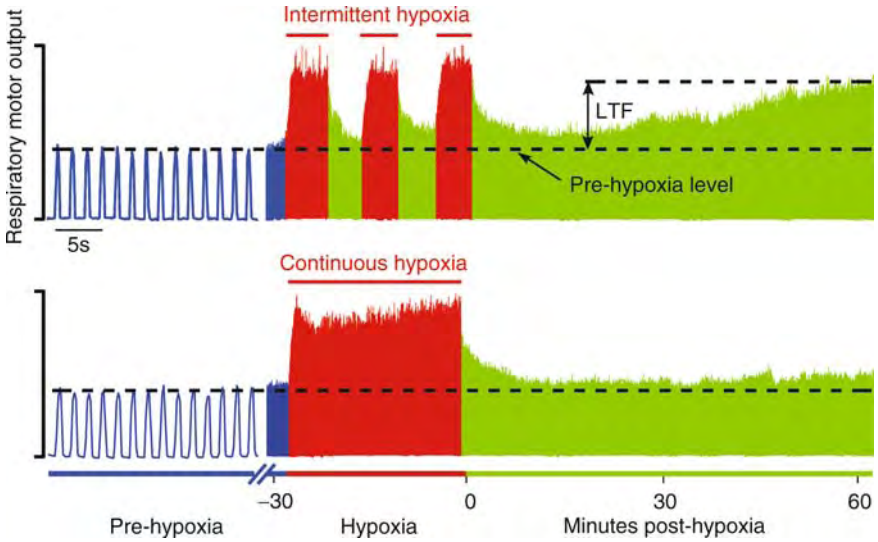
In humans, an etiologic role for central chemoreceptors in the medullary arcuate nucleus (located at the medial ventral surface of the brain) has been postulated in sudden infant death syndrome (SIDS) and this has been supported by observations of abnormal development of arcuate serotonin receptors [4]. Disruption of normal chemoreceptor function is also suggested in congenital central hypoventilation syndrome (CCHS). CCHS patients with a polyalanine expansion mutation in the *PHOX2B* gene have negligible sensitivity to elevated $PCO_2$ or hypoxemia [5].

## Airway Receptors

Respiratory reflexes arising from the airways serve both in protecting the airways as well as in regulating the depth and frequency of breathing. Protective reflexes include apnea, cough, sneeze, mucus secretion, and airway constriction that both protect the airways from irritants and facilitate the removal of potentially harmful substances. Sensory feedback also helps coordinate breathing with other behaviours such as locomotion or vocalization.

### *Receptors in the Nasal Passages and Pharynx*

Receptors in the mucous membranes of the nasal cavities are sensitive to cold and pressure changes associated with breathing as well as to inhaled irritants such as cigarette smoke and ammonia. Branches of the trigeminal nerve, including the anterior ethmoidal and



**Respiratory Reflexes. Figure 2** Respiration-related neural activity in an anesthetized and artificially ventilated rat demonstrates a form of respiratory plasticity known as respiratory long-term facilitation (LTF). On the left in each trace, electrical activity in the phrenic nerve (the nerve innervating the diaphragm, the principal inspiratory muscle) is integrated such that each peak represents a "fictive breath" that the artificially ventilated rat had intended to make. Under conditions of normal arterial oxygen and carbon dioxide (pre-hypoxia baseline; blue traces), the phrenic nerve bursts are rhythmic and relatively constant in frequency and amplitude. Ventilating the rats with lowered oxygen levels (red traces) causes differential effects on phrenic nerve activity depending upon the pattern of hypoxia exposure (intermittent, upper trace; continuous, lower trace). In both conditions, phrenic bursts increase in amplitude, primarily reflecting the increased activation of carotid body (peripheral) chemoreceptors. Following either pattern of hypoxia exposure, phrenic nerve activity also asymptotes toward baseline levels over several minutes following the return to normoxia (green traces). However, after intermittent, but not after continuous hypoxia, phrenic nerve burst amplitude again increases slowly and progressively over the next hour, even though arterial oxygen and carbon dioxide are at pre-hypoxia levels. This slow increase reflects LTF that is elicited in response to the repetitive exposure to hypoxia. This facilitation requires release of serotonin in the region of the motor neurons (Data provided by T.L. Baker-Hermann and G.S. Mitchell, reproduced with permission from Fundamental Neuroscience, 2nd Edition, edited by LR Squire, FE Bloom, SK McConnell, JL Roberts, NC Spitzer, MJ Zigmond, Academic Press, San Diego, 2003).

maxillary nerves convey the sensory information to the central nervous system. Respiratory motor responses to activation of these receptors include sneezing and apnea. Additional reflex components occur secondarily to alterations in the activity of the autonomic nervous system and include mucus secretion, bradycardia, and increased blood pressure.

The diving reflex is also elicited by receptors with afferent fibers in the trigeminal nerve. This reflex is elicited by water on the face or in nasal passages, and consists of apnea and peripheral vasoconstriction, along with marked increases in arterial pressure and bradycardia. Stimulation of the anterior ethmoidal nerve, which innervates the nasal passages, mimics the diving reflex. Its central terminations are found mainly in ventral aspects of the spinal trigeminal nucleus at levels caudal to the facial nucleus with additional terminations in the NTS and paratrigeminal nucleus.

### Laryngeal Receptors

The larynx is richly innervated by several subgroups of sensory receptors [6,7]. Their afferent fibers are mainly in the recurrent and superior laryngeal branches of the vagus nerve with terminations in the NTS. The receptors are located at the entrance to the trachea and lower airways and elicit strong protective reflexes including cough and apnea. The pronounced apneas elicited from laryngeal receptors has also suggested that abnormal development of their reflex pathways could contribute to SIDS. In contrast, a subset of laryngeal receptors promotes airway patency via activation of airway dilating muscles such as the genioglossus and posterior cricoarytenoid.

### Receptors in the Lower Airways

Receptors within the lungs and lower airways, *i.e.*, those below the larynx, are classified into two main types based on whether the sensory afferent fibers are myelinated or unmyelinated [6,8,9]. The afferent axons arising from both groups travel in the vagus nerves and terminate in middle and caudal aspects of the NTS. Receptors with myelinated axons constitute airway mechanoreceptors and are activated by distension of the airway during lung inflation or by a reduction in airway

dimensions during lung deflation, especially deflations below the normal end-expiratory volume. Two groups of receptors, slowly (SAR) and rapidly (RAR) adapting receptors, are identified based on their sensitivity to distension of the airways during lung inflation and the rate of accommodation in their response. An additional group of receptors, termed deflation activated receptors (DARs), are more prominent in small animals (e.g. rats). DARs share several common properties with RARs, which are more readily observed in larger animals and activation of either RARs or DARs elicits augmented inspiratory efforts.

*SARs* are located in airway smooth muscle. Their activation by lung inflation inhibits inspiratory motor activity, thereby shortening inspiratory duration and reducing tidal volume (termed the *Breuer-Hering inspiration-inhibiting reflex*). Maintaining inflation into the expiratory period prolongs expiratory duration (*Breuer-Hering expiratory facilitatory reflex*). The Breuer-Hering reflexes are activated during normal resting breathing in most mammals while in humans they appear to only significantly influence breathing pattern when tidal volumes increase to 2–3 times their resting values as may occur during muscular exercise. Activation of SARs has several additional effects, including reductions in airway smooth muscle tone resulting in bronchodilation, and reductions in heart rate and systemic vascular resistance.

*RARs* are located in airway epithelium and submucosa. While they are activated by lung inflation they are less responsive than SARs and tend to have little activity under normal breathing conditions. Their discharge adapts rapidly to lung inflation and they typically fire irregularly, giving rise to one or a few action potentials during lung inflation. They respond with a significantly more sustained discharge to inhaled irritants. RARs are implicated in a number of potent airway protective reflexes, including augmented breaths (sighs), airway constriction, mucus secretion and laryngeal closure. While they are generally believed to trigger coughing, this function has recently been related to a specific subset of polymodal A∂-fibers (termed cough receptors; [10]).

*DARs*. Some researchers group DARs with RARs and the degree to which these represent the same or separate populations requires further examination. Nevertheless, lung deflation triggers reflexes that shorten expiratory duration and increase inspiratory effort. There is also a reflex narrowing (adduction) of the glottis and stimulation of low intensity diaphragm activity during expiration that slows expiration. Together these responses help prevent alveolar collapse, and are particularly important in human infants as well as in other small mammals that have highly compliant chest walls.

*C-Fibers* constitute the largest class of pulmonary vagal afferent fibers (~75%). They are polymodal and nociceptive, responding to a variety of inflammatory mediators and inhaled irritants. Reflex changes in breathing in response to C-fiber activation involve rapid shallow breathing interspersed with apneas; additional reflex effects include bronchoconstriction, mucus secretion, hypotension, bradycardia and airway mucosal vasodilation. Beyond identification of the regions of C-fiber termination within the NTS, little is known concerning central pathways mediating these responses.

## Second and Higher-Order Neurons in Reflexes From Airway Mechanoreceptors

### Central Pathways of SARs

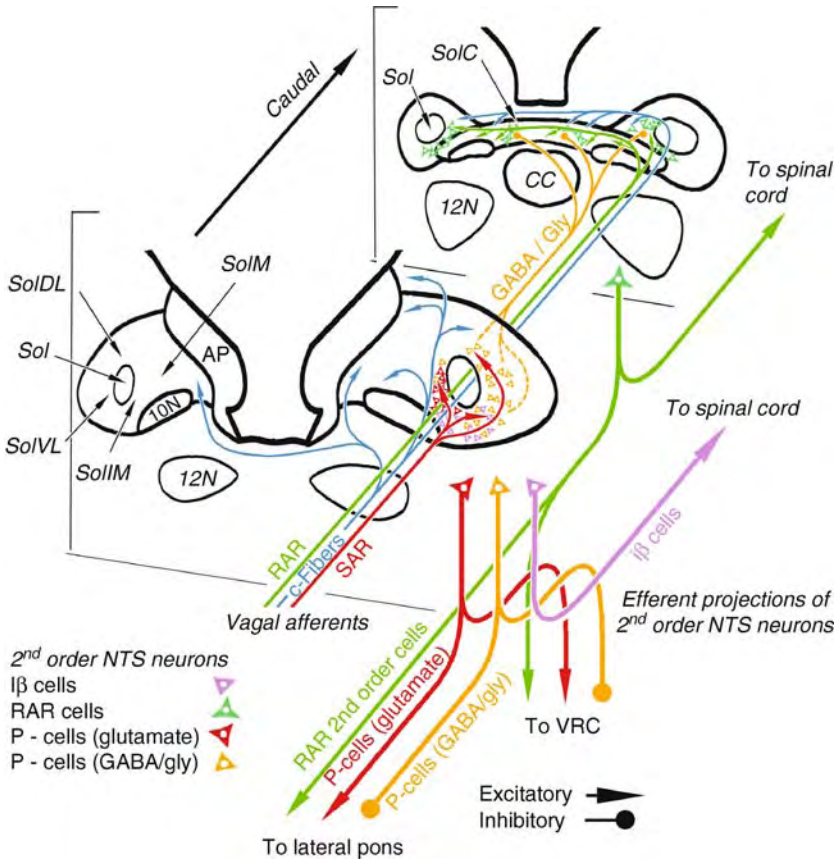
SAR primary afferent fibers terminate within mid to caudal portions of the NTS (Fig. 3) [6]. Only two functional classes of NTS neurons receive monosynaptic input from SARs (Fig. 3).

One type, termed Iβ neurons, exhibits inspiratory discharge patterns, and activation of SARs increases the discharge rate of these neurons. Iβ neurons are bulbospinal premotor neurons that monosynaptically excite phrenic motoneurons. These motoneurons innervate the diaphragm and this reflex accordingly provides positive feedback excitation of diaphragm inspiratory activity.

A second group of NTS neurons, termed pump-neurons, mediate Breuer-Hering reflex changes in respiratory rhythm. Pump neurons receive monosynaptic SAR input but are readily distinguished from Iβ neurons by the general absence of an inspiratory discharge when SAR input is removed. Consistent with the broad effects they elicit on respiratory pattern, their axons arborize extensively within pontomedullary regions (ventrolateral medulla and rostral dorsolateral pons) containing neurons responsible for generating the respiratory pattern. Many pump neurons are inhibitory, containing GABA with only a small percentage also containing glycine. Experimental evidence also suggests that there may be excitatory pump neurons, however, these cells have not yet been directly identified.

### Central Pathways of RARs

RAR primary afferent fibers terminate in caudal aspects of the NTS where they monosynaptically excite neurons termed RAR interneurons (Fig. 3) [6]. Like pump neurons, these interneurons provide extensive axonal arborizations to pontomedullary regions involved in respiratory pattern generation. RAR interneurons are believed to be excitatory and presumably facilitate the discharge of inspiratory neurons. RAR activation accordingly elicits augmented inspirations such as sighs, and the large inspiration preceding a cough. RARs are also stimulated by decreases in lung compliance that result from alveolar collapse. The resulting RAR-triggered large inspiration stretches the lung, reopening collapsed alveoli.



**Respiratory Reflexes. Figure 3** The topographical distribution within the NTS of three classes of pulmonary afferents. The terminal distribution slowly and rapidly adapting stretch receptors (SARs and RARs, respectively) and bronchopulmonary C-fibers is shown at two rostrocaudal levels of the NTS. The three afferent systems in general project to topographically separate NTS targets. The principal projections of their 2nd order neurons are also indicated. Among the known projections is an inhibitory projection of pump (P-) cells to RAR relay neurons in the NTS commissural subnucleus. See Fig. 1 for abbreviations (used with permission from [6]).

## Summary

Although seemingly effortless in the healthy individual, generating an optimal breathing pattern for $O_2$ and $CO_2$ homeostasis requires the integration of sensory information arising from a variety of receptors. These include multiple central and peripheral chemoreceptors for adjusting the magnitude of alveolar ventilation as well as multiple mechanoreceptors that respond to stretch of the airways and regulate the relative depth and rate of breathing to reduce energy expenditure. Sensory input is also important in the coordination of breathing with other systems, such those required for speaking, eating, walking, running, vomiting. Finally, sensory information is necessary for protection of the airways and lungs. Receptors in the nose, pharynx, larynx and lower airways elicit a variety of reflexes including coughs, sneezes and apnea that protect the airways from inhalation of noxious substances and increase mucous secretion that aids in their removal. Failure of any of these systems can be catastrophic, severely compromising the quality of life for an individual or ultimately leading to their death.

►Action Potential

## Resting Tremor

### Definition

Approximately 70% of patients notice tremor as the first symptom of Parkinson disease. Onset of tremor is usually in one hand and it may later involve the contralateral upper limb or ipsilateral lower limb.

Typically, the tremor is 3–5 Hz rhythmic "pill-rolling" movements of the thumb and index finger while the hand is at rest. There may be abduction and adduction of the thumb, or flexion and extension of the wrist, or of the metacarpophalyngeal joints. The tremor may also extend to the forearm with pronation–supination or even to the elbow and upper arm. During early disease, tremor is often intermittent and is evident only under stress. Tremor is worsened by anxiety, fatigue, and sleep deprivation. It diminishes with voluntary activity but may reappear with static posture (e.g. outstretched hands) and is absent during sleep. Resting tremor is enhanced by mental task performance, such as serial seven subtractions, and by motor task performance in a different body part. The hand tremor may also be enhanced during ambulation. Compared to essential tremor, the resting tremor of Parkinson disease is generally less prone to exacerbation by caffeine or improvement with alcohol.

►Parkinson Disease

## Restless Legs Syndrome

### Definition

Restless limbs syndrome is a common disorder with a prevalence of 5–15% in western countries. It is characterized by a distressing desire to move the legs, motor restlessness brought on by rest, worsening symptoms in the evenings and at night, and periodic limb movements during sleep. Although it can be seen with peripheral neuropathy, most cases of restless legs are not accompanied by neuropathy. There is an association between restless limbs and brain dopamine and iron deficiency. Therefore, checking iron and ferritin levels is part of the workup for restless legs syndrome. If iron deficiency is detected, it should be evaluated (anemia workup, etc.) and treated with iron supplementation. If a sleep study reveals sleep apnea together with periodic limb movements during sleep, the apnea component should be treated. Symptomatic treatment of restless legs and limb movements during sleep usually begins with a dopamine agonist (pramipexole or ropinirole). Dopamine agonists have longer durations of action compared to levodopa and one or two evening/bedtime dose(s) may suffice. If dopamine agonists are not well tolerated, a controlled release formulation of carbidopa/levodopa should be tried next, and the dose titrated as tolerated. Other adjunct medications include gabapentin, benzodiazepines, and low potency opioids as a last resort.

►Sleep – Developmental Changes

## Ret

### Definition

The signaling component of the glial cell line-derived neurotrophic factor (GDNF) family receptor complex. Ligand-binding to GPI-linked GFRα receptors (1–4) and subsequent induction of Ret dimerization results in Ret phosphorylation and activation of several signaling cascades, including those involving MAPK, PI3K and PLCγ.

# Reticular Core

►Reticular Formation

# Reticular Formation

Stefanie Geisler
Behavioral Neuroscience Branch, National Institute on Drug Abuse, Intramural Research Program, Baltimore, MD, USA

## Synonyms

Formatio reticularis; Substantia reticularis; Isodendritic core; Reticular core

## Definition

The reticular formation is a netlike structure of cells and fibers that extends throughout the core of the brainstem. It maintains vegetative functions, plays an essential role in coordinated motor behaviors and exerts control on cortical and thalamocortical activation. Extensive damage to the reticular formation is incompatible with survival.

## Characteristics

### Anatomical Organization and Concepts

The term reticular formation was coined by anatomists in the last century to describe a region in the core of the ►brainstem characterized by scattered neurons of various sizes and shapes with long, sparsely branching dendrites lying in and among multiple, differently oriented fiber systems. The dendrites of neighboring neurons overlap extensively with each other, giving the structure a netlike ("reticular") appearance. The reticular formation extends continuously from the ►caudal medulla oblongata to the ►rostral mesencephalon (and possibly beyond, see below).

Based on differences in cytoarchitecture, cytochemistry and connections, the reticular formation has been divided into three longitudinal zones, a median zone, which contains the ►serotoninergic raphe nuclei (Greek *raphe* = seam), a medial zone, characterized by big cells intermingling with many small ones and a lateral zone, which consists predominantly of (Fig. 1) small neurons and has fewer fibers than the medial zone (Fig. 1a–c).

More recently, an intermediate zone has been delineated between the medial and lateral ones (Fig. 1a, [1]). The intermediate zone comprises large, medium and small cells and exhibits slightly stronger ►acetylcholine esterase staining as compared to the adjacent medial and lateral zones. ►Cranial nerve nuclei (e.g. facial and cochlear) and relay nuclei (e.g. cuneate and red nuclei), which largely consist of densely packed neurons of similar appearance (Fig. 1d) are not included in the reticular formation.

### Nuclei of the Recticular Formation

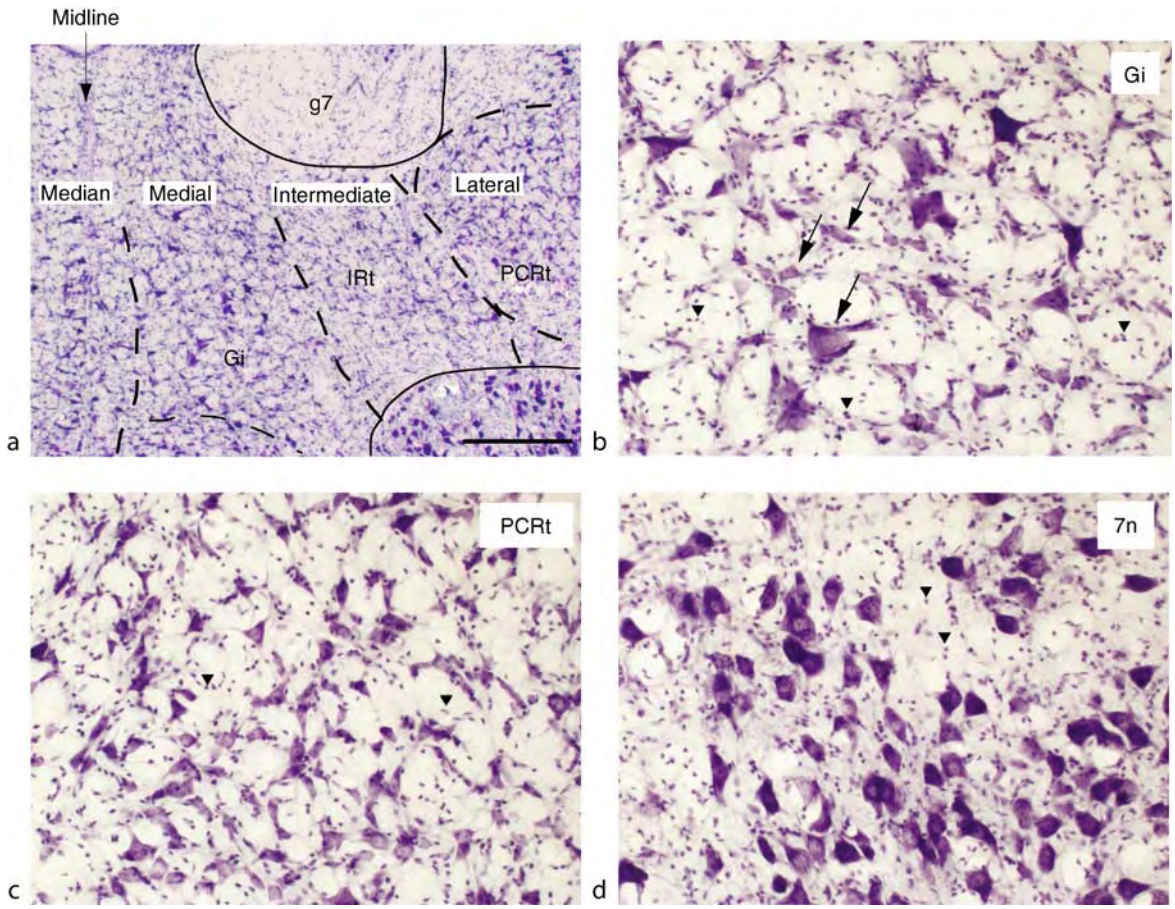
By analyzing Nissl stained (►Nissl Stain) sections of the human and rabbit brainstem Olszewski and colleagues noted cytoarchitectural heterogeneities, which led them (and subsequently others in other species) to suggest that the reticular formation consists of different nuclei [2,10]. An overview of reticular formation nuclei is given in Table 1.

At the medullary level of the medial reticular formation, the ►gigantocellular nucleus has been delineated, which is composed of prominent multipolar giant cells, as well as large, medium sized and some small neurons (Fig. 1a, b). It is surrounded by the gigantocellular nucleus pars alpha and the lateral and dorsal paragigantocellular nuclei, all of which also contain large neurons. The gigantocellular nucleus extends from the obex to the rostral medulla oblongata and is continuous caudally with the ventral reticular nucleus and rostrally with the ►caudal pontine reticular nucleus. The caudal pontine reticular nucleus extends to the rostral pons where it merges with the oral pontine reticular nucleus, which in turn extends rostralward to the level of the decussation of the superior cerebellar peduncle. Dorsal and ventral to the caudal pontine reticular nucleus are the dorsomedial tegmental and ventral pontine reticular nuclei respectively. The lateral zone consists, in order from ►caudal to ►rostral, of the dorsal reticular (caudal medulla), parvocellular (medulla; Fig. 1c), subceruleus (pons) and cuneiform nucleus (pons, ►mesencephalon). The mesencephalic reticular formation is dominated by the deep mesencephalic nucleus, which some authors regard as part of the medial and others as part of the lateral zone of the reticular formation. Some of the above mentioned nuclei have been further subdivided (see [2,3]).

In addition to the above-mentioned nuclei are some that are regarded by some, but not all, authors to be part of the reticular formation, e.g. the lateral reticular nucleus, ►parabrachial nucleus, locus ceruleus, pedunculopontine and laterodorsal tegmental nuclei, retrorubral field, and ventral tegmental area. It sometimes seems to be a matter of personal taste whether a nucleus is included in the reticular formation or not.

### The Veticular Formation and the Ascending Reticular Activity System

In 1949, Moruzzi and Magoun published a seminal paper describing studies in which they demonstrated that stimulation of the reticular formation in lightly



**Reticular Formation. Figure 1** (a) Photomicrographs showing some reticular formation nuclei in the median, medial, intermediate and lateral zones. Prominent, big neurons of the gigantocellular nucleus can be easily recognized. The gigantocellular nucleus is enlarged in (b), showing large and small neurons (*arrows*) side-by-side, one of the characteristics of the reticular formation. The very small cells (*arrowheads*) are not neurons, but glial cells. (c) shows an enlargement of the parvocellular reticular nucleus, which has neurons that are obviously smaller than those in the gigantocellular nucleus. Note also the different sizes and shapes of neurons. The facial nerve nucleus, which is not included in the reticular formation, is shown in (d). Its neurons are all of similar size and appearance and are more densely packed than those in the gigantocellular and parvocellular reticular nuclei (compare b, c, d). Abbreviations: *7n* facial nucleus, *g7* genu of facial nerve; *Gi* gigantocellular nucleus; *IRt* intermediate reticular nucleus; *PCRt* parvocellular reticular nucleus. *Arrows* point to neurons; *arrowheads* point to glial cells. The scale bar in (a) represents 0.5 mm in (a), 0.125 mm in (b–d).

anaesthetized cats evokes a desynchronization of the cortical ►EEG, closely resembling the changes observed in the human EEG upon transition from sleep to wakefulness or relaxation and drowsiness to alertness and attention [4]. Such EEG changes could be elicited by stimulation of the medial medullary, pontine and mesencephalic reticular formation and dorsal hypothalamus and subthalamus. They proposed a series of relays in the reticular formation ascending to the basal diencephalon and exerting influence on widespread areas of the cortex via a "diffuse thalamic projection system." These and other observations led to the concept of an ascending reticular activating system (often referred to in the literature as ARAS), which spurred extensive research and had an enormous influence on subsequent views concerning the neural basis of consciousness. Because potentials could be recorded from large cortical territories following stimulation of afferents from a particular source and impulses from several sources were found to reach the same region, it was assumed that the system would be entirely diffusely organized. Unfortunately, the term "ascending reticular activating system" describing a physiological concept was soon frequently used synonymously with the morphological term "reticular formation," which led Olszewski to comment [5]: "There are presently two reticular formations – an anatomic one and a physiologic one – and they do not correspond to each other."

## The Concept of the Isodendritic Core

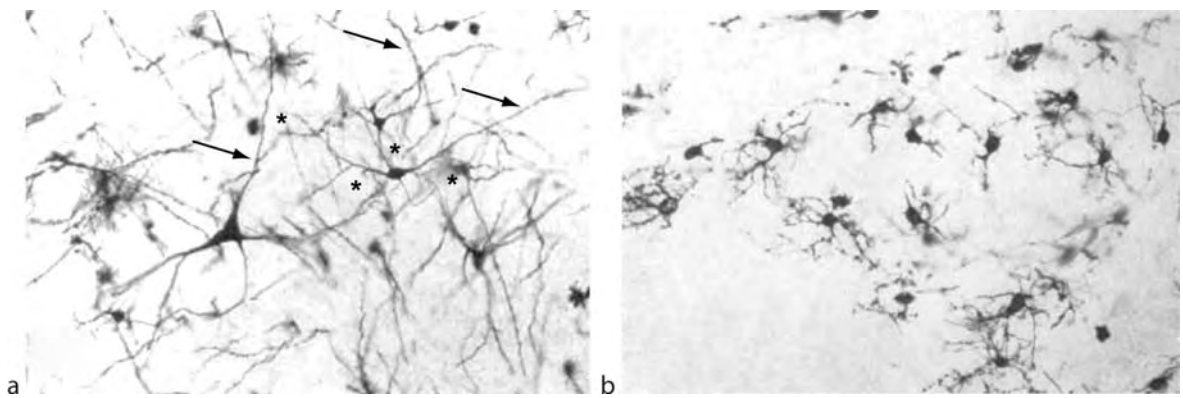
Due to the confusion surrounding the term reticular formation and the lack of a generally accepted definition, some scientists suggested that use of the construct be discontinued altogether (e.g. [5,6]), whereas others attempted to define it more precisely [1 and refs. therein]. Based on analyses of Golgi stained (►Golgi Stain) brain sections of different species Ramon-Moliner and Nauta described not one defining characteristic of reticular formation, but rather an aggregation of several morphological features that they concluded are found together only in the reticular formation: i) cytological polymorphism, large and small neurons are side by side (Fig. 1b); ii) generalized dendrites, long, radiating, relatively rectilinear and sparsely branching processes, iii) considerable dendritic overlap and iv) free intermingling of dendrites and passing myelinated and unmyelinated fiber bundles. Ramon-Moliner and Nauta called neurons (Fig. 2) with the generalized dendritic patterns found in the reticular formation "isodendritic" (from the Greek isos: similar, uniform, Fig. 2a) and distinguished them from allodendritic (allos: different) and idiodendritic (idios: peculiar) neurons (Fig. 2b).

Idio- and allo-dendritic neurons, also sometimes referred to as "hodophob" (hodos: path, pathway; phob: fearing), are characterized by short dendrites that ramify

**Reticular Formation. Table 1** Nuclei of the brainstem reticular formation

| Median | Medial | | Lateral |
|---|---|---|---|
| Raphe obscurus | Ventral reticular n. | Intermediate reticular n. | Dorsal reticular n. |
| Raphe pallidus | Gigantocellular reticular n. | | Parvicellular reticular n. |
| Raphe magnus | Dorsal paragigantocellular n. | | Subceruleus n. |
| Raphe interpositus | Lateral paragigantocellular n. | | Parabrachial n. |
| Median raphe | Gigantocellular n, pars alpha | | Cuneiform n. |
| Dorsal raphe | Caudal pontine reticular n. | | Laterodorsal tegmental n. |
| | Dorsomedial tegmental n. | | Pedunculopontine tegmental n. |
| | Ventral pontine reticular n. | | |
| | Oral pontine reticular n. | | |
| | Deep mesencephalic reticular n. | | |

Nuclei are ordered from caudal to rostral, colored boxes indicate where the nuclei are situated in the brainstem: ►blue – Medulla oblongata; ►orange – Pons; ►green – Mesencephalon. At medullary levels an intermediate zone has been delineated. Whereas the zones are easily recognizable at medullary levels (caudal), it is more difficult to distinguish them at rostral pontine and mesencephalic levels. Thus, at mesencephalic levels the allocation of nuclei to distinct zones is fairly tentative. Abbreviation: *n* nucleus.



**Reticular Formation. Figure 2** (a) Isodendritic neurons have long, sparsely branching dendrites (*arrows*) and overlapping dendritic fields (*asterisks*). (b) Allodendritic neurons have short dendrites, which ramify close to the cell body. Dendrites of neighbouring neurons largely do not overlap with each other. These Golgi preparations are adapted from figs. 6 and 7 of [1], with permission from Wiley Interscience.

close to the cell body and do not extend into passing fiber bundles (Fig. 2b). These neuron types are found, e.g. in sensory nuclei, like the cuneate nucleus. In contrast, the "reticular" isodendritic neurons are regarded as "hodophil" (phil: friendly).

Ramon-Moliner and Nauta's concept of reticular formation does not necessarily preclude the existence of regional differences and is not incompatible with parcellations suggested by Olszewski and others. Thus, although the extensively overlapping dendritic fields of reticular neurons make it difficult, if not impossible, to draw definite lines around nuclei, the division of the reticular formation into nuclei is nevertheless helpful and necessary (and widely employed today) to describe the locations of nerve cells, electrode placements and lesions within the reticular formation. Applying the criteria of Ramon-Moliner and Nauta, the lateral reticular nucleus is not part of the reticular formation because it consists of allodendritic neurons and has a restricted set of connections with the ►spinal cord and ►cerebellum. In contrast, e.g. the ►parabrachial nucleus, locus ceruleus, pedunculopontine and laterodorsal tegmental nuclei, retrorubral field and ventral tegmental area have sufficient reticular characteristics to be included. Furthermore, if these criteria are applied, the reticular formation is not confined to the brainstem, but also includes structures in the forebrain, such as the ►lateral hypothalamic and preoptic areas and the magnocellular ►basal forebrain [7]. Even if these areas are conservatively excluded from the reticular formation, their neuroanatomical organization suggests that they process information in a manner similar to that which occurs in the reticular formation of the brainstem.

## Connections and Functions of the Reticular Formation of the Brainstem

The reticular formation maintains pivotal vegetative functions (e.g. respiration, heart beat, blood pressure) and plays an essential role in coordinated motor behaviors (e.g. swallowing, chewing and ►locomotion). In addition, it functions as an intermediary through which amygdala, septum, and basal ganglia gain access to the autonomic and motor systems [8]. Via its ascending projections, the reticular formation exerts control on cortical and thalamocortical activation and functions.

## Medial Reticular Formation

Reticular neurons give rise to long ascending (e.g. to the cerebral ►cortex) and descending (e.g. to the sacral level of the spinal cord) axons that give off several collaterals along their course, thereby interconnecting different parts of the reticular formation [3]. For example the oral and caudal pontine reticular nuclei receive half of their afferents from other parts of the brainstem reticular formation. Other main afferents to the medial reticular formation arise in the ►prefrontal and ►sensory cortices, zona incerta, fields of Forel, lateral hypothalamus, preoptic area, substantia nigra pars reticulata, superior colliculus, central gray, cerebellum and spinal cord. The medial reticular formation projects mainly to the spinal cord and motor cranial nerve nuclei and to the laterodorsal and pedunculopontine tegmental nuclei, intralaminar thalamic nuclei, fields of Forel, parafascicular thalamic nucleus, zona incerta and lateral hypothalamus. The projections of the individual nuclei of the medial reticular formation differ in degree rather than kind. Thus, all parts of the medial reticular formation project to the telencephalon, but the largest number of neurons projecting there is located at the mesencephalic level, whereas only a few are situated at caudal pontine and medullary levels. Similarly, whereas many neurons in the gigantocellular nucleus project to the spinal cord, only a few in the mesencephalic reticular formation do so [3].

Neurons in the dorsal two thirds of the caudal pontine and medullary medial reticular formation project to the intermediate and ventral horn of the spinal cord, where the premotor interneurons and motorneurons for the axial and proximal musculature (i.e. trunk, hip, back, shoulder and neck) are situated. Thus, they play an important role in the control of posture, integration of the movements of body and limbs and the orientation of body and head. Because orienting movements of the head and eye are tightly linked, it might not be surprising that parts of the medial reticular formation that project to the spinal cord also possess neurons that innervate eye muscle motor neurons (oculomotor and ►abducens nuclei), which are necessary for horizontal ►gaze control. Neurons controlling the phylogenetically later developed vertical gaze control (trochlear and oculomotor nuclei) are situated further rostrally in the medial reticular formation.

Neurons in the medial reticular formation also influence wide areas of the cerebral cortex via their strong ascending projections to the laterodorsal and pedunculopontine tegmental nuclei and, to a lesser extent, to intralaminar thalamic nuclei (see Essay on Mesopontine Tegmentum).

## Lateral Reticular Formation

The lateral reticular formation receives afferents from the primary motor and ►somatosensory cortex, ►insular cortex, ►central nucleus of amygdala, bed nucleus of stria terminalis, central gray, trigeminal nuclei, rostral part of the ►nucleus of the solitary tract, red nucleus, other parts of the reticular formation and cerebellum. Neurons in the lateral reticular formation project predominantly to motor cranial nuclei (e.g. trigeminus, facial and ►hypoglossal) and the medial reticular formation.

Sensory information from jaw muscle spindle afferents and oral cavity (via trigeminal nuclei), taste (via the rostral part of the nucleus of the solitary tract),

visceral information (via the insular cortex) and oral motor information (from the motor cortex) are relayed to and integrated within the lateral reticular formation, which in turn projects to motor cranial nuclei containing neurons for muscles involved in swallowing, chewing and salivation. In addition, inputs from structures commonly regarded as being involved in emotional processing, such as ►amygdala, bed nucleus of stria terminalis and ►periaqueductal gray are integrated in the lateral reticular formation and relayed to, e.g. facial motor neurons and autonomic centers.

### The connections conceptualized

These anatomical data provide a general idea about the connections, but are insufficient to explain the precise circuits that underlie the functions of the reticular formation. Against the common perception that the reticular formation is organized in a diffuse way, the complex behaviors it is involved in require very specific and precisely tuned connections. Breathing, for example, requires the coordinated movements of jaws, lips, tongue, pharynx and larynx, can be controlled voluntarily, but usually happens automatically and has to adapt for eating, speaking, fighting or fleeing. Thus, a high level of specificity must exist in the reticular formation, but it is the very structure of the reticular formation that makes such a specificity very difficult to detect.

So, what might such an apparently disorganized structure be good for? To appreciate the functional anatomical organization of the reticular formation, it might be useful to compare it to a system that is quite differently organized, such as the primary motor or sensory system. The so-called lemniscal system carries sensory information via two synapses to the primary sensory cortex. Such a sensory pathway of minimal interruption rigorously maintains the topography of the sensory periphery and thus permits the exact localization of the source of the sensory stimulus. Hence, this system is very well suited for discriminative functions. The reticular formation, in contrast, consisting of neurons with long dendrites receiving multiple heterogeneous inputs and emitting axons that collateralize a lot, is especially well suited for integrative functions. As Nauta and Feirtag [9] state "Life depends on the innervation of the viscera: in a way all the rest is biological luxury. And vital systems ought to be organized on the principle that no single excitation should greatly affect their workings." It remains an exciting challenge to untangle the precise underlying neuronal networks.

# Reticulospinal Cells (Neurons)

### Definition

Neurons located within the reticular formation with an axonal projection to the spinal cord. Reticulospinal cells project to different levels of the spinal cord, some activating exclusively the most rostral segments whereas others activate the caudal ones.

# Reticulospinal Long-Lead Burst Neurons

Charles Scudder
Portland, OR, USA

### Definition

Reticulospinal neurons, in general, are neurons that have their somata in the mesencephalic, pontine, or medullary reticular formation and have axons that project at least as far as the upper-most spinal cord. Reticulospinal ►long-lead burst neurons (RS-LLBNs) (►burst cells – long lead (LLBNs)) are reticulospinal neurons that discharge before and during ►gaze saccades in a preferred direction that depends on the particular cell. Like other reticulospinal neurons, RS-LLBNs integrate input from

multiple sources and project to multiple targets. In the case of RS-LLBNs, the purpose is to generate coordinated eye, head, and sometimes trunk movements.

## Characteristics

### Higher-Order Processes

RS-LLBNs are part of a system of descending pathways that mediate orienting toward areas or objects of interest. The stereotypical ►orienting response depends on the species. Macaque monkeys move only their eyes if the target of interest is near the current direction of gaze, but will make a combined eye and head ►gaze movement for targets further away. Cats preferentially move the eyes and head together, and typically also redirect their pinnae and maybe their trunk. Rodents do all of the above with greater movement of the trunk. Human orienting is more flexible, but usually includes combined eye and head movements. The descending system that mediates this behavior includes the reticulospinal pathway, the tectospinal pathway, the corticospinal pathway, as well as less direct pathways.

The command to execute an orienting movement originates in cerebral cortex and involves many of the same structures as saccade generation. The ►lateral intraparietal cortex (LIP), the ►supplementary eye fields (SEF), and the ►frontal eye fields (FEF), which are themselves interconnected, project to the deep and intermediate layers of the ►superior colliculus as well as to other brainstem locations. Signals for these cortical areas, as well as those from subcortical areas, are integrated in the superior colliculus, and the colliculus issues the principal command to move the eye, head, etc. This command is conveyed to the brainstem, including the ►saccadic burst generator and reticulospinal neurons, and directly to the spinal cord. In cats, this "tectospinal" pathway is strong and consists of well studied ►tecto-reticulo-spinal neurons (TRSNs). In primates, the tectospinal pathway is weak and probably includes neurons that differ from the cat TRSNs. This means that primates rely heavily on reticulospinal pathways to orient.

The superior collicular projection to the brainstem provides the principal input to the RS-LLBNs and a smaller input to other reticulospinal neurons. Efferents from cerebral cortex provide additional input to RS-LLBNs, but not as much as to other reticulospinal neurons [1]. Cortical inputs arise from motor cortex and possibly premotor cortex. Another input to reticulospinal neurons, including RS-LLBNs, is from the ►fastigial nucleus of the midline cerebellum. The fastigial nucleus, in turn, receives indirect input from the superior colliculus, the FEF, the SEF, and motor cortex, and represents another pathway by which these cortical structures can influence RS-LLBNs. In fact, orienting movements in cats and monkeys are severely disrupted by chemical inactivation of the fastigial nucleus. Many reticulospinal neurons that receive input from the superior colliculus also receive input from the vestibular system [2], although the relevance for RS-LLBNs is controversial. Caudal reticulospinal neurons receive input from collaterals of more rostral reticulospinal neurons [1,3–5].

### Parts of the RS-LLBN System

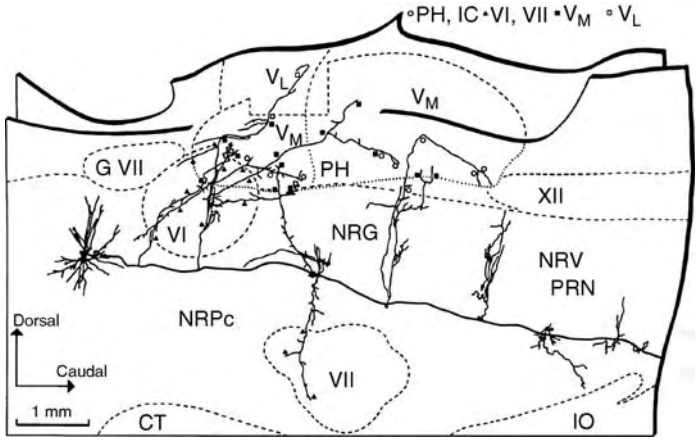
RS-LLBNs as well as other reticulospinal neurons are found in the medullary ►nucleus reticularis gigantocellularis (NRG), pontomedullary ►nucleus reticularis pontis caudalis (NRPc), and in the mesencephalic reticular formation in and near the ►interstitial nucleus of Cajal (INC) and the H-fields of Forel (called the ►riMLF in the monkey). Neurons have different properties in different areas, and in different species according to current incomplete data. In general, neurons in NRPc and dorsal NRG have horizontal preferred directions and appear to innervate horizontal eye and head movers, while those in ventral NRG and in the midbrain have vertical preferred directions and appear to innervate vertical eye and head movers. Behaviorally identified RS-LLBNs have mainly been studied using intra-axonal recording and subsequent injection with horseradish peroxidase.

#### *Cats*

The best studied RS-LLBNs are "eye-neck neurons," which have their somata in the NRPc rostral and/or ventral to the abducens nucleus [3]. Collaterals of the descending axon arborize in the abducens nucleus, the prepositus nucleus, the medial vestibular nucleus (all related to horizontal eye movements), the facial nucleus (mediating pinna movement), the dorsal NRG and the nucleus reticularis ventralis (containing reticulospinal neurons), and paramedian cell groups projecting to the cerebellum (Fig. 1) [3].

During attempted gaze shifts in head-fixed cats having electromyographic (EMG) electrodes implanted in the neck muscles, a typical eye-neck neuron exhibits a burst of spikes that begins 66–132 ms before the saccade (hence the long-lead designation), peaks during the saccade, and slowly decays to an end after saccade end but roughly coinciding with the end of the phasic component of neck EMG activity [6]. Eye-neck neurons also have a moderate firing rate during sustained EMG activity when the head is held eccentrically. Phasic and sustained activity increases with increasing eye movement towards the ►ipsiversive side and with increasing EMG activity in the ipsilateral neck muscles, but is not perfectly correlated with either alone. These discharges and the axonal arborization of these neurons both suggest a role in the coordinated activation of eye and neck muscles.

A second group of more caudally located RS-LLBNs has similar discharges but with very little sustained activity when the head is stationary [4]. Somata are



**Reticulospinal Long-Lead Burst Neurons. Figure 1** Camera lucida drawing of part of a cat reticulospinal neuron drawn in a parasagittal plane. The large soma is located in the PPRF just rostral to the abducens nucleus (VI), and the descending axon gives off branches that terminate in the abducens and facial motor nuclei (VI and VII), nucleus prepositus hypoglossi (PH), nucleus intercalatus (IC), the medial and lateral vestibular nuclei ($V_M$ and $V_L$), the nucleus reticularis gigantocellularis (NRG), and the nucleus reticularis ventralis (NRV). Symbols show where the branches left the plane of section, and are coded according to where the branches terminated (see Key). Other abbreviations; G VII = genu of the VIIth nerve, NRPc = nucleus reticularis pontis caudalis, PRN = paramedian reticular nucleus, XII = hypoglossal nucleus, IO = inferior olive, CT = corticospinal tract. Adapted from Grantyn et al. [3].

mostly located caudal to the abducens nucleus, but one was located rostral to the abducens. The axons do not collateralize to innervate any cranial motor nuclei, but rather innervate the paramedian reticular nucleus, interstitial cell groups in the MLF (which both project to the cerebellum), and nucleus reticularis ventralis. Preferred directions could have large vertical components, and one neuron had a contralateral preferred direction and an axon that descended in and innervated the contralateral medulla and spinal cord. The lack of projections to oculomotor structures, the projection to the spinal cord, and the phasic burst all imply these neurons function as head burst-neurons.

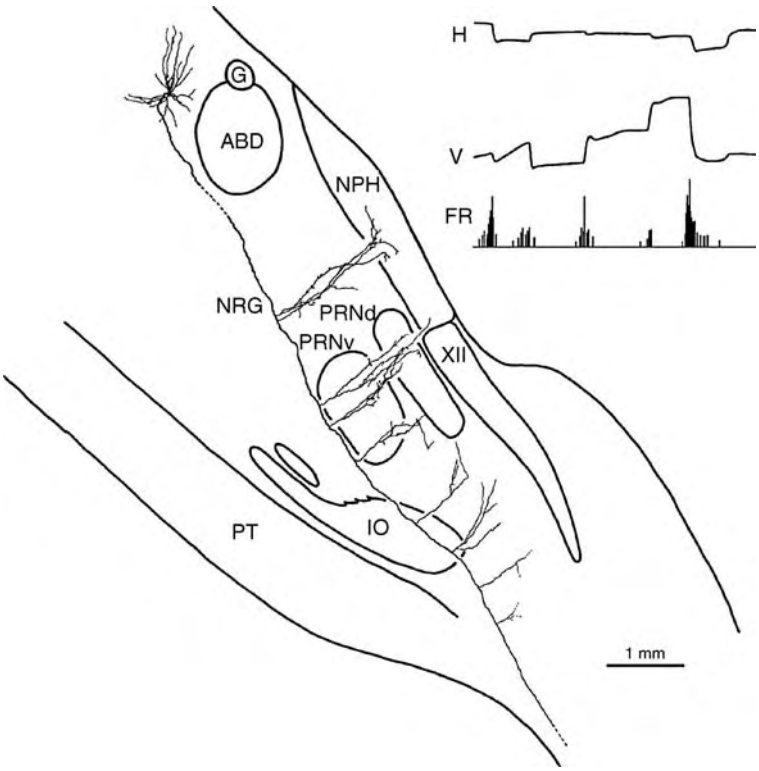
A third group of RS-LLBNs have their somata in the H-fields of Forel – the cat counterpart of the monkey ►rostral interstitial nucleus of the MLF. Called "augmenting neurons" by some, these neurons have a long build up beginning about 200 ms before upward gaze movements. The burst lasts about as long as the head movement in head-free alert cats and has a peak rate that is proportional to head velocity [7]. They also have a low-rate spontaneous discharge that is independent of eye position, and thus are only borderline LLBNs. Projections of augmenting neurons were studied electrophysiologically. Besides projecting to the spinal cord, augmenting neurons project to the midbrain cuneiform nucleus (containing saccade-related neurons) [8] and strongly to reticulospinal neurons both rostral and caudal to the abducens nucleus (NRPc and NRG) [5]. There are more typical LLBNs located at the caudal border of the H fields, but they do not have projections to the spinal cord.

### *Monkey*

Very little research has been devoted to reticulospinal neurons in monkeys. LLBNs have been recorded in NRPc that fire throughout the duration of the head movement in gaze saccades, but their potential spinal projections were not explored. Two groups of confirmed RS-LLBNs have been found in head-stabilized monkeys, but there are surely more than this.

Two RS-LLBNs with their somata in NRPc anterior and ventral to the abducens nucleus had preferred directions that were ipsiversive for one and down for the other [9]. Burst leads averaged 17 and 42 ms, and the number of spikes in the burst increased weakly with saccade size. As the monkeys had their heads stabilized, burst parameters could not be analyzed in relation to head movements. Axons traveled outside the paramedian tracts on their way to the spinal cord, and issued collaterals that innervated NRG, the middle of the prepositus nucleus, the paramedian reticular nuclei (both of which project to the cerebellum), and to the nucleus reticularis ventralis (Fig. 2). With the exception of the soma locations, these RS-LLBNs are similar to the head burst-neurons in the cat (group 2, above).

Three RS-LLBNs had their somata just lateral to the interstitial nucleus of Cajal [10]. All discharged preferentially for upward saccades beginning 25–105 before saccade onset, and the number of spikes increased with increasing saccade amplitude. The axons descended in the MLF and issued no collaterals until the caudal pons. They subsequently innervated raphe pontis, raphe obscurus, and the paramedian reticular nucleus, all of which project to the cerebellum, including oculomotor-related areas



**Reticulospinal Long-Lead Burst Neurons. Figure 2** Camera lucida drawing of a monkey reticulospinal neuron drawn in a parasagittal plane. The large soma is located in the PPRF just rostral to the abducens nucleus (ABD), and the descending axon gives off dorsally-coursing branches that terminate in the medullary reticular formation, the nucleus prepositus hypoglossi (NPH), and the dorsal and ventral paramedian reticular nucleus (PRNd and PRNv). Staining faded as the main axon entered the spinal cord (dotted line). Inset shows the firing rate (FR) of the neuron during saccades, shown as a horizontal component (H) and vertical component (V). Other abbreviations; G = genu of the VIIth nerve, NRG = nucleus reticularis gigantocellularis, XII = hypoglossal nucleus, IO = inferior olive, PT = pyramidal tract. Adapted from Scudder et al. [9].

in the first two cases. Axons additionally innervated ►raphe interpositus and the dorsal NRG, both containing neurons that are part of the saccadic burst generator, and more ventral parts of NRG containing reticulospinal neurons.

Both types of RS-LLBNs have heavy projections to the cerebellum via relay nuclei. These projections are perhaps especially appropriate in the monkey relative to the cat because primates are credited with more flexible eye-head strategies, and could rely on the cerebellum to insure the different combinations of eye and head movements end with gaze directed at the target.

## Lower level Processes

The innervation of the spinal cord has been studied in detail for cat reticulospinal neurons, but not for RS-LLBNs specifically. This is because staining of the intra-axonally filled RS-LLBNs described above always faded before reaching their terminations in the cord. Doubtlessly, RS-LLBNs share some features of the more general innervation. Reticulospinal neurons with somata in NRPc and NRG and receiving input from the superior colliculus project to upper cervical segments, including interneuron and motoneuron pools for the neck (Rexed laminae VII, VIII, IX). Motoneurons that are monosynaptically contacted by these reticulospinal neurons include those innervating the multisegmental dorsal muscles, splenius (a horizontal neck rotator) and biventer cervicis and complexus (a vertical neck rotator). Individual neurons in NRG innervate either splenius or biventer/complexus, but poorly innervate the other. Some NRPc and NRG reticulospinal neurons project to interneurons in the lower cervical segments (innervating forelimbs) and possibly lumbar segments (innervating hindlimbs). Activity in fore- and hind-limb muscles has been observed during orienting movements, but these could be a postural reaction as much as a direct product of orienting behavior. Reticulospinal neurons with somata in the H fields and receiving input from the superior colliculus make monosynaptic connections with biventer cervicis and

complexus motoneurons, but few with splenius, confirming the specificity of the H fields for vertical movements [1,5].

### Pathology

Excitotoxic destruction of the somata of neurons in the cat NRPc and NRG on one side produced severe to moderate deficits in producing ipsiversive gaze saccades, depending on the extent of the lesion. Vertical gaze saccades were also impaired when the head was oriented to the ipsilesional side. The loss of eye-saccades is presumably due to the destruction of the cells of the ►brainstem burst generator, and the loss of head-saccades is presumably due to destruction of the RS-LLBNs. ►Excitotoxic lesions of the H-fields in cats produced debilitating asymmetries in neck muscle tone when done unilaterally, and major deficits in vertical head saccades when done bilaterally. Lesions in humans produced by tumors or infarcts would likely result in more severe deficits due to the destruction of the many fibers of passage as well as destruction of reticulospinal neurons.

## Reticulospinal Neurons in Eye Movements

### Definition

Neurons of the brainstem reticular formation that project to the spinal cord. Anatomical studies have demonstrated that, on their way to the spinal premotor centers, axons of resticulospinal neurons (RSNs) emit numerous collaterals to various oculomotor and vestibular centers.

Together with some superior colliculus (SC) output neurons showing a similar pattern of projections, those RSNs that receive input from the SC are thus ideally positioned to decompose the collicular "desired gaze displacement" signal into motor commands for the eye and head platforms.

►Eye-Head Coordination
►Superior Colliculus

## Reticulospinal Tract

### Synonyms

Tractus reticulospinal ant; Anterior reticulospinal tract

### Definition

The medial reticulospinal tract begins in the caudal pontine reticular nucleus and in the caudal portion of the oral pontine reticular nucleus. It descends in the medial longitudinal fasciculus in the spinal cord. Its fibers terminate mostly in lamina VII and VIII of the spinal gray matter; but they also run in lamina IX in which the motoneurons for the trunk musculature lie.

►Pathways

# Reticulotectal Long-Lead Burst Neurons

Adonis Moschovakis
Institute of Applied and Computational Mathematics, and Department of Basic Sciences, University of Crete, Heraklion, Crete, Greece

## Synonyms

RTLLBs

## Definition

Saccade related long-lead burst neurons of the primate mesencephalic reticular formation (►cMRF) that project to the SC.

## Characteristics

### Higher Order Structure

Although they belong to the reticular formation, due to their location and projections RTLLBs can be thought to belong to a satellite system of the SC.

### Parts of This Structure

Figure 1 illustrates the salient morphological and physiological features of RTLLBs following the intracellular study of their discharge in alert squirrel monkeys, their subsequent injection with a tracer and the camera lucida reconstruction of their axons in the frontal plane [1]. RTLLB somata (Fig. 1b, arrow) are located in an area receiving strong input from saccade related neurons of the SC (see TLLBs). The territory occupied by RTLLB somata probably receive input from additional classes of SC neurons, as indicated by axonal reconstructions of single X neurons of the cat [2,3] and the monkey [4,1]. The axonal terminations of RTLLBs are contained within the intermediate and deeper layers of the SC, in both sides of the brain (Fig. 1b).

### Functions of the Structure

RTLLBs emit bursts of discharge which precede contraversive saccades, whether upward, downward or horizontal (Fig. 1a) by about 20 ms on average. They often do not discharge for saccades in the opposite direction (Fig. 1a, right-most example). Although the on-direction of many RTLLBs is roughly horizontal, the existence of RTLLBs with vertical and oblique on-directions has been documented [1]. The activity of RTLLBs provides a good estimate of the metrics of impending saccades; the correlation coefficient between the number of spikes in the burst, and the amplitude of saccades in their on-direction can be as high as 0.85.

### Higher Order Function

RTLLBs could belong to a highly conserved satellite system of the SC as cells with quite similar morphology have been encountered in lower phyla. Neurons with bilateral projections largely confined to the optic tectum have been found in the nucleus lateralis profundus mesencephali of the snake [5] and the dorsolateral tegmental nucleus in fish [6]. Also, saccade related signals were discovered in the intertectal commissure of fish [7] before the existence of saccade related signals in the superior colliculus of mammals became known. Given their discharge pattern and projections, RTLLBs are eminently qualified to supply the SC with an efference copy signal

(b) Frontal reconstruction of the axonal system of the same neuron from serial sections. (c) The axonal system of the same neuron as it appears when looking down upon the surface of the SC. Scale in (b) applies to both (b) and (c). Abbreviations: *Aq*, aqueduct; *C*, caudal; *MRF*, mesencephalic reticular formation; *PAG*, periaqueductal grey; *R*, rostral; *SGI*, stratum griseum intermediale; *SGP*, stratum griseum profundum; *SGS*, stratum griseum superficiale; *SO*, stratum opticum.

indicative of the metrics of ongoing saccades. Together with the visual input carried by L neurons (see ►SC – interlayer neurons) RTLLBs endow the SC with the machinery needed to implement the Vector Subtraction hypothesis (see ►Foveation hypothesis).

### Quantitative Measure for This Structure

Besides detailed quantitative descriptions of the pattern of their discharge, the 3D spatial distribution of the terminals deployed in the SC by single functionally identified RTLLBs has been described in squirrel monkeys [8]. When overlaid on a horizontal map of the SC, they can occupy a considerable portion of the rostrocaudal and mediolateral extent of its deeper layers (Fig. 1c).

# Retina

## Definition

The light-sensitive layered neural tissue that lines the posterior hemisphere of the eye and contains the photoreceptors (rods and cones) and the initial processing machinery for the primary visual pathways. It is a highly organized structure whose function is to capture, process, and transmit visual images to the brain. The signals generated by photoreceptors are then processed by other neurons in the retina before being transmitted to the brain as trains of action potentials by the axons of the retinal ganglion cells. Additionally, the retina serves to detect changes in ambient levels of light to regulate a multitude of non-visual photoresponses such as the pupillary light reflex.

Retinal bipolar neurons

## Definition

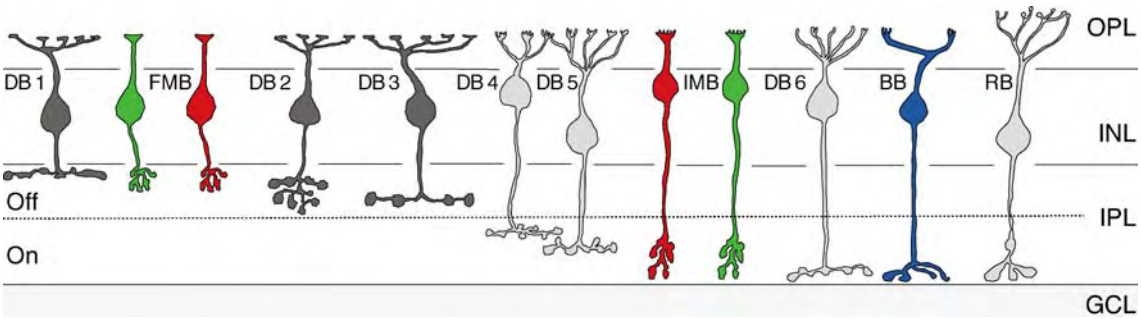
Bipolar cells are interneurons in the ►retina (►Vision), which transfer visual information from photoreceptors (rods and cones; ►Photoreceptors) to amacrine (►Retinal direction selectivity: Role of starburst amacrine cells) and ganglion cells (►Retinal ganglion cells). Bipolar cells consist of multiple (9–12) subtypes that differ in their morphology, synaptic connectivity, and response properties. Different types of bipolar cells process different visual modalities in parallel pathways. The following article describes the structure, distribution, synaptic connectivity, and function of bipolar cells in the mammalian retina.

## Characteristics

### Quantitative Description

#### *Morphology of Bipolar Cells*

The name "bipolar cell" is derived from its morphology. Bipolar cells have a cell body in the ►inner nuclear layer from which a primary dendrite extends into the ►outer plexiform layer and an axon extends into the ►inner plexiform layer (►Vision). Morphologically two major types, cone bipolar and rod bipolar cells, can be distinguished with respect to their connections with photoreceptors (►Photoreceptors). The dendrites of cone bipolar cells contact cone photoreceptors almost



**Retinal Bipolar Cells. Figure 1** Bipolar cell types in primate retina as analysed from Golgi-impregnated macaque retina. The axon terminals stratify at different levels of the inner plexiform layer (IPL). Diffuse bipolar cells (DB1 – DB6) non-selectively contact multiple cones in the outer plexiform layer (OPL). There are two types of midget bipolars, flat midget bipolar (FMB or OFF midget) and invaginating bipolar cells (IMB or ON midget). Both types contact single M- or L-cones and carry a chromatic signal. Blue cone bipolar (BB) cells contact S-cones selectively and carry an S-cone ON signal. Rod bipolar cells contact rod spherules and transfer scotopic signals.

exclusively and are thus involved in high-acuity daytime vision and colour vision (►Color processing). The dendrites of rod bipolar cells contact rod photoreceptors and are involved in night or ►scotopic vision.

Bipolar cells make up about 40% of all retinal neurons (apart from photoreceptors) and are the most numerous interneurons in the retina [1]. Each bipolar type is found across the retina and forms a regular mosaic.

### Diffuse Bipolar Cells

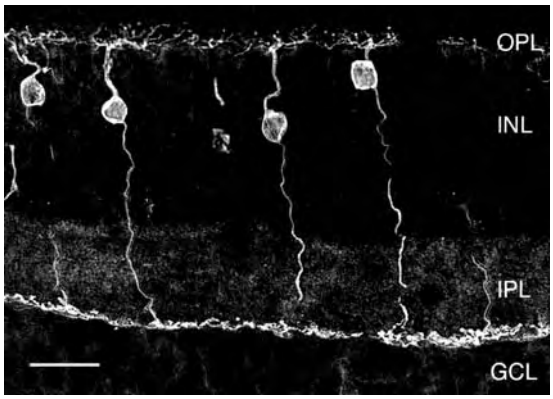
Cone bipolar cells are subdivided into OFF and ON bipolar cells [2]. The OFF bipolar cells hyperpolarise in response to light, whereas the ON bipolar cells depolarise. The axons of OFF bipolar cells stratify in the *outer* half of the inner plexiform layer. The axons of ON bipolar cells stratify in the *inner* half of the inner plexiform layer.

The OFF and ON cone bipolar types are further subdivided into at least nine subtypes with respect to their stratification in the inner plexiform layer and their connections with cones (Fig. 1) [1–6].

Most cone bipolar types contact five to ten cones, and have thus been named *diffuse bipolar* (DB) cells [3]. Some of these subtypes can be selectively labelled with immunohistochemical methods. An example of an immunohistochemically labelled ON bipolar type (DB6) from macaque retina is shown in Fig. 2.

Figure 3 shows the mosaic formed by DB6 cells in whole mount view. The fine dendrites form a dense meshwork across the outer plexiform layer. The somata are located in the outer half of the inner nuclear layer, and the axons tile the retina in a regular mosaic.

In recent years, a number of studies have estimated the density of bipolar cell types using a variety of methods including electron microscopy, Golgi-impregnation, immunohistochemistry, intracellular injection and photofilling [3–5]. The major conclusions from these quantitative studies are that all types have comparable densities

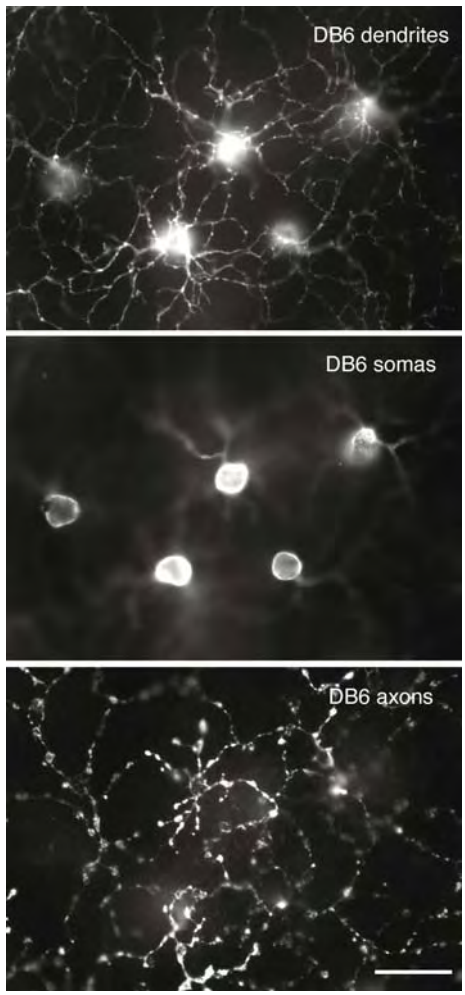


**Retinal Bipolar Cells. Figure 2** Diffuse bipolar cells in primate retina. DB6 cells (Fig. 1) are immunohistochemically labelled. Scale bar: 25 µm.

ranging between 1,000 and 3,000 cells/mm$^2$, and thus no type of bipolar cell usually predominates. The only exception to this rule is the midget bipolar cell in primate fovea (see below). The density of cone bipolar cells is usually lower than the cone density. However, since most bipolar cell types contact multiple cones, it is assumed that all cones provide input to all types of cone bipolar cells [1,3,6].

### Bipolar Cell Types Involved with Colour Vision

Most mammals possess two types of cones, one that is maximally sensitive to short wavelengths of the visible spectrum (S or blue cone), and one that is maximally sensitive to long wavelengths [7]. Mammals with two cone types have dichromatic colour vision. Trichromatic colour vision is based on the presence of a third cone type that is maximally sensitive to medium wavelengths. Among placental mammals, trichromatic colour vision has only been described in primates (►Color processing) [7].



**Retinal Bipolar Cells. Figure 3** Diffuse bipolar cells in primate retina. Whole mount view of immunohistochemically labelled DB6 cells. The cells are shown at different focal levels. Scale bar: 20 µm.

Three types of cone bipolar cells are involved with colour vision: blue cone bipolar cells, and two types of midget bipolar cells. The blue cone bipolar cells (BB, Fig. 1) are ON cells and receive input exclusively from S-cones. The axons of blue cone bipolar cells stratify close to the ganglion cell layer where they provide output to a special type of ganglion cell, the blue ON/yellow OFF ganglion cell [1,3,4,6,8].

Each blue cone bipolar cell receives input from between one and five S-cones (convergence), and each S cone contacts between one and five blue cone bipolar cells (divergence). The maximal density of blue cone bipolar cells is approximately 800 cells/mm$^2$, thus they are among the least numerous bipolar types in the retina.

In mammals, midget bipolar cells [1,3,4,6,9] are probably unique to primate retina where they are thought to play a role in trichromatic colour vision. Midget bipolar cells can be subdivided into ON and OFF types. The ON midget bipolar dendrites make ►invaginating synapses with cones, and have thus been named invaginating midget bipolar (IMB, Figure 1) cells. The OFF midget bipolar dendrites make flat synapses with cones, and are thus called flat midget bipolar (FMB, Fig. 1) cells. In the central retina, each midget bipolar cell receives input from a single cone and in turn contacts one ON or one OFF midget (parvocellular projecting) ganglion cell. Thus, each midget bipolar cell carries the chromatic signal of the cone type it contacts to the inner plexiform layer.

In central retina, midget bipolar cells are the most numerous cone bipolar type. The density of FMB cells was estimated in macaque retina. In central retina, their density follows the cone density (> 10,000 cells/mm$^2$). In peripheral retina, FMB cells contact more than one cone, and thus their density (< 5000 cells/mm$^2$) drops below the cone density [9].

### *Rod Bipolar Cells*

In all mammalian retinae only one type of rod bipolar cell studied to date has been described (RB, Fig. 1). Each rod bipolar cell contacts between ~20 and 100 rod ►spherules (►Retinal ribbon synapses) in the outer plexiform layer. Rod bipolar cells are depolarised by light, and thus are ON cells [2]. The axon terminals of rod bipolar cells are located at the border of the inner plexiform layer with the ganglion cell layer. The axon terminals of rod bipolar cells tile the retina in a non-overlapping mosaic (Fig. 4).

Rod bipolar axons provide output to AII amacrine cells, which then feed the rod signal into cone pathways [2,5,6].

The density of rod bipolar cells varies depending on the retinal location and between species. For example, in cat retina the density ranges between ~20,000 and 46,000 cells/mm$^2$, whereas in rabbit the density ranges between ~2,000 and 5,000 cells/mm$^2$. In macaque retina, rod bipolar cells are absent from the fovea, and the maximal density is ~15,000 cells/mm$^2$ at about 1–3 mm distance from the fovea. Thus, the density of rod bipolar cells is higher than that of individual cone bipolar cell types, but cone bipolar cells outnumber rod bipolar cells in total [1].

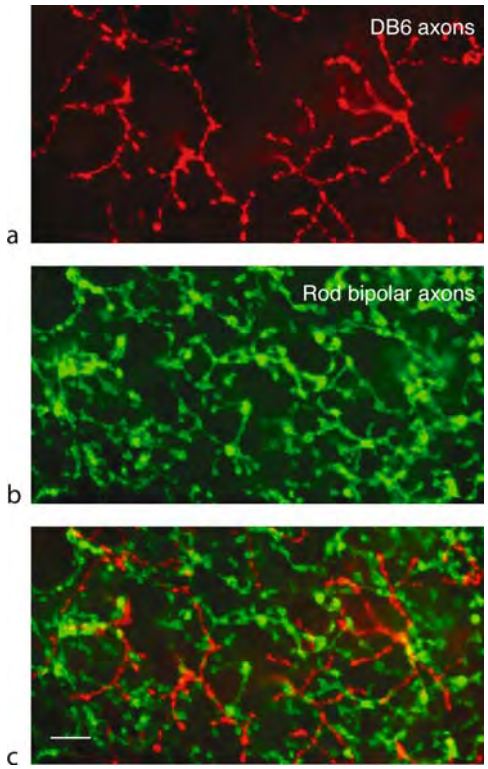
The ratio between rods and rod bipolar cells (numerical convergence) varies between species. It is 10:1 in central macaque retina, 15:1 in the *area centralis* of cat retina, and 50:1 in rabbit retina. However, the divergence between rods and rod bipolar cells is relatively constant. For all species studied, and at all eccentricities, between one and four rod bipolar cells are postsynaptic to each rod.

## Description of the Structure

### *Synaptic Connectivity in the Outer Plexiform Layer*

The synaptic terminal of a rod photoreceptor (rod spherule) is a relatively simple structure. It contains one or two synaptic ribbons (►Retinal ribbon synapses),

which are presynaptic to usually two rod bipolar and two horizontal cell processes at a single synaptic invagination. The rod bipolar cell dendrites form the central elements at this synapse [5].



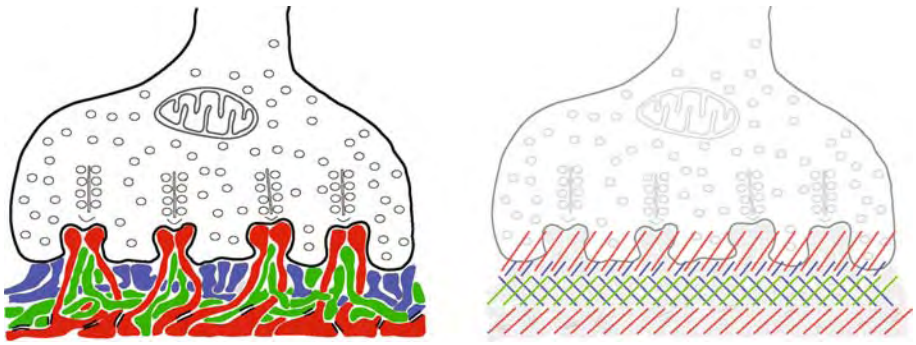
**Retinal Bipolar Cells. Figure 4** Whole mount view of the axonal terminals of two types of ON bipolar cells in primate retina (courtesy of Patricia Jusuf, NVRI, Melbourne). The two types of cell (rod bipolar and DB6) form separate mosaics but might share some postsynaptic cell types. Scale bar: 10 µm.

The synaptic terminal of a cone photoreceptor (cone ►pedicle; ►Retinal ribbon synapses) is a much more complex synapse (Fig. 5a).

It comprises of between 20 and 50 invaginating and several hundred flat contacts. The invaginating contacts consist of a presynaptic ribbon, one or two central elements deriving from ON cone bipolar cells, and two lateral processes deriving from horizontal cells (triad). The ►flat contacts are located at the base of the cone pedicle and derive mostly from OFF bipolar cells. In total, each cone pedicle makes about 500 contacts. The number of postsynaptic cells is lower as some cells receive multiple contacts. About 10–15 individual cone bipolar cells, comprising of a variety of different types, are postsynaptic to a cone pedicle [3]. Thus, at the cone pedicle, the first synapse in the retina, the light signal is distributed into multiple pathways [1,6,10].

Until recently, all invaginating bipolar processes were thought to belong to ON bipolar cells, whereas all flat contacts were thought to belong to OFF bipolar cells. However, in primate this rule applies strictly only to ON bipolar and OFF midget bipolar cells. Most OFF bipolar types make a mixture of both types ofcontact [3]. It is now known that it is the type of ►glutamate receptor expressed at bipolar dendrites that determines whether they are ON or OFF types.

In addition to the layers of invaginating and flat contacts, a third postsynaptic layer has been detected at a distance of about 1.5 µm from the cone pedicle base. This layer consists of junctions that have the appearance of desmosomes ("desmosome-like junctions") but do not contain any known protein normally present at junctions. Instead, these structures are postsynaptic densities that are located on horizontal cell processes and express ionotropic glutamate receptor subunits [10].



**Retinal Bipolar Cells. Figure 5** Schematic drawing of a cone pedicle in macaque monkey retina. (a) Four presynaptic ribbons and four triads are shown. Invaginating dendrites of horizontal cells (red) form the lateral elements, invaginating dendrites of ON bipolar cells (green) form the central elements of the triads. Flat contacts (blue) are mainly made by OFF bipolar cells. Desmosome-like junctions (black bars) are located at a distance of about 1.5 µm underneath the pedicle. (b) The same pedicle with the laminated expression of postsynaptic glutamate (red and blue) and GABA receptors (blue and green) is shown.

### Glutamate and GABA Receptors in the Outer Plexiform Layer

The neurons postsynaptic to photoreceptors express different types of glutamate receptors [6]. The ON bipolar cells express sign inverting metabotropic glutamate receptors (mGluR6) that act via G-proteins. Horizontal cells and OFF bipolar cells express sign conserving ionotropic (►AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid and ►kainate) glutamate receptors.

The ►neurotransmitter of horizontal cells is ►GABA (gamma amino butyric acid). $GABA_A$ and $GABA_c$ receptors are consistently found on the dendrites of bipolar cells. The presence of different types of postsynaptic receptors on different processes at the cone pedicle base results in a laminated arrangement (Fig. 5b) [10].

### Connectivity of Bipolar Cells in the Inner Plexiform Layer

In the inner plexiform layer, bipolar axon terminals form ribbon synapses (►Retinal ribbon synapses) onto two postsynaptic processes (►dyads). Cone bipolar axons usually contact one amacrine and one ganglion cell process, whereas rod bipolar axons do not contact ganglion cells but form dyads onto two amacrine processes, one of which belongs to the ►AII amacrine cell [2]. Different types of diffuse bipolar cells form different numbers of output synapses [5], but relatively little is known about the identity of their postsynaptic targets.

Bipolar axons make excitatory (sign-conserving) glutamatergic synapses. The two postsynaptic processes at a bipolar dyad usually express two different types of ionotropic glutamate receptors (AMPA, kainate and ►NMDA) [6].

The synaptic input to bipolar cells in the inner plexiform layer derives from amacrine cells containing the inhibitory neurotransmitters GABA or ►glycine. The axon terminals of different bipolar types vary with respect to the expression, subunit composition and frequency of $GABA_A$, $GABA_C$ and glycine receptor clusters [1,6].

## Higher Level Structures

OFF bipolar cells transfer their signals to OFF ganglion cells, whereas ON bipolar cells contact ON ganglion cells (►Retinal ganglion cells). The ganglion cells then transfer the bipolar signals to distinct regions in the brain. As bipolar axons stratify in distinct strata of the inner plexiform layer, they can only contact ganglion cells stratifying in the same stratum [1]. Some bipolar types provide input to only one type of ganglion cell (e.g., midget bipolar to midget ganglion cells in primate; CD15-OFF bipolar cells to ON-OFF direction-selective ganglion cells in rabbit (►Retinal ganglion cells; ►Retinal direction selectivity: Role of starburst amacrine cells) [4]. Some ganglion cell types receive input from only one bipolar type (e.g., midget ganglion cells). Other bipolar cell types contact more than one type of ganglion cell, e.g., DB3 cells in primate retina presumably contact OFF parasol (►magnocellular pathway) and the outer (OFF) tier of small bistratified cells (►koniocellular pathway) [3]. Finally, several types of bipolar cells can provide input to the same type of ganglion cell, e.g., cat alpha and beta cells, primate parasol cells and direction-selective cells in rabbit retina (►Retinal ganglion cells; ►Retinal direction selectivity: Role of starburst amacrine cells) [1].

## Function

Different morphological types of diffuse bipolar cells play different functional roles [6]. Physiological differences could be based on the presence of different types of glutamate receptors on bipolar dendrites, as well as distinct patterns of inhibitory input from horizontal and amacrine cells. For example, the type b2 and b3 OFF bipolar cells in the ground squirrel stratify at different levels of the inner plexiform layer and express distinct types of ionotropic glutamate receptors in the outer plexiform layer. The b2 cells express AMPA receptors and are involved in the transmission of transient responses to light. The b3 cells express kainate receptors and are involved with sustained light response. Studies in tiger salamander showed that different types of bipolar cells, with axon terminals at different levels of the inner plexiform layer, differ with respect to their light response characteristics. The idea that parallel streams in the visual system first diverge at the level of the outer flexiform layer is thus supported in all retinas studied so far (►Visual processing streams in primates). The question why the brain requires multiple afferent signals streams, and how these distinct streams are processed in the brain, remains a major challenge for visual neuroscience.

## Definition

### Color Vision in the Retina

The eyes of nearly all animals contain multiple classes of cone photoreceptor (►Photoreceptors), and the ability to discriminate objects by their ►spectral reflectance (►Color processing) is an almost universal feature of animal visual systems studied so far. The neural processes that give rise to color sensations begin in the retina, where certain neurons show selectivity for distinct regions of the visible spectrum. Color is not a property of objects or of retinal processes, but is a result of the brain's ability to interpret these neural signals. Humans and other primates normally show tri-variant (►trichromacy) color vision whereas most other mammals show more rudimentary (►dichromacy or "red-green color blind") color vision.

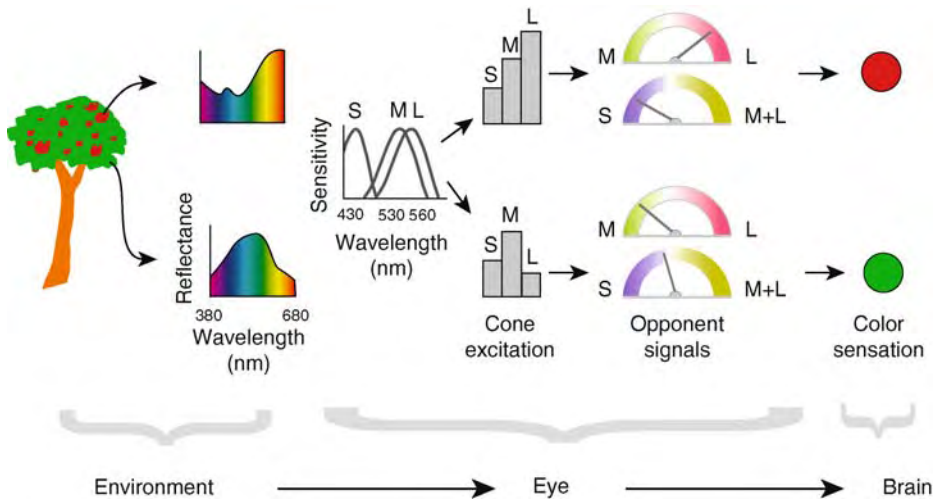
## Characteristics

### Description of the Process

#### *Encoding Spectral Signals*

Most humans show trichromatic color vision. This means that the eye contains three distinct classes of cone photoreceptors that are sensitive to different wavelength ranges in the visible spectrum, and that differential activation of these photoreceptors can be analyzed by the brain to yield color sensations. The cone photoreceptors are active under ►photopic (daylight) conditions whereas ►scotopic (night) vision is served by a single class of rod photoreceptor and thus is color blind (►color blindness).

Figure 1 gives an overview of spectral signal processing in the primate retina. Objects in the environment (in this example, a fruit-bearing tree) reflect more or less strongly the incident ►photons in the visible spectrum (the visible range is approximately 400–700 nm in the electromagnetic spectrum). For example (Fig. 1), a ripe red fruit on the tree reflects more long-wavelength photons than a green leaf on the tree, but the leaf will reflect more medium-wavelength photons than the fruit does. The shapes of these reflectance curves are determined by the physical-



**Retinal Color Vision in Primates. Figure 1** First stages of color vision. From *left* to *right*: objects in the environment show different reflectance spectra (in this example, the *upper row* shows fruit and the *lower row* shows foliage). These spectra are integrated into three separate wavelength bands by the short (S), medium (M) and long-wavelength (L) sensitive cones. The cone excitations are transformed into two cone-opponent signals (M − L) and (S − [M + L]) for transmission to the brain. The brain interprets these signals to yield color sensations.

chemical properties of the objects, and the spectrum and intensity of the light that illuminates the objects. Thus, color is not a property of the objects *per se* but is a result of the brain's ability to interpret the spectral reflectance of an object, relative to the reflectance of other objects in the ►visual field. This is the most important fact to learn about color vision and is an essential prerequisite for understanding spectral processing in the retina.

The first stage of vision is the transduction of light by photoreceptors (►Phototransduction). Each cone photoreceptor expresses one of three types of proteins called cone ►opsins, which together with the vitamin A derivative 11-cis-retinal form the only light-dependent stage of vision. The amino acid sequence of the opsin "tunes" its spectral sensitivity towards the short (peak ~430 nm), medium (~530 nm) or long (~560 nm) wavelength regions of the spectrum [1]. In other words, the probability of photon absorption is maximal at one of three constant positions in the spectrum, yet each receptor absorbs photons across a wide band of the visible spectrum (Fig. 1). Because the absorption spectra are broad, wavelength is confounded with intensity in each receptor's response. For example, a bright light at 500 nm or a dim light at 430 nm could produce identical photon absorptions by the short-wavelength sensitive (S) cones. It is only by comparing the output of different receptor classes that specific information about wavelength can be recovered. The photoreceptor responses or "cone excitations" are thus shown as the relative heights of the bars in Fig. 1, because each receptor effectively ignores the wavelength of absorbed photons across its sensitivity range. In summary, the ripe fruit on the tree yields a red sensation because it activates long wavelength sensitive (L) cones more than it activates the medium– (M) and short wavelength-sensitive (S) cones, whereas a leaf on the tree appears green because it activates the M cones more than the L or S cones. The reflectance spectra of these objects are collapsed into this trivariant, or trichromatic, signal at the first stage of color vision.

### Neural Signals Underlying Color Sensations

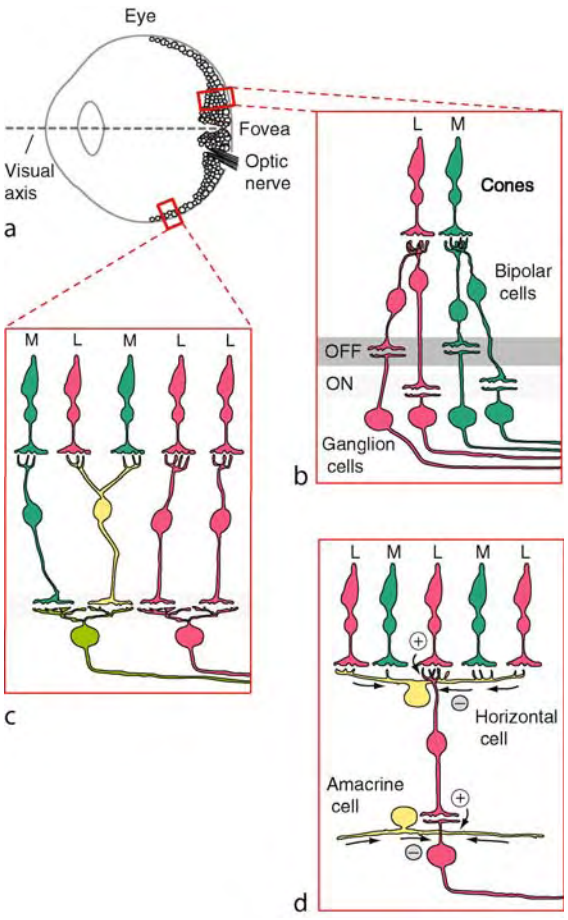
How are the signals that enable color sensations transmitted to the brain? The retinal structures described in the following sections yield two main signals called "►cone opponent" signals (Fig. 1). This term conveys the idea that activity of one cone type is subtracted from or "opposes" the activity of another cone type. One opponent channel pits the activity of M against L cones, the other pits the activity of S cones against a combination of M and L cones. Distinct anatomical pathways in the retina form the substrate of these opponent channels. For simplicity these are often referred to as "red-green" and "blue-yellow" pathways in the retina, although the perceptual color axes do not correspond exactly to the cone-opponent axes. It is also important to note that most retinal neurons respond to changes in either brightness (intensity) or color (relative spectral reflectance) of a stimulus, so do not form exclusive color-detecting channels [2] (►Color processing).

### Red-Green Pathways in the Retina

There is general agreement that the so-called "midget-parvocellular projecting" retinal pathway carries the M-L opponent signals which serve the red-green axis of color vision. This pathway forms the dominant output of the primate retina (it comprises ~80% of all ►optic nerve fibers), and carries signals serving high-acuity spatial vision in addition to signals for red-green color vision. The genes encoding M and L cone opsins diverged relatively recently in the evolutionary history of primates, yielding trichromatic color vision from the primordial dichromatic system thought to be common to most mammals [1,3]. The evolution of high-acuity spatial vision in primates may have enabled the more recent evolution of red-green color vision [4,5]. The idea is illustrated in Fig. 2. Figure 2a shows a schematic drawing of the primate eye, with the eye's output neurons (►Retinal ganglion cells) concentrated near the point of highest visual acuity (the ►fovea). The M and L cones are very tightly packed near the fovea to enable this high acuity, and each cone makes contact with two bipolar cells (►Retinal bipolar cells) of the midget-parvocellular pathway in addition to contacting other bipolar cells [6]. One of the midget bipolar cells responds to brightness decrements (off-type response) and the other responds to brightness increments (on-type response). These connections show one-to-one specificity (Fig. 2b), so the spatial acuity of the cone array can be preserved at subsequent processing stages. The spectral (M or L) signature of each cone in the array will likewise be preserved by this chain of excitatory synaptic connections, and yields four response signatures in midget-parvocellular cells: red-on, red-off, green-on and green-off. The red-green color signals thus are "piggybacked" on the system for high-acuity spatial signals.

The anatomical organization of the midget-parvocellular pathway in the peripheral retina is shown in Fig. 2c. Here, many of the midget bipolar cells make contact with two or more cones and will receive a mixed spectral signal if they contact cones of different type. The bipolar cells likewise make convergent connections with ganglion cells (Retinal ganglion cells) [2,7]. The spatial acuity and spectral purity of ganglion cell signals should thus decrease in the peripheral retina, and both spatial acuity and red-green color vision in the peripheral visual field are correspondingly poor [8].

How do the cone opponent properties of midget-parvocellular ganglion cells arise? Inhibitory interneurons (►horizontal cells and ►amacrine cells) are the most



**Retinal Color Vision in Primates. Figure 2** Red-green chromatic pathways in the eye. (a) schematic cross section of the eye showing concentration of ganglion cells near the fovea (F) on the visual axis (dashed red line). Ganglion cell axons form the optic nerve. (b) connections of midget-parvocellular pathway neurons near the fovea. Each cone is contacted in a one-to-one fashion by both on-type and off-type midget bipolar cells. The bipolar cells in turn contact midget ganglion cells. (c) connections of midget-parvocellular pathway neurons in mid-peripheral retina. For simplicity, only on-type connections are shown. Some midget bipolar cells receive convergent input from multiple cones, and most ganglion cells receive convergent input from multiple bipolar cells. Both these convergent steps will degrade the spectral purity of the ganglion cell response. (d) organization of inhibitory inputs to midget-parvocellular pathway ganglion cells. Horizontal cells and amacrine cells make widespread connections and feed mixed spectral signals to ganglion cells.

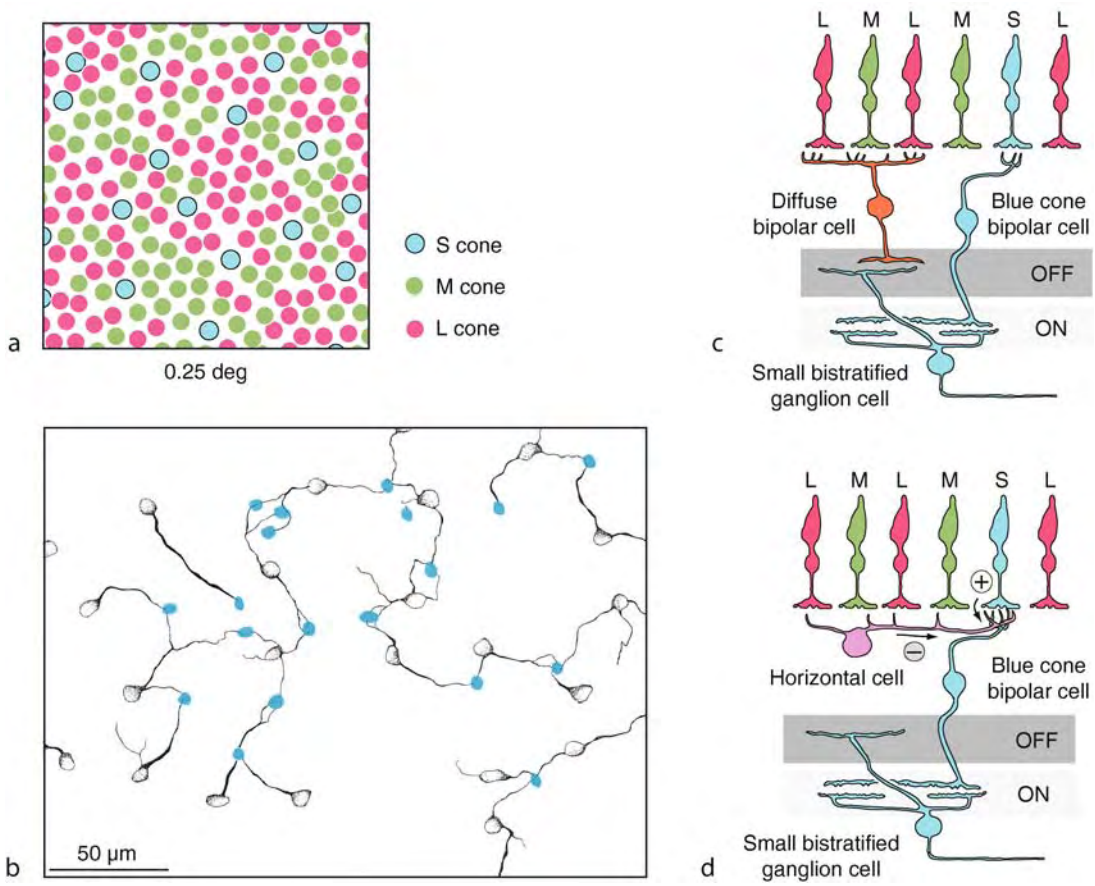
likely source of the opponent cone signals (Fig. 2d). One subtype of horizontal cell in primate retina (the H1 subtype) collects signals from M and L cones and provides feedback inhibition to these cones as well as to bipolar cells [2,7]. Anatomical connections of amacrine cells with midget-parvocellular ganglion cells are less well-understood, but as is the case with horizontal cells, amacrine cells should pool spatial signals originating in large numbers of M and L cones. Both these cell types thus provide a spectrally mixed inhibitory input to antagonize or "oppose" the spectrally pure (in the fovea) or biased (in the peripheral retina) excitatory inputs from midget bipolar cells.

There is functional (physiological) evidence that both excitatory and inhibitory inputs to parvocellular ganglion cells show greater spectral selectivity than predicted by the pure "random wiring" scheme outlined above, but to date there is no direct anatomical evidence for cone-selective connections in the midget-parvocellular pathway [2,7]. This functional selectivity likely arises from subtle changes in the strength of synaptic connections rather than specific wiring between specialized cell classes, of the type described below for the blue-yellow retinal pathway.

### *Blue-Yellow Pathways in the Retina*

The short wavelength sensitive (S) cones form less than 10% of all cones in the primate retina (Fig. 3a). Molecular studies show that a distinct S cone pigment emerged before the mammalian radiation, and thus could form the basis for a primordial color vision system in mammals [1,5]. The main synaptic output of S cones in primates is to a single class of bipolar cell called the *blue cone bipolar cell*. These bipolar cells form a specific network contacting S cones (Fig. 3b) and transmit on-type signals (corresponding to increases in the ▶photon catch of S cones) from the S cone array. The blue cone bipolar cells contact a specific class of ganglion cell called the small bistratified (blue-on) cell. The small bistratified cells get excitatory input from S cones and inhibitory input from M and L cones, to yield a "blue-on, yellow off" cone opponent response [9]. There are two sources of inhibition from M and L cones. First, the small bistratified cell receives synaptic input from off-type diffuse bipolar cells, which contact predominantly M and L cones. Second, the S cones and the blue-cone bipolar cells receive inhibitory input from the H2 subtype of horizontal cell, which gets synaptic input from all cone types. This spectrally mixed inhibitory input opposes the spectrally pure S cone input to blue cone bipolar cells [7]. The selective connections of S cones with blue cone bipolar cells and H2 horizontal cells are preserved across the primate retina, so the deterioration in blue-yellow chromatic sensitivity with increasing visual field eccentricity is not as marked as the deterioration in red-green sensitivity [8].

The question how off-type signals from S cones are transmitted to the brain has not been fully resolved. At least two types of sparsely-branched or "wide field"



**Retinal Color Vision in Primates. Figure 3** Short-wavelength sensitive (S) cone pathway. (a) fragment of the cone photoreceptor mosaic in macaque retina [modified from ref. 15]. (b) connections of blue-cone bipolar cells (*grey*) with S cones (*blue plaques*) in marmoset retina [modified from ref. 16]. The dendrites of blue cone bipolar cells make dominant contact with S cones. (c) schematic vertical section through primate retina showing connections of a small bistratified (blue-on) ganglion cell with blue cone bipolar and diffuse bipolar cells. (d) a second source of cone opponent inputs to blue-on ganglion cells arises from inhibitory feedback by the H2 subclass of horizontal cell.

ganglion cells show blue-off type responses, and presumed targets of these cells in the brain show large receptive fields [7,10]. One of these cell types also shows intrinsic, melanopsin-based photosensitivity and may contribute to ►circadian entraining as well as to color vision [7,11]. Connections from S cones to off-type midget bipolar cells have been reported in macaque fovea, but S cones in marmoset retina make negligible connections to midget cells and only sparse connections with diffuse, off-type bipolar cells [6,12]. Whether these differences reflect true species differences or methodological differences is not yet clear.

In summary, there is clear evidence for a selective network transmitting on-type signals from S cones to the brain to yield a "primordial" dichromatic color vision channel. A specific network of S cone connections to bipolar cells has also been shown in mouse retina [13], and the question whether this or other elements of S-cone circuits are common to other diurnal mammals has become an interesting topic in comparative neurology.

## Higher Level Processes

### *Central Targets for Chromatic Signals*

The main target for all ganglion cell axons in primates is the dorsal ►lateral geniculate nucleus (LGN) of the ►thalamus. The dominant input to the parvocellular layers of the LGN is from midget ganglion cells, and accordingly in trichromatic primates most parvocellular cells show red-green chromatic opponent properties. Geniculocortical relay cells (►Geniculostriate connections) in the parvocellular layers project to granular layer 4Cβ in the ►primary visual cortex. By contrast, blue-on and blue-off type responses are segregated to the intercalated or koniocellular division of the LGN [10]. Koniocellular relay cells show relatively diffuse

cortical projections including supragranular layers 3 and 4A in the primary visual cortex: consistently, blue-on and blue-off type responses of presumed geniculate afferents can be recorded from these layers [14]. The two chromatic streams thus remain segregated at least to the early stages of cortical processing, and the mechanism by which these channels combine to enable color perception remains an outstanding and fascinating topic in neuroscience.

# Retinal Direction Selectivity: Role of Starburst Amacrine Cells

Susanne Hausselt, Thomas Euler
Department of Biomedical Optics, Max-Planck Institute for Medical Research, Heidelberg, Germany

## Definition

### Direction-Selectivity in the Retina

Computing the direction of image motion is an essential task for the visual system. The retina's ability to detect the direction of image motion (►direction selectivity or DS) was first described more than 40 years ago [1]. ►Direction-selective ganglion cells (DSGCs) (►Retinal ganglion cells) fire vigorously when a stimulus is moving in a certain direction ("preferred"), while remaining silent when the same stimulus moves in the opposite ("null") direction (Fig. 1). ►Starburst amacrine cells (SACs) [2,3] are retinal interneurons closely intertwined with the direction-selective circuitry in the retina. While there is common consensus that SACs are crucial for the computation of motion direction, the exact nature of their involvement is still controversial. For review and further reading see [4,5].

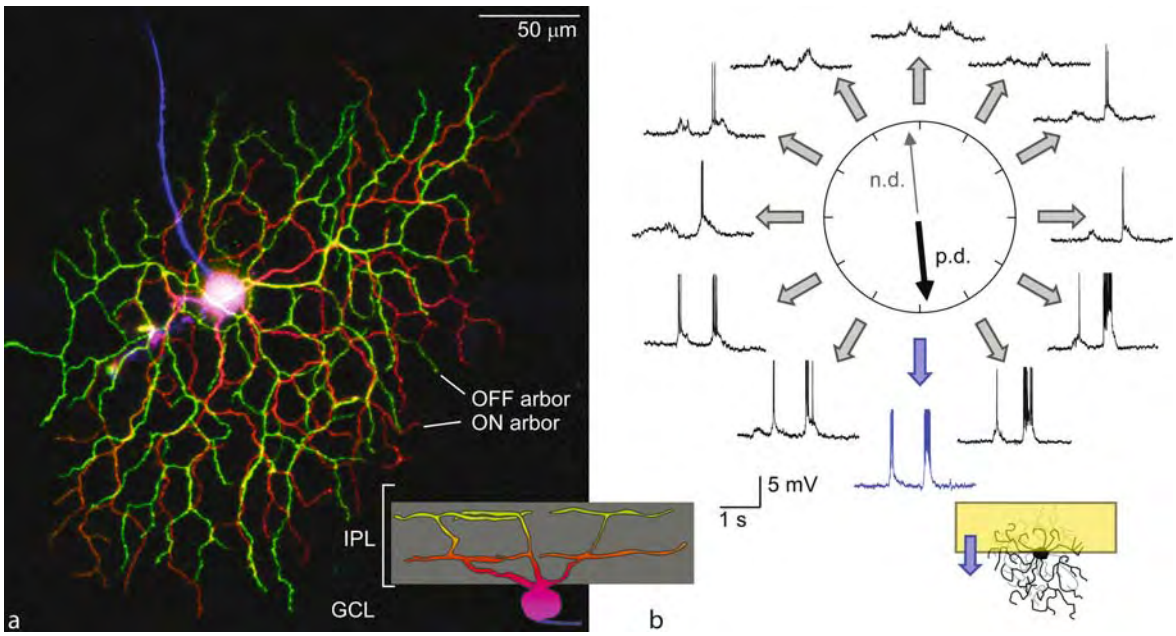
## Characteristics

### (Quantitative) Description

#### *Direction-Selective Ganglion Cells (DSGCs)*

Direction-selective ganglion cells (►Retinal ganglion cells) have been primarily studied in rabbit retina, where they account for 10% of the ganglion cells. They have functionally and morphologically equivalent counterparts in other mammals and in non-mammalian vertebrates. Most research has focused on the ON/OFF DSGC (Fig. 1a), which has a bistratified dendritic tree with one arborization in the outer half (the OFF sublamina) of the ►inner plexiform layer (IPL), and another arborization in the inner half (the ON sublamina) of the IPL.

This arrangement allows responses to the direction of image motion of dark objects on a light background – mediated by the OFF arbor – as well as to objects brighter than the background – mediated by the ON arbor. The cell comes in four functional subtypes, each preferring one particular direction of motion (as an example see Fig. 1b). A second type of retinal direction-selective cell is the monostratified ON DS ganglion cell, which prefers one of three particular directions (see *Function*). Each DSGC subtype tiles the retina with little dendritic overlap making directional information for any of the preferred directions available at every retinal location.

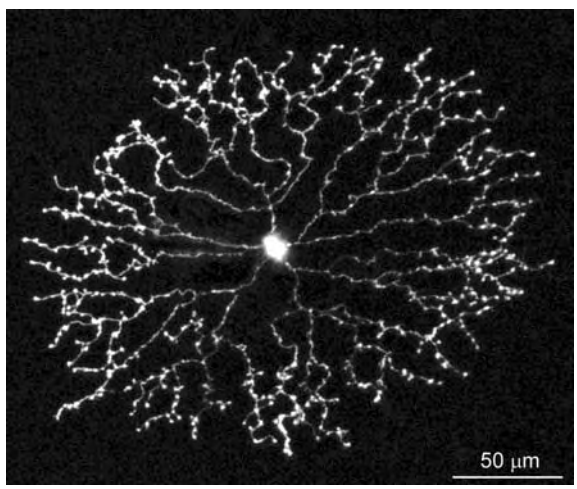


**Retinal Direction Selectivity: Role of Starburst Amacrine Cells. Figure 1** (a) Fluorescent dye-injected ON/OFF direction-selective ganglion cell in a flat mounted rabbit retina (pseudo-color codes retinal depth). The two dendritic arbors stratify in the ON (red) and OFF (green) sublaminae of the IPL. (b) Electrical responses of a DSGC to a bar moving in 12 directions across its receptive field (see inset): both the leading (ON) and the trailing edge (OFF) of the bar elicit responses (p.d.: preferred, n.d.: null direction).

### *Starburst Amacrine Cells (SACs)*

The dendrites of SACs closely co-fasciculate with the dendrites of DSGCs, and therefore have long been implicated in the computation of direction selectivity. (Strictly speaking, SAC neurites are not dendrites as they not only receive input, but also make output synapses – this is the case for most amacrine cells.) Unlike most other retinal neurons, SACs display a tremendous dendritic overlap (30–70 fold coverage) and, hence, offer plenty of "substrate" to provide the different DSGC subtypes with adequate neural circuitry. When SACs are removed from the circuitry, e.g., by gene-targeted cell ablation [6], direction-selective responses in DSGCs are abolished, confirming that SACs play a crucial role for direction-selectivity.

Starburst cells have been found in non-mammalian and mammalian species including primates. SAC morphology is well conserved among species: several primary dendrites radiate symmetrically from the soma before dividing into smaller branches (Fig. 2). The distal third of the branches is decorated with bead-like swellings (varicosities) [3]. SACs contain two transmitters, ►γ-aminobutyric acid (GABA) and ►acetylcholine (ACh). Due to the presence of ACh, they are also called "cholinergic amacrine cells." Two subtypes of SACs exist: OFF SACs co-stratify with the OFF dendritic arbor of the ON/OFF DSGCs, whereas



**Retinal Direction Selectivity: Role of Starburst Amacrine Cells. Figure 2** Starburst amacrine cell in a flat mounted rabbit retina injected with a fluorescent dye. The cell's morphology is reminiscent of a "starburst" fireworks display.

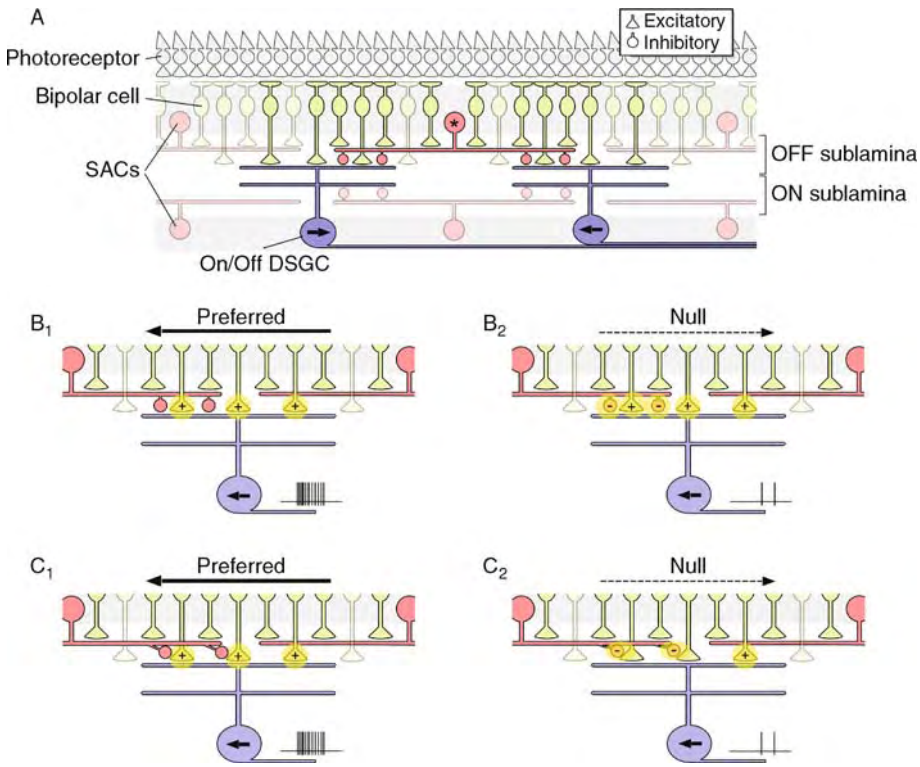
ON SACs co-stratify with the ON dendritic arbor of the ON/OFF DSGC and the ON DSGC dendritic arbor. Despite the opposite polarity of their light responses, ON- and OFF-SACs are considered functionally equivalent.

## Description of the Process

As recognized in the first studies on DSGCs in rabbit retina [1], the generation of direction-selectivity could be attributed to spatially offset inhibition biased towards the "null" direction. This proposal assumes asymmetrical wiring, such that the DSGC receives inhibition preferentially from interneurons displaced to one side of its ►receptive field (Fig. 3a). It was proposed that motion in the "null" direction triggers inhibition (via the spatially displaced interneurons) before the stimulus reaches and excites the DSGC directly. If the inhibition is sufficiently delayed or, alternatively, long-lasting, it will coincide with the direct excitation and prevent the DSGC from responding. Motion in the opposite ("preferred") direction, on the other hand, will also trigger inhibition, but too late to prevent the DSGC from responding.

### *Pre- or Postsynaptic*

It was originally proposed that direction-selectivity is computed by such a delay-based "veto"-mechanism from non-directional inputs in the DSGC itself. Detailed electrical recordings from DSGCs (reviewed in [5]), however, revealed that the inputs that DSGCs receive are already directionally tuned, with inhibitory input being larger for "null" direction motion, and excitatory input being larger for "preferred" direction motion. While is consistent with spatially offset inhibition in general, this finding suggests that the DSGC's response is substantially determined by the ratio of excitation and inhibition, and less by their temporal sequence in the DSGC, as originally proposed. More importantly, this indicates that direction-selectivity is already computed in interneurons presynaptic to the DSGC. Postsynaptic processing in the dendrites of DSGCs essentially supplements the



**Retinal Direction Selectivity: Role of Starburst Amacrine Cells. Figure 3** (a) Schematic retinal cross section illustrating the direction-selectivity circuitry. The central SAC (*) serves (here: inhibits) two DSGCs with opposite preferred directions (indicated by arrow). For simplicity, cholinergic input, other amacrine cells involved and connections in the ON sublamina of the IPL are omitted. Proposed direction-selectivity mechanisms: (b) *Direction-selective inhibition*: preferred motion (i) elicits a response in the DSGC, because the left SAC's dendrite, which is connected to the DSGC, is not activated by this motion direction, while the right SAC's dendrite is activated but not connected. Null direction motion (ii) elicits no response in the DSGC, because the left SAC's dendrite is activated and inhibits the DSGC. (c) *Direction-selective excitation*: the left SAC (or, alternatively, another amacrine) inhibits the excitatory input from bipolar cells presynaptically to the DSGC for null direction motion [2], but not for preferred direction motion [1]. A similar mechanism could also be implemented via excitatory (cholinergic) connections from SACs.

presynaptic direction-selective mechanisms by sharpening the directional tuning.

### Multiple Mechanisms

Retinal direction-selectivity is largely independent of contrast, mean brightness and velocity of the stimulus. This robustness alone suggests that different mechanisms at multiple levels participating in the generation and amplification of direction-selectivity [reviewed in 5]. This is also reflected by the fact that both inhibitory and excitatory inputs to DSGCs are by themselves direction-selective.

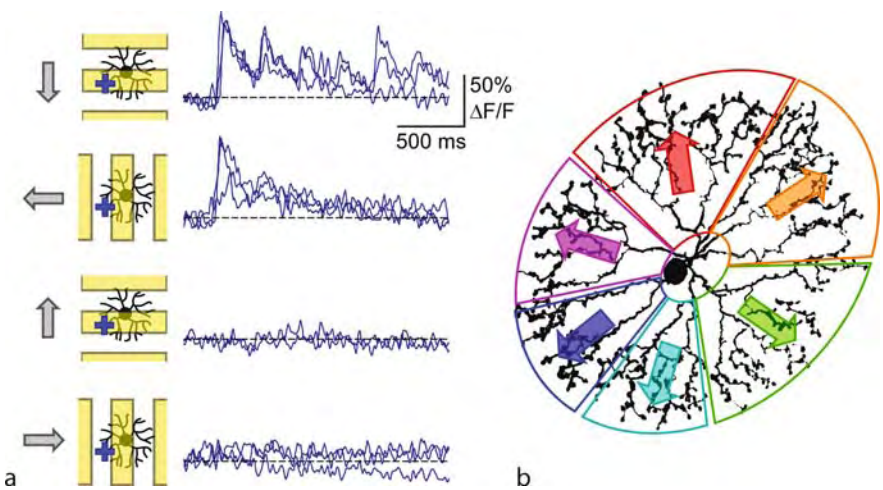
### Direction-Selective Inhibition

Pharmacologically blocking ►$GABA_A$ receptors has consistently been shown to abolish direction-selectivity in DSGCs, indicating that the direction-selective inhibition is mediated by GABAergic input [8]. This GABAergic input is at least partially provided by SACs (Fig. 3b). More importantly, light-evoked $Ca^{2+}$ signals optically recorded in the distal SAC dendrites are direction-selective (Fig. 3a) [9]. Thus, it is highly likely that GABA release from SACs is also direction-selective, because the SACs' output synapses are located in the distal dendrites [3], and their GABA release has been shown to be $Ca^{2+}$-dependent [10]. Furthermore, SACs appear to make direct GABAergic synapses with DSGCs, which seem to be highly asymmetrical and fit the requirements for spatially offset inhibition. Paired recordings have shown that DSGCs receive inhibitory synaptic input from SACs located on the "null side" of the DSGC's receptive field, but do not receive synaptic input from SACs on the "preferred side" [11]. Alternatively, (additional) directionally tuned inhibitory input may come from other, yet to be identified amacrine cells; however, direct evidence for this is lacking so far.

### Direction-Selective Excitation

The excitatory input to DSGCs is ►glutamatergic as well as cholinergic. The glutamatergic input comes from bipolar cells (►Retinal bipolar cells) and appears to be directionally tuned, but it is not yet clear by which synaptic circuitry. Such tuning could result from suppression of bipolar cell activity for "null" direction motion (Fig. 4c); however, it is not known which amacrine cell could supply the required spatially offset inhibition to the bipolar cell terminals. The SAC is a potential candidate, and ultrastructural evidence for SAC output onto bipolar cell terminals does exist, but such contacts seem to be too sparse [3]. Alternatively, bipolar cell activity could be enhanced by motion in the "preferred" direction (facilitation), but again an appropriate pathway has not yet been unequivocally identified.

It is likely that DSGCs receive excitatory input from SACs via cholinergic synapses, because DSGCs express ►ACh receptors. ACh receptor blockers reduce the firing of DSGCs, and SACs are considered the only source of ACh in the retina [2]. Since ACh release from SACs is $Ca^{2+}$ dependent and SAC dendritic $Ca^{2+}$ signals are direction-selective, one would expect that ACh release is also direction-selective. Nonetheless, the cholinergic pathway is enigmatic in several ways (reviewed in [4]): Laser ablation of SACs on the preferred side of a DSGC reduced its excitatory input. However, paired recordings of SACs and DSGCs failed to show direct cholinergic connections [11]. Blocking ACh receptors appears to reduce direction-selectivity in



**Retinal Direction Selectivity: Role of Starburst Amacrine Cells. Figure 4** (a) Dendritic $Ca^{2+}$ responses (as relative change in fluorescence ΔF/F) optically recorded from a distal SAC dendrite to a bar grating moving in four different directions. Only motion from the soma roughly towards the tip of the imaged dendrite (indicated by a blue cross) elicits a response (from [9], Fig. 4a, modified). (b) SAC dendritic branches signal centrifugal motion.

DSGCs for certain stimuli (like bar gratings). On the other hand, in the presence of GABA receptor blockers, ACh antagonists reduce DSGC responses independent of motion direction, suggesting that cholinergic excitation is symmetrical [12].

## Higher Level Processes

### Direction Selectivity from Network Interactions

Various models of retinal direction-selectivity are based on network interactions to explain the generation of the direction-selective signals observed in the DSGCs (reviewed in [4,5,13]. The models differ in the complexity of interactions, and by the number and types of neurons recruited, but the basic principles are similar: spatially offset inhibition and asymmetrical wiring. Depending on the model, the spatially offset inhibition is provided by SACs or by not yet identified amacrine cells. In either case, most, if not all, network models assign some central role to SACs, ranging from simply relaying signals to DSGCs to providing essential direction-selective output. As a general mechanism for rendering signals direction-selective, both facilitation and suppression have been suggested.

### SAC Networks

Starburst cells form a network with attractive properties. Reciprocal cholinergic excitation among SACs is prominent in the developing retina, but seems to be strongly reduced during retinal maturation. GABAergic interactions between neighboring SACs are prominent in the adult retina, and have long been suspected to be crucial for the generation of direction-selectivity (e.g., [13]). An excited SAC inhibits its neighbors, which in turn reduces their inhibition onto the first SAC, and effectively amplifies excitation. Thus, SAC dendrites pointing in the same direction could stabilize each other's responses. Such network interaction may well serve to enhance DS [10]. Nonetheless, GABAergic inhibition appears not to be pivotal to render SAC output direction-selective, because blocking GABA receptors does neither abolish direction selectivity in the SACs' dendritic $Ca^{2+}$ not in their somatic volatage response [14].

## Lower Level Processes

### Direction Selectivity from Intrinsic SAC Properties

While in the network models direction selectivity arises primarily from neuronal interactions, a second group of models suggests that direction selectivity is initially generated in SAC dendrites as a result of intrinsic properties. Note that network models and intrinsic models are not necessarily mutually exclusive, but rather complementary.

At first glance SACs appear to be very symmetrical neurons (Fig. 2), which seems to disagree with the role of a detector of motion direction. In fact, SACs are better viewed as a collection of "wedge-shaped" direction detectors represented by the primary dendrites (Fig. 4b). The dendritic branches are largely electrically isolated and respond independently to local light stimulation [8]. Thus, they can be considered as largely "autonomous" computational units [14]. In contrast to the whole cell, the dendrites are indeed highly polarized structures. Synaptic inputs and outputs are differentially distributed along the dendrites: input synapses are located along the whole length, whereas output synapses are associated with the varicosities on the distal third of the branches [3]. Each principal branch responds more strongly to centrifugal motion (towards the dendritic tips) than to centripetal motion (towards the soma) [8], thus displaying dendritic direction selectivity. The mechanism underlying dendritic direction selectivity in SACs is not yet fully understood. Several "cell-autonomous" models of SAC dendritic direction selectivity have been proposed, each of them employing different (but not necessarily mutually exclusive) intrinsic mechanisms and properties.

*Morphology and Amplification.* Computational studies have suggested that the starburst dendrite morphology, with its steady increase of input synapses towards the dendritic tips, would generate a weak direction-selective dendritic signal by itself (e.g., [13]). This small direction-dependent difference in membrane potential (►Membrane potential – basics) could be amplified by other mechanisms, such as differential activation of voltage-gated channels. Starburst cells express several types of voltage-gated $Ca^{2+}$ channels (►Calcium channels – an overview) that would be suitable. Support for this comes from the fact that blocking $Ca^{2+}$ channels that are predominant on SACs abolishes direction selectivity in DSGCs, while leaving the DSGC's responsiveness to light intact. It is also possible that voltage-gated $Na^{+}$ channels (►Sodium channels) play a role; however, it is uncertain whether SACs generate spikes carried by $Na^{+}$.

*Chloride Gradient along the Dendritic Branches.* Immunocytochemical and physiological experiments suggest that a differential expression of the chloride transporters NKCC1 and KCC2 (►Chloride channels and transporters) leads to a chloride concentration ($[Cl^{-}]$) gradient within the SAC dendrite (with high $[Cl^{-}]$ in and near the soma) [15]. Such a gradient would render the proximal GABAergic inputs excitatory, whereas the distal GABAergic inputs would remain inhibitory. In this model, the temporal sequence in which proximal and distal GABAergic inputs occur (centrifugal vs. centripetal) lead to the generation of direction-selective transmitter release from the SAC distal dendrites.

*Intracellular "Calcium Wave".* An important question is how spatially offset inhibition can be delayed

long enough so that it coincides with excitation in the DSGC. A similar question arises for the signal propagation within the SAC dendrite: If constructive and/or destructive interactions of inputs create dendritic direction selectivity in SACs, what causes the required delay? As electrical propagation seems too fast, it has been proposed that an intracellular $Ca^{2+}$ "wave" supported by $Ca^{2+}$-induced $Ca^{2+}$ release (within the SAC) may provide suitable delays.

### *Other, Yet Unidentified Interneurons in the DS Circuitry*

A general problem with proposing that interneurons other than the SAC perform essential direction-selectivity computations is lack of neuronal "substrate." Retinal neurons usually tile the retina; such that their density appears too low to build local circuitries dedicated to each of the seven DSGC subtypes at every retinal location (see *Function*). Local dendritic processing – as implemented in SACs – may be a solution. In the case of bipolar cells, as has been proposed, this would be demanding. To tune the output of single branches of a bipolar cell axon to different preferred directions would require a tremendous locality of processing.

## Involved Structures

### *Ultrastructural Basis of Direction Selectivity*

While it is commonly agreed that retinal direction selectivity requires spatial asymmetries in the wiring of the circuitry, a directly corresponding anatomical correlate has not been unequivocally identified. It has so far not been possible to predict a DSGC's preferred direction from its anatomy. Although at the ultrastructural level complex arrangements of amacrine cell synapses onto DSGC dendrites have been described [16], systematic asymmetries in the wiring of the direction-selectivity circuitry have not been found. The only available evidence for asymmetrical wiring comes from paired recordings [10]. Another puzzle is the location of GABA release sites on SACs. Synapses with ACh-containing vesicles could be located in the varicosities, whereas, due to the lack of conventional ultrastructural features, GABA release sites have not yet been localized on SAC dendrites.

## Function

For visually oriented animals, it is a matter of survival to swiftly detect moving objects (►local image motion) and reliably discriminate their direction of motion. In addition, motion of the whole visual field (►global image motion) provides important information about head/body movements (►Visual motion processing; ►Optic flow). Hence, coding the direction of image motion is an important task for the visual system. The three preferred motion directions of the ON DSGCs correspond to rotation around the axes defined by the three ►semicircular canals in the inner ear (reviewed in [4]). The cells respond preferentially to global motion and project to the ►accessory optic system (AOS), thus, ON DSGCs are thought to provide a correctional signal for ►eye movement and gaze-stabilization. This is supported by the finding that ablating SACs leads to a loss of the ►optokinetic reflex [6]. The four preferred directions of the ON/OFF DSGCs are roughly aligned with the extraocular rectus muscles and, therefore, with the cardinal ocular rotation directions. ON/OFF DSGCs seem to contribute some input to the optokinetic system, however, they send projections to the ►superior colliculus and the ►lateral geniculate nucleus (LGN), indicating that their signals also serve other functions, possibly including control of spatial attention (►Visual attention). The responses of ON/OFF DSGCs to moving objects are attenuated by synchronous motion of the background, indicating that they preferentially signal local motion. Nonetheless, there is no functional evidence so far that signals from retinal DSGCs take part in higher visual processing of motion direction.

## Development

Up to now there is no satisfactory explanation of how the direction selectivity circuitry is wired during retinal development. That direction selectivity is established at the time of eye-opening suggests that the wiring process does not require visual stimulation.

## Definition

The retinal ganglion cells (RGCs) are the output stage of retinal information processing. They are the only cells in the retina with axons that leave the eye. The ganglion cell axons form the ►optic nerve and transmit retinal information – in the form of spike trains – to the visual target areas in the brain. The name "ganglion cell" derives from the anatomical notion that these cells constitute the "*ganglion nervi optici*," i.e. the cluster of somata that give rise to the fibers of the optic nerve. The ganglion cell somata are located in the ►ganglion cell layer (GCL), the innermost layer of the retina. The dendrites of the ganglion cells ramify in the ►inner plexiform layer (IPL) where they are postsynaptic to bipolar cell axons and amacrine cell processes (►Retinal bipolar cells). There are more than a dozen different types of ganglion cell in all mammalian retinae studied so far. They differ in dendritic field size and dendritic branching pattern, and they receive input from different bipolar and amacrine cell types, and hence have different functional properties. The various types are specialized to encode different aspects of a visual scene, e.g. fine spatial detail (visual resolution), brightness, color, or movement. These ganglion cell types are the basis of distinct parallel visual pathways relaying a decomposed representation of the visual scene to distinct target areas in the brain [1–5].

## Characteristics

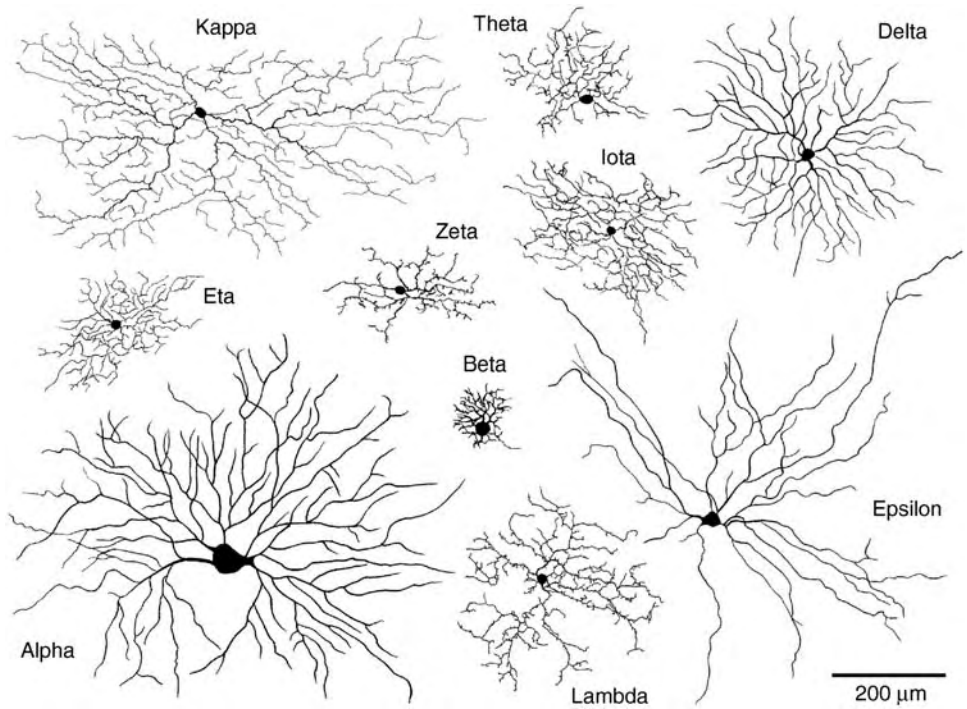
### Description

Among mammals, ganglion cells have been morphologically and functionally most thoroughly studied in the cat, the rabbit, and some primates [1,2,4,6,7]. More recently, detailed morphological classifications of mouse and rat ganglion cells have been added [8]. These comparative studies suggest that there is a basically similar set of about 15–20 ganglion cell types in all mammals, but formal proofs of homology are still lacking (Figs. 1–3). The accounting of types in any one species differs between authors depending on the classification criteria applied. For historical reasons, the nomenclature of types differs between species. The present article focuses on the most thoroughly studied ganglion cell types in the cat and primates, which continue to serve as benchmarks for ganglion cell classifications.

### Alpha Ganglion Cells/Primate Parasol Cells

Alpha ganglion cells have been identified morphologically in all mammalian species studied to date [6]. At every retinal location, they are the type with the largest soma, the largest-caliber, fastest-conducting axon, and a large dendritic field. The dendritic tree is circular-to-oval with stout radial, relatively densely branched dendrites that rarely overlap, and it is monostratified in the IPL (Figs. 1, 2, and 4).

Alpha cells have been identified as the brisk-transient (Y) cells of physiology [1,6,9]. They comprise two functional subtypes, ON alpha cells and OFF alpha cells, as defined by their response to light (see *dendritic stratification* below). The ►receptive fields of alpha/Y cells are large and have a concentric organization with an excitatory centre and a larger antagonistic, inhibitory surround [9,10]. Alpha/Y cells show a vigorous transient (phasic) response whenever there is a stimulus change; their response to stationary, constant stimuli decays within the first few tenths of a second following stimulus onset. Alpha/Y cells respond best to rapid



**Retinal Ganglion Cells. Figure 1** A selection of ganglion cell types in the cat retina. The cells have been dye-injected and are seen in flat view, all drawn at the same scale. Cat ganglion cell types are named by Greek letters. Each type is characterized by a specific morphology, e.g. alpha cells have a large soma and a large dendritic tree formed by stout dendrites, whereas kappa cells have a small soma and a large dendritic tree formed by fine dendrites. The axons exiting from the soma have been omitted. Cell drawings kindly provided by David M. Berson.

spatial or temporal changes of coarse patterns, hence they can be considered as "novelty detectors." They are very sensitive to low luminance contrasts, but not to chromatic stimuli.

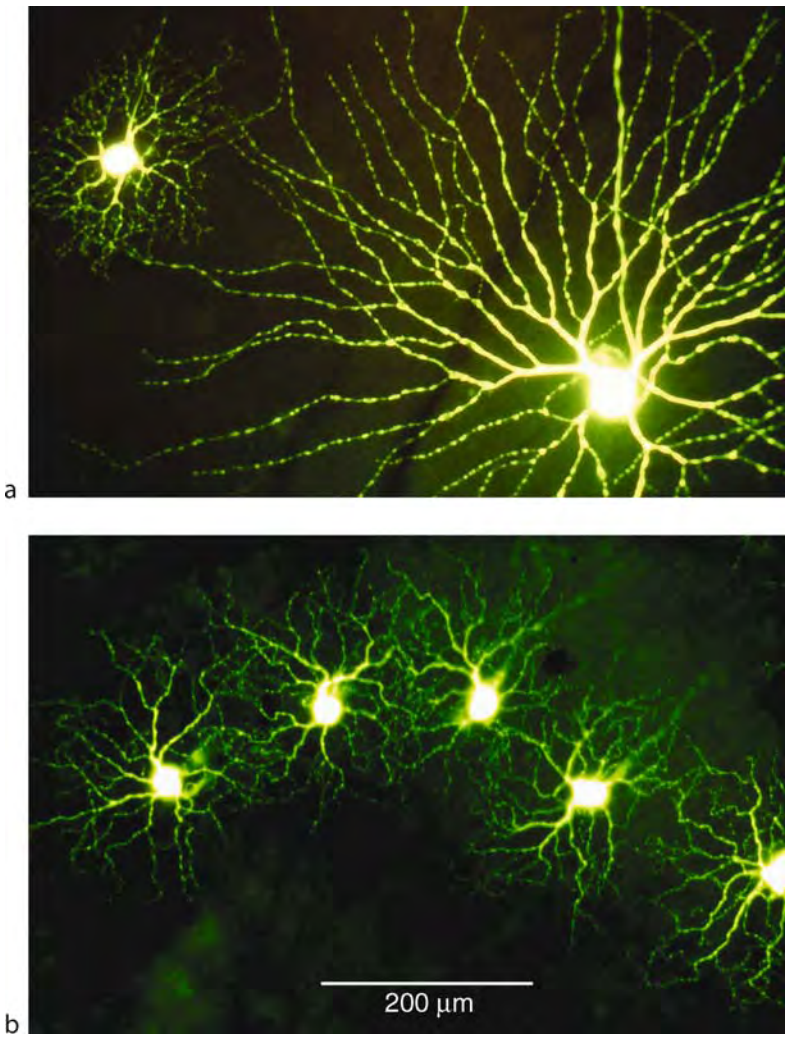
The corresponding cell type in primate retinae is thought to be the ►parasol (= umbrella-shaped) cell [4,5]. Due to its axonal projection to the ►magnocellular (M) layers (of the lateral geniculate nucleus), it is also termed ►M cell. The parasol cell is morphologically very similar to the alpha cells in other species (Fig. 3).

Like the alpha cells of non-primates, the parasol cells comprise two functional subtypes, ON and OFF, and their relatively large receptive fields have an ►antagonistic centre-surround organization [10]. The response to visual stimuli is transient. Parasol cells respond well to achromatic "luminance" stimuli and poorly to chromatic stimuli. There are also, however, functional differences between primate parasol and cat alpha cells. For example, alpha cells show non-linear spatial summation whereas parasol cells show linear summation. Thus, the question of correspondence between parasol and alpha cells remains contentious [6].

## Beta Ganglion Cells/Primate Midget Cells

The beta ganglion cells have medium-sized somata and medium-caliber axons. Their dendritic trees are very small and circular-to-oval, with radial, relatively densely branched dendrites that rarely overlap (Figs. 1, 2, and 4). Like those of alpha cells, they are monostratified in the IPL. In fact, beta cells look like miniature versions of alpha cells. Accordingly, they collect input from only a few bipolar cells and are the high-resolution (visual acuity) system of the retina. Beta cells have been identified as the brisk-sustained (X) cells of physiology [1,9]. Like the alpha/Y cells, the beta/X cells comprise two functional subtypes, ON and OFF, and their small receptive fields show an antagonistic centre-surround organization [9,10]. However, their response to visual stimuli is sustained (tonic). Beta/X cells respond well to small, high-contrast, stationary stimuli.

In primate retinae, the ganglion cell type with the smallest dendritic and thus receptive field is termed midget ganglion cell [4,5]. Due to its axonal projection to the ►parvocellular (P) layers (of the lateral geniculate nucleus), it is also termed P cell. The midget cells may be homologous to the beta cells of cat and other mammals. Midget ganglion cells have medium-sized somata and very small dendritic trees that are relatively densely branched and monostratified in the IPL (Fig. 2). They comprise two functional subtypes, ON and OFF, with concentric antagonistic receptive fields [10]. The dendritic trees of the central-most



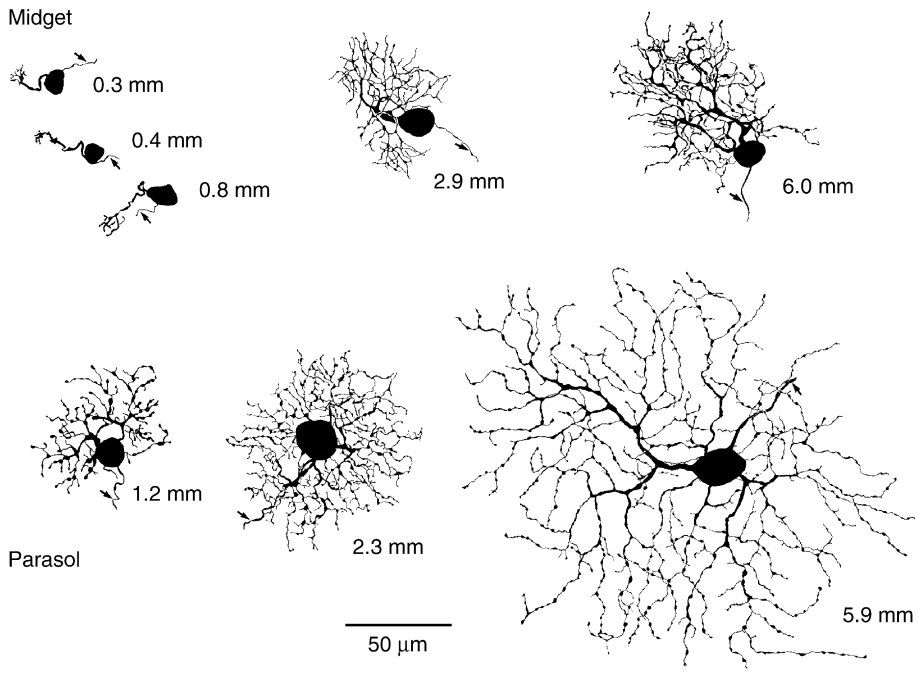
**Retinal Ganglion Cells. Figure 2** Examples of ganglion cells that have been individually injected with the fluorescent dye lucifer yellow. (a) Flat view of a neighboring alpha (*right*) and beta (*left*) ganglion cell in peripheral dog retina. (b) Flat view of a group of neighboring alpha cells in central rat retina. The scale bar applies to A & B. A, modified from Peichl (1992) J. Comp. Neurol. 324:590–602; B, modified from Peichl (1989) J. Comp. Neurol. 286:120–139.

midget cells near the ►fovea are so small that each contacts just one midget bipolar cell (►Retinal bipolar cells), which likewise contacts just one cone. This foveal 1:1:1 connectivity, termed the midget system, is the anatomical basis for the high visual acuity of diurnal primates and man. As a corollary, the single cone input conveys to a midget cell the spectral tuning of that cone. The midget cells are widely considered to be the retinal keystone of the red-green chromatic channel of trichromatic primates, doing "double duty" in spatial resolution and color vision. The blue-yellow chromatic channel is implemented by other ganglion cell types [4] (►Color processing).

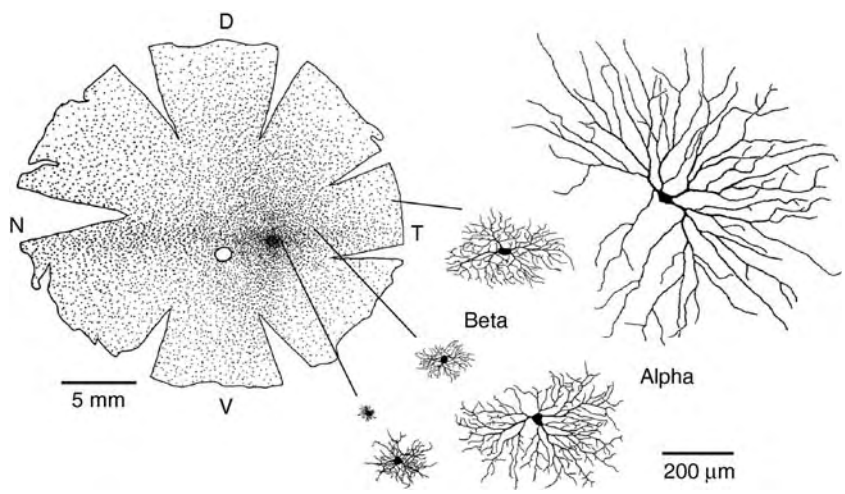
Interestingly, rabbit, mouse and rat do not possess a ganglion cell type that easily fits the morphological characteristics of beta cells [6–8]. It is possible that the beta cell is not as ubiquitous as the alpha cell, and that in some species another type of ganglion cell subserves spatial resolution.

## Intrinsically Photosensitive, Melanopsin-Containing Ganglion Cells

A recently discovered ganglion cell type that appears to subserve "non-image-forming" functions is the "intrinsically photosensitive retinal ganglion cell" (ipRGC) [4,11]. The most intriguing feature of ipRGCs is that they contain the putative photopigment melanopsin and are directly sensitive to light. In addition, they receive conventional photoreceptor input via bipolar cells. The ipRGCs seem to play a major role in



**Retinal Ganglion Cells. Figure 3** Midget (*upper row*) and parasol (*lower row*) ganglion cells in the retina of the marmoset, a diurnal primate. The cells have been dye-injected and are seen in flat view, all drawn at the same scale. Both cell types increase in size with increasing distance from the fovea (distance given for each cell), but at each location the midget cells are smaller than the parasol cells. Axons are marked by arrows. Note that these marmoset cells are smaller than their presumed counterparts in cat, the beta and alpha cells (Fig. 4); 6 mm is peripheral in the smaller marmoset retina. Modified from [5], courtesy Paul R. Martin.



**Retinal Ganglion Cells. Figure 4** Variation of ganglion cell population density and ganglion cell size across the cat retina. *Left*: Schematic map of the ganglion cell density in a whole retina; radial cuts were made to flatten the retina. From the region of highest ganglion cell density, the *area centralis* in temporal retina, cell density decreases monotonically towards the retinal periphery. The open circle signifies the optic nerve head. *Right*: Dye-injected alpha and beta ganglion cells at three distances from the *area centralis*, showing that dendritic field size increases as cell density decreases, while the size difference between alpha and beta cells is maintained. D, dorsal; V, ventral; N, nasal; T, temporal. The left scale bar applies to the map, the right scale bar to the individual cells. Modified from Peichl (1990) Optometrie 3/1990:3–12.

the entrainment of ►circadian rhythms, as evidenced by their projection to the circadian pacemaker, the ►suprachiasmatic nucleus (SCN), and in regulating ►pupil constriction, as evidenced by their projection to the ►pretectum. The ipRGCs constitute a small fraction of the ganglion cells (1–3% in rodent retinae, ~0.2% in primate retina). Their dendritic trees in the IPL are relatively large but sparsely branched. The cells show a sluggish, tonic ON response that is monotonically increasing with the light intensity.

## Other Ganglion Cell Types

Many of the non-alpha and non-beta ganglion cell types occur at low densities, each constituting a small fraction of the total ganglion cell population. In primates, these other types mostly have larger dendritic fields than the parasol cells; some are sparsely and some rather densely branched [4]. In the cat, there is a wider range from rather small to very large types (Fig. 1). Some of these types have a concentric antagonistic receptive field organization, others do not, and for some morphologically recognized types, functional data are lacking.

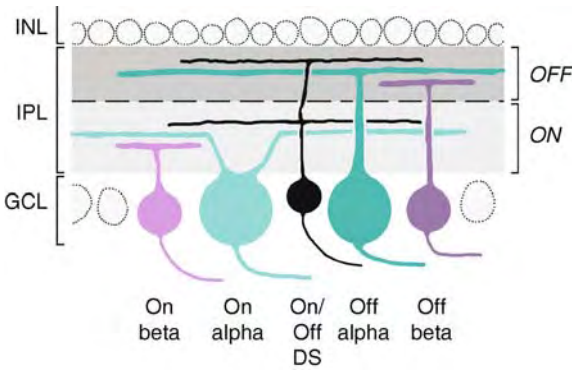
Examples of further well-studied ganglion cell types are two kinds of direction-selective (DS) ganglion cells, the monostratified ON-DS cell and the bistratified ON/OFF-DS cell (►Retinal direction selectivity: Role of starburst amacrine cells). They are specialized to detect retinal image movement. Another example is the primate "small bistratified" cell, which shows a blue-yellow antagonism and serves in color processing [4] (►Color processing).

## Dendritic Stratification and Light Response

ON ganglion cells have a receptive field centre that is activated by a light increase, OFF ganglion cells are activated by a light decrease in the receptive field center. These response characteristics are determined by their input neurons. The inner plexiform layer (IPL) is morphologically and functionally clearly stratified to keep these different processing circuits segregated (Fig. 5).

Cells stratifying in the *outer* part of the IPL are OFF cells, whilst those stratifying in the *inner* part are ON cells. The stratification level of the ganglion cell's dendritic field ensures appropriate (ON or OFF) bipolar cell input. The actual thickness of the two strata differs from species to species, in some they are nearly equal, in others the ON stratum may be twice as thick as the OFF stratum (because it also contains the axon terminals of the rod bipolar cells, which are ON cells; ►Retinal bipolar cells).

Both the alpha/parasol ganglion cells and the beta/midget ganglion cells are dichotomous, comprising equally numerous subpopulations of ON and OFF cells. Their monostratified dendritic trees ramify in the inner sublamina and the outer sublamina of the IPL, respectively (Fig. 5). The ON-DS ganglion cells also monostratify in the inner sublamina, while the ON/OFF-DS ganglion cells have bistratified dendritic trees.



**Retinal Ganglion Cells. Figure 5** Schematic drawing of the functional stratification of the inner plexiform layer (IPL) in the mammalian retina as seen in a transverse section. The dendritic trees of OFF ganglion cells stratify in the *outer* (distal) part of the IPL, those of ON ganglion cells in the *inner* (proximal) part. The ON/OFF direction selective (DS) ganglion cell has a bistratified dendritic tree with dendrites in the ON and the OFF stratum. Ganglion cell types are rendered in different colors. *Abbreviations*: INL, inner nuclear layer; GCL, ganglion cell layer.

## Retinal Topography and Population Properties

A basic requirement of retinal organization is that the complete computing machinery has to be present at each retinal location in order to process a visual stimulus wherever it hits the retina. To achieve this, ganglion cells (and most other retinal neurons) are distributed economically across the retina. The members of each functional type (e.g. ON alpha cells, OFF alpha cells, ON beta cells, and OFF beta cells) tile the retina, such that their dendritic trees cover the retinal surface without gaps and without too much overlap [1]. The grain of this tessellation is finest in the central retina (the ►*area centralis* of most mammals, and the fovea of primates), where highest visual acuity is achieved. It becomes coarser toward the retinal periphery, where complete coverage is obtained by a less dense spacing and larger individual dendritic trees for each ganglion cell type (Figs. 3 and 4). Relative size differences between the ganglion cell types are preserved across the retina.

The alpha/parasol ganglion cells with their large dendritic trees require a low packing density. Depending on species, they only constitute between 1 and 10% of the total ganglion cell population [6]. Nevertheless, they exhibit uniform coverage and contribute to processing at each retinal point. The beta/midget ganglion cells have much smaller dendritic trees and correspondingly higher

packing densities. In the cat retina, about 50% of the ganglion cells are beta cells, in the primate retina, about 80% of the ganglion cells are midget cells.

## Lower Level Processes

The response characteristics of the different ganglion cell types are thought to be set mainly by the specific mix of synaptic inputs from different bipolar and amacrine cell types [1–3,5]. The sustained (tonic) beta/midget cells are probably driven by tonic bipolar cells, and the transient (phasic) alpha/parasol cells by phasic bipolar cells (Retinal bipolar cells). A ganglion cell's specific dendritic geometry, and hence electrotonic properties (►Electrotonic spread), also contribute to its response characteristics. The antagonistic surround of a ganglion cell's receptive field is mediated by lateral inhibitory input, partly directly from amacrine cells to the ganglion cell, and partly from horizontal cells to the bipolar cells (►Lateral interactions in the retina). The ganglion cells operate at high (►photopic) as well as low (►scotopic) light levels, i.e. the cone pathway and the rod pathway converge onto the same ganglion cells. The luminance-dependent functional switch from the cone pathway to the rod pathway is regulated by dopaminergic amacrine cells [2].

## Higher Level Processes

There is homologous electrical coupling by ►gap junctions between the dendrites of neighboring alpha/parasol cells of the same centre sign (ON with ON, OFF with OFF), and heterologous ►gap junctional coupling between alpha/parasol cells and certain amacrine cell types. ON/OFF-DS cells also show homologous gap junctional coupling, likely to be restricted to partners with the same direction tuning. Modulated electrical coupling allows changing associations between neighboring ganglion cells. It probably is the basis for the high incidence of synchronous firing among homotypic neighbors. Synchronous firing, i.e. concerted activity among multiple ganglion cells, which has been observed in retinal multineuron recordings, may represent a "population coding" or "multiplexing" that is more powerful in encoding visual stimuli than the independent activity of individual cells [12]. Beta/midget cells do not show such electrical coupling, probably because signal spread across neighbors would decrease spatial resolution.

Each ganglion cell type projects to specific thalamic and/or midbrain target structures and specific subdivisions within these target structures [4,5]. This indicates segregation of the various retinal processing channels also at higher processing levels. The ►lateral geniculate nucleus (LGN) and ►superior colliculus (SC) are targets for several ganglion cell types. Other nuclei are more selectively targeted, and some ganglion cell types innervate several targets by axon collaterals.

## Function

Visual acuity, dominantly mediated by the beta/midget system, is of more importance to some species than to others. In the diurnal primates, the midget system provides the anatomically possible maximum of acuity by fully exploiting the tight foveal cone packing. In the crepuscular-to-nocturnal cat, there is a considerable convergence from cones to beta cells even in the *area centralis*, "giving away" some of the acuity theoretically possible with the cone packing density. Here perhaps, evolutionary pressure was less on high acuity and more on a good signal-to-noise ratio at dim light. The latter requires signal summation over several photoreceptors, in addition to the presence of rods in the *area centralis*.

Alpha/parasol cells, with their large receptive fields, are thought to contribute little to acuity or to color vision. Their particular responsiveness to changing stimuli (novelty detectors), and their fast conduction velocity, would make them an "alarm" or "warning" system to direct visual attention (►Visual attention) to objects entering the visual field. Alpha/parasol cells also play an important role in global form perception (►Form perception) and depth perception (►Binocular vision). Both alpha/parasol and beta/midget cells project to the lateral geniculate nucleus and hence provide major inputs for cortical, "higher" visual processing.

The ON direction-selective ganglion cells project to the ►accessory optic system, the ON/OFF direction-selective ganglion cells project to the ►optokinetic system, the superior colliculus and the lateral geniculate nucleus. Both types are thought to contribute to the discrimination between self-movement and object movement (Retinal direction selectivity: Role of amacrine cells). The intrinsically photosensitive ganglion cells are specialized to encode ambient light intensities, they are involved in synchronizing circadian rhythms with the solar day and in regulating the pupillary light reflex. These three ganglion cell types are examples for retinal channels feeding into subcortical, "lower" visual processing systems.

For many of the less well-characterized ganglion cell types, we lack a clear idea of their role in image analysis. On the one hand, it is clear that there are basic parallel processing channels feeding specific parts of visual information into ganglion cell types with different response properties. On the other hand there is increasing awareness that retinal image processing works by a finely tuned and stimulus-dependent interplay of these many different channels, rather than by a strict dedication of "one type for this task, one type for that task." For example, primate parasol cells, despite their large receptive fields, play a significant role in hyperacuity (►Visual acuity, hyperacuity). Actually, there seem to be more types of ganglion cell (and of other retinal neurons) than we need to account for the functions we currently attribute to the retina [2].

We still have to learn a lot about this intriguing piece of neural tissue.

# Retinal Implant

## Definition

Device intended to restore useful vision in pathologies that selectively affect the photo-detectors of the retina while leaving relatively intact the other retina neurons and the fibers of the optic nerve (such as retinitis pigmentosa and macular degeneration). These devices share with cochlear implants the basic design principles and requirements, but are at a much earlier stage of development than cochlear implants (there is at least a 20–30 years gap), because of the greater information density (thousands of hair cells on the basilar membrane vs. millions of photodetectors on the retina) and the more complex structure of the sensor.

►Computer-Neural Hybrids

# Retinal Lateral Interactions

Martin Wilson
Department of Neurobiology, Physiology and Behavior, College of Biological Sciences, University of California Davis, Davis, CA, USA

## Synonyms

Lateral interactions in the retina

## Definition

The influence of signals generated by retinal neurons on the activity of other neurons laterally distant in the retina.

Many processes are covered by this term, some acting over short distances between immediately adjacent neurons, and others acting over virtually the entire extent of the retina [1]. Lateral interactions occur at all levels in the retina, from the ►photoreceptors, the input neurons of the retina, through to ganglion cells (►Retinal ganglion cells), the output neurons of the retina. Lateral interactions may be positive or negative. Light falling on a patch of retina may augment the signal generated in neurons in an adjacent patch or it may diminish this signal. Lateral interactions are often time-dependent and may also depend on special features of the stimulus such as stimulus velocity or the wavelength of the illuminating light.

There are several different mechanisms known to mediate lateral interactions. Some forms of lateral interaction, particularly those occurring in the inner retina, are known only from indirect and incomplete evidence and are not well understood.

## Characteristics

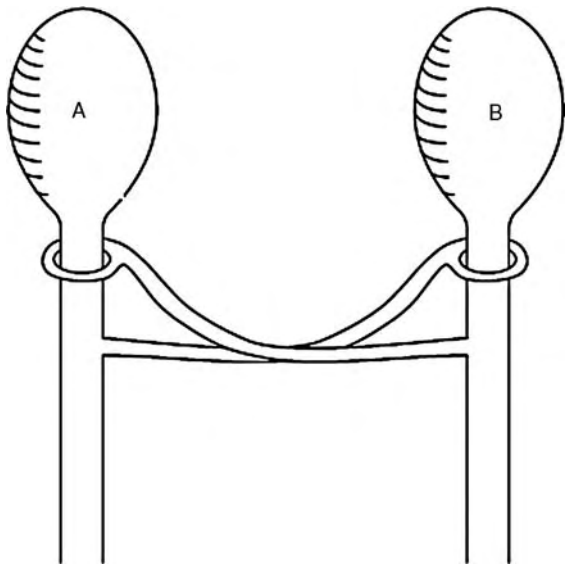
The best known form of lateral interaction in the retina is lateral inhibition. Lateral inhibition was inferred by Ernst Mach in the 1860s on the basis of psychophysical experiments. Much later it was shown that lateral inhibition was one of the first neural operations performed in the compound eye of the horseshoe crab, *Limulus*, where eccentric cells, roughly the equivalent

of ganglion cells in the vertebrate retina, are thought to make inhibitory ►synapses with their neighbors (Fig. 1). Hartline and his colleagues quantified the effect of lateral inhibition on the steady-state firing rate of eccentric cells by writing simultaneous equations [2]. The firing of every eccentric cell is influenced by the firing of every other eccentric cell, so that, considering only a pair of illuminated eccentric cells, A and B, the responses of A and B, $r_{A,}$ and $r_B$ are given by:

$$r_A = e_A - K_{A,B}\left(r_B - r_B^0\right)$$

$$r_B = e_B - K_{B,A}\left(r_A - r_A^0\right),$$

where $e_A$ is the response of A in the absence of stimulation to B, $K_{A,B}$ is a term representing the strength of inhibitory connection from B to A, $r_B$ is the response of B, and $r_B^0$ is a threshold firing rate for B below which it exerts no inhibition on A. Terms for the response of B have analogous meanings. These simple piecewise linear equations give a good approximation of the responses of eccentric cells for different patterns of light falling on the *Limulus* eye and capture the essential features of lateral inhibition.

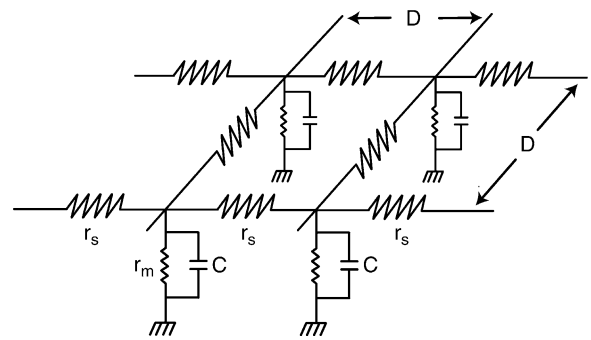


**Retinal Lateral Interactions. Figure 1** The idea underling the quantitative description of inhibitory interactions in the *Limulus* retina [2]. A pair of adjacent eccentric cells, A and B, each capable of independent excitation by light, are shown as cell bodies with axons sending information to the brain and collaterals that make local inhibitory connections with each other. The excitation of one cell tends to reduce the response of its neighbor. A subtle but important feature of the inhibition, reflected in this diagram and in the descriptive equations, is that it is recurrent. By this is meant that for any cell, the inhibitory effects of neighbors are exerted upstream of any inhibitory output from that cell.

The organization of the vertebrate retina is radically different from that of *Limulus* and yet lateral inhibition is similarly one of its first processing steps. To understand how lateral inhibition operates in the outer vertebrate retina it is necessary to consider all three general classes of neuron found there, their lateral interactions, and their ►receptive fields.

Photoreceptors have very small receptive fields, though in many instances these are at least slightly broader than expected from the anatomical dimensions of the photoreceptor. The explanation for this enlargement is that photoreceptors are weakly coupled together via ►gap junctions (Photoreceptors) so that signals leak from one photoreceptor to its neighbors. Quantitative models of signal spread through the photoreceptor network have been based on square or hexagonal networks in which each photoreceptor is represented by a resistor and a capacitor, coupled to its neighbors through resistors representing gap junctions (Fig. 2). This kind of model gives a reasonable approximation for the spread of small signals through the network but misses some of the network's time-dependent properties. More sophisticated models, incorporating the voltage-dependent conductances of photoreceptors, show that, at least for the amphibian and turtle retina, the network has strongly time-dependent properties [4,5].

Photoreceptors pass signals to both horizontal cells and bipolar cells (►Retinal bipolar cells) (Fig. 3). Horizontal cells are strongly coupled homotypically via gap junctions, with the result that signals spread widely throughout the network of horizontal cells, giving these neurons very broad receptive fields. Because the coupling between horizontal cells is so strong, individual cells can be ignored and the network approximated

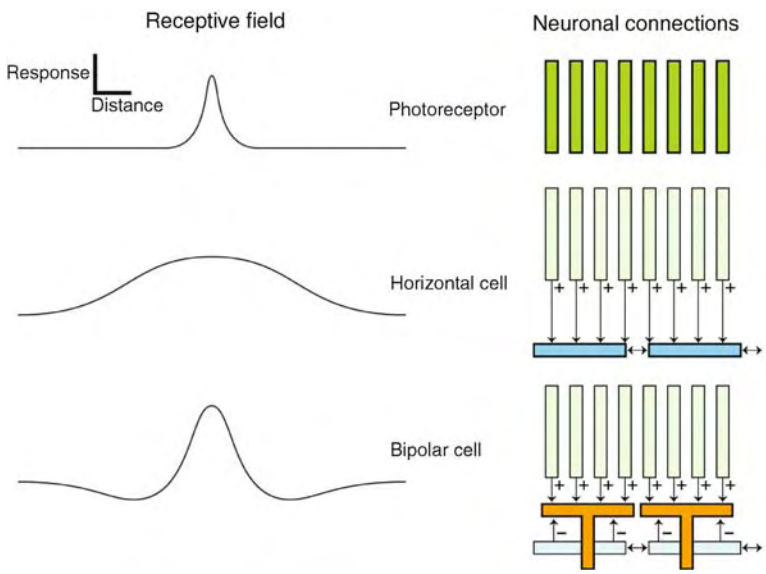


**Retinal Lateral Interactions. Figure 2** A schematic representation of part of a network of coupled photoreceptors based on [3]. In this model, photoreceptors are arranged in a square grid separated by a distance, D. The resistors, $r_s$, represent the coupling resistance of the gap junctions between adjacent photoreceptors while the photoreceptors themselves, positioned at every node of the grid, are represented by a capacitance and a membrane resistance.

to a continuous and homogeneous sheet. The distribution of voltage in this model is given by a second-order partial differential equation for which useful analytical solutions have been found [6].

Bipolar cells, in contrast to horizontal cells, are not strongly coupled and also differ from horizontal cells in having a receptive field comprising two distinct regions. A relatively narrow central region receives input from overlying photoreceptors but outside this lies an annulus of inhibitory, or antagonistic surround. If a spot of light falling in the central region depolarizes the bipolar cell, a spot falling in the surround would hyperpolarize the cell, and a large patch of light covering both center and surround would produce no sustained response (although it would produce transient responses when the light comes on and when it goes off). Loosely speaking, the bipolar cell receptive field is generated from the sum of the inputs from overlying photoreceptors and a sign-reversed input from horizontal cells of much larger spatial extent, as summarized in Fig. 3. How horizontal cell inputs "sum" is not entirely clear and there is evidence supporting both inhibitory synaptic feedback to photoreceptor terminals and inhibitory synaptic feedforward to bipolar cells as well. Neither of these proposed mechanisms is entirely satisfactory and an alternative idea based on extracellular current flow has recently been revived [7].

The lateral spread of signal between neurons coupled together via gap junctions can be inferred from intracellular recording from a pair of cells. Current injected into one cell produces a voltage in the other, and by examining pairs of neurons at known separations, it is possible to measure signal spread directly and estimate the electrical parameters of the network. This direct approach has been applied to photoreceptors and horizontal cells but a less direct method has proved useful between other cell types. The injection of small tracer molecules, often fluorescent molecules, into a single cell, implies the presence of coupling gap junctions if fluorescence appears in nearby cells. This method is not easily amenable to quantitative analysis, moreover gap junctions differ in the size of tracer molecule they allow to pass, nevertheless it has the huge advantages that intracellular injection into only a single neuron is required, and even very sparse connections can be revealed this way. The tracer molecules Biocytin and Neurobiotin have revealed a previously unsuspected wealth of coupling, both homo- and heterotypic, between neurons in the inner retina. Although this coupling implies the lateral spread of signal, electrical coupling between neurons is known to serve other



**Retinal Lateral Interactions. Figure 3** The receptive fields of the neurons in the outer retina and an explanatory schematic showing how these receptive fields are generated. For simplicity only one spatial dimension is shown, equivalent to mapping receptive fields using a long thin bar of light moved orthogonal to its long axis. Photoreceptors, shown in green, have narrow receptive fields, only slightly wider than the width of an individual receptor. Horizontal cells (blue), in contrast, have wide receptive fields because they collect signals from all their overlying photoreceptors and are strongly coupled to each other, thereby allowing signals to spread laterally. Bipolar cells (orange) collect signals from a relatively small group of overlying photoreceptors but also receive signals of opposite sign from nearby horizontal cells. This arrangement gives rise to a receptive field in which light falling in the center of the field, dominated by direct input from overlying photoreceptors, produces a response whose sign is opposite to that produced by more lateral stimuli in which horizontal cell input dominates.

functions, such as the synchronization of spiking, and it may transpire that the spatial aspects of this coupling are inconsequential.

## Higher Level Processes

Perceptual illusions (►Visual illusions), such as Mach bands and the Hermann grid illusion, originate from lateral interactions in the retina [8].

## Lower Level Components

Lateral interactions are mediated through gap junctions and synapses. In some instances it is possible to say which specific gap junction subunits are present in which retinal neurons but in many instances this is not yet known. The synapses and their ►transmitters mediating lateral interactions are known in outline but, as always, the details of the inner retina are much less clear than those of the outer retina.

## Process Regulation

A large body of evidence shows that many, but not all, of the gap junctions that mediate lateral signal spread in the retina can be functionally closed by transmitters and ►neuromodulators. Best known is the example of coupling between horizontal cells in the retinas of fish and turtle [9,10]. ►Dopamine, which is released by neurons in the inner retina, and plays a role in switching the retina from ►scotopic to ►photopic conditions, clearly uncouples horizontal cells by elevating intracellular ►cAMP, thereby decreasing the receptive field size of these neurons and greatly restricting the ability of injected dye molecules to move between cells. A similar effect is seen in AII ►amacrine cells [11] that, in low-light conditions when rod photoreceptors dominate, are coupled together and are a crucial link in the transmission of rod signals.

In addition to dopamine, ►nitric oxide also closes gap junctions, in this case acting through ►cGMP, and probably also plays a role in light/dark adaptation, though how these two agents, dopamine and nitric oxide and perhaps others, act together and what their different functional roles might be, is not known. In general though, there are good theoretical arguments for modulating the spatial dimensions of lateral inhibition to optimize it for different ambient light intensities. In flies, the measured spatial extent of lateral inhibition is reasonably well matched to theory [12] but in vertebrate retina no similar comparison has been attempted.

## Function

Lateral inhibition clearly enhances edges, which, very likely, is a necessary step in the task of parsing the visual world into separate, identifiable objects. Unfortunately, this idea does not lead easily to a quantitative theory.

Another way of looking at the function of lateral inhibition, initiated by H. B. Barlow and subsequently built on by others, has its roots in ►information theory and is known as *predictive coding* (►Sensory systems). The starting point for this approach is the postulate that the visual system is interested in all spatial information, i.e. edges are accorded no special *a priori* value. Key ideas are (1) that the retina has been optimized for efficiency of information transfer to the brain. This is a plausible conjecture, if only because there are obvious anatomical constraints on the thickness of the ►optic nerve and therefore the number of output channels from the retina. A more subtle constraint is exercised by intrinsic noise within a neuron that limits its information carrying capacity. (2) There exist statistical regularities in the spatial and temporal structure of the images falling on the retina. For example, the intensity of light falling on any point in the retina is likely to be similar to the intensities found adjacent to that point, first, because of blurring caused by the eye's optical limitations, and second, because the visual world is not a random pattern of dots. (3) From point 2, we can say that some information is redundant and, on the basis of point 1, ought not to be transmitted to the brain.

Lateral inhibition performs this task of redundancy removal and permits the efficient use of the limited bandwidth provided by retinal neurons. Simply put, this view of lateral inhibition is that it is a way of computing a best guess for the signal expected at any point in the retina, based on a weighted sum of the signals from points around it. This best guess is then subtracted from the actual signal, thereby allowing any deviations from the guess to fill the bandwidth of that neuron.

On the basis of these arguments we would predict that the strength and extent of lateral inhibition should be matched to the statistics of different visual environments. An important contributor to these statistics is the variance in the number of photons arriving, which is a function of light intensity. At low light intensities a statistically reliable best guess requires that a large number of points be included, in other words lateral inhibition should become broader [12]. At higher light levels, where signal-to-noise ratios are higher, the best guess would include only those points in the immediate neighborhood.

The spatial characteristics of different scenes, a beach versus a forest for example, ought, from the principles of predictive coding, to elicit different lateral interactions within the retina. Some evidence from ganglion cell recordings suggests that this may be occurring in the inner retina, probably mediated by amacrine cells, though the mechanism is presently unknown [13].

While lateral inhibition has provided a path into some of the deepest questions concerning the design of the nervous system, positive lateral interactions have also stimulated a careful consideration of function.

The function of coupling between horizontal cells is fairly apparent, but what about photoreceptor coupling? At first sight this is puzzling, not only because

photoreceptor coupling is apparently the opposite of lateral inhibition, for which there is a good understanding, but also because it must degrade spatial resolution.

A crucial concept in understanding photoreceptor coupling is that photoreceptors are very high-gain detectors for which noise is an inescapable problem. Some of this noise is produced by the thermal activation of the molecules involved in transduction (►Phototransduction) but a large contribution comes from chance fluctuations in the number of photons caught. Even for cones operating in the photopic range, few enough photons are caught per integration time that these fluctuations compromise the reliability of the signal. Coupling between photoreceptors is a form of signal averaging that improves the signal-to-noise ratio by canceling out some of the uncorrelated noise found in every cell. This engineering trick necessarily involves trading a gain in reliability (improved signal-to-noise ratio) for spatial resolution. But the trade is definitely worthwhile. In the case of mammalian cones, coupling increases the signal-to-noise ratio by about 70% by allowing some signal to leak into neighboring photoreceptors. The spatial blurring this causes actually turns out to be less than the blurring caused by the imperfect optics of the eye, so in fact no resolution is sacrificed by coupling [14].

While mammalian cones have coupling that is, in effect, strong enough to spread signals only to immediate neighbors but no further, poikilothermic vertebrates have somewhat stronger coupling between their photoreceptors. Undoubtedly the same arguments about signal-to-noise ratio apply, but as first noticed by Hodgkin and his collaborators, signal spreads a long way through the rod network shortly after a light comes on, but then contracts down to a much smaller area. A plausible, though unproven idea stemming from this finding is that the retina, at the level of bipolar cells, might employ two sampling strategies to read the rod network: one with good temporal resolution but poor spatial resolution, and the other with the converse properties [5].

# Retinal Photoreceptors

Nathan S. Hart
School of Biomedical Sciences, University of Queensland, St. Lucia, Brisbane, QLD, Australia

## Synonyms

Visual cells; Rods; Cones

## Definition

Photoreceptor cells are light-sensitive neurons that respond with a graded change in the release of ►neurotransmitter (►Glutamate) from their ►synaptic terminal. Photoreceptors are found in most classes of metazoan organism and vary widely in structure and function. Photoreceptors are predominantly located in the ►retina of both invertebrate and vertebrate eyes, where they are involved in vision, but they may also be located extraocularly on the integument or in the brain.

## Characteristics

### Quantitative Description

Photoreceptors are neurons that respond with a graded change in transmembrane potential (►Membrane potential – basics), to the absorption of photons by light-sensitive proteins (►Photopigments) embedded in specialized regions of their plasma membrane. The size,

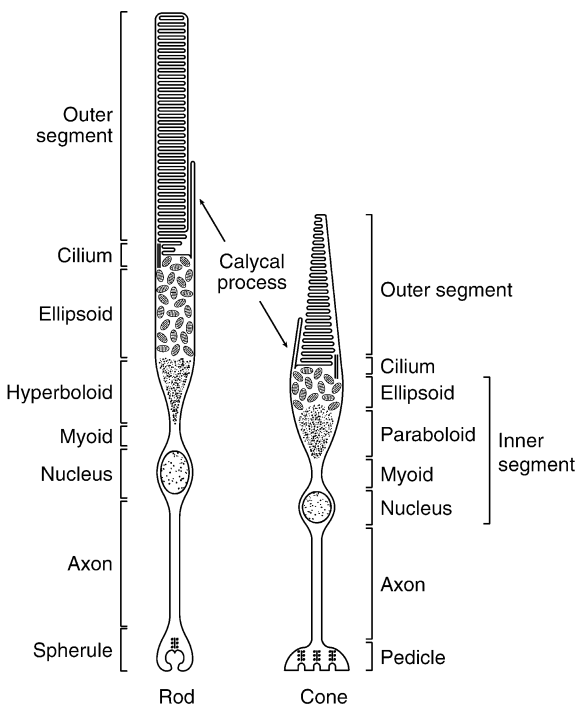
R

shape, ultrastructure, biochemistry, electrical properties and developmental origins of photoreceptors vary considerably across the animal kingdom. For the sake of brevity, the following descriptions are related to vertebrate visual photoreceptors (rather than non-visual retinal or extraocular photoreceptors), and in most cases, draw upon mammalian examples.

### Photoreceptor Types

The vertebrate retina is inverted by virtue of its developmental origins and, consequently, the photoreceptors are situated close to the ►sclera at the back of the eye. They point away from the incident light, which must traverse the other retinal layers before reaching the photoreceptors [1]. There are two distinct types of retinal photoreceptor: ►rods that operate under low light (►Scotopic) levels of illumination and ►cones that operate under bright light (►Photopic conditions). The rod-cone nomenclature reflects differences in aspects of photoreceptor morphology in the mammalian retina: the outer segments of rods are rod-like whereas cone outer segments are typically conical (Fig. 1).

However, it should be remembered that this is not always the case – even within the same retina – and it can be misleading to classify photoreceptors using morphology alone; rods and cones also differ in their biochemistry, physiology and function.



**Retinal Photoreceptors. Figure 1** Schematic representations of vertebrate rod and single cone retinal photoreceptors. Oil droplets – found in the photoreceptor ellipsoid in some species – are not shown. See text for details.

The human retina contains a single type of rod photoreceptor but three spectrally distinct cone types, which each contain a different cone photopigment maximally sensitive to blue, green and red light (see ►Photopigments). The cones of humans and other placental mammals, lungfish and elasmobranchs are all of the "single" type. Amphibians, marsupials, monotremes, birds, reptiles and teleost fish possess an additional photoreceptor type that consists of a pair of closely opposed cone cells. They are usually referred to as double cones when the two members are unequal in size – with a larger "principal" and a smaller "accessory" member – and twin cones when the two members are of similar size and shape. The closely opposed outer segments of the two members are separated from those of other photoreceptors – but not each other – by the processes of ►retinal pigmented epithelium (RPE) cells; the two members are thought to be both optically and electrically coupled.

Double cones are more widely distributed among the vertebrate classes, and both members usually contain the same spectral type of photopigment. Often, but not always, the principal member (and occasionally the accessory member) contains an oil droplet (see below). Twin cones occur predominantly in teleost fishes, and may have identical or distinct photopigments in each member, even within the same retina.

### Retinal Topography

The absolute density and relative proportion of rods and cones varies as a function of visual ecology. Strongly diurnal species (e.g. most birds, turtles) have a lower rod:cone ratio than nocturnal species (e.g. many rodents) and, in some cases, lack rods altogether (e.g. lizards). The average human retina contains about 4.6 million cones and 92 million rods, giving a rod to cone ratio of about 20:1 (excluding the ►fovea). In contrast, nocturnal rodents have rod to cone ratios of around 100:1 [2].

Moreover, the topographic distribution of photoreceptors across the retina is usually non-uniform. Most animals have a retina with one or more areas of increased photoreceptor density, which permit increased spatial sampling of the retinal image and provide high acuity vision over a defined region of visual space. The areas are often circular and usually occur in the central (►Area centralis) or temporal (►Area temporalis) retina, but may also form horizontal streaks (►Area horizontalis).

In some cases, the vitreal surface of the retina is indented above the area of highest photoreceptor density. This type of area is called a fovea, and the foveal indentation or pit is a result of the lateral displacement of secondary retinal neurons from the

optical path, to provide the incident light with unimpeded access to the photoreceptor layer. The shape of the foveal pit varies in curvature, and may serve to magnify the image projected onto the retina by virtue of the difference in ►refractive index between the vitreous and retina. The human fovea contains approximately 200,000 cones, with reported peak densities ranging from 100,000 to 320,000 cells $mm^{-2}$. Cone density falls rapidly with increasing eccentricity: at 10° eccentricity – or 3 mm from the centre of the fovea – it averages 7,000 cones $mm^{-2}$. Rods are excluded from the human fovea but attain their highest density of around 160,000 cells $mm^{-2}$ in a perifoveal ring located at 18° eccentricity or about 5 mm from the centre of the fovea [3].

## Description of the Structure

Vertebrate photoreceptors are comprised of three morphologically and functionally distinct regions: the outer segment, inner segment and synaptic terminal.

### *Outer Segment*

Human rod outer segments are 2 μm in diameter and vary in length with retinal eccentricity from 24 μm at the periphery to 40 μm in the parafoveal region. Human foveal cone outer segments are 30–40 μm in length, are less tapered/conical than cones located in the periphery and have a diameter of about 0.8 μm [1]. The outer segments of cones in the peripheral retina are more conical but only about half as long. Photoreceptor outer segment dimensions also vary widely with habitat and life history. For example, nocturnal species, or those inhabiting light-limited environments such as the deep sea, tend to have longer and wider outer segments than diurnal species in order to capture more of the available light.

Rod outer segments consist of stacks of isolated membranous discs or "saccules" bounded by the plasma membrane. Each saccule is around 19 nm in thickness. The periodicity of saccule spacing is 28 nm and, in humans, there are around 1,000 saccules in each rod outer segment. In contrast, cone outer segments are formed by multiple infolding of the plasma membrane. Both the saccule and infolded plasma membranes are packed with photopigment molecules that absorb the incident light. The high lipid content of the outer segment endows it with a high refractive index relative to the surrounding extracellular space. Consequently, the outer segment acts as a waveguide, and light entering at the base is contained and propagated along its length by total internal reflection.

The base of the outer segment is connected to the inner segment by a modified non-motile ►cilium, which projects through a narrow cytoplasmic bridge ("ciliary stalk") that is 1 μm in length. In some species, such as rodents, a second contiguous cytoplasmic bridge is observed. A number of fine processes originating from the inner segment, called calycal processes, extend distally along the outer segment for approximately one third of its length and probably provide mechanical support. In rod outer segments, the calycal processes are contiguous, with indentations in the plasma membrane that overlie – but do not invaginate – scalloped incisures in the radial edge of the saccule membrane.

### *Inner Segment*

The inner segment contains all the structures necessary for cellular metabolism and protein synthesis. It may also contain organelles that help to capture and/or spectrally filter the incident light and to focus it onto the outer segment. The most important structures are described below:

### *Ellipsoid*

Photoreceptors contain numerous ►mitochondria in the distal portion of their inner segment. These are packed together in a highly refractile body called the ellipsoid, and may be oriented with their long axis parallel to that of the photoreceptor, as in mammals, or clumped randomly. Photoreceptors are energetically demanding cells and the mitochondria must generate sufficient adenosine triphosphate (ATP) to support cellular function, in particular the maintenance of ►sodium/potassium ($Na^{\pm}/K^{\pm}$) pumps (Ion transport) in the plasma membrane, the production of photopigment molecules and the turnover of guanosine 3′,5′ cyclic monophosphate (cGMP; see ►Phototransduction).

In the mammalian retina, cones contain many more mitochondria than rods, but it is not readily apparent why they should do so on a metabolic basis [4]. It is possible that they also have an optical function by increasing the refractive index of the inner segment. Both the inner and outer segments have a higher refractive index than the surrounding medium and, at least in cones, the inner segment is significantly wider than the outer segment. Light striking the inner segment is funnelled by total internal reflection into the outer segment, a physical phenomenon known as waveguiding. Consequently, the cross-sectional area of the inner segment, rather than that of the outer segment, defines the photon capture area of the photoreceptor. Human foveal cones are 2.3 μm in diameter whereas those in the peripheral retina are 7.9 μm in diameter, a difference that confers a 12-fold increase in photon capture area and, therefore, optical sensitivity [1].

The ellipsoids of some species show further specializations. The proximal region of the cone ellipsoid in some lizards contains aggregations of extended endoplasmic reticula, known as refractile bodies, which may well have a light-gathering function in addition to any putative metabolic storage role. Similarly, tree shrews (*Tupaia* sp.) have large distended mitochondria ("megamitochondria") with visible but irregular cristae, which may confer

an enhanced light-gathering ability to the ellipsoid. This structure could replace the colorless oil droplets present in the cones of their ancestors and retained by marsupials but lost by other placental mammals [5]. Other modified mitochondria (ellipsosomes) are present in the ellipsoids of teleost fish and contain filtering pigments that resemble reduced cytochrome C.

### Oil Droplets

The photoreceptors of a number of species contain an inclusion located either within or just distal to the ellipsoid, known as an oil droplet. As their name suggests, oil droplets are composed predominantly of lipids, but they may also contain light-absorbing ►carotenoid pigments. Pigmented oil droplets are found in the cones of birds, turtles, lizards and lungfish; colorless oil droplets occur in some geckos, anuran amphibians, chondrostean fishes, marsupials and some monotremes. Oil droplets are absent from lampreys, teleosts, elasmobranchs, snakes, crocodilians and placental mammals [6].

Pigmented oil droplets act as filters that tune the spectral sensitivity of the photoreceptor, in most cases narrowing the spectral sensitivity function and shifting the wavelength of peak sensitivity to a wavelength longer than the wavelength of maximum absorbance ($\lambda_{max}$) of the photopigment in the outer segment. Non-pigmented oil droplets probably serve a similar function to ellipsosomes in capturing and focusing light into the outer segment.

### Paraboloid and Hyperboloid

The rod and cone inner segments of some holosteans, amphibians, birds and reptiles contain a granular structure proximal to the ellipsoid known as the paraboloid (cones) or hyperboloid (rods). It is thought to act as a store of glycogen, presumably supporting the high metabolic activity of the cell.

### Myoid

The myoid region lies proximal to the ellipsoid (and paraboloid/hyperboloid if present) but distal to the nucleus. It contains free ribosomes, rough endoplasmic reticulum (RER) and the Golgi apparatus, and it is the site of protein synthesis in the photoreceptor. Photopigment ►messenger RNAs from the nucleus migrate to the RER and are translated into opsin proteins (see ►Photopigments) that are eventually packaged into small vesicles by the Golgi apparatus. These vesicles migrate to the ciliary stalk, pass through the cytoplasmic bridge into the outer segment and become incorporated in the saccule and plasma membranes. In some lamprey and lizard species, the entire myoid contains a diffuse yellow-orange pigment that, like the pigmented oil droplets, spectrally filters the incident light before it reaches the outer segment.

In some "lower" vertebrates (e.g. fish, amphibians) the myoid is motile. Cone myoids contract in the light and elongate in the dark; the opposite is true for the rod myoid. These so called "retinomotor movements" are substantial (50–70 μm) and represent a form of light/dark adaptation, the function of which is to shield the rods in the retinal pigmented epithelium during the day but fully expose them at night. Myoid contraction and elongation is controlled by both light-dependent and endogenous (circadian) mechanisms [7].

### Synaptic Terminal

Beneath the myoid lies the nucleus and, proximal to this, a thin fiber (axon) that connects the inner segment to the synaptic terminal. The synaptic terminal of a photoreceptor cell ramifies in the outer plexiform layer of the retina and is the site of communication with other retinal neurons. The graded changes in outer segment transmembrane potential that occur as a result of the phototransduction process propagate electrotonically (►Electrotonic spread) to the synaptic terminal and are communicated to other retinal neurons in two ways. Firstly, the electrical potential may be transferred passively to adjacent photoreceptors via low-resistance intercellular junctions, called ►gap junctions. Secondly, changes in membrane potential at the synaptic terminal alter the internal $Ca^{2+}$concentration and modulate the rate at which ►synaptic vesicles fuse with the plasma membrane and release neurotransmitter (glutamate) into the synapse.

The morphology of rod and cone synaptic terminals differs markedly. The rod synaptic terminal ("►spherule") is roughly spherical and contains a single invagination ("synaptic cleft") within which lie the processes of two to five rod bipolar cells and two horizontal cells (►Retinal bipolar cells; ►Inherited retinal degenerations; ►Vision). The cone synaptic terminal ("►pedicle") is much larger and almost pyramidal in shape. In the mammalian retina, peripheral cones have much larger pedicles than foveal cones and display as many as 50 synaptic clefts. Like the rod spherule, the synaptic clefts of cone pedicles contain the processes of two or more cone bipolar cells and two horizontal cells [8].

In both rod and cone synaptic terminals, the active zone immediately above the synaptic clefts contain one (cones) or two (rods) synaptic ribbons that modulate the release of neurotransmitter (see ►Ribbon synapses). Rod and cone bipolar cell processes entering the synaptic cleft are termed "central" or "invaginating" processes. Other bipolar cell processes contact the cone pedicle on either side of the invaginating processes ("semi-invaginating" processes) or diffusely across the base of the pedicle ("flat" processes). Consequently, each cone pedicle may make several hundred synapses with 10 or more postsynaptic neurons.

## Higher Level Structures

In the mammalian retina, rods contact only one type of bipolar cell, the rod ON bipolar (►Retinal bipolar cells). Cone photoreceptors synapse with up to 11 different types of ON and OFF cone bipolar cells. In other vertebrates, both rods and cones may contact the same bipolar cell, which may be either ON or OFF and either rod- or cone-dominated. Photoreceptors are presynaptic to horizontal cells in a sign-conserving manner, i.e. ►hyperpolarization of the photoreceptor transmembrane potential results in a hyperpolarization of the horizontal cell. However, horizontal cells feed back onto photoreceptors in a sign-inverting manner that antagonizes the effects of transmembrane hyperpolarization, reduces glutamate release and allows the outer retina to adapt to steady illumination [1].

## Regulation of the Structure

In the dark, a balanced flow of cations into the outer segment and out of the inner segment (known as the dark current) maintains a moderate depolarization of the transmembrane potential. The magnitude of the dark current in the rods (−34 pA) and cones (−30 pA) is similar in the macaque monkey. Stimulation of photoreceptors with light causes a reduction in the dark current due to phototransduction. This change in dark current is called the photocurrent and, although both rods and cones are capable of signaling the absorption of a single photon of light, the photocurrent produced by a single photoisomerization event (see ►Phototransduction) is much smaller in cones (33 fA) than it is in rods (700 fA) [1]. Consequently, more photons per unit time are required by cones than rods to provide a large enough change in glutamate release at the synaptic terminal to be reliably detected by the bipolar cells and, therefore, rods are better for vision under low levels of illumination.

There are also qualitative differences in the time course of the photocurrent between rods and cones. The magnitude of the photocurrent peaks about 50 ms after the onset of light in primate cones but takes up to four times longer in the rods. Moreover, the rod photocurrent decays more slowly, taking up to one second to return to zero, whereas cones recover up to five times faster. These differences in response and recovery kinetics enable cone pathways to respond to higher temporal frequencies than the rods, although at the expense of absolute sensitivity.

Photoreceptor outer segments are renewed continuously. Rod saccules are shed from the distal tip of the outer segment in packets of 8–30, where they are taken up in phagocytotic vesicles ("phagosomes") by RPE cells. Shed saccules are replaced by the synthesis of additional membrane at the base of the outer segment, where new photopigment molecules generated in the inner segment are incorporated. Cones shed and regenerate membrane in a similar fashion to rods, although newly synthesized photopigment molecules can diffuse to any location in the membrane, as the outer segment is not compartmentalized. Membrane shedding follows a circadian rhythm; cone membranes are shed after dusk when the visual system begins to rely on rods, and rod saccules are shed at dawn when cones become dominant [9].

## Function

The retina is a two-dimensional sensor array that extracts salient features from the image of a three-dimensional world projected onto the back of the eye by the lens and cornea (►Vision). The size, packing density, spectral sensitivity and electrical response characteristics of the photoreceptors limit the spatial, temporal and chromatic information that can be extracted from that image.

Rods are more sensitive than cones and are used in dim light (scotopic) conditions. Most vertebrates, including humans, have only one spectral class of rod and, consequently, are essentially color blind at night. Cones, on the other hand, function at higher (photopic) light levels. The possession of both scotopic and photopic photoreceptor types – otherwise known as a ►duplex retina – has the primary function of extending the range of light intensities over which the visual system is operational. For most animals, this range varies over 10 log units from starlight to bright sunlight [1].

Where multiple spectral types of cone are present, their outputs can be compared by secondary neurons to extract chromatic information from the retinal image. The ability to distinguish objects based on their color (spectral reflectance) independently of brightness is called color vision (►Color processing). Most mammals have only two spectral types of cone and have a dichromatic color vision system. Humans and some primates have three spectral cone types and are trichromats. Birds have a tetrachromatic color vision system based on four spectral types of single cone photoreceptor [10]. The function of double/twin cones is unclear, despite being the most numerous photoreceptor types in many species. Limited evidence suggests that, at least in the avian retina, double cones mediate purely achromatic (brightness discrimination) tasks, including motion detection, and are not involved in color vision.

## Definition

Ribbon synapses are specialized synapses of the primary sensory neurons of the eye (retinal ►photoreceptors) and ear (►cochlear hair cells and ►vestibular hair cells). They are also formed by ►retinal bipolar cells, ►vestibular receptor cells, and fish ►electroreceptors. Morphologically, these synapses are characterized by a presynaptic electron-dense bar, the ►synaptic ribbon, at the site of ►neurotransmitter release (Fig. 1). Ribbon synapses support continuous release of the neurotransmitter ►glutamate, and modulate the rate of release in response to graded changes in membrane potential (►Membrane potential – basics).

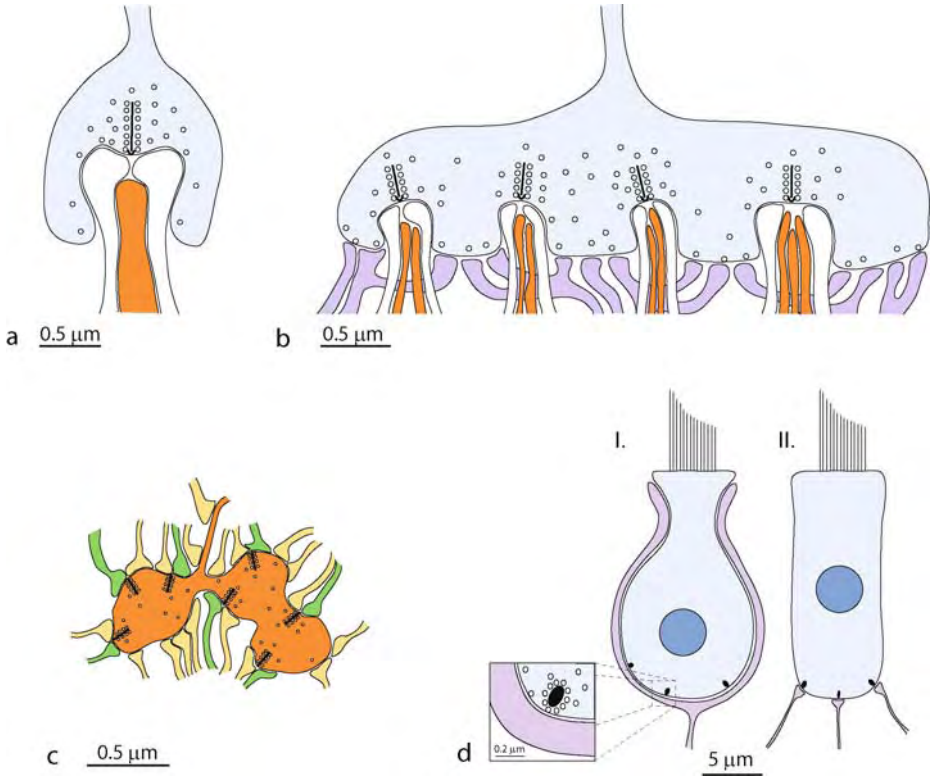
## Characteristics

### Description of the Structure

Anatomically, ribbon synapses are characterized by the presence of a structural specialization of the ►active zone, the synaptic ribbon. The synaptic ribbon is a planar structure in retinal photoreceptors and bipolar cells, and a spheroid structure in inner ear hair cells where it is also referred to as a "synaptic body" (Fig. 1). The ribbons are attached to the plasma membrane and typically extend perpendicularly into the cytoplasm up to several hundred nanometers. The ribbon is surrounded by a monolayer of ►synaptic vesicles that are tethered to the ribbon by fine filaments. Vesicles at the base of the ribbon are docked on the plasma membrane and represent the readily releasable pool of synaptic vesicles. Those tethered further up the ribbon provide a reserve pool of synaptic vesicles. Synaptic ribbons vary in size and shape depending on the cell, but for a particular cell type, such as the mammalian rod photoreceptor, the total ribbon area and geometry vary comparatively little, even between species.

Photoreceptor ribbon synapses are the most structurally complex of ribbon synapses. Photoreceptor ribbon synapses are formed by an invagination into the photoreceptor terminal, over the apex of which lays the synaptic ribbon, and into which postsynaptic processes from ►horizontal cells (►Lateral interactions in the retina, ►inherited retinal degenerations, ►vision) and bipolar cells protrude (Fig. 1). Rod photoreceptor terminals (referred to as ►spherules) contain a single invagination that gives rise to one or two ribbon synapses [1], whereas cone photoreceptor terminals (referred to as ►pedicles) contain 10–30 invaginations, depending on whether they are in the central or peripheral retina, each invagination corresponding to a single ribbon synapse (Fig. 1). The large synaptic ribbons of rod photoreceptors curve around the invagination in a characteristic horseshoe shape, which can be clearly discerned at the light microscopic level by immunofluorescent staining of ribbon proteins (such as bassoon or RIBEYE, see Fig. 2).

The photoreceptor synaptic ribbon is attached to the plasma membrane via a linear, trough-shaped structure, the ►arciform density. The arciform density defines the site of neurotransmitter release, or active zone, of the photoreceptor ribbon synapse (Fig. 2b). The plasma membrane is pinched where it contacts the arciform density to form a ridge along the underside of the invagination. Synaptic vesicles at the base of the ribbon are docked on the plasma membrane, fusing on either side of the arciform density. Two postsynaptic horizontal cell processes, known as "lateral elements," extend

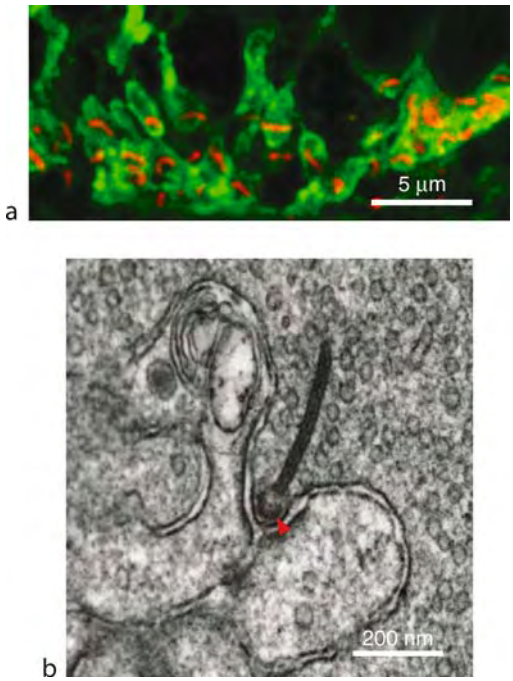


**Retinal Ribbon Synapses. Figure 1** Schematic diagrams of ribbon synapses in the retina and inner ear, drawn approximately to scale (as indicated). (a). Rod photoreceptor terminal (spherule) containing a vesicle-covered synaptic ribbon with an arciform density at its base. Postsynaptic horizontal cell (white) and rod bipolar cell (orange) processes protrude into the invagination, opposed to the site of transmitter release. (b) Cone photoreceptor terminal (pedicle) containing four separate ribbons with their associated arciform densities, and postsynaptic invaginations of horizontal cell (white) and ON-cone bipolar cell (orange) processes. OFF-cone bipolar cells (purple) make synapses at flat contacts, outside the invaginations. (c) Cone bipolar cell terminal (orange) containing multiple small ribbons. Postsynaptic amacrine cell (yellow) and ganglion cell (green) processes are opposed to the sites of neurotransmitter release. (d) Type I (I.) and type II (II.) inner ear hair cells contain spherical synaptic bodies, covered with tethered vesicles. Type I hair cells form a single calyceal terminal, whereas type II hair cells make synapses with individual afferent boutons, each bouton receiving input from a single ribbon.

their tips close to the synaptic ribbon. One or more bipolar cell processes, known as "central elements", occupy the central region of the invagination, with their tips located at a further distance from the ribbon. An electron micrograph of a photoreceptor ribbon synapse will often exhibit a "triad" arrangement, with two horizontal cell processes flanking a single bipolar cell process within the invagination postsynaptic to the ribbon. Rods make synaptic contacts with only one type of bipolar cell, the rod bipolar cell. Cones contact both ON-bipolar cells (depolarize in light) and OFF-bipolar cells (hyperpolarize in light) (►Retinal bipolar cells). At cone ribbon synapses it is only the ON-bipolar cells that extend their dendrites into the invagination; OFF-bipolar cells contact cone pedicles outside the invaginations at basal contacts.

Bipolar cell and hair cell ribbon synapses are simpler in structure (Fig. 1). They both lack invaginations and arciform densities. It is unclear how the ribbons are anchored to the plasma membrane in these cells. As in photoreceptors, bipolar cell synaptic ribbons are planar structures sitting perpendicular to the plasma membrane above a linear active zone, although they are smaller than photoreceptor ribbons. Two postsynaptic processes from amacrine cells (►Retinal direction selectivity: role of starburst amacrine cells) and ganglion cells (►Retinal ganglion cells) abut the bipolar cell membrane, one on either side of the active zone. Each bipolar cell terminal forms multiple ribbon synapses.

Hair cells also contain multiple ribbons, averaging ~20/cell, each covered with a layer of one hundred to several hundred tethered synaptic vesicles. Each hair cell ribbon synapse releases glutamate onto a single postsynaptic ending/contact. Type I vestibular hair cells are enveloped by a single calyceal terminal, which receives the output from all of the hair cell's ribbon synapses;



**Retinal Ribbon Synapses. Figure 2** (a) Individual arc-shaped synaptic ribbons, labeled with an antibody to RIBEYE (red), are seen within rod and cone photoreceptor terminals (green) in a confocal micrograph through the ►outer plexiform layer of the rat retina. (b) Rod ribbon synapse ultrastructure is observed in more detail by transmission electron microscopy. The synaptic ribbon, in transverse section, is perpendicular to the cell membrane, and overlies an arciform density (red arrowhead). Vesicles of neurotransmitter are evident throughout the terminal, with a subset of these tethered to the ribbon. Postsynaptic horizontal and rod bipolar cell processes invade the terminal, opposed to the site of neurotransmitter release.

whereas each ribbon synapse of a type II vestibular hair cell has a separate post-synaptic dendrite [2]. Hair cells in the cochlea also have only one post-synaptic afferent/dendrite per ribbon [3]. Hair cell synaptic ribbons are often spherical, but elongated and planar ribbons are also found, especially in type II vestibular hair cells.

## Quantitative Description of Ribbon Synapses in the Retina

Reconstruction of rod spherules in the cat retina reveal a planar synaptic ribbon ~2 µm in length (or two half-sized ribbons), extending from the plasma membrane into the cytoplasm by ~0.4 µm. Each face of the ribbon binds approximately 385 synaptic vesicles, 65 of which lie along the bottom of the ribbon docked at the plasma membrane on each side of the arciform density. Cone synaptic ribbons are smaller but more numerous than in rods. Cone ribbons are ~1 µm long and extend from the plasma membrane into the cytoplasm by ~0.2 µm. Although different ribbons within a cone terminal vary in length, the total ribbon length and number of tethered vesicles per cone is quite uniform within a retinal locus. The 20 or so ribbons in a primate foveal cone tether a total of ~3,600 synaptic vesicles, ~720 of which are docked at the plasma membrane [4]. Bipolar cells, depending on their type, contain from 30–100 synaptic ribbons, but they are small compared to photoreceptor ribbons, tethering several dozen vesicles each. The total number of ribbons and associated docked vesicles per ►synaptic terminal may be related to the information content that has to be transmitted by the neuron [4]. For example, rod photoreceptors transmit the detection of single photons in very dim light, like starlight, whereas cones must transmit finely graded changes over orders of magnitude of light intensity (►Photoreceptors, ►Phototransduction).

The most detailed and quantitative description of a ribbon synapse has been obtained for the mammalian rod photoreceptor. Digital reconstruction of primate and cat rod spherules from serial electron micrographs has revealed the following invariant features of rod ribbon synapses [1]: Each spherule contains a single invagination approximately 1µm in diameter, and two synaptic units. Post-synaptically, each unit is made up of two lateral elements (horizontal cell dendrites) and at least one central element (rod bipolar cell dendrite). Although there are always two sets of postsynaptic processes, presynaptically a spherule may contain either one or two synaptic ribbons. However, even in cases where a spherule contains a single ribbon, the ribbon contacts two discrete arciform densities, each ~1.0 µm in length. Typically, the two arciform densities are in different planes, so that a single ribbon will twist to contact both. The volume of extracellular space within the invagination is small, roughly 0.1µm$^3$, and the most distant bipolar cell glutamate receptors from the active zone (as defined by the arciform density) are within 1.5 µm. Thus, diffusion of glutamate to receptors on all postsynaptic processes should be rapid.

## Higher Level Structures

The principal component of synaptic ribbons is the ribbon-specific protein, RIBEYE, composed of a unique N-terminal domain possessing a self-aggregating activity that may be important for the polymerization of the ribbons, and a C-terminal domain that is identical (minus the first 20 amino acids) to the transcriptional co-repressor, C-terminal binding protein 2 (CtBP2) [5]. Other proteins associated with the ribbons are components of the presynaptic matrix at conventional synapses including RIM (rab3-interacting protein), and the large (>400 kD) scaffolding proteins bassoon and piccolo, suggesting that at least some aspects of ribbon function are equivalent to that served by the presynaptic matrix at the active zone of conventional synapses. Bassoon has

been localized by post-embedding immuno-electron microscopy to the base of photoreceptor ribbons close to the plasma membrane, whereas piccolo and RIM are localized towards the distal portion of the ribbon [6]. In mice deficient in bassoon, photoreceptor and hair cell synaptic ribbons are either absent or free-floating in the cytoplasm [7,8] suggesting that bassoon is required for anchoring the ribbons to the plasma membrane.

The presynaptic $Ca^{2+}$ channels at ribbon synapses are localized to the plasma membrane at the base of the ribbons [6]. Ribbon synapse $Ca^{2+}$ channels belong to the L-type $Ca^{2+}$ channel family (►Calcium channels – an overview), and are of the subtypes Cav1.3 ($\alpha_{1D}$) in cone photoreceptors and hair cells, and Cav1.4 ($\alpha_{1F}$) in rod and cone photoreceptors and some bipolar cells. A distinctive characteristic of the ribbon synapse $Ca^{2+}$ channels is that they are non-inactivating, an essential property for maintaining transmitter release during prolonged depolarization, as occurs in darkness.

The majority of synaptic vesicle-associated proteins are identical between ribbon and conventional synapses; however, there are a few significant differences [9]. For example, ribbon synapses are the only synapses known not to contain ►synapsins, peripheral membrane proteins of synaptic vesicles at conventional synapses. Synapsins immobilize synaptic vesicles in the absence of action potentials by linking them to the actin-based cytoskeleton, and then release them upon $Ca^{2+}$ influx to replenish the readily releasable pool. At ribbon synapses, which are tonically active, synaptic vesicles are in constant flux and synapsins are not needed. Retinal ribbon synapses also differ in which ►syntaxin gene they express. At conventional synapses, syntaxin 1 is one of the key proteins catalyzing synaptic vesicle fusion. Retinal ribbon synapses are the only synapses known not to contain syntaxin 1 but to contain syntaxin 3 instead. This substitution may reflect differences in the regulation of synaptic vesicle fusion between ribbon and conventional synapses.

## Function

Ribbon synapses are formed by sensory neurons of the visual, auditory, and vestibular systems. These neurons are electrotonically compact (►Electrotonic spread), and track changes in external stimuli with graded changes in their membrane potential (in contrast to axon-bearing neurons that fire action potentials). The graded changes in membrane potential in turn modulate the rate of tonic release of the neurotransmitter, glutamate. Synaptic ribbons are not found in neurons that undergo action potential-driven transmitter release. As at other chemical synapses, neurotransmitter is released at ribbon synapses by the $Ca^{2+}$-dependent fusion of neurotransmitter-filled synaptic vesicles with the plasma membrane. Calcium enters the nerve terminal through voltage-sensitive $Ca^{2+}$ channels that open in response to membrane depolarization and close upon hyperpolarization. Photoreceptors are depolarized in darkness and undergo a continuous stream of synaptic vesicle fusion in this state. Absorption of photons hyperpolarizes the photoreceptor, closing $Ca^{2+}$ channels and reducing glutamate release (►Phototransduction). The synaptic ribbons most likely serve to maintain a pool of synaptic vesicles in close proximity to the active zone, and ensure the continual replenishment of synaptic vesicles during prolonged depolarizations. They have also been proposed to facilitate compound fusion of vesicles, or simultaneous fusion of multiple vesicles [10].

The critical role of the synaptic ribbons in ►synaptic transmission at ribbon synapses is illustrated by the phenotype of the bassoon knockout mouse. Elimination of bassoon prevents synaptic ribbons from anchoring at the plasma membrane. The physiological consequence is a drastic impairment of synaptic transmission between photoreceptors and depolarizing bipolar cells [7]. Likewise, in hair cells of the bassoon knockout mouse, patch-clamp recordings (►Intracellular recording) indicate a 50% reduction in fast ►exocytosis. The hair cell recordings also reveal substantially smaller $Ca^{2+}$ currents in the bassoon knockout mouse compared to wild-type, suggesting that recruitment and stabilization of $Ca^{2+}$ channels at hair cell active zones may be dependent on association with synaptic ribbons [8].

## Retinal Slip

### Definition

Motion of the visual image on the surface of the retina. Slip of the visual image across large portions of the retina is the stimulus that stimulates optokinetic eye movements, and also the stimulus that produces the adaptation (improvement) of the optokinetic system.

►Optokinetic Response Adaptation

## Retinitis Pigmentosa

### Definition

A group of hereditary retinal degenerations characterized by loss of peripheral vision (constricted visual fields) and night vision (nyctalopia). Although a vast variety of genetic mutations have been identified, patients with Retinitis Pigmentosa display similar symptoms and ocular fundus appearance in the end stage of the disease: bone spicule pigment deposits, pale atrophic optic nerve head and attenuated blood vessels.

►Inherited Retinal Degenerations

## Retino-geniculo-cortical Pathway

### Definition

A large fraction (at least 90%) of retinal ganglion cells project to visual cortex through the lateral geniculate nucleus. This pathway is thought to be most important for visual perception. Non-geniculo-cortical pathways, such as the pathways through the suprachiasmatic nucleus or pre-tectum involve smaller numbers of ganglion cells and in some cases have specialized functions (e.g. suprachiasmatic nucleus is involved in diurnal rythyms).

## Retinohypothalamic Tract

Ignacio Provencio
Department of Biology, University of Virginia, Charlottesville, VA, USA

### Synonyms

RHT

### Definition

A monosynaptic neural projection that extends from the ►retina to the hypothalamus.

### Characteristics

#### Origin and Projections

The retinohypothalamic tract (RHT) originates from a subset of ►retinal ganglion cells (RGCs). In rodents, this small cohort of cells represents only about 1–2% of all RGCs of which 80% or more express the ►photopigment melanopsin, thereby making them intrinsically photosensitive. However, compared to ►rod and cone photoreceptors, these photoreceptive cells are relatively insensitive to light. The sparse, varicose dendritic arbors of murine ►intrinsically photosensitive RGCs (ipRGCs) arise from 2 or 3 primary dendrites emanating from perikarya about 20 μm in diameter. ipRGC dendritic fields have a mean diameter of 450 μm and tile the retina with substantial overlap. The arbors themselves contain melanopsin and are capable of ►phototransduction, giving each of these cells a capture radius of approximately 15° of visual space. These overlapping dendrites coupled with the relative photic insensitivity of ipRGCs are consistent with the sensory characteristics observed in many non-visual responses to light such as the synchronization (►entrainment) of circadian rhythms to the astronomical day. Relative to the visual system, the circadian axis requires higher levels of light to elicit a response and can integrate photic stimuli over longer temporal intervals and broader

spatial domains. In essence, while the visual system functions like a camera, the "photoreceptive net" arising from the widely distributed ipRGCs functions like a photographer's light meter [1,2].

In most animals examined to date, the ipRGCs are distributed evenly throughout the retina. In rats and primates, however, there is a shallow density cline peaking in the superiotemporal and parafoveal retinal domains, respectively. The principal target of the RHT is the ►suprachiasmatic nucleus (SCN), the site of a primary ►circadian pacemaker. The RHT is the anatomical route by which information about environmental light levels is conveyed from the eye to the SCN, where it is processed and used to entrain a multitude of circadian rhythms to the prevailing ►light:dark cycle. Among these are circadian rhythms of activity, daily variations in core body temperature, and 24-h rhythms in levels of hormones such as ►melatonin and cortisol [2,3].

The topography of the retinal innervation to the SCN is highly variable across mammalian species and even varies significantly among the rodents. In general, the ventrolateral aspect of the SCN receives the most dense innervation from the retina and is coextensive with the distribution of vasoactive intestinal peptide (VIP)-positive cells. However, it should be noted that the entire SCN receives some retinal afferents [3,4].

The degree to which the retina projects to each SCN also varies significantly among mammals. Contralaterality of retinal projections to central visual structures is highly correlated with the lateral placement of the eyes on the head. For example, mammals such as rodents with very limited binocular vision due to laterally positioned eyes show a high degree of contralaterality of the retinal projections to the dorsal lateral geniculate nucleus (LGN). By contrast, the retinal projections of primates and cats that have frontally positioned eyes are not contralaterally dominant, but rather extend an equal number of contralateral and ipsilateral retinal projections to the geniculate body.

The degree of bilaterality of the RHT demonstrates no such correlation to the lateralization or frontalization of the eyes. Perhaps the most striking example is that of the scaly anteater whose laterally placed eyes results in a total binocular field of only 15°, a feature that is reflected in the optic chiasm where greater than 99% of retinal fibers cross the midline and project to the contralateral lateral geniculate. However, both eyes project an equal number of axons to each SCN. As previously mentioned, primates, due to very frontalized eyes, have an extensive binocular visual field and accordingly, have equally weighted bilateral projections to central visual sites. This is in stark contrast to the projections to the SCN which are heavily ipsilaterally weighted. For example, in the gibbon, almost 90% of fibers emerging from one retina project to the ipsilateral SCN, whereas visual projections are balanced [5].

In the hamster, about 5% of the RGCs of the RHT bifurcate and send axonal collaterals to both SCN. In addition, some RGCs that project to the SCN via the RHT also send axonal collaterals to other non-visual retinorecipient sites in the brain such as the ►intergeniculate leaflet and the ►olivary pretectal nucleus. Whether this is a common feature across all mammals remains to be determined [4]. It should be noted that while the SCN is the primary and best-studied target of the RHT, other hypothalamic sites receive RHT innervation. These include the retrochiasmatic area, the subparaventricular zone, the perisupraoptic nucleus and the lateral hypothalamus [2,3]. Understanding how these regions mediate responses to light is a subject of ongoing investigation.

## Neurotransmitters

There is abundant evidence that ►glutamate is the primary neurotransmitter of the RHT [6,7]. Among this evidence is the presence of anti-glutamate immunoreactivity in presynaptic terminals within the SCN of rat and mouse. Furthermore, glutamate release can be induced in the SCN by electrically stimulating the optic nerve and glutamate application mimics that effect of light on the SCN. However, some investigators have observed that application of glutamate onto the SCN does not accurately mimic the circadian phase shifting effect of light, although administration of the glutamate agonist *N*-methyl-*D*-aspartate (NMDA) does indeed mimic light and these effects can be blocked by NMDA antagonists. Intraperitoneal injection of MK801, a competitive NMDA receptor antagonist, blocks the phase-shifting effect of light on mouse circadian locomotor rhythms [4].

A hallmark of the lateral geniculate, a well-characterized target of glutamatergic neurotransmission, is an abundance of the ►glutamate vesicular transporters VGluT1 and VGluT2. The SCN, however, shows low expression of both of these proteins. The presence of glutamate receptors in the SCN, however, reinforces a prominent role for glutamate as the primary neurotransmitter of the RHT. In addition to NMDA receptors, ionotropic receptors sensitive for the glutamate agonist α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) are found throughout the SCN. In particular, receptors composed of the GluR2 subunits are localized to the ventrolateral aspect of the SCN where most axonal terminals of RGCs are found. It must be considered that glutamate receptors are frequently expressed in astrocytes, thus raising the possibility that glutamate functions indirectly as a neuromodulator. Alternatively, astrocytes themselves may serve as a source of glutamate, released in response to some other signal originating from the RHT. Finally, derivatives of glutamate, such as *N*-acetylaspartylglutamate (NAAG) may play a role in RHT neurotransmission. NAAG is released from RGC terminals in a

calcium-dependent manner and can be converted to its constituent amino acids within the synaptic cleft. The prospect of NAAG as a primary RHT neurotransmitter is diminished by the fact that it is only found in a fraction of the retinorecipient aspect of the SCN [4].

Nitric oxide (NO) also plays a critical role in transferring information about environmental light levels from the retina to the SCN. The phase shifting effect of light (or glutamate) on SCN slice preparations can be faithfully mimicked by NO generators such as sodium nitroprusside. Moreover, these effects are blocked by the application of the competitive nitric oxide synthase (NOS) inhibitor $N^G$-nitro-*L*-arginine methyl ester (L-NAME). This inhibition, however, can be reversed by increasing the availability of *L*-arginine, the natural substrate of NOS. The emerging evidence suggests that glutamate released from the presynaptic terminals of retinal afferents binds to NMDA receptors in postsynaptic SCN cells. This, in turn, results in a transient increase in intracellular calcium concentrations, thereby leading to activation of nNOS and the subsequent production of NO [4,8]. Because of the inherent instability of NO, such a mechanism could provide very fine spatial and temporal resolution to signaling occurring at the synapses of retinal afferents.

►Pituitary adenylyl cyclase activating peptide (PACAP) is one of a handful of peptide transmitters that may modulate the glutamatergic-based signaling of the RHT. PACAP is colocalized with glutamate and it has been suggested that all melanopsin-containing RGCs express PACAP [9]. Evidence from other systems where a small-molecule and a peptide neurotransmitter coexist in presynaptic terminals has shown that the small molecule transmitter is released upon weak or transient presynaptic stimulation. Stronger tonic stimulation results in release of both classes of transmitter, thereby encoding a broad dynamic range of stimulus strength. Similarly, weak retinal illumination may result in the release of glutamate from RHT terminals, while higher levels of light induce the release of PACAP.

Several labs have conducted experiments where PACAP has been applied *in vitro* to SCN slices or infused *in vivo* to hamsters. These experiments have not produced a consensus regarding PACAP's role in RHT neurotransmission. Additionally, mice null for PACAP show modest circadian effects. They show no re-entrainment deficits when exposed to a shifted light:-dark cycle, no diminution in the lengthening of circadian period in response to constant light, and no loss of ►masking behavior, i.e., acute light-induced suppression of nocturnal locomotor activity. However, these animals did exhibit attenuated circadian responses to ►phase-advancing or ►phase-delaying pulses of light and they displayed a modestly shortened ►free-running circadian ►period. The PACAP-specific receptor PAC1 has been knocked out in mice. The behavioral phenotype of these mice is rather subtle; they exhibit light-induced phase delays of circadian activity rhythms that are about 30% longer than wild-type mice [4]. By contrast, mice null for the VPAC2 receptor, which binds PACAP and VIP, are ►arrhythmic. This dramatic phenotype, however, is difficult to attribute to PACAP signaling because of the non-specificity of the receptor [10].

Finally, the tachykinin, substance P (SP), has been implicated as a neuromodulator of the RHT. This implication has been challenged because localization of SP to any RGCs, much less RGCs that comprise the RHT, has been equivocal. It has been reported that SP does not colocalize with PACAP in the retina and that bilateral enucleation does not abolish SP immunoreactivity. SP's proposed neuromodulatory role in RHT transmission remains to be shown conclusively [4].

## Concluding Remarks

The identification and characterization of ipRGCs has provided new insight into a major constituent of the RHT. The specifics of how information is transferred from the retinal afferents to SCN neurons, and how this information is subsequently processed by these neurons remains a critical gap in our body of knowledge. However, it also represents a fertile field for future investigations.

## Retinotopic Frame of Reference

### Definition
Also, "Oculocentric frame of reference." A reference frame specifying the location of a visual target with respect to the position of the eyes in space.

## Retinotopy

### Definition
The visual field is represented in orderly maps in occipital cortex in retinal centered coordinates. The left half of the visual field is represented in the right hemisphere and vice versa, whereas the upper visual field is mapped to the inferior occipital cortex (below the calcarine sulcus) and vice versa. Therefore, when subjects hold their eye position constant (e.g. when they maintain central fixation), the region of occipital cortex that responds to a particular stimulus in the visual field can be determined within these maps. This is known as the retinotopic representation of the visual stimulus.

## Retrograde Messenger

Takako Ohno-Shosaku
Department of Cellular Neurophysiology, Graduate School of Medical Science, Kanazawa University, Kanazawa, Japan

### Definition
Retrograde messenger is a chemical substance that is released from postsynaptic neurons and acts on

presynaptic neurons. In the nervous system, information coded by action potentials is transferred from neuron to neuron at a specialized site called "synapse" (Fig. 1). The transmission at ►chemical synapses is generally one-directional. Neurotransmitters are released from presynaptic terminals on the arrival of action potentials, and transmit a signal to postsynaptic neurons by activating the corresponding receptors (Fig. 1a). In contrast to this fundamental anterograde information transfer, the signaling from postsynaptic to presynaptic neurons is called retrograde signaling (Fig. 1b) [1,2]. The retrograde signaling can be mediated by either a diffusible factor that is called "retrograde messenger," or a direct interaction of presynaptic and postsynaptic membrane-bound elements. In typical cases, a retrograde messenger is released from the postsynaptic site lacking morphologically specialized structures for release (e.g. ►active zone), activates the receptors located on presynaptic terminals, and influences the function of presynaptic terminals (i.e. transmitter release) (Fig. 1b).

## Characteristics

### Quantitative Description

The substances so far proposed as retrograde messengers are ►endogenous cannabinoids (endocannabinoids) [3], ►nitric oxide (NO), ►carbon monoxide (CO), ►arachidonic acid, platelet-activating factor, neurotrophic factors, and some classical neurotransmitters or neuropeptides [2]. Among them, endocannabinoids are the most widely accepted substances as retrograde messengers in the brain. Major endocannabinoids are arachidonoylethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG) (Fig. 2).

Anandamide is the amide of arachidonic acid with ethanolamine, and the molecular weight is 347.54. 2-AG is the glycerol derivative in which the second hydroxyl group is linked to arachidonic acid residue by an ester bond, and the molecular weight is 378.55. The structural features of endocannabinoids are quite different from classical neurotransmitters, and shared by lipid messengers such as eicosanoids, which mediate signals of inflammation and pain.

## Lower Level Components

### *Arachidonoylethanolamide*

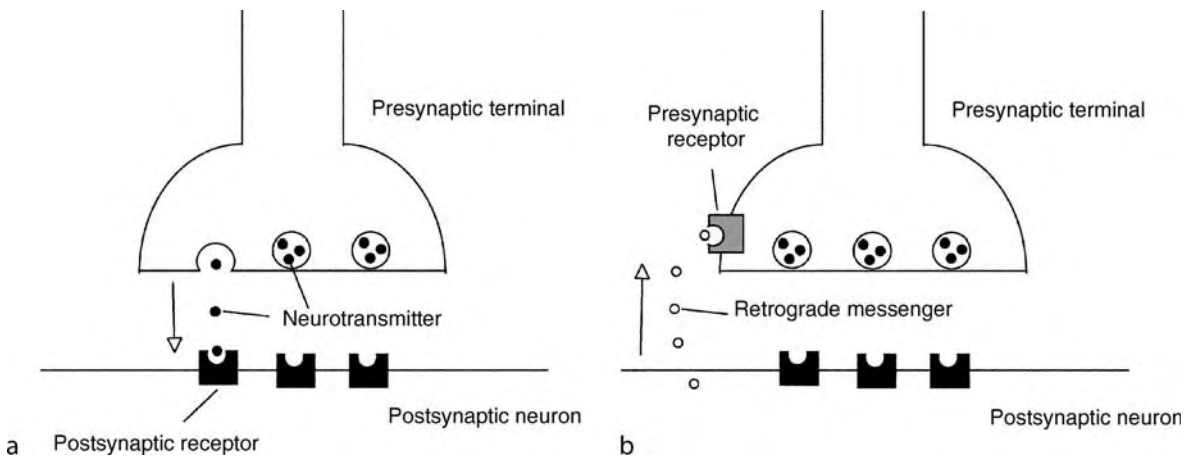
Arachidonoylethanolamide, known as "anandamide," was the first endocannabinoid to be identified. The name of anandamide is based on the Sanskrit word for bliss and tranquility, *ananda*. Anandamide binds to both CB1 and CB2 ►cannabinoid receptors, but displays lower affinity for CB2 compared to CB1 receptors.

### *2-Arachidonylglycerol*

2-Arachidonoylglycerol (2-AG) is another major endocannabinoid, and binds to both CB1 and CB2 receptors. 2-AG is widely distributed in the brain and periphery. The level of 2-AG is reported to be much higher (ca. 170 times) than anandamide in brain tissues. This molecule is the most likely candidate for the endocannabinoid that mediates retrograde synaptic modulation at hippocampal and cerebellar synapses.

### *Other Putative Endocannabinoids*

Other putative endocannabinoids include noladin ether and virodhamine. Noladin ether is an ether-linked analogue of 2-AG. Virodhamine is the ester of arachidonic acid with ethanolamine. It is not determined whether these molecules actually mediate retrograde signals.



**Retrograde Messenger. Figure 1** Synaptic transmission and retrograde signaling. In synaptic transmission (a), neurotransmitters are released from presynaptic terminals, and bind to postsynaptic receptors. In retrograde signaling (b), retrograde messengers are released from postsynaptic neurons, and activate presynaptic receptors.

## Higher Level Processes

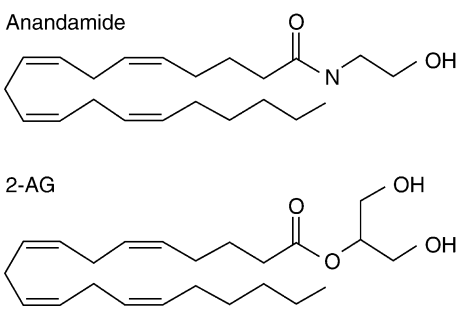
### *Interneuronal Communication*

In the anterograde signaling, classical neurotransmitters, neuropeptides, neurotrophic factors, and some other substances are released from presynaptic terminals, and produce rapid changes in membrane potential (i.e. generation of postsynaptic potentials) as well as long-term structural and metabolic changes in the postsynaptic cells. In the retrograde signaling, retrograde messengers including some of the substances used for the anterograde signaling are released from postsynaptic cells, and influence the function or morphology of presynaptic neurons. In addition to these diffusible factors, direct interactions of presynaptic and postsynaptic membrane-bound elements (e.g. cadherins) are also involved in interneuronal communication between presynaptic and postsynaptic neurons.

## Lower Level Processes

### *Synthesis of Endocannabinoids (Anandamide and 2-AG)*

Anandamide formation in neurons is a two-step process. The first step is the transfer of an arachidonic acid group from the *sn*-1 position of phosphatidylcholine to the head group of phosphatidylethanolamine (PE) by the enzyme *N*-acyltransferase, resulting in the formation of *N*-arachidonyl-PE. The second step is the cleavage of *N*-arachidonyl-PE by phospholipase D (PLD), which produces anandamide and phosphatidic acid (Fig. 3a) 2-AG is formed through two distinct pathways. The first step of the main pathway is the cleavage of phosphatidylinositol (PI) by the enzyme PI-specific phospholipase C (PI-PLC), producing 1,2-diacylglycerol (DAG). The second step is the further cleavage of DAG by DAG lipase, yielding 2-AG (Fig. 3b). The alternative pathway involves phospholipase $A_1$ and lyso-PLC. The PLD and DAG lipases responsible for endocannabinoid formation have been identified. Among several types of PI-PLC, β type PLC (PLCβ) is the most important for 2-AG formation.



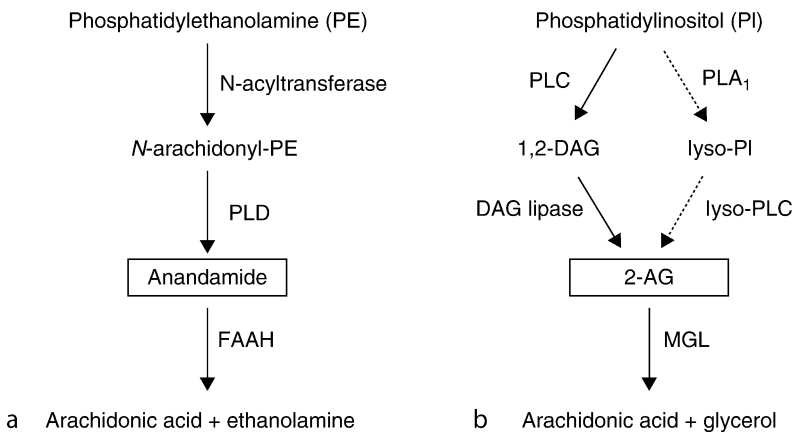
**Retrograde Messenger. Figure 2** Chemical structures of two major endocannabinoids.

### *Breakdown of Endocannabinoids (Anandamide and 2-AG)*

Anandamide is broken down into arachidonic acid and ethanolamine by the enzyme fatty acid amide hydrolase (FAAH) (Fig. 3a). 2-AG is broken down into arachidonic acid and glycerol by the enzyme monoacylglycerol lipase (MGL) (Fig. 3b). These enzymes have been identified. They exhibit unique distributions in the brain. In general, FAAH is a postsynaptic enzyme, whereas MGL is presynaptic.

### *CB1 Receptor Signaling at Presynaptic Terminals*

The CB1 receptor is densely distributed on presynaptic axons and terminals in various regions of the brain. They include excitatory synapses on cerebellar Purkinje cells (both climbing fiber and parallel fiber synapses), inhibitory synapses on cerebellar Purkinje cells, part of hippocampal inhibitory synapses including CCK-positive basket cell to pyramidal cell synapses, and inhibitory synapses from the striatum to globus pallidus. Activation of presynaptic CB1 receptors suppresses the release of the



**Retrograde Messenger. Figure 3** Pathways of formation and degradation of two major endocannabinoids. *PLD* phospholipase D; *FAAH* fatty acid amide hydrolase; *PLC* phospholipase C; *$PLA_1$* Phospholipase $A_1$; *DAG* diacylglycerol; *MGL* monoacylglycerol lipase.

transmitters (glutamate or GABA). This CB1-mediated suppression can be caused by inhibition of voltage-gated $Ca^{2+}$ channels, activation of $K^+$ channels, direct effect on release machinery, or some other unknown mechanisms.

## Process Regulation

The release of retrograde messengers from postsynaptic neurons is generally controlled by neural activity. For example, endocannabinoids are produced on demand in response to depolarization-induced elevation of intracellular $Ca^{2+}$ concentration [4,5], or activation of Gq-coupled receptors such as group I metabotropic glutamate receptors [6] and $M_1/M_3$ muscarinic receptors [7] (Fig. 4). As endocannabinoids are membrane-permeable, they are considered to diffuse across the plasma membrane to the extracellular space immediately after production (Fig. 4).

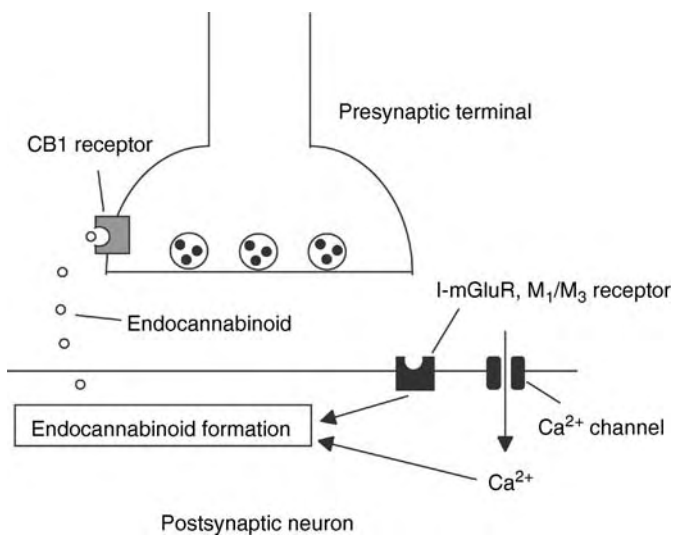
Endocannabinoids are produced much more effectively when $Ca^{2+}$ elevation and receptor activation coincide [8]. The released endocannabinoids then work as retrograde messengers (Fig. 4), and are removed from the extracellular space through uptake and enzymatic degradation. Other membrane-permeable factors such as NO and CO can be produced in response to certain conditions, and released to the extracellular space. In contrast, membrane-impermeable factors including classical neurotransmitters and neuropeptides are supposed to be stored in vesicles, and secreted through exocytotic mechanisms in response to certain triggering stimuli such as an elevation of intracellular $Ca^{2+}$ concentration.

## Function

Retrograde messengers play important roles in formation, maturation, and plasticity of synaptic connections. Among them, most attention has been focused on their crucial roles in activity-dependent modulation of synaptic transmission, including both short-term and long-term forms of synaptic plasticity.

Endocannabinoids mediate retrograde signals involved in several forms of short-term synaptic plasticity including ►DSI, ►DSE, and ►receptor-driven retrograde suppression. The CB1 receptor is widely distributed in the brain, and located densely on many, but not all, types of presynaptic terminals. At CB1-expressing synapses, endocannabinoids released from the postsynaptic neurons activate presynaptic CB1 receptors, and thereby suppress the transmitter release. Endocannabinoid release is triggered by elevation of intracellular $Ca^{2+}$ concentration, activation of Gq-coupled receptors, or combination of the two [8] (Fig. 4). Under physiological conditions, endocannabinoid-mediated retrograde suppression is triggered by synaptic activity that can produce postsynaptic $Ca^{2+}$ elevation and Gq-coupled receptor activation. Thus, the endocannabinoid-mediated retrograde suppression provides a feedback mechanism, by which the postsynaptic neurons receiving synaptic inputs can retrogradely influence the function of CB1-expressing presynaptic terminals. This endocannabinoid-mediated retrograde suppression is reversible and thus classified as a form of short-term synaptic plasticity. However, endocannabinoids are also involved in long-term synaptic plasticity, especially long-term depression (LTD), in some brain regions including the striatum and amygdala [9,10].

It has been reported that dopamine can be released from dendrites of dopaminergic neurons. Some other classical neurotransmitters or neuropeptides are also proposed to be released from dendrites [2]. They



**Retrograde Messenger. Figure 4** Endocannabinoid-mediated retrograde signaling. Endocannabinoid production is induced by postsynaptic depolarization-triggered $Ca^{2+}$ influx, or activation of Gq-coupled receptors such as group I metabotropic glutamate receptors (I-mGluRs) and $M_1/M_3$ muscarinic receptors. The endocannabinoids that are produced are then released from postsynaptic neurons, and activate presynaptic CB1 receptors to suppress the transmitter release.

include glutamate, GABA, and dynorphin. Although the actual release mechanisms of these substances are not fully elucidated, it is likely that these substances also contribute to short-term plasticity.

Synaptic activity can induce long-term potentiation (LTP) or depression (LTD) depending on the pattern of activity. Membrane-permeable factors such as NO, CO, arachidonic acid and platelet-activating factor have been proposed to contribute to long-term synaptic plasticity, especially LTP. However, there are many controversial results, and general consensus has not yet been reached as to the possible roles of these factors as retrograde messengers in long-term synaptic plasticity.

Retrograde messengers also play important roles in formation, maturation and refinement of synaptic connections, especially at early developmental stages. These processes require information exchange between presynaptic and postsynaptic cells through anterograde and retrograde signals. Although molecular mechanisms of these signals are not clearly elucidated, it has been proposed that neurotrophic factors, including nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF), could play important roles in these processes.

### Therapy

#### *Cannabinoids for Therapies*

Marijuana, which contains the natural cannabinoid $\Delta^9$-tetrahydrocannabinol, as well as several commercially-available synthetic cannabinoids (nabilone and dronabinol) are clinically effective for several disorders such as nausea from cancer chemotherapy, chronic pain, and exhaustion in AIDS patients. However, these drugs also have psychoactive side effects such as dizziness and thinking abnormalities. They are inherent problems, because the CB1 receptor is widely distributed in the brain. To avoid these problems, it has been attempted to develop drugs that enhance the endocannabinoid signaling in a target-specific manner.

## Retrograde Neuron Reaction

►Neuronal Changes in Axonal Degeneration and Regeneration

## Retrograde Tracing

### Definition

A method for visualizing the neurons of origin of an axonal pathway. A dye is injected into the region of the nervous system where axons are thought to terminate. The dye is absorbed by the axons and transported back to the cell bodies allowing them to be visualized.

## Retrograde Tracing Techniques

### Definition

Neuron tracing techniques take advantage of the fact that axoplasmic transport of materials goes in both directions within the axon. Retrograde flow of materials is toward the cell body. Early studies of retrograde transport used the enzyme horseradish peroxidase (HRP), which after injection into nerve tissue is picked up at axon terminals by micropinocytosis. The HRP is transported back to the cell body of the neuron where it can be made visible with a variety of chemical reactions. More recent studies use retrograde immunocytochemical and fluorescent labeling techniques to visualize neuron morphology.

## Retrograde Transport

### Definition

Retrograde transport is a process, mediated by the microtubule motor dynein, by which chemical messages are sent from the axon back to the cell. Fast retrograde transport can cover over 100 mm/day.

## Retronasal/Orthonasal Olfaction

### Definition

Orthonasal smell perception occurs when volatile molecules are pumped in through the external nares of the nose and activate the sensory cells in the olfactory epithelium. This is the route used to sense odors in the environment.

Retronasal stimulation occurs during food ingestion, when volatile molecules released from the food in the mouth are pumped, by movements of the mouth, from the back of the oral cavity up through the nasopharynx to the olfactory epithelium. It is activated only when breathing out through the nose between mastications or swallowings. This is the route used to sense aromas of food.

►Flavor
►Olfactory Epithelium

## Retrospective Monitoring

### Definition

Retrospective monitoring refers to metamemory experiences when one searches for and retrieves the origin and content of information stored in long-term memory.

It has been studied by examining the experiences of "tip-of-the-tongue" (TOT), which one has when the information one tries to remember feels like right on the edge of the tongue), and of "feeling-of-knowing" (FOK).

►Metacognition

## Retroviral Vectors

### Definition

These are retroviruses used to insert novel genes into neurons or other cells by infecting them.

## Rev-erbα

### Definition

Member of the nuclear hormone receptors with hemin as a potential ligand. Identified as the main circadian repressor of the *Clock* and *Bmal1* genes. Nuclear orphan receptor that binds to the consensus sequence ([A/T]A[A/T]NT[A/G]GGTCAtermedRORE, in the promoter of target genes. The gene is transcribed from the opposite strand of the erba gene, which is a cellular homolog of the viral oncogene v-erbA.

►Clock-Controlled Genes
►Clock Genes

## Reverberation

### Definition

The persistence of sound in an enclosed space, as a result of multiple reflections, after the sound from the source has stopped.

►Acoustics

## Reverberation Time

### Definition

The time between the offset of the originating sound and when the reverberant sound remaining in the enclosed space is 60 dB (a factor of 1,000 in pressure) less than the level of the originating sound.

►Acoustics

## Reversal Learning

### Definition

In reversal learning, a particular discrimination task is first learned and then the reinforcement contingencies are reversed. In other words, once the subject has learned to discriminate a reinforced from a non-reinforced stimulus, it has to learn to reverse its response to such stimuli. Such reversals tend to be difficult since there are negative transfer effects; e.g. the individual tends to persist in responding to the stimulus that was originally reinforced. Eventually, however, this tendency becomes weaker, and the response to the alternative stimulus becomes more frequent until it is consistently evoked.

►Reinforcement

## Reversal Potential

### Definition

Reversal potential (also called Nernst potential) is the membrane voltage at which there is no net flow of a particular ion from one side of the membrane to the other.

►Membrane Potential: Basics
►Synaptic Transmission

## Reverse Real-Time quantitative PCR (RT-qPCR)

### Definition

Complementary DNA (cDNA) is first made from an RNA template, using a reverse transcriptase enzyme. A specific sequence of cDNA is then amplified and the amount of product produced at the end of each PCR cycle is evaluated by measuring signal strength of fluorescent markers. Since PCR generates products at an exponential rate, the relative abundance of template can be compared between samples. Alternatively the absolute abundance of template can be determined if reference dilutions of template are used. RT-qPCR can also refer to Reverse Transcriptase quantitative PCR, Real-time quantitative PCR (PCR).

►Serial Analysis of Gene Expression

## Reverse Signaling: Nervous System Development

Li Yu, Yong Rao
Centre for Research in Neuroscience, Department of Neurology and Neurosurgery, McGill University Health Centre, Montreal, QC, Canada

### Definition

Reverse signaling refers to the signaling mechanism by which a known membrane-bound ligand also functions as a receptor to trigger intracellular signaling events in the ligand-bearing cell, thereby modifying its behavior. Such dual function of a membrane protein as both ligand and receptor allows the ligand-receptor system to mediate bi-directional signal exchange between two neighboring cells, thus greatly increasing the plasticity of intercellular communications. Two major reverse signaling pathways mediated by ephrin and semaphorin have been implicated in regulating the development of the nervous system.

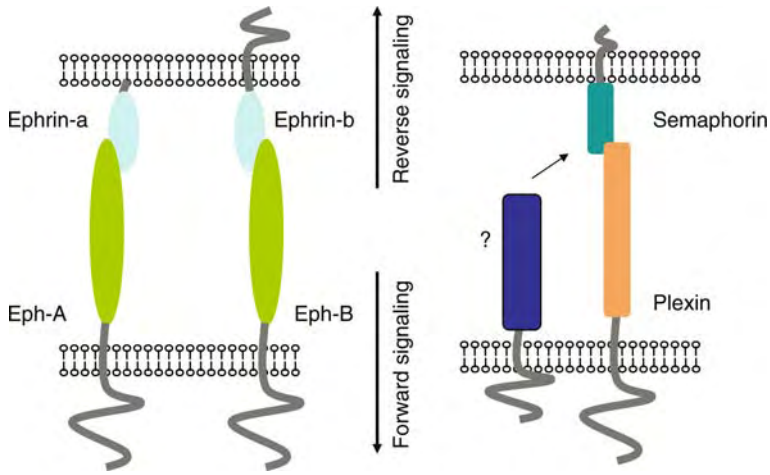
### Characteristics

#### Description of Reverse Signaling Mechanism

##### *Ephrin Reverse Signaling*

Ephrins were originally identified as ligands for the Eph-family receptor tyrosine kinases. Ephrins are divided into A and B subclasses. A subclass ephrins are tethered to the cell membrane by a glycosylphosphatidylinositol (GPI) anchor, while each B subclass ephrin contains a hydrophobic transmembrane segment spanning the plasma membrane followed by a short cytoplasmic domain [1–3]. Based on sequence homology and their preference for binding ephrins, Eph receptor tyrosine kinases are also classified into two subgroups, including ephrin-A-binding Eph-As and ephrin-B-binding EphBs [1–3].

Early studies of the ephrin-Eph interaction focused on understanding the signaling mechanism by which activation of Eph by ephrin modulates downstream signaling proteins to regulate cellular behaviors. This type of Eph-mediated signaling in response to ephrin binding is called ►forward signaling (Fig. 1). Each Eph family member has a highly conserved domain architecture in the cytoplasmic region that is comprised of a



**Reverse Signaling: Nervous System Development. Figure 1** Bi-directional signaling mediated by two ligand-receptor systems. Binding of ephrin and semaphorin activates Eph and Plexin forward signaling, respectively. Binding of Eph and Plexin can also activate ephrin and transmembrane semaphorin to trigger reverse signaling, respectively. The identity of cell surface protein (*colored in blue*) that activates semaphorin reverse signaling during neural development is unknown.

juxtamembrane region, a kinase domain, a SAM (sterile α domain) domain and a PDZ-domain binding motif [1–3]. Binding of ephrin to the extracellular region of Eph induces conformational changes, allowing the Eph cytoplasmic domain to modulate the activity and/or subcellular localization of downstream signaling proteins, which then modulate cytoskeletal reorganization leading to an attractive or repulsive response.

Later studies show that the binding between ephrin and Eph is capable of triggering downstream signaling events in both ephrin-expressing- (i.e., reverse signaling) and Eph-expressing (i.e., forward signaling) cells (Fig. 1), and thus mediates ►bi-directional signaling [1–3]. The action of ephrins as receptors to mediate reverse signaling relies on their ability to modulate the activity and/or subcellular localization of downstream signaling proteins in response to Ephs. EphrinBs can utilize both phospho-tyrosine residues and the PDZ domain-binding motif in its cytoplasmic domain to recruit downstream signaling proteins. For instance, Eph-induced ephrin-B1 phosphorylation of the conserved tyrosine residues provides a docking site for the ►SH2 domain (Src Homology 2 Domain) of the adaptor protein Grb4 [4]. Grb4 in turn links ephrin-B1 to multiple signaling pathways through the binding of its multiple ►SH3 domain (Src Homology 3 Domain) to proline-rich proteins (e.g., Abl-interaction protein-1 (Abi-1), c-Cbl-associated protein (CAP) and scaffolding protein axin), thus modulating ►focal adhesion and cytoskeletal reorganization [1,3]. Ephrin-Bs can also recruit downstream signaling proteins (e.g., glutamate-receptor-interacting-protein-1 (GRIP1), GRIP2, syntenin, protein kinase C-interacting protein-1 (PICK1), tyrosine phophatase PTP-BL, and PDZ-RGS3) in a phosphorylation-independent way via the PDZ domain-binding motif in their C-terminus [1,3]. Ephrin-B-mediated reverse signaling can also directly stimulate the enzymatic activity of Fak (focal adhesion kinase) to regulate focal adhesion [5].

Although ephrin-As do not have a cytoplasmic domain, they are also capable of mediating reverse signaling in response to Eph binding [1–3]. Ephrin-As are localized to ►lipid rafts, specific plasma membrane microdomains consisting of glycosphingo-lipids and cholesterol, where ephrin-As presumably associate with other membrane protein complexes. The activation of ephrin-As can lead to the recruitment of intracellular signaling proteins such as the ►Src family kinase Fyn to lipid rafts, which in turn regulates downstream proteins to modulate cytoskeletal reorganization and cell adhesion [6].

### *Semaphorin Reverse Signaling*

Semaphorins are a large family of secreted and transmembrane proteins that share a conserved ~500 amino-acid Semaphorin (Sema) domain at the amino terminus [7]. Semaphorins can also mediate bi-directional signaling. Semaphorins mediate forward signaling by functioning as ligands to bind and activate their receptors ►Plexin and ►neuropilin, which in turn initiate a cascade of signaling events in Plexin and/or neuropilin-expressing cells to regulate cytoskeletal changes for directed axonal growth and cell movement. Like ephrin-Bs, some transmembrane semaphorins can also mediate reverse signaling by utilizing their cytoplasmic domains to recruit intracellular signaling

proteins (Fig. 1). For instance, binding of Plexin-A1 to the extracellular region of Semaphorin-6D increases the association of its cytoplasmic domain with the Abl tyrosine kinase, but decreases its association with Mena, a member of the enabled (Ena)/vasodilator-stimulated phosphoprotein (Vasp) family proteins [7]. In Drosophila, it also appears likely that direct association of the transmembrane semaphorin-1a via its cytoplasmic domain with the fruitfly Enabled protein mediates semaphorin-1a-dependent reverse signaling [8]. The changes in the activity and/or localization of these semaphorin-associating intracellular signaling proteins contribute to the cytoskeletal reorganization necessary for cell migration and axonal projections.

## Function of Reverse Signaling in Neural Development

The function of reverse signaling in a ligand-receptor system mediating bi-directional signaling in neural development can be specifically assessed in several ways [2]. For instance, wild-type ligand or receptor in mice would be replaced with a mutant version incapable of interacting with intracellular signaling proteins by gene targeting, thus selectively inactivating reverse- or forward signaling, respectively. The contribution of reverse or forward signaling would then be assessed by comparing the phenotype displayed in the above mutants to that caused by the loss of both forward- and reverse signaling that occurs in receptor or ligand null mutants. Reverse signaling can also be selectively inactivated in zebrafish and Xenopus by expressing a dominant-negative version of a transmembrane ligand in which the cytoplasmic domain mediating reverse signaling is deleted. The dominant-negative mutant is still able to mediate forward signaling through binding to its receptor, but interferes with reverse signaling through competing with wild-type counterpart for receptor binding. In Drosophila, the contribution of reverse signaling can be determined by assessing whether null ligand mutants are rescued by expression of a mutant ligand that is capable of activating its receptor but defective in reverse signaling. The phenotype that is not rescued by the reverse-signaling-defective mutant ligand likely reflects the function of reverse signaling mediated by this ligand.

### Ephrin Reverse Signaling in the Vertebrate Neural Development

#### The Formation of Anterior Commissure Tract

The projection of both ►acP axon tract and ►acA axon tract of ►anterior commissure in mice requires ephrin reverse signaling [1,2]. Both ephrin-B2 and Eph-B2 are required for the guidance of acP axons. However, ephrin-B2 is expressed in acP axons and functions in a cell-autonomous manner, whereas Eph-B2 is expressed in cells underlying acP axons and is required non-cell-autonomously for the projection of acP axons. That the guidance of acP axons requires an intact cytoplasmic domain of ephrin-B but not the kinase domain of Eph-B2 supports the involvement of ephrin-B2 reverse signaling in the guidance of acP axons. The activation of ephrin-B2 reverse signaling by Eph-B2 appears to initiate a repulsive response that guides acP axons toward the midline. The guidance of both acP and acA axons also requires the activation of ephrin-A reverse signaling by Eph-A4, which functions non-cell-autonomously as a ligand to attract acP and acA axons. The identity of the ephrin activated by Eph-B4 in acP and acA axons remains unclear.

#### Retinotectal Mapping Along Dorsal-ventral Axis

In the vertebrate visual system, retinal ganglion cells in the eye project axons into the optic tectum in a topographic fashion along both anterior-posterior and dorsal-ventral axes. While ►topographic projections of retinal ganglion axons along the anterior-posterior axis are directed by the ephrin-As-Eph-As forward signaling [1,3], dorsoventral topographic projections appear to require the ephrin-B-mediated reverse signaling [2]. In Xenopus, retinal ganglion cell axons display a decreasing dorsal-to-ventral expression gradient of ephrin-B2 and B3 in the retina, while Eph-B1 shows a complementary expression pattern (i.e., decreasing ventral-to-dorsal gradient) on cells in the optic tectum. In vivo and in vitro studies suggest strongly that Eph-B1 in the ventral tectum activates ephrin-B2 and B3 expressed on dorsal retinal ganglion axons to initiate reverse signaling leading to an attractive response, which targets dorsal ganglion axons toward the ventral tectum.

#### Establishment of Vomeronasal Map

The vomeronasal organ (VNO) is involved in detecting pheromones. VNO axons projected from the vomeronasal epithelium are targeted topographically to specific glomeruli comprised of sensory projections in the accessory olfactory bulb (AOB) during embryonic development. Topographic projections of VNO axons appear to involve an attractive response mediated by ephrin-A5 reverse signaling when activated by Eph-A6 [2]. Ephrin-A5 is expressed differentially in VNO axons and required for their topographic projections. The difference in the expression level of ephrin-A5 appears to dictate onto which regions of the accessory olfactory bulb VNO axons are targeted: i.e., axons with higher level of ephrin-A5 are targeted to regions with higher level of Eph-A6 and vice versa.

### Semaphorin Reverse Signaling in Neural Development in Drosophila

Several recent studies, including our own, suggest strongly that transmembrane semaphorin-1a-mediated reverse signaing plays an important role in regulating neural development in Drosophila [8–10]. While it has been shown that reverse signaling mediated by

transmembrane semaphorin-6D is required for the guidance of myocardial patterning in vertebrates [7], future studies are needed to determine if semaphorin reverse signaling is also involved in regulating the vertebrate neural development.

### *The Formation of Giant-fiber-motor Neuron Synapse in Drosophila*

The ►giant fiber system of Drosophila is involved in controlling the jump-and-flight response. During development, a giant interneuron in the giant fiber system of the brain projects an axon into the second thoracic segment where the axon forms synapses with a motor neuron, which in turn controls the activity of the jump muscle. Semaphorin-1a is required both pre- and postsynaptically for the formation of giant-fiber-motor neuron synapes, suggesting a role for semaphorin to mediate bi-directional signaling between pre- and postsynaptic partners [8]. Overexpression of wild-type semaphorin-1a, but not a truncated semaphorin-1a mutant protein lacking the cytoplasmic domain, causes a gain-of-function phenotype. These data suggest that the participation of semaphorin-1a in synapse formation involves the action of semaphorin-1a reverse signaling. It remains to be determined whether Plexin or other semaphorin-interacting proteins function as a ligand to activate semaphorin-1a in synapse formation.

### *Photoreceptor Axon Guidance in Drosophila*

In the Drosophila adult visual system, R1-R6 photoreceptors project their axons from the retina to the superficial layer of the optic lobe, the lamina. During development, R1-R6 axons temporally stop at their intermediate target region in between two layers of glial cells prior to establishing synaptic connections with lamina neurons. We found recently that the transmembrane semaphorin-1a functions cell-autonomously in photoreceptor axons for the proper arrangement at the intermediate target region [9]. The function of semaphorin-1a in photoreceptor axons requires its cytoplasmic domain, consistent with a role for semaphorin-1a as a receptor to mediate reverse signaling. The identity of cell surface proteins that activate semaphorin-1a reverse signaling in photoreceptor axons remains to be determined.

### *Dendritic Targeting of Olfactory Projection Neurons in Drosophila*

In the development of the Drosophila olfactory system, projection neurons project their dendrites onto discrete units called glomeruli in the ►antennal lobe, the first olfactory information relay center equivalent to olfactory bulb in vertebrates. Different types of odorant receptor axons form one-to-one precise connections to dendrites projected from different types of projection neurons at glomeruli. Semaphorin-1a displays a differential expression pattern on dendrites of projection neurons. Genetic analysis showed that semaphorin-1a is required differentially in projection neurons for the targeting of their dendrites onto discrete glomeruli in a cell-autonomous manner, indicating a role for semaphorin-1a as a receptor for dendritic targeting [10]. Consistently, the cytoplasmic domain of semaphorin-1a is shown to be indispensable for its function, which likely reflects its role in recruiting downstream signaling proteins within the dendrites of projection neurons. The guidance cue that activates semaphorin-1a reverse signaling in dendrites is unknown.

# Reward

## Definition

A reward or positive reinforcer is any stimulus an animal will work to obtain. Often these stimuli have

biological significance to the animal such as food, shelter or sex, a class of stimuli sometimes referred to as primary or unlearned reinforcers. Other types of reward are initially affectively neutral but acquire value through being associated with a primary reinforcer.

An example of such a stimulus for humans is money which acquires value by virtue of its capacity to be exchanged for other kinds of primary reinforcers such as food or shelter.

## Rheological Models

Marcelo Epstein
Schulich School of Engineering, University of Calgary, Calgary, AB, Canada

### Definition

A rheological model consists of an assembly of one-dimensional *rheological elements*, each of which can be seen as a black box with two protruding terminals.

### Description of the Theory

Each rheological element is characterized by a deterministic relationship between the (history of the) relative displacement (or *elongation*) $u(t)$ between the terminals and the (history of the) applied force $f(t)$. In other words, knowing the displacement function $u(t)$ for all past times $t$ up to the present, the present value of the force can be uniquely determined by some mathematical operation or vice versa. The merit of this one-dimensional oversimplification of the complexity of a true continuum constitutive theory (q.v.) lies in the fact that, by combining a small number of rheological elements in series and in parallel, a wealth of mathematically tractable, surprisingly varied and suggestive force-elongation responses is obtained. Two rheological elements are said to be *connected in series* if one of the terminals of the first is connected to one of the terminals of the second, in such a way that the remaining two unconnected terminals are considered as the terminals of the new combined-element black box. Let $[f_1(t), u_1(t)]$ and $[f_2(t), u_2(t)]$ denote, respectively, the force-elongation pairs of the first and second elements connected in series. The main feature of a series combination is that both elements experience the same force, while the elongation of the combined black box is the sum of the elongations of the original elements. Denoting by $[f(t), u(t)]$ the force-elongation pair of the combined series black box:

$$u(t) = u_1(t) + u_2(t) \qquad f(t) = f_1(t) = f_2(t). \quad (1)$$

Two elements are said to be *connected in parallel* if each terminal of one element is connected to a counterpart in the other element. The two common terminals thus obtained are considered as the terminals of the combined black box. As a result, both elements experience necessarily the same elongation, while the forces are added to produce the response of the combined element. Using the same notation as before, for the ►parallel arrangement:

$$u(t) = u_1(t) = u_2(t) \qquad f(t) = f_1(t) + f_2(t). \quad (2)$$

R

Some of the most common elements in use are: the ►*linear spring*, the ►*linear damper* (or *linear dashpot*) and the ►*contractile element*. The linear spring is characterized by two material constants: the *rest length* $L_0$ and the *stiffness constant* $k$. By convention, in the linear spring the elongation $u$ is measured with respect to the rest length (in other words, when the elongation vanishes, the distance between the terminals is equal to the rest length). The force at time $t$ is then proportional to the elongation at that time, namely:

$$f(t) = k\,u(t). \tag{3}$$

Thus, the linear spring provides a purely elastic response, whereby the past history of the ►deformation plays no role, except for the fact that the material always remembers its "original" rest length. The linear damper, on the other hand, is completely characterized by a single material constant $c$ called the *viscous constant*. There is no rest length. The force-elongation relation is given by the equation:

$$f(t) = c\,\dot{u}(t). \tag{4}$$

In a linear damper the only fact that counts in determining the force between the terminals at a given time is the speed of elongation $\dot{u}(t)$ at that time. In other words, the past history plays a role, albeit limited to the very immediate past. More sophisticated history elements can be defined. Finally, the contractile element is a useful device with important applications to muscle ►mechanics. It can be thought of as a frictionless slider that produces no force, whatever the value of the elongation may be. In muscle mechanics applications, however, it is usually assumed that this behavior is characteristic of the *inactive state* only and that the contractile element may be *activated*, so that in the *active state* the force-elongation response abides by an ad-hoc law (for example, a so-called *force-length relation*).

To illustrate the variety of material responses that can be obtained by means of rheological models, the *Maxwell model*, obtained by placing a linear spring and a linear dashpot in series is considered. It is not difficult to show that the response of the Maxwell model is completely contained in the following first-order ordinary differential equation:

$$\dot{u} = \frac{\dot{f}}{k} + \frac{f}{c.} \tag{5}$$

If a force $f_0$ is suddenly applied, an instantaneous elongation of value $u_\infty = \frac{f_0}{k}$ develops completely at the expense of the spring, while the dashpot does not have time to react. As time goes on, however, if the force is kept at a constant value, the elongation will keep growing steadily at the expense of the deformation of the damper. If the force is suddenly removed, the spring goes instantaneously back to its original length, while the damper immediately stops deforming. At the end of the process, therefore, the Maxwell model retains a residual deformation. The response of a system to a suddenly applied load that remains constant in time is known as ►*creep*.

If a linear spring and a damper are combined in parallel, the result is the *Voigt model*. It is governed by the differential equation:

$$f = ku + c\dot{u}. \tag{6}$$

A sudden application of a force is met with no instantaneous response, since the damper cannot react immediately. As time goes on, however, an exponential growth of the elongation is observed which approaches asymptotically the value $u_\infty = \frac{f}{k}$. If the force is suddenly removed, the spring will slowly bring back the system to its original rest length. This is the type of behavior observed when sitting on a feather- or down-filled cushion. This effect is sometimes described as "delayed ►elasticity," although the response is anything but elastic.

A more realistic description of the behavior of many materials is obtained by combining in parallel a Maxwell model with a linear spring. The result is known as the *Kelvin model* or the *standard linear solid*. Its creep response is similar to that of a Voigt model, except that, just like a Maxwell model, it also has an instantaneous elastic response, governed by the spring added in parallel.

If instead of subjecting the various models to a sudden force they are subjected to a sudden elongation, the response obtained in terms of the decay of the resulting force as time goes on is known as ►*relaxation*.

## Rho Family of Small Guanosine Triphosphatases (Rho GTPases)

### Definition

Rho family of small guanosine triphosphatases (Rho GTPases) are important intracellular signaling proteins involved in various aspects of neuronal morphogenesis including migration, polarity, axon growth and guidance, dendrite arborization, spine plasticity, and synapse formation. Acting as intramolecular switches, the Rho GTPases transduce signals from various extracellular ligands to the cytoskeleton. They exist in two states: a GTP-bound active state, and a GDP-bound inactive state. Guanine nucleotide exchange factors turn on Rho GTPases by facilitating the exchange of GDP for GTP, and GTPase activating proteins increase their GTPase activity, helping to turn them off.

►Cytoskeleton
►Growth Cones
►Neural Development

## Rho GTPases

Ryan Petrie, Nathalie Lamarche-Vane
Department of Anatomy and Cell Biology, McGill University, Montreal, Quebec, Canada

### Synonyms

Rho Family of Small GTP-Binding Proteins

### Definition

The Rho family of small GTP-binding proteins consists of 22 mammalian proteins related to each other based on the similarity of their amino acid sequence to the first family member to be identified, RhoA. These proteins are relatively small (less than 25 kDa) and all possess an intrinsic GTPase activity, which hydrolyzes the guanosine triphosphate (GTP) into guanosine diphosphate (GDP). The bound nucleotide regulates the activity of the GTPase, rendering it inactive or active in the case of GDP or GTP, respectively.

### Characteristics

The ►Rho GTPases are expressed in all cells from fertilization through adulthood and their activity is critical to many aspects of cell biology that are required for normal functioning of the organism [1]. When

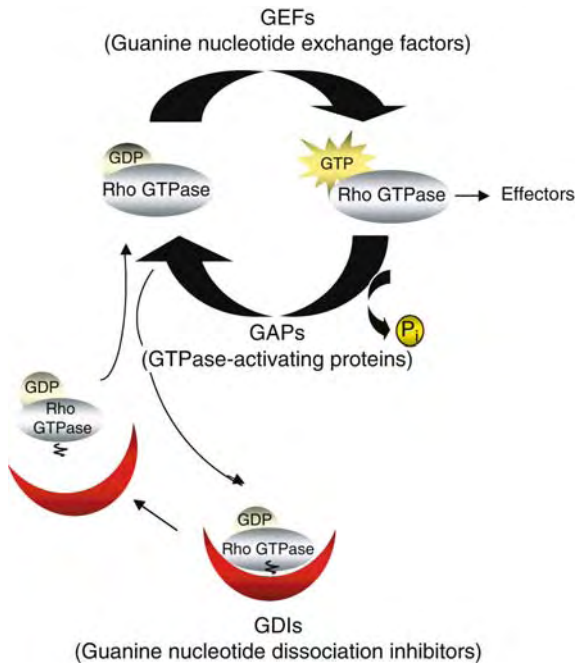
active, the Rho GTPases can activate a diverse array of intracellular signaling pathways. RhoA, Rac1, and Cdc42, the best characterized members of the Rho family of small GTPases, regulate the assembly of the ►actin and ►microtubule cytoskeleton, a filamentous network of proteins within a cell that control cell shape, cell adhesion, cell polarity and cell migration. Specificity of Rho GTPase signaling is achieved by the coordinated regulation of the nucleotide bound state of the GTPase and the region of the cell to which the active form of the protein is targeted.

## The Cycling of GTP and GDP Regulates Rho GTPase Activity

Each of these monomeric GTPases acts as a molecular switch to control the downstream signaling pathways. The cycling of GDP-GTP binding to Rho GTPases is tightly regulated by three families of proteins. The GTPase is unable to exchange the bound GDP for free GTP in the cytosol without the help of proteins termed ►guanine nucleotide exchange factors (GEFs). In response to external stimuli, GEFs are activated and bind the GDP-bound conformation of Rho GTPases leading to the release of GDP. Then, the Rho GTPases in a free-nucleotide transition state are able to bind GTP in the cytosol and activate downstream effectors in their active GTP-bound conformation. The activity is terminated by ►GTPase-activating proteins (GAPs), which enhance the intrinsic GTPase activity, leading to the inactive state of the GTPase. Additionally, ►guanine nucleotide dissociation inhibitors (GDIs) can sequester Rho GTPases in their GDP-bound, inactive state (Fig. 1).

## Subcellular Localization of Rho GTPases

While inactive GTPases are usually restricted to the cytoplasm, the active forms are localized to the surface of membranes within the cell, such as plasma, golgi, or endosomal membranes. The correct intracellular localization of active GTPases is critical for their regulation and coupling to downstream signaling pathways. The targeting information is contained in the ►CAAX box present at the C-terminal end of the GTPase amino acid sequence [2]. This sequence is modified by the addition of an isoprenyl group on the side chain of the cysteine, which is then able to insert into membrane lipid bilayers. Additionally, there is a short stretch of basic residues upstream of the CAAX box that confers specificity to each Rho GTPase and influences into which membrane the isoprenyl chain inserts. The specificity in action is also achieved by the restricted subcellular distribution of GAPs and GEFs, which results in the inactivation/activation of the Rho GTPases being tightly coupled to specific regions of the cell.



**Rho GTPases. Figure 1** *Cycling of Rho GTPases.* Rho GTPases exist in either an inactive, GDP-bound state or an active, GTP-bound state. Three families of proteins tightly regulate this GDP/GTP cycle. GEFs stimulate the exchange of GDP for GTP, thereby activating the GTPases. GAPs enhance the intrinsic GTPase activity, leading to the inactive GDP-bound form. GDIs bind to the GDP-bound GTPase and sequester the protein in the cytosol.

## Functions of Rho GTPases During Development of the Nervous System

### *Neuron Polarization and Axon Specification*

During the initial stages of the development of the nervous system when neural precursors are generated by cell division, the cells lack features such as dendrites or axons and are non-polarized [3]. To begin the process of forming axons and dendrites the cells must specify which region of the plasma membrane will begin to extend away from the cell body in order to form elongated structures known as ►neurites. These structures will ultimately become the single axon and several dendrites of the nascent ►neuron, a process known as neuronal polarization. In vitro studies have revealed key roles for the Rho GTPases Cdc42 and Rac1 in the initial polarization of a neuron [4]. Cdc42 is targeted to a sub-region of the plasma membrane and recruits the polarity complex of Par3, Par6, and the atypical protein kinase C, a conserved multiprotein complex used throughout evolution to polarize different cell types. The polarity complex in turn recruits the GEFs Tiam1 and STEF, which catalyze the exchange of GDP for GTP on Rac1. The active Rac1 mediates the formation of filamentous actin and neurite formation ultimately polarizing the cell.

### Axon Guidance

As the nervous system develops, newborn neurons extend axons towards their cognate targets. The neuronal growth cone, located at the tip of the growing axon, is a highly motile structure acting as a sophisticated signal transduction device, capable of recognizing extracellular guidance cues and translating them into directed neurite outgrowth [5]. Over the past 15 years, a combination of cellular and genetic studies has led to the identification of highly conserved families of guidance molecules that can be either membrane-bound factors or secreted molecules, acting over short or long distances, respectively, to guide the growth of axons. They include the classical molecular cues: netrins, slits, ephrins, and semaphorins [6].

Cytoskeletal rearrangements are crucial during growth cone guidance. The growth cone is enriched in the cytoskeletal elements F-actin and microtubules that are rapidly remodeled in response to environmental cues and direct the migration of the growth cone [5]. There is now compelling evidence demonstrating a role for RhoA, Rac1, and Cdc42 as important signaling elements downstream of most, if not all, guidance cue receptors [7]. Indeed, Rho GTPases mediate a cascade of responses from receptors to actin remodeling within the neuronal growth cone. For instance, Rac1 interacts directly with the semaphorin receptor plexin-B1, suggesting that Rac1 plays a role in mediating the repulsive activities of semaphorins. On the other hand, the Rho-specific GEF, PDZ-RhoGEF LARG, interacts with plexin B to activate RhoA signaling, provoking growth cone repulsion and collapse. Ephexin, a GEF for RhoA and Cdc42, binds to Eph receptors to modulate Ephrin-induced growth cone collapse, whereas the slit receptors Robo mediate axon repulsion by interacting with srGAP that inhibits Cdc42. Finally, Rac1 and Cdc42 are important mediators of the signaling response of axons to the netrin-1 receptor DCC. Overall, it is clear that Rho GTPases are important regulators in axon pathfinding and guidance, and it is the correct balance of localized Rho GTPase activities through GEFs and GAPs that will determine the appropriate attractive and repulsive response of an axon to extracellular cues.

### Dendritogenesis and Structural Plasticity of the Dendritic Arbor

During the maturation of connectivity within the central nervous system (CNS), dendrites are highly dynamic. The branched structure of the dendrites is highly enriched in the cytoskeletal elements and it is the controlled remodeling of these structures that is responsible for the shape and complexity of the dendritic arbor. In many cases, dendritic spines are the location of the synaptic connections and their size and number correlate with their ability to transmit the correct information from axon to dendrite. The ability of Rho GTPases to convert the upstream signals into cytoskeletal changes leads to remodeling of the dendrites [8]. For example, N-methyl D-aspartate (NMDA) receptors transmit excitatory transmissions mediated by L-glutamate. Activation of NMDA receptors increases the activity of Cdc42 and Rac1 while decreasing the activity of RhoA, leading to the stabilization of the dendritic spines [7]. The regulation of the growth and elaboration of the whole dendritic architecture represent an important mechanism of plasticity in the central nervous system.

### Axon Regeneration in the CNS

The activity of the Rho GTPase family member RhoA is known to induce acto-myosin contractility within the cell and to produce mechanical forces that can retract actin-dependent structures such as neurites [9]. Inhibition of RhoA in neuronal cells leads to neurite extension over substrates that would not normally be permissive for neurite outgrowth. Many reports are now suggesting that RhoA is highly activated following lesions in the CNS and mediates many of the signals associated with the growth suppressive environment of the CNS following injury. For example, myelin associated glycoprotein (MAG) is released from the damaged myelin sheath and binds to the NOGO receptor to activate RhoA, preventing regrowth of the damaged axons. This is accomplished because RhoA activates in turn Rho-kinase (ROCK), which is able to induce intracellular acto-myosin contractility that prevents axon outgrowth following injury. Therefore, RhoA is now a promising pharmacological target for therapy in an aim to promote ►axon regeneration in the CNS following injury.

## Implication of Rho GTPase Dysfunction as Being Causative for Mental Retardation

The importance of Rho GTPases in the nervous system development is further highlighted by research studies linking dysfunction in Rho GTPase signaling pathways and mental retardation in the adult. In this situation mutations in specific genes affect the developmental program such that the organism develops abnormally [7]. Malformed dendrites and dendritic spines are common in these conditions and are hypothesized to be important indicators of the mechanisms of impaired cognition in mental retardation. For example, in non-syndromic x-linked mental retardation, three genes out of a total of 13 have been pinpointed to be mutated and are encoding either regulators of Rho GTPases or downstream mediators of the pathways activated by Rho GTPases. In particular, the *OPHN-1* gene encodes the protein oligophrenin-1, which contains a RhoGAP domain shown to negatively regulate RhoA, Rac1, and Cdc42. It is specifically expressed at high levels in both axons and dendrites throughout the brain and a

mutation causing decreased levels of the oligophrenin-1 mRNA is associated with mental retardation. In addition, the *ARHGEF6* gene encodes a GEF that activates Rac1 and Cdc42 and a truncation mutant protein missing the first 28 amino acids is associated with mental retardation. Finally, the serine/threonine kinase activity of PAK3, a member of the p21-activated protein kinase family (PAK) family of proteins, acting downstream of Rac1 and Cdc42, has been found to be compromised in individuals with this neurological disorder.

### Concluding Remarks

RhoA, Rac1, and Cdc42 regulate a wide variety of intracellular signaling pathways to mediate many aspects of the development of the nervous system. The Rho family of GTPases includes 19 other members, the roles of which are relatively unknown. Future research will undoubtedly reveal many novel functions of this diverse family of proteins in the development of the nervous system.

# Rhythmic Jaw Movements

►Mastication

# Rhythmic Movements

Ole Kiehn
Mammalian Locomotor Laboratory, Department of Neuroscience, Karolinska, Stockholm, Sweden

## The Behavior

Rhythmic movements are motor acts that are characterized by the activation of groups of muscles in a recurring or cyclic pattern. Rhythmic movements are found in all animals ranging from invertebrates to man and include various behaviors that are continuously ongoing, like ►respiration, are episodic, like ►swimming, ►mastication and ►walking, or brief like ►scratching and the ►startle response. The rhythmic movements are generated by localized neuronal networks, called ►central pattern generators, or CPGs. Activity in the CPGs directly controls the timing (rhythm) and phasing (pattern) of ►motoneurons, whose activity in turn activates the ►muscles needed to generate the rhythmic movements; e.g., the limb muscles acting on the leg during walking or intercostals muscles and the diaphragm acting on the lungs during respiration. Thus, the term CPG alludes to the fact that these neuronal networks are restricted to specific regions of the central nervous system and, when appropriately activated, are capable of generating both the timing and phasing of rhythmic movements without receiving patterned ►sensory information. The CPG for respiration or mastication in vertebrates is, for example, localized in the ►brainstem while the CPGs for swimming, scratching and walking are localized in the ►spinal cord. The CPGs controlling rhythmic movements in invertebrates are typically localized to ganglionic structures, like to the ►stomatogastric ganglion that controls the foregut movements in Crustaceans or to the chain of midbody ganglia that control ►leech swimming. Traditionally, rhythmic movements were studied in intact or semi-intact animals. Because of the distinct network localization, numerous preparations have been developed where the part of the central nervous system that contains the CPG network can be studied in isolation in vitro.

## External Control

Although CPGs are able to intrinsically generate the timing and phasing of rhythmic movements, they do not function in isolation. Rather, in most cases their activity is often turned on and off by an external command signal. For example, when a cat starts to walk or a fish starts to swim, the spinal CPGs are activated by activity in descending fiber tracts originating in the brainstem [1,2]. Initiating signals originating in the forebrain are funneled through the ►basal ganglia and conveyed to nuclei in the diencephalon (►diencephalic locomotor region) and mesencephalon (►mesencephalic locomotor region) and then to excitatory ►reticulospinal neurons in brainstem ►locomotor regions in the midbrain and diencephalon. The reticulospinal neurons then project to the spinal locomotor network and provide the external ►excitatory drive needed to initiate and maintain the rhythmic activity. Similarly, descending inputs from "head ganglia" to CPGs in the stomatogastric ganglion or the swimming CPG in leech can turn specific rhythmic motor behaviors on and off [3]. Sensory inputs, like loud sound or sudden changes in light, might be the direct trigger for the descending signal leading to escape or startle responses [4], which is followed by more persistent rhythmic movements. Sensory inputs are also triggers for the scratching movements where the motor behavior is initiated by tactile stimulation applied to the skin [5].

## Sensory Information

Although rhythmic motor outputs can be generated in the absence of sensory information CPGs receive sensory feedback. Some of these sensory signals cause corrections of the rhythmic movements, as when a person is stumbling over an object. In this case ►cutaneous sensory receptors mediate the corrective signal to the CPG circuit [6]. Other sensory signals are involved in phase transitions and amplitude modulation of the rhythmic movements and are caused by ►proprioceptive feedback from the moving appendages. Examples of sensory inputs that are involved in phase transitions are feedback from ►stretch receptors in the lungs that regulate the transition from inspiration to expiration, joint receptors in the hip in mammals that regulate the transition from stance to swing and sensory receptors in the wing of the locust that influence the transition from wing depression to wing elevation [6,7]. Load receptors, like ►tendon organs, or stretch receptors in muscles, like ►muscle spindles, also provide proprioceptive cues for phase transitions and are actively involved in modulating the amplitude variation of rhythmic movements [7–9].

## Basic Network Features

The intrinsic function of rhythmic motor networks is defined by the synaptic interconnections between the

CPG neurons in the network and the membrane properties of the neurons. A minimal characterization of the network function therefore requires that CPG component neurons are identified, that the connectivity between individual neurons is established, and that the salient membrane properties are described. An analysis at this level of detail has only been obtained in a limited number of rhythmic motor systems both in invertebrates and in vertebrates.

Notable examples in invertebrates of CPGs that have been characterized in detail are the swim CPGs in the mollusks *Clione* [10], and *Tritonia* [11], the heart-beat network in leech [3,12], and the CPG circuits in the stomatogastric ganglion controlling foregut movements in Crustacea [13]. Because of the small number of cells (less than 30 neurons), the complete network connectivity has been worked out and the cellular properties of individual CPG neurons have been determined in great detail. From the analysis of these small CPG networks, it is clear that each CPG network has its specific characteristics and that none of them are alike. However, several basic network and cellular building blocks can be extracted from the analysis [11]. Network elements include extensive ►reciprocal inhibition in a ►half-center fashion, delayed ►feed-forward excitation, ►electrical coupling and ►graded synaptic release. These network elements alone do not determine the timing and phasing that the CPG network produces but they interact with cellular properties that actively interpret the synaptic activity and contribute to timing and phasing. Such cellular elements are ►bursting pacemaker properties that can provide sustained rhythmic drive, post-inhibitory rebound firing that helps escape inhibition and is generated ►by h-channels (►HCN) and ►T-type calcium channels, ►plateau potentials generated by ►persistent calcium or sodium channels, ►calcium-activated calcium channels (►CAN channels) that amplify and prolong synaptic inputs, delayed activation generated by activation of potassium channels with slow kinetics (►A-Type channels), and spike-frequency adaptation generated by ►calcium-activated potassium channels [14].

In vertebrates, the CPG organizations for ►swimming in lamprey and in ►*Xenopus* tadpole have been revealed in great detail [15,16]. The core of these networks consists of ►excitatory ►CPG interneurons and ►inhibitory glycinergic ►interneurons. The glutamatergic interneurons project ipsilaterally and provide the excitatory drive to other CPG interneurons and motoneurons necessary to produce sustained rhythmic drive on one side of the cord. The glycinergic interneurons are ►commissural interneurons projecting to the contralateral side where they connect to all CPG neurons and motor neurons and mediate reciprocal inhibition segmentally so that when one side is active the other side is inactive. This half center organization is the basis for the side-to-side undulatory swimming. The rhythm itself is not dependent on inhibitory connections, but can be generated in a network of mutually coupled excitatory neurons. Each one of the about 100 spinal segments that makes up the lamprey spinal cord appear to contain such a basic CPG unit [17]. These units are coupled both in the ascending and descending directions. These connections provide the basis for the ►intersegmental coordination of muscular activity along the length of the body that is required for the animal to swim. Similarly to invertebrate CPGs, a large number of intrinsic membrane properties influence the rhythmogenic capability of the swim CPG neurons and participate in patterning of the motor output [18,19].

The large number of neurons controlling any given behavior in mammals has made it difficult to reveal the detailed network organization of, for example, the CPGs controlling mammalian ►walking [20], ►mastication [21] or ►respiration [22–24]. Knowledge about the functionally of these CPGs is, however, advancing rapidly. For the walking CPG, the key network functions are the rhythm generation, ipsilateral coordination of flexors and extensors across the same or different joints in a limb, and ►left-right coordination [20]. The rhythm is generated by glutamatergic ipsilateral projecting interneurons [25]. The exact identity of these neurons has not been determined. The circuits underlying coordination of flexors and extensors segmentally and intersegmentally include inhibitory ►Ia interneurons and ►Renshaw cells, as well as a number of unidentified interneurons. Functional analysis of left-right circuitries in the mammals suggests that ►intersegmental coordination provided by ►commissural interneurons is involved in binding motor synergies along the cord, while inhibitory ►intrasegmental commissural connections control segmental alternation and excitatory commissural connections control synchronous activity [20]. It thus appears that some basic characteristics of swimming CPG and walking CPG network structure are preserved. However, the commissural circuitries seem more complex in the walking CPG than what has been described for the swimming CPG. Additionally, while network elements in the swimming CPG appear to be composed of homogenous populations of neurons, similar network elements, such as the rhythm generation network in the walking CPG, appear to be composed of more heterogeneous populations of neurons. Thus, additional network layers are added when moving from a non-limbed to a limbed CPG. Similar to what is seen in invertebrate and lower vertebrate neurons, mammalian CPG neurons express to a variable degree rhythmogenic/pacemaker-like membrane properties or phase-regulating membrane properties [14,22–24,26].

A new addition to the CPG network analysis is methods for genetically dissecting the neuronal circuits.

Such methods include genetic silencing or activation of molecularly defined populations of neurons and have been applied to both invertebrate and vertebrate CPGs. In networks with many neurons, such manipulations can more directly link a population of CPG neurons to a specific network function than traditional electrophysiological methods are able to do [27].

## Neuromodulation of Rhythmic Movements

A lesson that has been learned from studies of CPGs in both invertebrates and vertebrates is that the overall network function is flexible and can be changed by ►neuromodulation that acts on individual CPG neurons and connectivity [28,29]. The neuromodulation may be the result of neurotransmitters and hormones released from sources outside the CPG circuits (►extrinsic neuromodulation) or the neuromodulation may be the result of neurotransmitters and signals released from active CPG neurons (►intrinsic neuromodulation). Examples of extrinsic ►neuromodulatory systems are the numerous ►amine and ►peptide containing systems that project to stomatogastric ganglion [28,30] and the descending 5-HT or dopamine systems in vertebrates [31]. Examples of intrinsic ►neuromodulatory systems are neurotransmitters released from swim CPG neurons in *Tritonia* [32], adenosine released from CPG neurons tadpole [18] and endocannabinoids from CPG neurons in the lamprey [33]. In all cases, the targets for neuromodulators are ligand-gated ion channels and/or chemical or electrical synaptic transmission. Because neuromodualtors have these ubiquitous network targets, they can change timing, phasing or amplitude of the rhythmic movements separately or all of these parameters at ones. Thus in some cases, the neuromodulation is a fine tuning of the rhythmic motor behavior, while in others the neuromodulation causes dramatic switching in the motor coordination.

## Disorders of Rhythmic Movements

Primary disorders of rhythmic movements are not common, although a number of respiratory dysfunctions involve defects in network function and/or its modulation [22]. Secondary disorders of rhythmic movements are due to injury of the external control systems, for example, damage to the spinal cord that leads to loss of ambulatory ability below the lesion. The ultimate way of restoring the rhythmic motor behavior after spinal cord injury is to promote re-growth or ►regeneration of the severed fibers across the injury. An alternative approach is ►neuro-rehabilitation. Experiments in animals with ►spinal cord injury have shown that sustained ►locomotor training on a treadmill in combination with drugs that activate the spinal locomotor CPG can lead to substantial recovery of the lost locomotor capability [34,35]. Clinical trials have shown that humans with partial spinal cord injury also can benefit from such ►locomotor rehabilitation therapy [34,35].

## Ribonuclease (RNase)

### Definition

An enzyme that catalyses the hydrolysis of an RNA resulting in either cleavage to smaller RNA units or by degradation to constituent nucleotides.

## Ribosome

### Definition

A ribosome is a non-membranous organelle that translates of a mRNA molecule into a polypeptide chain. It consists of 65% ribosomal RNA and 35% ribosomal proteins.

## Riddoch Phenomenon or Syndrome

### Definition

When visual cerebro-cortical area V5 is disconnected from area V1 (with which it is reciprocally connected and from which it normally receives its visual input) but has a secondary visual input that reaches it without passing through area V1, the subject can still experience visual motion consciously though crudely.

►Blindsight
►Visual Perception

## Rigidity

### Definition

An increased resistance to passive stretch that is nearly equal in both agonist and antagonist muscles and generally uniform throughout the range of motion of the joint being tested. It may be sustained (plastic or lead pipe) or intermittent and rachetty (cogwheel). Although cogwheel rigidity is usually thought to be Parkinsonian rigidity complicated by Parkinsonian tremor, it may occur in the absence of tremor and the frequency felt by the examiner tends to be higher than that of the visible resting tremor.

►Parkinson Disease
►Resting Tremor

## Rigor Configuration

### Definition

The rigor configuration in the cross-bridge cycle is associated with the end-state of the power stroke with the nucleotide products (ADP and P) having been released. In order to advance from the rigor configuration, ATP is required to release the cross-bridge from actin.

►Molecular and Cellular Biomechanics
►Power Stroke
►Sliding Filament Theory

## RNA Interference

### Definition

RNA interference – this procedure is abbreviated RNAi. It consists of the down-regulation of gene expression by using specific double-stranded ribonucleic acids. The specific or chosen RNA base pairs with its complementary strand of mRNA resulting in the degradation of the latter.

►GAL4/UAS

## RNA Localization

►mRNA Targeting: Growth Cone Guidance

## RNA Synthesis

►DNA Transcription

## RNA Translation

### Synonyms

Protein synthesis; Polypeptide synthesis

### Definition

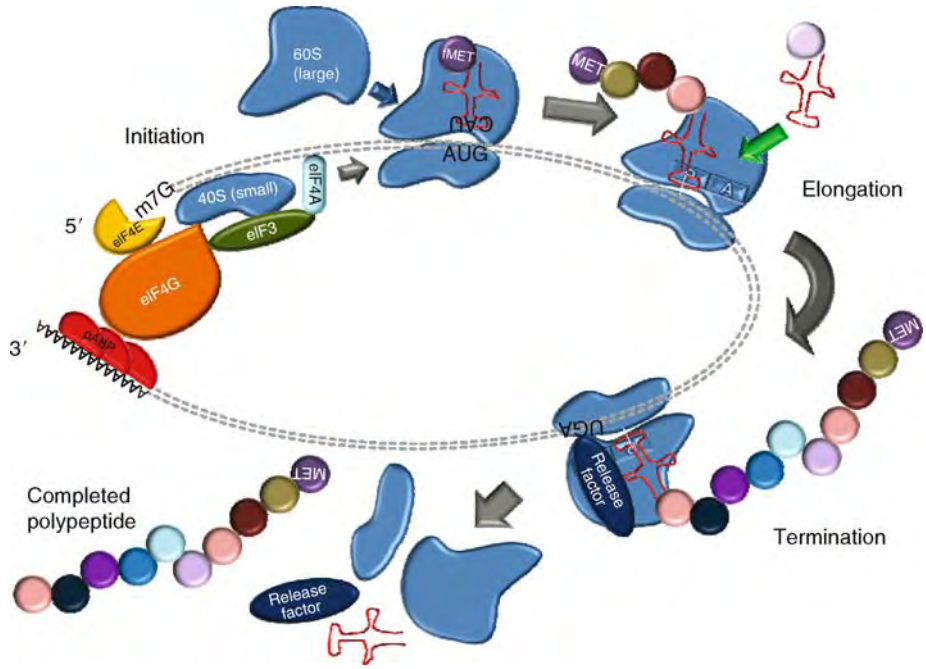
RNA translation is the process whereby the genetic information encoded in messenger RNA (►mRNA) is translated by specialized cytoplasmic complexes (ribosomes) into a polypeptide. This process is essential for the function of all cell types, and each step of translation represents a highly regulated event.

### Characteristics

Eukaryotic mRNAs are initially transcribed from genetic information encoded in the nuclear DNA. After processing by various nuclear proteins (e.g., splicing factors), mRNAs are exported to, and subsequently translated within, the cytoplasm. The basic process translates the sequence of bases organized in three letter codons within the mRNA into a specific polypeptide string of linked amino acids. As more is learned about mRNA translation, it has become apparent that this process is a highly regulated event with several levels of control including storage of mRNAs in a non-translating state and restriction of translation to specific sub-domains within the cytoplasm. Many of these regulatory events are mediated by sequences encoded within the mRNA itself. Each mRNA can be functionally divided into several regions including the 5′ cap, the 5′ untranslated region (UTR), the ►open reading frame (ORF), the 3′ UTR and a 3′ domain consisting of repeated adenosine bases that are added post-transcriptionally (Fig. 1).

In a generalized model, the ORF is the most important region, with the information within encoding a specific protein, while the UTRs are thought to play roles in regulating localization, degradation and restrictions in the translation of the mRNA.

The core component of the cellular complex that reads the genetic information in the ORF and translates it into a specific protein is the ribosome. Several ribosomes can bind to a single mRNA to form a larger translation complex called a polysome. The genetic information in the ORF of the mRNA is read in three base segments by a collection of ►transfer RNA (tRNA) molecules that contain a complementary RNA code (anti-codon) that recognizes and binds a particular nucleotide triplet (codon) in the mRNA. A parallel cellular process specifically links each tRNA to the amino acid that corresponds to the codon (Fig. 2). The ribosomal complex processes along the mRNA and through the progressive recruitment of specific amino-acid linked tRNAs. The amino acids delivered by the tRNAs to the ribosome are covalently joined to produce the polypeptide encoded by the mRNA. This process is regulated at several levels. For example, proteins that will remain inside the cell are translated on free ribosomes in the cytoplasm while the ribosomes-mRNA-nascent polypeptide complexes translating exported or membrane bound proteins are trafficked to the endoplasmic reticulum. However, there are several other regulatory events during mRNA translation including: editing of the mRNA after it is transcribed (►RNA editing), sub-cellular localization of mRNAs, sub-cellular restriction of mRNA translation, sequestering multiple non-translating mRNAs in protein complexes and selective mRNA degradation.



**RNA Translation. Figure 1** RNA translation: Initiation – RNA binding proteins that specifically interact with the 5′ m7G cap and 3′ UTR regions of mRNAs form the translation initiation complex. A complex of poly A binding protein (pABP, *red*) interacts with the 3′ poly A tail, while eukaryotic Initiation Factors (eIFs) form a complex at the 5′ end of the mRNA. The major proteins in this complex include the cap-binding protein eIF4E (*yellow*), and the eIF4G (*orange*), eIF3 (*green*) and eIF4A (*pale blue*). They serve to position the 40S (small) ribosomal subunit on the mRNA. In most cases of mRNA translation, the 40S subunit is thought to scan along the mRNA in a 5′-3′ direction until it reaches an AUG codon where a specialized tRNA (fMET) brings in the first amino acid and the 60S (large) ribosomal subunit joins the complex to form a complete ribosome.

## Details of mRNA Translation

The translation process is often divided into three stages (Fig. 1): Initiation –where a complex of proteins (►eukaryotic initiation factors, eIFs) recruits ribosome(s) to the mRNA where they move to the beginning of the ORF, Elongation – which encompasses the processing of the ribosome along the coding region of the mRNA linking amino acids brought by specific transfer RNAs (tRNAs) into a growing polypeptide chain and Termination – which occurs at the end of the ORF characterized by the disassembly of the ribosomal complex and release of the full-length polypeptide.

## Initiation

Eukaryotic ribosomes contain a large and small subunit, each formed from a specific collection of ribosomal proteins and non-coding ribosomal RNAs (rRNAs). When an mRNA is to be translated, the small subunit of the ribosome first binds to a site "upstream" (on the 5′ side) of the ORF. This activity is mediated by an initiation-complex consisting of ►eukaryotic initiation factor (eIF) proteins that bind to the 7 methylguanosine cap (m7G) [►RNA binding proteins Structures/Processes/Conditions] in the 5′ and UTR. This also requires interaction with proteins that bind the polyA+ sequence of the 3′ UTR (Fig. 1). The small ribosome subunit then proceeds along the 5′ UTR region of mRNA in a 5′ -> 3′ direction until it encounters an AUG-►start codon (Fig. 1). At this point it joins with a large ribosomal subunit to form a functional ribosome. Ribosomes contain two sites that contain tRNA molecules, the P-site which usually contains a peptidyl-tRNA molecule (i.e., a tRNA with the growing peptide attached) and an A-site which normally recruits aminoacytled –tRNAs which bring in additional amino acids for incorporation into the polypeptide (Fig. 1). Translation is initiated by an "initiator" tRNA, the only tRNA that can bind directly to an empty P-site of the ribosome. Most often in eukaryotes, this initiator tRNA encodes a methionine (Met) amino acid. At this point the ribosome is ready to recruit additional aminoacytled –tRNAs and proceed to synthesise a full length polypeptide. In special cases, other mechanisms can also initiate mRNA translation. This includes termination re-initiation, where ribosomes are re-directed to translate the same mRNA multiple times. Also, initiation can occur at an AUG codon other than the one nearest the m7G cap (leaky scanning), and ribosome shunting. Finally, there is an alternative to m7G cap-dependent translation initiation where internal ribosome entry sites (IRES) along the mRNA direct translation.

**RNA Translation. Figure 2** Codon usage table: Codons are grouped by the first (*left*) and second (*top*) position. Note that in many cases the third position is redundant and that codons with a common first and second position base base often encode encode the same amino acid.

## Elongation

In eukaryotic cells, there are 20 amino acids commonly used for protein synthesis. Each tRNA contains a region with three unpaired nucleotides (anti-codon) which binds the corresponding codon in the mRNA. The use of three bases to encode each amino acid means that there are actually ($4^3$) different possibilities that can be used to uniquely encode them providing 64 unique identities. Thus, there are more codons than amino acids and therefore considerable redundancy in the code, with some amino acids encoded by four or more tRNAs with different anticodons. A separate process couples each specific amino acid to their representative encoding tRNA (s) via an activating enzyme (aminoacyl-tRNA synthetase). Also, some tRNAs can recognize more than one codon. This modified base pairing at the third nucleotide of a codon is called "wobble-pairing." For example, the phenylalanine tRNA with the anticodon 3′ AAG 5′ recognizes UUC and UUU. Also, some codons are reserved for specialized functions. AUG signals for the beginning of each ORF and for the amino acid methionine (Fig. 2). As a result, there is usually a methionine at the amino terminal of the polypeptide synthesized from the mRNA. Any AUG codons after this point are interpreted for the insertion of an internal methionine.

Elongation of a nascent ribosome associated polypeptide is an iterative process in which a series of specific aminoacytled –tRNAs, are recruited to their respective three-base codons within the A-site adjacent to the P-site (Fig. 1). Once this occurs, elongation factors hydrolyze GTP (an energy source) to covalently link to the incoming amino acid to the existing polypeptide (Fig. 1). At this point the tRNA at the P site is released and the ribosome moves one codon (3 bases) downstream. The newly-arrived tRNA at the A-site, while still attached to the nascent polypeptide, shifts to the P site and opens the A site for recruitment of an aminoacyl-tRNA that carries an amino acid corresponding to the next codon. This occurs via another protein elongation factor and requires the energy of hydrolysis of another molecule of GTP. Once the ribosome complex clears the recruitment site, it is possible to recruit additional ribosome complexes to a single mRNA. Often a single mRNA molecule is translated simultaneously by many ribosomes. This multi-ribosome complex is called a polysome.

## Termination

Translation of a protein is normally finished when the ribosome reaches one or more ►STOP codons (UAA, UAG, UGA) (Fig. 2). Normally, there are no corresponding tRNA molecules with anti-codons for STOP codons. Instead, specific proteins (release factors) recognize these codons when they arrive at the A site of the ribosome and release the completed polypeptide (Fig. 1). During this process the ribosome complex is dissociated back into its corresponding subunits, which are then available for translation of additional mRNAs (Fig. 1).

## Regulation of mRNA Translation

Regulation of mRNA translation appears to be a much more common mechanism for regulating protein expression that was previously thought. There are several mechanisms that limit mRNA translation to specific cellular sub-domains. In addition, cytoplasmic mRNAs have a finite life and like mRNA transcription, degradation of mRNAs is also a regulated process. This includes the surveillance and destruction of aberrant mRNAs as the proteins translated from these mRNAs would potentially be detrimental to cell function. Also, there is an entire ►RNA interference [Structures/Processes/Conditions] regulatory system that employs small ►non-coding RNA molecules that also regulate translation and/or mRNA degradation (i.e., ►RNAi). These events are regulated through specific RNA binding proteins [Structures/Processes/Conditions] that interact with the RNA either before or after it is exported into the cytoplasm for translation. It is now thought that there is a dynamic balance between translation by ribosomes and cytoplasmic RNA regulatory complexes for access to mRNAs.

## RNA Transport Particles

In many cell types, mRNAs are transported to specific sub-domains to regulate protein expression. This process is important for establishing cellular asymmetry during cell division or directed cell migration. This process also appears critical for aspects of neuronal function, including axon guidance and nerve regeneration [1]. The RNA particles that contain these transported mRNAs also contain several of the proteins involved in translation including ribosomal subunits (Fig. 1). It is thought that translation is suppressed during mRNA transport.

## Processing-bodies

Processing bodies (P-bodies) are thought to be primarily sites of mRNA degradation although there are cases where they also sequester mRNAs away from the translational protein complexes to be released later. Degradation-specific P-bodies contain a complex that break down the mRNA by removing the 7mG cap and a 5′-3′ exonuclease that subsequently breaks down the mRNA [2]. These structures also appear to be a destination for mRNAs that are being regulated by the RNAi pathway.

## Stress Granules

In mammalian cells, stress granules appear during events that seem to require a rapid shift in the translational events within a cell [3]. They are proposed to be sites where pools of translationally arrested mRNAs are stored as they contain several proteins also involved in mRNA translation such as the small ribosomal subunit. Functionally, these structures seem to have a role in sorting, remodeling and exporting mRNAs either for subsequent translation or storage in complexes such as P-bodies.

## Preventing Translation of Mutated mRNAs

Eukaryotic cells possess several surveillance mechanisms to ensure the fidelity and appropriate translation of cytoplasmic mRNAs. Translation of aberrant mRNAs would obviously present a disadvantage to a cell. Defects in mRNA molecules can arise via mutations in the DNA of the encoding gene, or by errors that occur during transcription. Some of these errors would have no effect on translation, especially if they occur in the third (wobble) position of a codon due to codon redundancy (Fig. 2). However, mRNAs with incorrect amino acid codons or premature STOP codons would produce truncated proteins that would be ineffective or even harmful.

## Nonsense Mediated mRNA Decay

One process that removes non-sense mutations (premature stop codons) is the nonsense mediated decay (NMD) pathway [4]. Briefly, the complex of the RNA binding proteins that mediate joining of the last exons during nuclear RNA splicing remain associated with the mRNA as it is exported to the cytoplasm. During the first round of mRNA translation, these complexes are removed. If the ribosome complex dissociates from an mRNA via a premature termination codon, one or more of these complexes are not removed, and their retention marks the aberrant mRNA for selective destruction.

## Nonstop mRNA Decay and the Exosome

Nonstop transcripts contain no functional STOP codon. These mutations often occur during mRNA processing either by abnormal splicing or premature addition of the polyA+ tail. During translation of these mRNAs, termination does not occur and the ribosome complex reaches the end of the poly(A) tail. If this occurs, the Ski7 protein binds to the empty A site overhanging the 3′ end of the mRNA and recruits it to the exosome [5]. This exosome complex is the primary mediator of 3′-5′ mRNA degradation that targets old mRNAs for degradation due to shortening of their 3′ poly A+ tail.

## RNase H

### Definition

Ribonuclease is a general term for enzymes which catalyse the hydrolysis of RNA into smaller fragments. Ribonucleases are grouped into several sub-classes within Enzyme Class 2.7. (phosphorolytic enzymes) and Enzyme Class 3.1 (hydrolytic enzymes). RNase H cleaves the 3′-O-P-bond of RNA in a DNA/RNA duplex to produce 3′-hydroxyl and 5′-phosphate terminated products. Since RNase H hydrolyses RNA in a DNA:RNA duplex without degrading the DNA, it is commonly used to remove the RNA template after first strand cDNA synthesis.

## Romberg Sign

### Definition

Simply put, while standing and with the feet together, a positive Romberg sign is when the subject sways or steps out with the eyes closed but not with the eyes open. The amount of sway should make the examiner worried that the subject will fall since most people will sway a little with this test.

The interpretation of an abnormal Romberg test is not simple. A great deal of the nervous system is involved when performing the Romberg test and multiple small deficits in many systems could be present. In other words, the nervous system functions together. For instance, adequate strength in the legs is required. Proximal or distal weakness will prevent the subject from making corrections in stance. Significant cerebellar dysfunction will cause the subject to be unsteady with feet together and eyes open, while mild cerebellar dysfunction might only reveal itself with the eyes closed.

With intact cerebellar and motor function, one maintains balance using the visual, vestibular and proprioceptive systems. Since the Romberg test is performed with the eyes closed, abnormalities in either of the other two systems can cause an abnormal Romberg test. Classically,

the Romberg test assumes that the vestibular system is intact. That may not be a good assumption if dizziness is the primary complaint. In the classic situation, if the subject closes their eyes and significantly sways or steps out, the implication is that proprioception is impaired. If proprioceptive and vestibular functions were both intact, closing the eyes would not be a problem.

Proprioceptive function is transmitted through large diameter myelinated peripheral nerves and the dorsal columns of the spinal cord to nuclei in the brain stem. Peripheral neuropathy, vitamin B12 deficiency, multiple sclerosis and neurosyphilis are examples of diseases to consider when the Romberg sign is positive.

## Rough Endoplasmic Reticulum (RER)

### Definition

The endoplasmic reticulum (ER) is an extensive membrane network of tubes and sac-like structures held together by the cytoskeleton. Some parts of the ER are covered with ribosomes on the surface, which give them a rough appearance at the level of the electron microscope. Ribosomes assemble amino acids into proteins based on instructions from the nucleus. and insert the freshly produced proteins directly into the ER, which processes them and then passes them on to the Golgi apparatus.

## Route Navigation (or Taxon Navigation)

### Definition

In route navigation the traveler is guided by a memorized set of turns and straight paths to reach a goal. Rule sets such as "at the big rock turn left; next, at the fallen tree bear right and proceed…" are examples of route learning. In animals route learning is based on operant conditioning. In humans it is usually accomplished by "following directions" generated by another (cultural transmission). Route learning can be effective but is inflexible.

## Saccade – Delayed

### Definition
Saccades that are voluntarily withheld, after a targeting eccentric stimulus appears, until a central fixation stimulus is turned off. The temporal overlap between the time of target appearance and the turning off of the fixation point is called the delay period.

►Saccade
►Saccadic Eye Movement

## Saccade, Saccadic Eye Movement

### Definition
A rapid conjugate eye movement that shifts the line of sight (center of gaze) rapidly from one part of the visual field to another, mainly used for orienting towards an object of interest. It is characterized by stereotyped relationships between amplitude, duration, and peak velocity. In human subjects, peak velocity typically rises along with saccade amplitude up to a saturation level of 400–500° $s^{-1}$ which is reached when the amplitude exceeds 10–30°, whereas duration rises linearly at a rate of 1.5–3 ms per degree starting from a minimum of 20–30 ms. Saccades are the only type of eye movements that can be readily executed at will (as when scanning a picture), but are also intimately involved in reflexive and involuntary behaviors:

Suddenly occurring visual, but also auditory and tactile, stimuli elicit reflexive saccades toward the stimulus location (visual grasp reflex), and during seemingly quiet fixation the eyes are engaged in an ever continuing series of microsaccades which go unnoticed by the individual. Saccades are thought to be essentially preprogrammed according to visual information arising at latest about 100 ms before movement onset although some possibility of "on-line" modification by concurrent sensory stimuli has been noted.

►Microsaccades

# Saccade Adaptation

Charles A. Scudder
Portland, OR, USA

## Definition

Saccade adaptation is a process for maintaining saccade accuracy based on evaluating the accuracy of past saccades and appropriately correcting the motor commands for subsequent saccades. An adaptive process is required to maintain saccade accuracy because saccades have too short a duration relative to the long delays in the visual pathways to be corrected while in flight. It is a true adaptive process in that it is unconscious, accuracy improves gradually over repeated trials, and when complete, removal of the original error by experimental intervention produces a new saccadic error (dysmetria) in the opposite direction that can only be eliminated by a new process of adaptation.

The normally high accuracy of saccades is largely the product of continuous adaptation. Numerous components of the oculomotor system, such as the eye muscles, cranial nerves, and central pathways, gradually change during development and aging, and these changes would produce saccadic inaccuracy if uncorrected. Adaptation can sometimes maintain accuracy after pathological changes occurring in any of these components.

## Characteristics

### Methods to Measure Adaptation

Saccade accuracy is quantified by measuring the endpoint of the saccade relative to the location of the target. In a typical experimental setup, subjects fixate a small stationary target spot, and after a delay, the target jumps to a new location. Subjects must quickly shift their gaze (make a saccade) to re-fixate the displaced target. Beginning at the initial fixation point, the target displacement and the saccade are expressed as vectors in polar coordinates. Adaptation can be expressed as a decrease in saccade error, which is the angular error (difference between the angles of the target and saccade vectors) together with the amplitude error (difference between the amplitudes of the target and saccade vectors). Alternatively, it can be expressed as the amplitude of the saccade relative to the amplitude of the target displacement, with 100% being perfect. This ratio is often called ►gain, but the term has mechanistic connotations that are inappropriate for saccade adaptation.

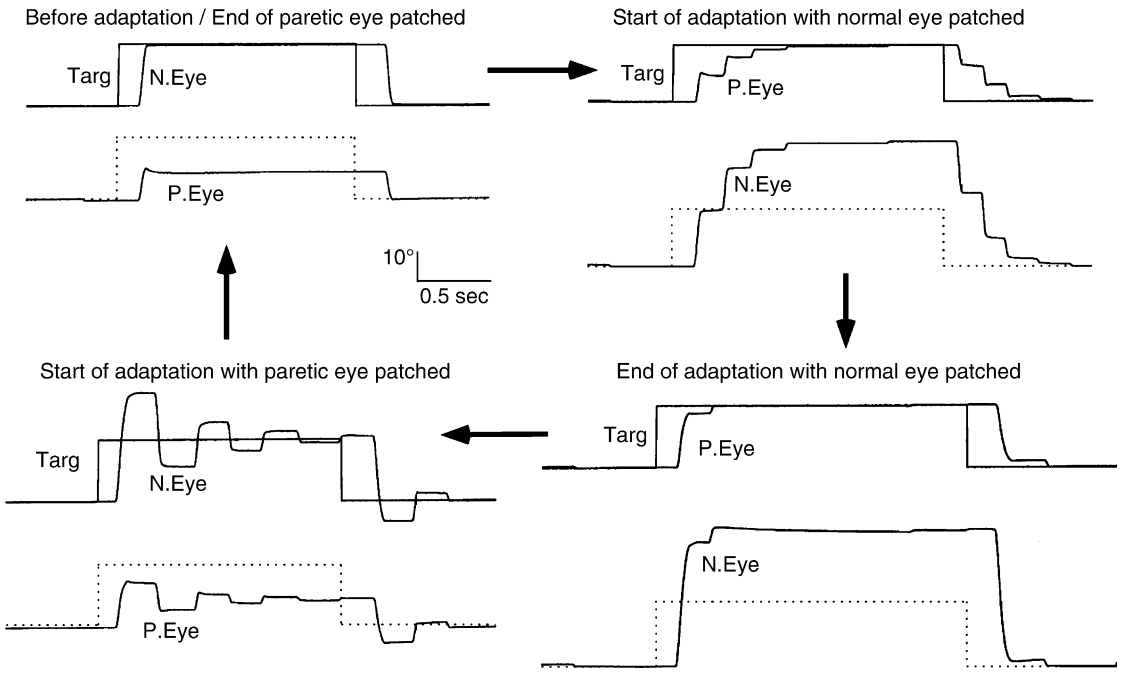
Although saccade adaptation is an everyday occurrence, an experimental intervention is usually invoked to reveal its power and features. The first experimental paradigm was modeled after human pathology. Patients who develop a ►paresis of one or more muscles in one eye produce saccades that have different amplitudes in each eye. If the patient had been using the normal eye to view the world, the normal eye would make accurate saccades, but the eye with paresis (the "paretic eye") would make saccades too short to land on the target (undershooting saccades). If an experimenter placed an opaque patch over the normal eye and forced the patient to use the paretic eye, saccades in the paretic eye would initially undershoot, but would also increase in size (adapt) over the period of about a day until they were nearly accurate [1]. Saccades in the normal eye would also increase in size so that they would overshoot the target. Of course, the normal eye is patched so that the CNS is unaware of the overshoot. Subsequently, if the patch is removed from the normal eye and placed over the paretic eye, the now viewing normal eye continues to overshoot the target. The overshoots gradually diminish until saccade metrics are restored to the state before the eye was ever patched. The paradigm has been adapted for use in animals by surgically weakening the medial and lateral rectus muscles of one eye to produce an artificial paresis [2], and an example of such adaptation is shown in Fig. 1.

In a second paradigm for producing saccadic adaptation, a target steps away from the fixation point, and while the saccade is in flight, the target is displaced again so that the otherwise accurate saccade will not land on the target [3,4]. The "intrasaccadic" target displacements can be backward relative to the first target step, forward, or to the side, and are typically 15–40% of the amplitude of the first target step. Repeated trials of the same type (e.g., all back-stepping) cause a consistent error that is gradually corrected by adaptation. Figure 2 illustrates this process for a human subject tracking a target where the initial target step of about 9° is followed by an intrasaccadic step of 3° backwards. In the space of 150 trials, the amplitude of the saccade decreases from overshooting the displaced target to essentially landing on the target. When the intrasaccadic step is discontinued at trial 375, saccade amplitude remains at its reduced value for some time even though the saccade now undershoots the target. In fact, a new gradual process of adaptation is required to increase saccade amplitude back to normal. A similar process of adaptation of saccade direction occurs if the intrasaccadic step is perpendicular to the initial target step.

### Characteristics of Saccade Adaptation

#### *A True Adaptation?*

Data indicate that the above changes in amplitude are the product of a true sensory-motor adaptation rather than the product of conscious effort or some covert "strategy." First, the majority of human subjects are unaware of the intrasaccadic steps and therefore could



**Saccade Adaptation. Figure 1** Adaptation of saccade size produced by patching of either the normal or the paretic eye. The four stages of adaptation are shown for typical single trials, and are in clockwise order (*large arrows*). Horizontal position is illustrated for the visible target (Targ), normal eye (N.Eye), paretic eye (P.Eye), and the unseen target for the patched eye (*dotted lines*). Initially, the patch covered the paretic eye and the normal eye viewed the target (*top left*). Adaptation was initiated by switching the patch to cover the normal eye so that saccades in the viewing paretic eye were severely undershooting (*top right*). After viewing with the paretic eye for a day or more, saccade size increased in both eyes (*bottom right*). Finally, switching the patch back to cover the paretic eye resulted in severely overshooting saccades in the viewing normal eye (*bottom left*). Long-term adaptation to this situation produced decreases in saccade size and a return to normal-sized saccades in the normal eye (*top left*).

not form such a strategy. Second, discontinuation of the intrasaccadic steps (e.g., at trial 375, Fig. 1) does not produce an immediate reversal of the change in saccade size, even though the adapted size is now an encumbrance. Third, repeated sessions of adaptation and reversal do not result in any faster changes. Fourth, when examined under similar experimental conditions, the paretic-eye and intrasaccadic-step paradigms produce similar amounts of adaptation in similar amounts of time [2].

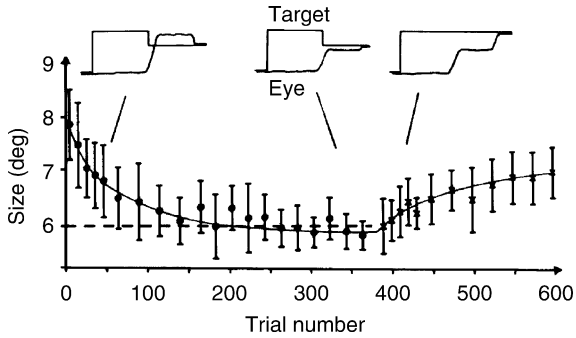
### Conjugate or Monocular?

Adapted saccades are conjugate by default, even in the paretic-eye paradigm where one eye is patched. However, if disparate visual stimuli are presented to each eye, a limited ability to adapt each eye disconjugately can be demonstrated.

### Time Course

The time course of adaptation varies tremendously depending on the details of the paradigm and the species. Adaptation in humans is approximately ten times faster than that in monkeys under comparable experimental conditions. Adaptation is faster (as much as two times) when decreases in saccade size are required compared to when increases are required. Adaptation is also faster when there are few potential targets (e.g., subjects saccade back and forth between two targets) than when there are many (e.g., saccades are made to an array of targets with multiple rows and columns) [2,4].

The wide range in rates of adaptation might indicate that different sites and/or mechanisms of plastic changes are invoked with different paradigms or in different species. However, these apparent differences are probably more quantitative than qualitative. For instance, a very rapid form of adaptation has been identified in both monkeys [2] and humans [4], but in the former, it accounts for only a small part (<10%) of the total possible change, whereas in the latter it accounts for 20–85%. Consequently, many human experiments are terminated before a slower (monkey-like) form of adaptation could be revealed. Similarly, the paretic-muscle paradigm produces slow adaptation when subjects view the natural world outside the laboratory. However, the rate is the same as in the



**Saccade Adaptation. Figure 2** Time course of adaptation of saccade size produced by using the intrasaccadic-step paradigm. Saccade size is plotted against the number of trials. To a target step about 9°, the monkey makes a slightly undershooting saccade (*left inset*), but the 3° backward step that occurs during the saccade makes it appear to the monkey that the saccade overshoots the target. After repeated trials with backward intrasaccadic steps, the saccade declines in size so that it slightly undershoots the displaced target (middle insert, and dotted line on plot). Elimination of the backward intrasaccadic steps at trial 375 renders the newly adapted saccade to seriously undershoot (*right insert*). The apparent ►saccadic dysmetria is slowly reversed (figure adapted from Deubel [3]).

intrasaccadic-step paradigm when the number of targets is the same, indicating that the paretic-muscle paradigm does not invoke a separate mechanism of adaptation [2].

### *Adaptation Fields*

If saccades are adapted using target steps of one size and direction, and the effects are tested using target steps of various sizes and directions, it is found that the induced change in saccade size decreases with increasing disparity between the test and adapted target step (reviewed in [5]). The range over which training transfers (generalizes) to steps of other sizes and directions is called the adaptation field. This finding explains the previous result that adaptation is slower with increasing numbers of potential targets. That is, adaptation of saccades to each target in the array occurs with incomplete benefit from adaptation to other targets in the array.

By default, adaptation fields are only weakly dependent on eye position *per se*. That is, adaptation to 10° rightward target steps at one location mostly transfers to 10° rightward target steps anywhere else in the visual field. However, adaptation can be rendered position dependent if training is position dependent [2,5]. For instance, training with backward intrasaccadic steps when looking left, and forward intrasaccadic steps when looking right, produces decreases in saccade size when looking left and increases in saccade size when looking right. Moreover, in humans with paresis of one extraocular muscle, saccadic size in the paretic eye is eye-position dependent, and adaptation is correspondingly position dependent when the paretic eye is forced view the world [1].

### *Transfer of Adaptation to Different Tasks*

The situation in monkeys is simple; adaptation using one saccadic tracking task produces adapted saccades when measured in any other saccadic task. For instance, training using intrasaccadic steps and the simple "targeting" task described above produces comparable, or nearly comparable, adaptation of express saccades evoked in a ►gap task (very short latency reflexive saccades, see ►Saccades-Express), saccades measured in a ►memory-guided saccade task (saccades to a target flashed on and off 1 sec earlier), self-paced saccades to fixed targets, and catch-up saccades during smooth pursuit. In humans, transfer is more complicated. In general, transfer of adaptation from simpler paradigms (targeting task and gap task) to "higher-order" saccades (scanning and memory-guided) is weak, and visa-versa (reviewed in [5]). The data have been taken to mean that humans have more than one site of adaptation (see below).

## Upstream Conditions

Adaptation is a process of detecting errors and incrementally correcting them in subsequent movements. Obviously, the visual error produced when the line of sight does not fall on the target is the operational error that drives adaptation. However, after the dysmetric saccade, subjects immediately make a corrective saccade to remove the visual error. The nervous system could use either a neural representation of the visual error or a copy of the efferent command for the corrective saccade to serve as the error signal to induce the synaptic changes that underlie adaptation. Experimental tricks that produce visual error without corrective saccades show that the neural representation of visual error is used as the predominant signal that drives adaptation (reviewed in [5]).

## Involved Structures

*A priori*, any of the structures involved in generating saccades could potentially harbor the synapses that change to produce adaptation. These include the major cortical areas (►frontal eye fields, ►supplementary eye fields, and ►lateral intraparietal area), the ►superior colliculus, the midline ►cerebellum, and the burst generator itself. The characteristics of adaptation constrain the choice. The existence of adaptation fields implicates a structure whose neurons have movement fields or a structure that receives input from one with movement fields. The existence of eye-position dependent adaptation implicates a structure that is at least potentially aware of current eye position. This would

appear to rule out the burst generator per se, the collicular synapses on burst-generator neurons, and arguably the superior colliculus itself, because all three areas are thought to encode only eye or gaze displacement. These conjectures have been tested by neurophysiological experiments in the superior colliculus. Experiments using saccades evoked by microstimulation of the colliculus either during the adapting or testing phase have been inconclusive (reviewed in [5]), perhaps because microstimulation does not evoke saccades in the same way as normal targeting saccades. On the other hand, measurements of the ►movement fields of neurons in the superior colliculus show that they change minimally as a result of adaptation, indicating that the adaptation takes place downstream of the colliculus [6].

The cerebellum is downstream of the superior colliculus (see ►Cerebellum – role in eye movements) and satisfies behavioral criteria noted above. In addition, it has been strongly implicated in adaptation in other motor systems and has a wealth of identified mechanisms of synaptic plasticity. Physiological experiments in monkeys strengthen the conjecture that it has a major role in saccade adaptation. Permanent lesions of the ►oculomotor vermis or fastigial nucleus severely impair or abolish the ability to adapt saccade size using intrasaccadic steps [7]. Temporary inactivation of the caudal fastigial nuclei using a GABA agonist produces dysmetria and prevents the expression of adaptation while the drug is active, but not after the drug has worn off [8]. Presumably, plastic changes had occurred upstream of the fastigial nucleus, e.g., in the vermis. Finally, the discharges of fastigial-nucleus neurons change as a result of adaptation of saccade size in a manner adequate to have produced the changes in size [9].

Adaptive changes in humans probably also involve the cerebellum [10], but the failure of changes to transfer to saccade tasks different from the training paradigm and the predominance of a very rapid form of adaptation indicates that another site might also be involved in some tasks. Functional MRI data do not implicate another structure [10], but the data are not definitive. There are other possibilities, including that most changes could occur in the cerebellum, but separate channels from different sources (the superior colliculus or frontal eye fields) are maintained and separately adapted.

# Saccade Remapping

## Definition

Saccade-related shift of visual target representation in The central nervosu system (CNS). Conceivably due to processes subsumed under the rubric "Vector-subtraction hypothesis" (see Foveation Hypothesis) it is consistent with the well documented saccade-related shift of the receptive field of neurons sensitive to a direct or memorized visual stimulation (see Lateral intraparietal area (LIP) for a description of such visual receptive fields). This observed shift, which sometimes occurs in anticipation of the actual movement of the eyes, likely contributes to the neural processes suppressing the awareness of visual instabilities caused by saccadic eye movements.

Thus by extension, saccade remapping also refers to visual stability processes and to space constancy processes which allow us to encode our environment independently of eye movements.

# Saccade-Vergence Interactions

Lawrence Mays
University of North Carolina at Charlotte, Charlotte, NC, USA

## Definition

►Saccades are very fast (up to 700°/s) movements of the eyes which are generally employed to shift gaze from one object to another. In general, saccades are conjugate, in that the two eyes move in the same direction and by the same amount, even if only one eye is allowed to view the target. Saccades may be horizontal, vertical, or oblique. Horizontal ►vergence (Disparity dependent vergence, Radial flow dependent vergence) movements are very slow (5°/s to 50°/s) movements of the eyes in the opposite direction in the horizontal plane, and are used to transfer gaze between objects at different distances from the observer. Horizontal vergence movements are part of a near response, and are associated with ocular accommodation, which is the change in lens power needed to focus on a nearer or farther object (see ►Accommodation-vergence interaction). Saccade-vergence interaction refers to the increase in the speed of vergence observed when saccades occur during vergence movements, or alternatively, to the inequality of the sizes of horizontal saccades when they occur during vergence movements [1].

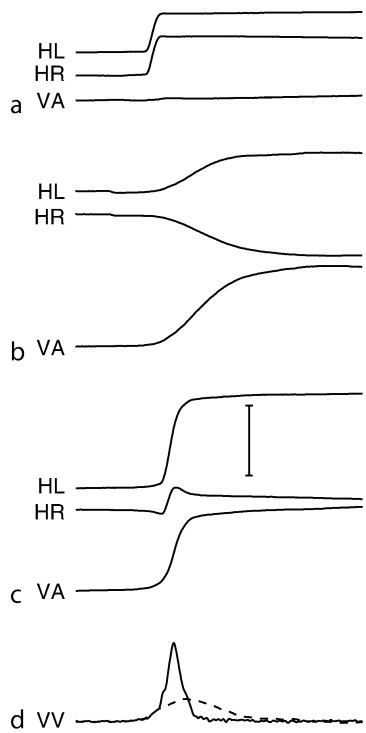
## Characteristics

### Upstream Events/Conditions

Saccades may be voluntary or involuntary, and are usually directed toward visual targets in the environment, or they may be spontaneous or occur in response to other (e.g. auditory) cues. Saccades between targets that are equidistant from the observer do not involve vergence movements, aside from a small rapid divergence-convergence transient (►Divergent eye movement, ►Convergent eye movement), which may be due to mechanical factors. A horizontal saccade between two targets spaced 8° apart is shown in Fig. 1a. A saccade-free, or smooth, vergence movement between a far and a near target is shown in Fig. 1b. Vergence movements occur in response to shifts in gaze between visual targets at different distances. Vergence movements can occur in the absence of saccades, but this is rare in the natural environment; to do so, the far and near targets must be aligned with a point halfway between the eyes, as was the case for this example. Vergence movements have been extensively studied in the laboratory in this situation. There is evidence that the neuronal circuits for saccades and vergence movements are somewhat independent, although utilize the same ►extraocular motoneurons [2]. Lesions of the pons and ►medial longitudinal fasciculus (MLF) may impair horizontal saccades without a major effect on vergence [3], while some midbrain lesions may impair vergence while leaving horizontal saccades relatively unaffected.

### Downstream Events/Conditions

If the vergence and saccadic subsystems were essentially independent, then one might expect the eye movements produced by each to sum linearly when a saccade occurs during a vergence movement. That this is not the case can be seen in Fig. 1c and d. This can be seen by noting the relative sizes of the horizontal saccades (Fig. 1c), or by comparing the vergence velocity profile for the saccade-vergence trace with that of the similar smooth vergence (saccade-free) case (Fig. 1d). There is a rapid acceleration of vergence during the saccade, which causes vergence movements during saccades to be completed more quickly than if



**Saccade-Vergence Interactions.**
**Figure 1** Saccade-vergence interaction. This figure shows an 8° horizontal saccade (a), an 11.5° smooth horizontal vergence movement (b), and the interaction when a saccade of this size occurs during the vergence movement (c). (d) shows the vergence velocity profiles for the saccade + vergence (solid line) compared to the vergence only (dashed line) case. Abbreviations are: *HL*, horizontal left eye position; *HR*, horizontal right eye position; *VA*, vergence angle (i.e. HL-HR); *VV*, vergence velocity (first derivative of VA). The scale bar is 10°, and the time base is 500 ms.

there were no saccades. If the saccade and the vergence events summed linearly, the vergence velocity profiles in Fig. 1d would be identical. Not only do saccades speed vergence; it appears that vergence movements slow saccades.

## Involved Structures

The same extraocular motoneurons (►medial rectus for adduction, abducens for abduction) (►Ocular adduction, ►Ocular abduction) are utilized for both saccades and vergence movements, although not necessarily to the same extent. The pre-motor circuitry is quite different for the two types of eye movement. For vergence, some midbrain ►near response neurons appear to project to the medial rectus subdivisions of the oculomotor nucleus [4] and carry a signal related to vergence and accommodation but are unrelated to the conjugate movements characteristic of saccades. Most near response cells have precisely the vergence signal needed by medial rectus motoneurons, that is, they increase their firing rate linearly for convergence (convergent eye movements), and also have an appropriate vergence velocity signal. A small number of midbrain near response cells decrease their firing rate for convergence (divergence cells), and so have the appropriate signal for abducens motoneurons, but this connection has not been documented.

The pre-motor commands for horizontal saccades are organized in the pons. Two types of saccadic burst neurons (also called short- or medium-lead burst neurons) are found [5]. ►Excitatory burst neurons (EBNs) provide an excitatory burst to ipsilateral abducens neurons (motoneurons and internuclear neurons) and so provide the appropriate velocity command for the high-speed saccades. Inhibitory burst neurons show the same pattern of activity (i.e., burst for the horizontal component of an ipsilateral saccade) but inhibit the contralateral abducens nucleus during the saccade. Saccadic burst neurons are inhibited by pontine ►omnipause neurons, which are located in the nucleus raphé interpositus. Omnipause neurons are normally active during wakefulness, and must cease firing in order for a saccade to occur.

►Abducens internuclear neurons are located within the abducens nucleus but are not motoneurons. Their axons cross the brain at the level of the abducens nucleus and ascend the medial longitudinal fasciculus to provide excitatory input to the medial rectus motoneurons. To the extent that abducens internuclear neurons receive the same inputs as abducens motoneurons, the abducens internuclear pathway serves to ensure that the two eyes move conjugately in the horizontal plane. Abducens internuclear neurons do not provide a vergence signal to the medial rectus motoneurons, and damage to the internuclear pathway disrupts adduction for conjugate gaze shifts but not convergence [3]. Indeed, nearly all abducens internuclear neurons decrease their firing rate for convergence (as do abducens motoneurons) and so they provide an inappropriate vergence signal to the medial rectus motoneurons, which must be overcome by the near response cell input to these motoneurons [6].

## Mechanism of the Interaction

Three mechanisms for this non-linear interaction between saccades and vergence have been proposed. The first explanation is that there is a non-linear interaction between saccadic and vergence commands at the level of the extraocular muscles, since the same extraocular muscles are used to execute both saccades and vergence movements. A strong argument against this explanation is that purely vertical saccades are about as effective at speeding vergence as horizontal saccades. This should not be the case if the interaction depended upon an interaction at the level of the extraocular muscles since different muscles are used for horizontal and vertical eye movements.

The second explanation notes that the sizes of the saccades in the two eyes are markedly different, and proposes that under the condition of shifting gaze between objects at different distances and directions, the normally conjugate saccadic system is allowed to operate in a disconjugate, or disjunctive mode (►Disjunctive eye movements), and produce different saccades for the two eyes [7]. One argument in favor of this explanation is the observation that, for unequal horizontal saccades occurring during vergence, some saccadic burst cells have activity associated with the movement of the right eye and some are associated with the left eye [8]. The possibility that saccadic pre-motor elements might command the eyes to move different distances suggests that the saccadic system is responsible for the speeding of vergence in this situation. On the other hand, there are strong arguments against this view. Studies of the activity of abducens motoneurons and internuclear neurons show that any separate right eye/left eye pre-motor signals are commingled and essentially lost at the level of the motoneurons [6]. Furthermore, it is clear that abducens internuclear neurons do not convey an appropriate vergence signal to the medial rectus motoneurons. Moreover, it is difficult to reconcile the idea that speeding of vergence is due to unequal horizontal saccades when it occurs with vertical saccades, which employ different motoneuron pools and different pre-motor circuitry.

A third view is that there is a mechanism that selectively speeds vergence during a saccade. According to this idea, the saccadic system generates equal saccades for the two eyes, but the occurrence of the saccade accelerates the vergence command, and the resulting rapid change in vergence angle, synchronized with the saccade, causes the saccade in one eye to be larger than that in the other. Indeed, it has been suggested that

pontine omnipause neurons, which inhibit saccadic burst neurons and must be turned off during saccades, also inhibit vergence burst neurons [9]. If so, then these vergence burst cells would be allowed to fire more vigorously during saccades, speeding vergence. Alternatively, some component of the saccadic burst signal could be combined with the vergence velocity signal to speed the vergence movement.

### Methods to Measure this Event/Condition

Saccade-vergence interactions require methods to measure eye movements with high temporal and spatial resolution. In general, faithful recording of saccades requires a sampling rate of at least 500 samples/s and small vergence movements should be recorded to nearest 0.1°. Non-contacting infrared techniques can be used if only horizontal movements are to be recorded. If vertical saccades are to be measured, scleral search (electromagnetic) coils should be considered.

## Saccadic Burst Generator

### Definition

The saccadic burst generator is a neural network in the brain stem that converts saccadic-related signals from higher level sensorimotor structures into intense bursts of activity that temporally drive the oculomotor neurons. The bursts of neural activity can be excitatory for agonist motoneurons and inhibitory for antagonists. The generator may also include gating circuits that help to control the onset and end of the bursts.

►Brainstem Burst Generator
►Saccade, Saccadic Eye Movement

## Saccadic Dysmetria

### Definition

Is a repeatable failure of saccadic eye movements to land on their intended target. The error can be one of saccade amplitude (either undershooting or overshooting) or one of saccade direction. Dysmetria can be produced by pathology within the orbital tissues, extraocular muscles, or in the brain. The brain has robust adaptive capabilities to make conjugate corrections for dysmetria, and limited capability to make monocular corrections.

These capabilities are thought to require the midline cerebellum, so enduring conjugate dysmetria is frequently due to pathology of the cerebellum.

## Salivary Secretion Control

Gunnar Tobin
Department of Pharmacology, The Sahlgrenska Academy at Göteborg University, Göteborg, Sweden

### Definition

The control of salivary secretion depends on reflex nerve impulses that involve afferent limbs, medullar salivary nuclei and an efferent limb consisting of the ►parasympathetic and sympathetic secretomotor and vascular nerves. Except for a scanty spontaneous secretion from minor salivary glands, the secretory process is elicited entirely by activity in the autonomic glandular innervation, albeit endocrine stimuli may modulate saliva composition. Also the glandular blood flow is principally controlled via the innervation with other influences, such as hormones having little effect. At rest, a small secretion normally occurs as a result of reflex glandular activation and the spontaneous secretion. Taste and mastication are important sensory inputs leading to activity in the two divisions of the ►autonomic nervous system, which act synergistically in the control of salivary secretion.

### Characteristics

#### Quantitative Description

Saliva is produced by three pairs of major glands and a number of minor glands (labial, buccal, lingual, palatinal) [1]. The parotid (20–30 g) and submandibular glands (8–10 g) are conspicuously larger than the sublingual gland (3–5 g). The resting flow in healthy individuals usually amounts to 0.3–0.4 ml/min, which have the relative glandular contributions: submandibular 65%, parotid 20% and the sublingual and the minor glands 5–10% each. In stimulated flow of whole saliva, the parotid part may be as large as 50%.

#### Higher Level Structures

##### *Anatomy [1,2]*

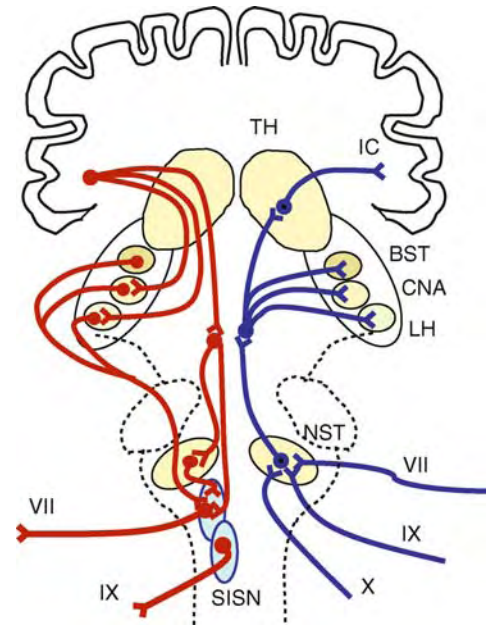
The parotid gland is located frontal and caudal to the auditory canal and surrounds the dorsal part of the mandible. On the masseter surface, close to the parotid duct, additional glandular tissue may occur (accessory parotid gland). The submandibular gland is located caudal to the parotid gland and medially to the body of the mandible, while the sublingual gland is located in the floor of the mouth cranial to the mylohyoid muscle. The minor salivary glands underlie most of the oral mucosa except the gingiva and the dorsum of the tongue, and in contrast to the major glands these glands may produce saliva spontaneously. The arterial blood flow supply is derived from various branches of the external carotid artery, and the venous drainage is provided by tributaries of the external and internal jugular veins.

### *Autonomic Nerves*

The parasympathetic preganglionic nerve fibers leave the central nervous system via the facial and the glossopharyngeal ►cranial nerves. The fibers in the facial nerve depart the nerve within the skull and run in the chorda tympani before fusing with the lingual nerve; some fibers of facial nerve reach palatinal glands by other routes. The ►postganglionic fibers of ganglion submandibularis innervate the submandibular and the sublingual glands as well as minor lingual glands. The glossopharyngeal fibers enter the otic ganglion via n. petrosus minor, and the relatively long postganglionic nerve fibers reach the parotid gland and minor buccal glands via the auriculotemporal nerve. The postganglionic fibers of the sympathetic innervation originate in the superior cervical ganglion and follow the blood vessels to the glands.

### *Central Connections*

Figure 1 shows a schematic illustration of taste afferents, projections to areas of the ►limbic system and cortical level and efferent system [3]. Tentatively, ►limbic areas are associated with feeding- and drinking-related behavior and the cortex with discrimination of taste intensity and quality. The salivatory centers receive impulses from other brainstem nuclei and from the forebrain, and these impulses may be modulated by ►inhibitory or excitatory synapses. The precise location of the sympathetic salivary center is not identified, but the sympathetic impulses are outflows from the upper thoracic spinal cord. Vascular nerves are a separate set of efferent nerves than the secretomotor efferents, at least sympathetic, and while the parasympathetic vascular efferents are controlled by salivatory centers, the sympathetic are under central vasomotor control.



**Salivary Secretion Control. Figure 1** Schematic illustration based on studies in rats [3] of parasympathetic efferent system (facial nerve – submandibular/sublingual glands and glossopharyngeal nerve – parotid gland; to the left in illustration) and taste afferent system (facial, glossopharyngeal and ►vagal nerves; to the right). Taste information is relayed via neurons of the solitary nucleus (NST) to a second-order of neurons in the parabrachial nucleus. The dorsal ►thalamus (TH) projections of the nucleus terminate in the insular cortex (IC), while a ventral route to the limbic system terminates in the ►lateral hypothalamic area (LH), the central nucleus of the amygdale (►amygdala) (CNA) and the bed nucleus of the stria terminalis (BST). Direct and indirect descending projections reach the medullar parasympathetic superior ►salivatory center (the only one characterized). This salivatory center consists of the ►salivatory nuclei (superior and inferior salivatory nuclei) (SISN), the former connected to the submandibular and sublingual glands, and the latter to the parotid gland.

## Lower Level Components

### *Histology [4]*

The glandular parenchyma consists of secretory endpieces (acini), often capped by cells in the form of demilunes, and of ducts. The endpieces consist of serous cells, producing a protein- and enzyme-rich secretion, of mucous cells, producing a secretion rich in glycoconjugates (e.g. mucin), and of seromucous cells, sharing features of each of the other two. The human parotid gland is a homocrine serous gland, the submandibular a heterocrine (mixed seromucous), while mucous cells dominate in the sublingual gland. Minor glands are heterocrine except the mucous palatinal and the serous lingual von Ebner's glands. Contractile myoepithelial cells surround the secretory endpieces and the intercalated ducts into which the saliva produced by the endpieces drains. In the succeeding striated ducts, an active transport of electrolytes from the saliva to the bloodstream occurs. Eventually the striated ducts empty into the excretory ducts.

### *Innervation [4]*

Generally, human salivary glands are densely innervated by ►cholinergic and ►adrenergic fibers, but the adrenergic innervation of sublingual and minor salivary glands is sparse or deficient. Fibers containing neuropeptides (►NANC transmitters; mainly ►vasoactive intestinal peptide (VIP) and ►neuropeptide Y (NPY)), also occur. The NANC transmitters often co-exist with a classical autonomic ►neurotransmitter in the same fiber. In animals, VIP and acetylcholine, and occasionally the enzyme ►nitric oxide synthase, may occur in the same parasympathetic postganglionic neuron, while NPY may co-exist with noradrenaline.

### Receptors

►Muscarinic receptors, alpha- and beta-►adrenoceptors as well as NANC transmitter receptors (VIP receptors) occur abundantly on parenchymal cells and in the glandular vasculature, and moreover, muscarinic receptors and $\alpha_2$-adrenoceptors occur on nerve terminals [5]. Glandular $\alpha_1$- and $\beta_1$-adrenoceptors have been described in human glands. While both muscarinic M1 and M3 receptors occur in human labial glands, all five subtypes exist in the rat submandibular gland but still with M3 subtype dominance. However, receptors for a number of transmitters, hormones and factors have been described in human salivary glands (e.g. epithelium growth factor (►EGF), androgen, progesterone, aldosteron and glucagons) and considering findings in animals, the list grows even longer and includes ►tachykinin (NK1), purine, ►serotonin and ►GABA receptors.

## Structural Regulation

### Ontogenesis and Neuronal Trophic Effects

Salivary glands arise in the embryo from the proliferation of epithelial cells into the mesoderm, forming a cord that becomes canalized, and postnatal the terminal cells are developed into the fully mature secretory endpieces. Parasympathetic responses occur already at birth, while sympathetic appear some days later. The autonomic innervation affects size and sensibility of salivary glands, and, as shown by animal studies, loss of the parasympathetic NANC drive causes a profound atrophy and ►denervation supersensitivity [4,6]. Acetylcholine seems to be of less significance for long-term regulations, but noradrenaline have structural effects; stimulation of the β−adrenoceptor induces increase in glandular size. In addition to the neuronal structural regulation, hormones (i.e. different steroid hormones including oestrogen, progesterone and androgens) may affect cell growth and gland size.

## Higher Level Processes

### Activation of Reflexes

During eating, increases in efferent outflows are attributed to stimulation of different ►sensory receptors; ►gustatory receptors, ►mechanoreceptors, ►olfactory receptors and nociceptors [2]. The gustatory-salivary reflex, activated by strong sour stimulus evokes a maximal secretory response, while other basic stimuli (salt, bitter, sweet) give smaller. However, secretion elicited by sweet and salt is richer in protein, suggesting quality-specific activation of parasympathetic and sympathetic fibers. Mastication activates mechanoreceptors in the periodontal ligament (►Ruffini endings) and in the mucosa, which results in greater ipsilateral responses than contralateral. Smell may evoke secretion by chemical irritation of free nerve endings and by odorants stimulating nasal olfactory receptor neurons (olfactory-salivary reflex); the latter exists in the submandibular but not in the parotid gland. Noxious and non-noxious stimuli of oral tissues also activate salivary reflexes, while the existence of oesophageal, visual and psychic reflexes is a matter of debate. Hyposalivation during fear is, however, explained by central inhibition of salivatory centers reducing the efferent outflow.

### Sensory Inputs and Efferent Impulses

In animals, the efferent outflows from the salivatory centers depend on the sensory modality and on which confined oral area is being stimulated, and preganglionic parasympathetic and sympathetic neurons respond differently to taste, tactile and noxious mechanical stimulation [3]. The preganglionic parasympathetic neurons discharged spontaneously at a low firing rate, when examined in hamsters and rats, and fired to reflex stimulation by phasic-tonic or ►tonic activity (periodically up to 30 Hz). Neurons assumed to be a vasodilator type, tended to fire at a slightly higher frequency. Nevertheless, the ganglionic transmission from pre- to postganglionic neurons varies between species. Some species (e.g. rats) have ganglion cells that are innervated by a single preganglionic axon, while others have a multiple innervation yielding discharges in postganglionic neurons in short bursts, each at a very high frequency as seen in sheep. Also, sympathetic neurons may have a spontaneous and irregular discharge, in which the number of bursts increases by a sensory input.

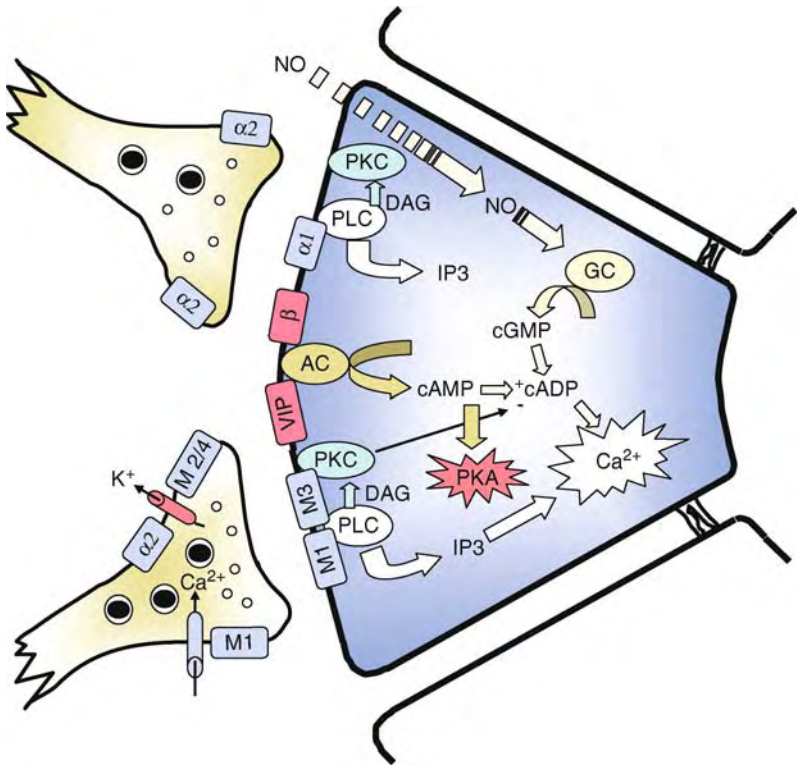
## Lower Level Processes

### Receptor Pathways and the Cellular Secretory Mechanisms

Saliva, containing approximately 99% water and 1% of electrolytes and proteins, is produced in two steps – first formation of isotonic primary saliva by secretion from the secretory endpieces, and second reabsorption of sodium and chloride and some secretion of potassium and bicarbonate in the ducts [5]. Since the ducts are relatively impermeable for water the secondary saliva becomes hypotonic, but less so at increasing flow rates. Receptors being preferentially hydrokinetic (muscarinic ►acetylcholine receptors and $\alpha_1$-adrenoceptors (and tachykinin receptors in some species) activate the $Ca^{2+}$-dependent pathway, while the proteokinetic type (β-adrenoceptors and VIP receptors) activates the cAMP-pathway (Fig. 2) [4,7]).

The combined stimulation of both pathways results in ►potentiation of the responses, but responses are also modulated by prejunctional receptors that facilitate or inhibit transmitter release. The intracellular events leading to fluid secretion is elicited when $Ca^{2+}$ rises, but how water moves is not fully clarified (Fig. 3 [7]).

Proteins are primarily secreted from acinar cells with the addition of a small proportion from ducts cells. Low



**Salivary Secretion Control. Figure 2** Schematic illustration of ►G-protein-coupled receptors for principal transmitters and key molecules of the intracellular pathways in a salivary secretory cell innervated by adrenergic and cholinergic/VIPergic neurons (modified from [3]). Transmitter binding to $\alpha_1$-►adrenoceptors, muscarinic M1 or M3 receptors induces via activation of phospholipase C phosphatidylinositol-4,5-bisphosphate to be hydrolyzed into inositol-1,4,5-trisphosphate ($IP_3$) and diacylglycerol (DAG), leading to increase in the intracellular $Ca^{2+}$ levels and to activation of ►protein kinase C (PKC). Transmitter binding to β-adrenoceptors activates ►adenylate cyclase that elevates $[cAMP]_i$ thereby activating ►protein kinase A (PKA). Nitric oxide synthesized from L-arginine by nitric oxide synthase, passes through the cell membrane and activates soluble ►guanylate cyclase leading to the formation of cGMP. cGMP may activate ADP-ribosyl cyclase, leading to the formation of cADP ribose. cADP ribose and ►$IP_3$ receptors induce the release of stored $Ca^{2+}$. The activity of ADP-ribosyl cyclase is stimulated by cAMP, while protein kinase C seems to inhibit the enzyme. The connections provide possible ways for fluid and protein secretion by activation of any pathway. ►Presynaptic inhibition by muscarinic (M2 or M4) receptors and $\alpha_2$-adrenoceptors, hyperpolarizing (increased conductance of ►$K^{\pm}$ channels) the neuronal membrane, may restrain transmitter release. Presynaptic muscarinic M1 receptors may similarly affect ►$Ca^{2\pm}$ channels, thereby facilitating calcium influx and ►neurotransmitter release.

intensity of sympathetic and parasympathetic activity engage the ►regulatory and the ►constitutive route, respectively, while high parasympathetic intensity is necessary for activating the ►regulatory route [4].

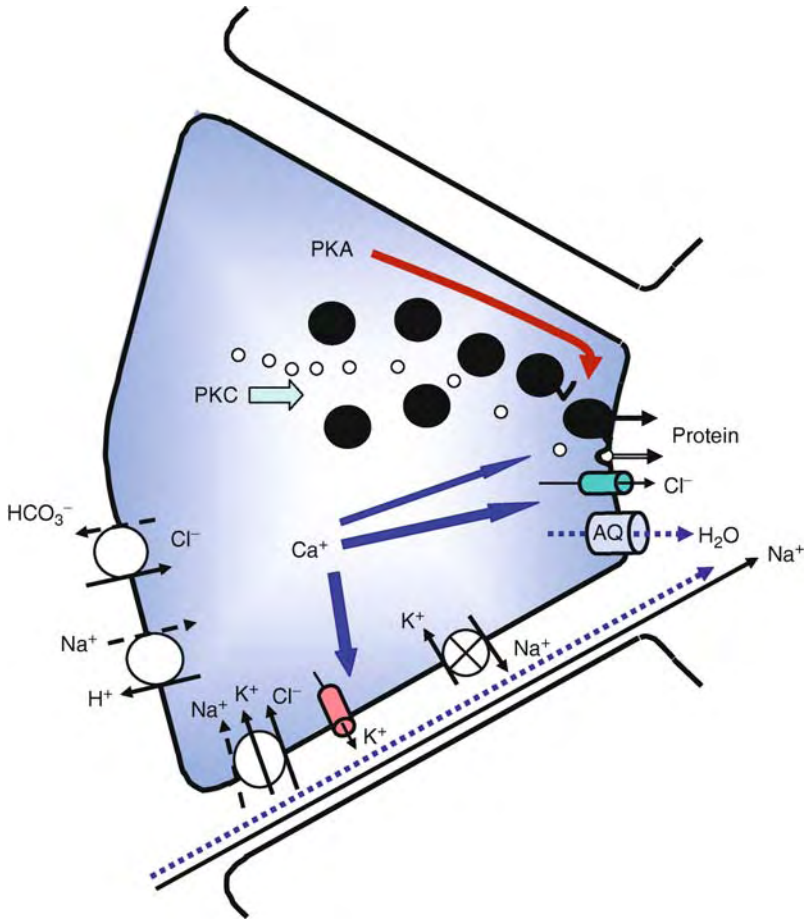
## Process Regulation

### *Fluid Responses*

The autonomic impulses evoke secretion by releasing acetylcholine, noradrenaline and neuropeptides from glandular nerve terminals [4–6]. While parasympathetic activity evokes a copious secretion relatively poor in protein, activity within the sympathetic innervation evokes a sparse but protein-rich secretion. Although α- or β-adrenoceptors evoke little fluid secretion, they are important for protein and enzyme secretion, in particular $\beta_1$-adrenoceptors. Activation of the parasympathetic muscarinic receptors, predominantly of the M3 subtype, elicits most of the fluid secretion (Fig. 4). However, muscarinic M1 receptors also contribute to the salivary response as studies in animals indicate, in particular at low intensity of nerve activity (Fig. 5 [8]). The initiation of secretion is supported by parasympathetic and sympathetic ($\alpha_1$) induced contraction of myoepithelial cells [4].

### *Vascular Responses*

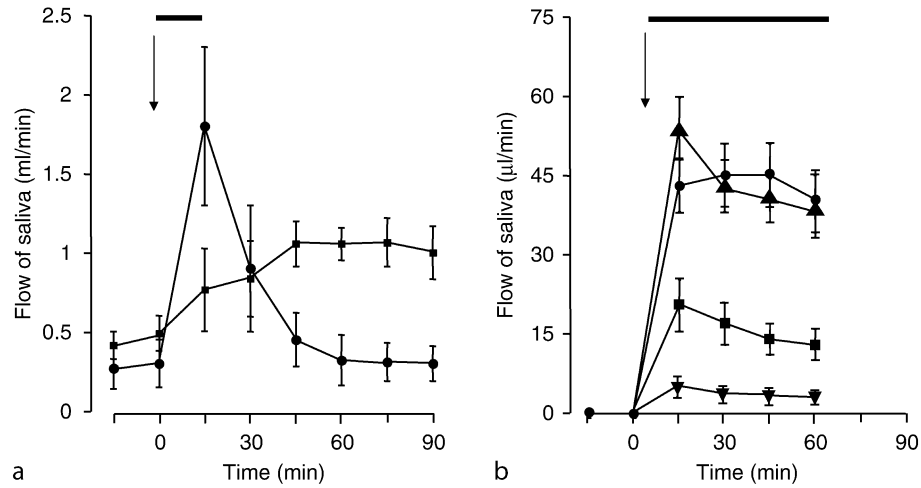
Blood flow is not a secretion-limiting factor initially, since the interstitial fluid will preserve the response. However, in short, because of increase in interstitial oncotic pressure, salivation will cease unless the blood



**Salivary Secretion Control. Figure 3** Schematic illustration of key molecular events leading to fluid and protein secretion in a secretory salivary cell (drawn from data from [4]). In the resting state, the intracellular $Ca^{2+}$ concentration of the secretory cell is low, and the $Ca^{2+}$ activated ►$K^{\pm}$and ►$Cl^-$ channels are closed. When the $Ca^{2+}$ concentration increases, the $K^+$ and $Cl^-$ channels open; effluxes of $Cl^-$ and $K^+$ occur via luminar and basolateral membrane channels, respectively. Chloride enters the secretory cell via a sodium-chloride co-transporter (NKCCl) in the basolateral membrane, for which energy is provided by the inwardly directed electrochemical gradient for $Na^+$. The increase in intracellular $Na^+$ concentration stimulates $Na^+/K^+$ATPase (►$Na^{\pm}$-$K^{\pm}$ pump) to the expense of cellular ►ATP. The luminar secretion of $Na^+$ seems to occur via the paracellular pathway driven by the electrochemical gradient across the epithelium. Water is transported by osmosis by the paracellular pathway and/or via aquaporin channels in the acinar cell membrane. Proteins, synthesized in the rough endoplasmic reticulum are transported in vesicles from the Golgi complex either to storage in granules (regulatory route) or directly to the plasma membrane (constitutive route). In the granular exocytosis, protein kinase A plays a key role by activating binding proteins (►Docking/priming; ►VAMP2 to t-SNAREs), and $Ca^{2+}$ seems to enhance membrane fusion. Protein kinase C has been connected to protein secretion, possibly by affecting binding proteins.

flow increases. While parasympathetic activity invariably increases it (Fig. 5), sympathetic activity exerts variable effects.

The parasympathetic-evoked increase is, as shown by animal experiments, largely mediated by neuropeptides (i.e. VIP [9]). In contrast to the cholinergic vasodilatation that occurs at low intensity of parasympathetic activity and which is partially un-dependent on nitric oxide synthesis, the atropine-resistant vasodilatation seems to be completely dependent. Also in man, VIP is a potent vasodilator and causes *in vitro* relaxation of the submandibular artery. At rest, a tonic activity within the sympathetic innervation maintains a glandular vascular resistance by α-adrenoceptor-mediated constriction, probably enhanced by NPY. However, during sympathetic activity, blood flow may still be preserved and thereby also the flow of saliva, as has been shown by animal studies [9]. Namely, after discontinuation of electrical stimulation of the sympathetic nerve, an adrenoceptor-mediated after-dilatation occurs that may be larger than the preceding vasoconstriction. Since sympathetic neurons fire in bursts during reflex-induced



**Salivary Secretion Control. Figure 4** Fluid responses (means±SEM) induced by different stimulation techniques in healthy adults (A; n = 5) and in anaesthetized rats (B; n = 3–6). A) Flow of saliva, without tongue movements or mastication in response to lozenges containing malic acid placed on the tongue (*filled circle*; dissolving period indicated by horizontal bar;) and to oral pilocarpine (*filled square*; 5 mg; administration indicated by arrow). B) Flow of saliva from rat parotid glands induced by application of one drop of citric acid (*filled circle*; 5%) on the tongue every 30 s (horizontal bar), by electrical stimulation of the auriculotemporal nerve (*filled triangle*; 40 Hz; horizontal bar), by electrical stimulation of the sympathetic nerve (*filled inverted triangle*; 50 Hz 1:10 s; horizontal bar) or by pilocarpine (*filled square*; 2 mg/kg IV; arrow). The diagrams in figure 4 are drawn from unpublished material and redrawn from data in Götrick et al. (2004) J Dent Res 83:393–397; Götrick, Tobin (2004) Arch Oral Biol 49:969–973).

activity, this is likely to occur repeatedly during physiological conditions.

### *Transmitter Interactions*

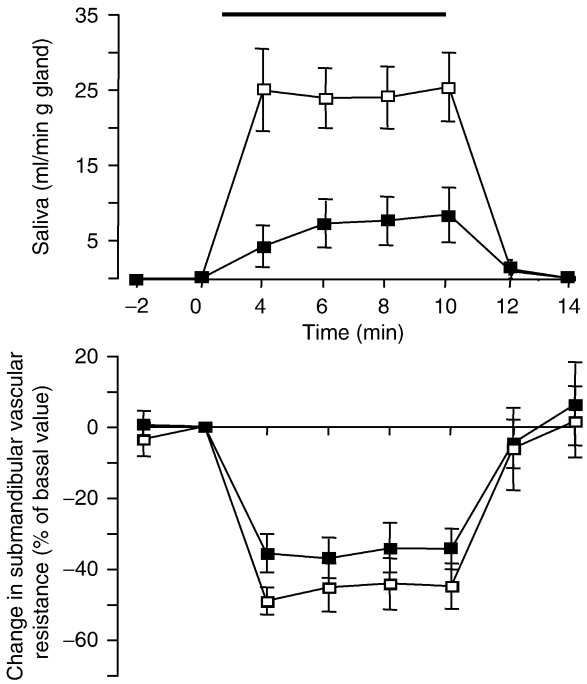
Simultaneous parasympathetic and sympathetic stimulations potentiate the responses as reflected by the fact that strong gustatory stimulations result in maximal flow rates of whole saliva (5–10 ml/min). In some species, administration of neuropeptides into the bloodstream evokes fluid and/or protein secretion; e.g. ►substance P (mainly fluid) and ►VIP (protein with or without a sparse fluid response), and when the parasympathetic nerve is stimulated electrically in these species, an atropine-resistant secretory response occurs [6]. *In vitro* examinations of the human submandibular glands do not indicate that these peptides induce any flow of saliva on their own, but VIP probably contributes by potentiating effects; muscarinic responses are potentiated by VIP (see Fig. 4 illustrating NANC + acetylcholine interaction; nerve response), and VIP elevates the content of ►cAMP in human submandibular glands. Co-localization of transmitters in single neurons implies that the relative amounts being released vary depending on the rate and pattern of the firing [9]. The release of VIP requires a high intensity of nerve activity (>10 Hz) and, as shown in animals, parasympathetic ►burst stimulation at high frequencies enhances vasodilatation and protein secretion, occasionally also salivation; *n.b.* maximal functional responses usually occur at 15–40 Hz (cf. preganglionic discharge). Furthermore, in burst patterns, the long duration effects of neuropeptides improve the prerequisites for the classical transmitters acting thereupon, and additionally, the pattern takes advantage of transient facilitation by neuronal excitatory receptors and avoids the hold back at less neuronal activity by prejunctional inhibition [10].

## Function

The main functions of saliva are lubrication, protection and digestion [1]. Lubrication facilitates speaking and swallowing, the water of saliva moistens and the mucins bind food particles into bolus formation. Mucins lubricate and protect the mucosa, and salivary EGF benefits its repair. Protective roles are exerted by removing substances from the oral cavity (oral clearance), and by the buffer capacity by bicarbonate, phosphate and proteins in saliva. Salivary proteins may also protect against infections (e.g. IgA, peroxidase and lysozyme). The enzymes α-amylase (parotid) and lipase (lingual von Ebner's glands) may initiate digestion of starch and triglycerides, respectively. Saliva also fulfils a taste-aiding function by dissolving flavor compounds, a necessity for taste receptor activation.

## Pathology

Salivary gland dysfunction, deleterious to oral health, could originate from primary glandular conditions (e.g. radiation, inflammatory diseases such as ►Sjögren's syndrome, duct stones, retention cysts and tumors) or could be secondary to systemic conditions (e.g.



**Salivary Secretion Control. Figure 5** Flow of saliva (upper panel) and changes in submandibular vascular resistance (lower panel; perfusion pressure/blood flow; reflecting changes in glandular blood flow) in response to electrical stimulation of the chorda lingual nerve in anaesthetized sheep at 2 Hz for 10 min (indicated by horizontal bar) before (*open square*) and after (*filled square*) administration of pirenzepine (100 nmol/kg IV; "M1-selective" dose). Responses are mean±SEM (n = 4). (Redrawn from material presented at the Physiological Society, Dec 2003; Tobin and Edwards, 2004, J Physiol 555P:C19).

medications, endocrine and autoimmune diseases, neurological disorders and infections [1,5]). The conditions often result in ►xerostomia, most commonly to medication, Sjögren's syndrome and radiation towards the head and neck region. Due to the complexity of the reflexes involved in the control of salivary secretion, the targets for possible xerogenic effects are numerous, as also reflected by synergistic effects by multiple medications (polypharmacy). The principal mechanism of xerogenicity is by an anticholinergic action or by interference of central pathways.

### Therapy

Salivary enhancement therapies are either topical, local therapies or systemic therapies ([5], Fig. 4). Chewing gums and flavor lozenges as well as oral rinses are pillars in the palliative therapy. Acupuncture is a suggested local therapy, assumed to cause relief of xerostomia by inducing release of neuropeptides. A number of drugs have the potential to intensify the flow of saliva. Pilocarpine causes significant increases in most patients irrespective of the cause of xerostomia, but shows the typically adverse effects of a parasympathomimetic. In order to find secretagogues with less adverse effects, agents such as ►acetylcholine esterase inhibitors, $\alpha_2$-antagonists and agents up-regulating substance P have been evaluated in clinical trials.

## Saltatory Conduction

### Definition

Conduction in myelinated axons depends upon a similar pattern of circular current flow. However, myelin is an effective insulator, and current flow through it is negligible. Instead, depolarization in myelinated axons jumps from one node of Ranvier to the next, with the current sink at the active node serving to electrotonically depolarize to the firing level the node ahead of the action potential. This jumping of depolarization from node to node is called saltatory conduction. It is a rapid process, and myelinated axons conduct up to 50 times faster than the fastest unmyelinated fibers.

## Synonyms

Cytoskeleton of the sarcomere

## Definition

Structural proteins are necessary to guarantee the correct assembly and maintenance of the ►sarcomere, the smallest unit of the ►myofibril. This multiprotein complex is essential for muscle contraction and mutations in structural proteins can lead to hereditary myopathies.

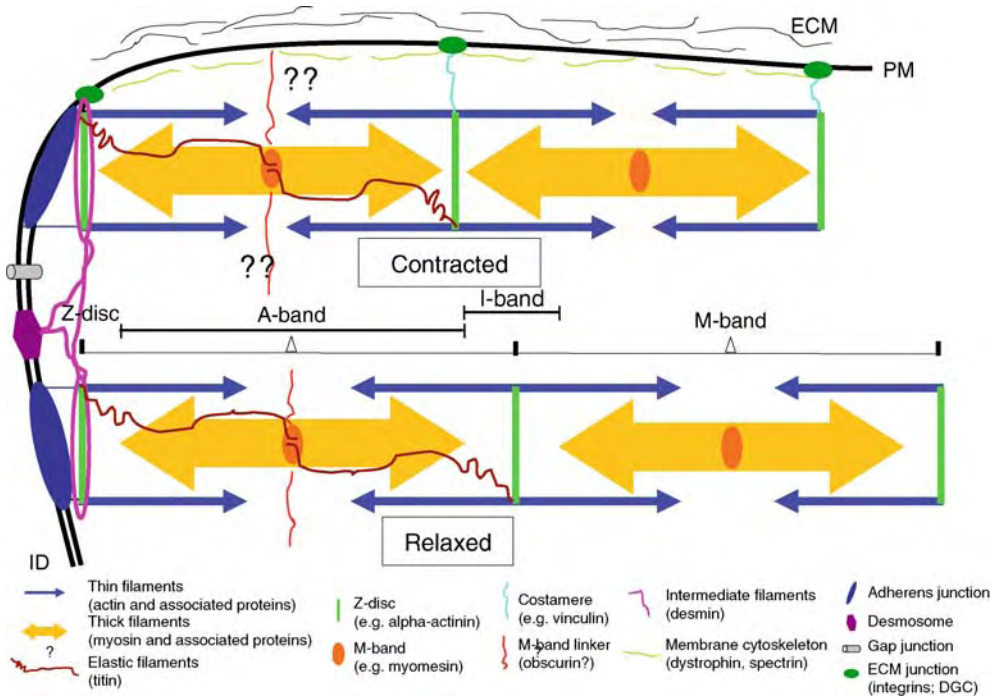
## Characteristics

The sarcomere is the smallest subunit of a myofibril, the contractile multiprotein complex in striated muscle cells (Fig. 1).

It is defined as the region between two Z-discs, which anchor the thin filaments, which are composed of actin and its associated proteins. Contraction is brought about by the interaction between actin and myosin, which is organized in a bipolar fashion to the thick filaments. These are anchored in the middle of the sarcomere in the M-band, which provides connection with the third filament system in muscle, the elastic filaments composed of titin. The thick filaments are equivalent to the A-bands (anisotropic), which are seen as dark broad bands in the polarization microscope and in electron micrographs. They alternate with the I-bands (isotropic), which have the darker contrasted Z-disc as a transverse structure in their middle. To provide maximum force output the contractile filaments in muscle are arranged to paracrystalline multiprotein complexes. Despite their extremely regular appearance, sarcomeres are constantly renewed with an approximal protein half-life of about 3 days. Increased physiological demand leads to the addition of sarcomeres in a process called ►hypertrophy. Also protein isoform composition can change, depending on developmental stage, muscle fiber type and mechanical stress, which is sensed in the sarcomere itself at transverse structures such as the Z-disc and the M-band [1]. A multitude of structural proteins are needed to bring about the regular arrangement of the sarcomere during embryonic development and to maintain it during lifetime. A key role seems to be played by the Z-disk protein alpha-actinin, the M-band protein myomesin and titin filaments stretching in between, which can be considered as the "backbone" of the sarcomere.

### Titin – Combining Scaffolding, Elasticity and Signaling

Titin (also called connectin) is regarded as the most important structural protein of the sarcomere since it spans throughout half a sarcomere and functions as a "molecular ruler" for the integration of most sarcomeric proteins, several signaling proteins and even metabolic enzymes [1]. Titin has a unique size with a molecular weight >3,000 kDa, leading to a single protein of about 1 μm length and lack of titin prevents the assembly of sarcomeres [1]. Titin is mainly composed of fibronectin type II and immunoglobulin modules. Its N-terminus is anchored at the Z-disk, where it interacts with actin filaments, alpha-actinin and telethonin and the protein stretches then throughout the sarcomere to the M-band, where its C-terminus overlaps with titin molecules coming from the other half sarcomere [2]. In addition to providing structural stability and functioning as a building plan, titin also contributes elasticity to the sarcomere due to the presence of inserted non-modular



**Sarcomere Structural Proteins. Figure 1** Simplified schematic representation of sarcomeres and associated structural proteins. The thin (actin) and thick (myosin) filaments are represented as *solid blue* and *yellow arrows*, respectively to indicate their contractile behavior. Structural proteins can be classified according (i) to their location within sarcomeres (titin, actin-associated proteins in the thin filaments and Z-disc, myosin associated proteins in the thick filaments and M-band) (ii) by providing lateral or terminal links of the sarcomeres to contact structures at the plasma membrane (lateral: costameres; terminal: adherens junctions and desmosomes) and (iii) by integrating adjacent sarcomeres (intermediate filaments like desmin; obscurin?). Only one titin filament per half sarcomere is shown. The distance between two neighboring Z-discs is about two micrometers. *ECM* extracellular matrix; *PM* plasma membrane; *ID* intercalated disc; ►*DGC* dystrophin glycoprotein complex.

sequences mainly in the I-band region, whose length depends on muscle type and developmental stage [2]. This huge protein also possesses a kinase domain in its C-terminal region, whose activity is mechanically regulated and can trigger a signaling cascade to the nucleus [1].

## Sarcomere Structural Proteins of the Z-Disc and the Thin Filaments

Z-Discs are the terminal anchorage sites of the thin filaments and are characterized by the presence of sarcomeric alpha-actinin, which is a muscle-specific isoform of the actin cross-linking protein. In addition a plethora of other proteins has been identified at the Z-discs in recent years [3]. These play mainly a structural role (alpha-actinin, actin, titin N-terminus; nebulin C-terminus, CapZ), a signaling role (MLP, calcineurin) or potentially both (FATZ/myozenin/calsarcin2, ZASP/Cypher/Oracle, ALP, myotilin, telethonin/T-cap, gamma-filamin, myopalladin, enigma, myopodin, ArgBP2). The N-terminal region of titin binds both actin and alpha-actinin and is probably essential for the formation of the first complexes to be organized in a regular pattern during ►myofibrillogenesis [4]. In mature sarcomeres the two most N-terminal domains of titin form a sandwich-like complex with telethonin to provide additional stabilization [2]. Neighboring Z-discs are linked by a cytoskeletal network that is composed of the muscle specific intermediate filament protein desmin (Fig. 1).

The thin filaments are constituted by two about one micrometer long filamentous chains composed of globular actin, which are entwined in a stretched helix. At the Z-disc end, which is also called the barbed end, they are capped by Cap-Z, at the end that stretches towards the middle of the sarcomere, the pointed end, they are capped by tropomodulin [5]. Tropomyosin dimers stretch along seven of these globular actins and interact with the troponin complex, which consists of troponin T, troponin I and troponin C. Calcium release by the sarcoplasmic reticulum triggers a conformational change in the troponin – tropomyosin complex, which makes actin more accessible for the myosin heads and eventually leads to muscle contraction.

Actin filaments have a precisely defined length that depends on the muscle fiber type. In skeletal muscle, the length regulation is mainly contributed by nebulin, a <900 kDa structural protein, whose C-terminus is

anchored at the Z-disc and which stretches through the internal groove of the helical actin filaments. Cardiac muscle expresses a shorter variant, nebulette, which is also anchored at the Z-disc, but which stretches only up to one third of the thin filament [3].

## Sarcomere Structural Proteins of the M-Band and the Thick Filaments

The transverse structure in the middle of the sarcomere is called the M-band. Depending on muscle fiber type, a different number of substructures can be defined by electron microscopy, the M-lines. The most important protein of the M-band appears to be myomesin, which is present in all vertebrate sarcomeres. Myomesin provides a structural link in the form of an antiparallel dimer between the tails of the myosin filaments and the C-termini of titin [6]. Due to its biophysical properties myomesin also contributes elasticity transverse to the direction of contraction in the sarcomere [6]. The elastic properties of the M-band are fiber-type specific and depend on the molecular composition of the M-band. Fast fibers express M-protein in addition to myomesin and show a rigid three-dimensional structure, while slow fibers or embryonic heart muscle express the EH-myomesin isoform in addition to myomesin and are more compliant [6]. Further evidence for the importance of the M-band region for sensing mechanical load comes from observations that the titin kinase domain, which is localized adjacent to the M-band, can be activated by stretch [1]. This induces a signaling cascade that eventually can lead to changes in gene expression via the transcription factor SRF (serum response factor) [1]. The M-band region also serves as anchorage site for several metabolic enzymes [7], for skeletal muscle calpain and for signaling proteins such as members of the MURF family, which bind either to titin itself or to adapter proteins [1].

The precise assembly of myosin to the thick filaments and their length is under tight control of the titin A-band region, which displays a super-repeat pattern of its modular domains and also interacts tightly with myosin. It is currently estimated that six titin filaments are associated with a half thick filament [2]. The super-repeat pattern also defines the association of MyBP-C to a subset of the A-band region. MyBP-C is probably important for the maintenance of thick filament structure, but may in addition also play a role for the fine-tuning of contraction, especially in cardiac muscle.

## Structural Connections Between the Sarcomere and the Plasma Membrane

Due to the considerable forces that are exerted during contraction it is absolutely essential that the sarcomeres are anchored properly to the plasma membrane and that they are also integrated between each other. The terminal anchorage sites of the myofibrils are adherens junctions at the intercalated disk in cardiac muscle and focal contacts at the myotendinous junction in skeletal muscle and involve the anchorage of actin filaments emanating from the last Z-disc. A structural protein that seems to be important in these contact sites is N-RAP, a nebulin-related protein that is also known to interact with actin and several cell junction-type proteins [5].

In addition there are lateral connections between the sarcomeres and the plasma membrane. These are present at the level of the Z-disc, where they are called costameres and are mainly composed of vinculin and integrins, which mediate the contact to the extracellular matrix that surrounds muscle cells laterally [5]. By electron microscopy also filamentous connections between the M-band and the plasma membrane were observed, which may be based on obscurin, another high molecular weight modular protein of the sarcomere [6]. Additional structural stabilization is contributed by spectrin, which connects the edges of the Z-disks to membraneous compartments such as the sarcoplasmic reticulum as well as to the plasma membrane itself and by dystrophin, which via the dystrophin glycoprotein complex (►DGC) links the muscle cell cytoskeleton to extracellular laminin filaments [5].

Links between neighboring myofibrils are mainly mediated via the intermediate filament cytoskeleton, which is composed of desmin in muscle and which is concentrated at the level of the Z-disk. Currently it is unclear whether and how myofibrils are integrated at the level of the M-band. Among the currently identified proteins in this region, myomesin and obscurin are the most likely candidates for this role [6].

## Pathology

In the last decades mutations in structural sarcomeric proteins could be linked to different types of muscle disease [3], ranging from congenital myopathies (e.g. actin, tropomyosin, troponin T, gamma-filamin, myotilin, nebulin) and muscular dystrophies (e.g. titin, myotilin, telethonin, ZASP, desmin, nebulin, myosin heavy chain, dystrophin) to hereditary cardiomyopathies such as hypertrophic cardiomyopathy (titin, actin, MLP, troponin T, troponin I, troponin C, tropomyosin, myosin heavy chain, myosin light chain, MyBP-C) or dilated cardiomyopathy (titin, alpha-actinin, MLP, ZASP, actin, troponin T, tropomyosin, desmin, MyBP-C, myosin heavy chain, metavinculin, dystrophin). These myopathies can be clinically heterogeneous with a significant variability in severity and time of onset and a type of muscle disease is also not always strictly linked to a mutation in a particular protein. The position of the mutation in the respective molecule and its effect on protein stability and interaction with other proteins may define the final phenotype of the disease.

# Satellite Cells in Muscle

## Definition

Satellite cells are located between the sarcolemma and the basal lamina of the muscle fiber, and remain in a non-proliferative quiescent state. They represent undifferentiated myogenic precursor cells, which have the ability to re-enter the cell cycle either in order to generate new muscle fibers or to provide new myonuclei to the parent fiber. Unlike myonuclei, satellite cells retain their ability to divide following myotrauma or exercise, and therefore have a unique role in the regeneration and growth of adult skeletal muscle that cannot be fulfilled by the post-mitotic myonuclei.

# Saxitoxin (STX)

## Definition

Saxitoxin (STX) is a paralytic toxin in marine dinoflagellates that, in some seasons, “bloom” and discolor the seawater (“red tide”). The shellfish feeding on them become contaminated and are highly dangerous to eat. Through the marine food chain, it can poison humans. The mechanism of toxicity is very similar to that of Tetrodotoxin (TTX). Saxitoxin binds from the outside of the cell membrane to various forms of Voltage-dependent $Na^+$ Channels and blocks the channel in an activation-state-independent manner.

# SC – Buildup Neurons

Edward L. Keller
Smith-Kettlewell Eye Research Institute,
San Francisco, CA, USA

## Synonyms

Prelude neurons

## Definitions

►Saccade-related neurons in the superior colliculus (SC) that display extensive low frequency discharge, well before the onset of a saccade into the ►movement field (►of a neuron) of the cell have been called buildup [1] or prelude [2] neurons.

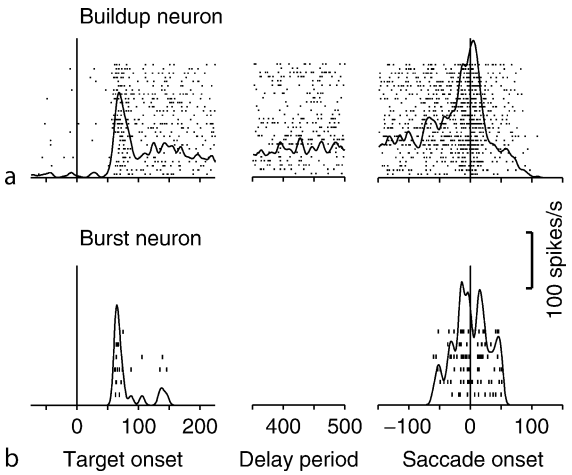
## Characteristics

### History and Function

Saccade-related neurons in the superior colliculus (SC) in the alert monkey, which displayed a long buildup of low frequency discharge well before the onset of optimal saccades, were first described by Sparks et al. [3] and Mohler and Wurtz [4]. Sparks et al. [3] called cells that began a buildup of discharge approximately 80–100 ms before saccade onset in a ►reaction time task, class II neurons. They contrasted the gradual buildup of this type of SC neuron with another class of collicular neuron, which showed only a discrete high-frequency burst of activity that commenced about 20 ms before saccade onset. They argued that these two classes of collicular neurons formed separate classes. In contrast, Mohler and Wurtz [4] emphasized the earlier discharge of cells before saccade onset as a function of the depth of the neuron's location below the superficial layers of the SC. Deeper cells tended to have earlier discharge, but the amount of pre-saccadic lead varied gradually with depth into the SC. Based on their observations, the latter authors did not attempt to assign SC neurons into two separate classes, and did not assign a name to the deeper cells with longer pre-saccadic discharge. They also noted that deep cells tended to have larger movement fields.

Glimcher and Sparks [2] subsequently called a group of SC neurons with long-lead discharge before saccades into their movement field, prelude bursters. They distinguished this group of neurons in a cued, movement-selection task in which activity of prelude bursters began soon after a central visual cue indicated which of two potential eccentric targets was to be the goal of a delayed saccadic (►Saccade – delayed) response. This pre-saccadic activity was present when the cue required a saccade to the target located in the cell's movement field. They hypothesized that prelude bursters participate in the process of movement goal selection.

Munoz and Wurtz [1] identified delay-period activity in a group of SC neurons in a ►delayed saccade task and codified the name "buildup neurons" for these cells, which they argued formed a separate class of SC neurons that discharged (for movements into the center of the cell's movement field) at rates >30 spikes/s during the 100-ms period of time ending 100 ms before saccade onset. They showed further that neurons in this class tended to be located more ventrally in the intermediate and deep layers of the SC than the other class that they called "burst neurons", neurons that began their discharge just before saccade onset. Finally, they stated that buildup cells displayed ►open-field response characteristics because they discharged for all saccades (in the preferred direction) larger than the center of the cell's response field. Based on this last characteristic and the timing of buildup cell discharge, they suggested that buildup neurons form a functional group of cells in which a rostrally spreading wave of activity codes the dynamic progression of a saccade, which ends when the wave of activity in buildup cells reaches the rostral pole of the SC. Figure 1 shows examples that contrast the difference of discharge patterns in SC buildup and burst neurons in a delayed saccade paradigm. In this paradigm, a monkey continued to fixate a centrally located visual spot when an



**SC – Buildup Neurons. Figure 1** Examples of the discharge patterns of a buildup and a burst cell recorded in the monkey SC during a delayed saccade paradigm. Each dot in the raster plots shows an individual discharge of a cell. Each row in the rasters shows a single trial. The curves in each plot show the average spike density of the cell's activity for the set of illustrated trials (Gaussian smoothing parameter = 4 ms). Plots on the left are aligned on the appearance of the target, those in the center are aligned on the end of the delay period when the fixation spot goes off (500 ms), and those on the right are aligned on saccade onset. (Modified by permission from [5]).

S

eccentric target appeared near the center of the cell's movement field. The two plots on the left, which are aligned on the appearance of the target, show that both cells have a brisk visual response that begins about 50 ms after target onset. The animal was required to maintain fixation at the central location after the appearance of the target until the fixation spot was extinguished. When the fixation spot was extinguished, the animal made a saccade to the location of the target. The two plots in the center show the activity in the two neurons aligned on the end of the delay period at 500 ms. Only the buildup cell shows activity in the delay period. The two plots on the right show the activity of the two cells aligned on the initiation of the saccade to the target. The buildup neuron shows a substantial amount of irregular activity in the period well before saccade onset, and exceeds the criterion used by Munoz and Wurtz [1] in the period of time ending 100 ms before saccade onset to be classified as a buildup neuron. The burst neuron shows a more discrete burst of activity that begins about 50 ms before saccade onset, and no activity in the period of time earlier than 100 ms before saccade onset.

Anderson et al. [6], using a delayed-saccade task, showed that SC saccade-related cells form a continuum in the level of their pre-saccadic discharge in a delayed-saccade task. They argued that cells like those shown in Fig. 1 formed the end points of such a continuum. In order to compare their cells sampled over a broader anatomical extent of the SC to those recorded by Munoz and Wurtz [1], they used a similar pre-saccadic level of discharge measure to arbitrarily define buildup cells. The later authors also provided evidence, using a two-dimensional estimation of the spatiotemporal population discharge in the SC, against the hypothesis that buildup cells participated in an organized, rostrally progressing wave of activity that controlled saccade duration during saccades. Instead, they hypothesized that buildup cells participated in saccade control in a similar fashion to burst cells, with population activity that peaked just before saccade onset and declined during saccades. However, neither burst cell or buildup cell discharge could command saccade end because considerable population activity remained at saccade end, particularly in buildup cells. Anderson et al. [6] confirmed the earlier observation [1] that SC cells with larger relative levels of pre-saccadic activity tended to be located more ventrally in the SC and to have open-field response characteristics. A subset of buildup cells have been reported to continue to discharge during the period of time when saccade trajectory was interrupted by electrical ►microstimulation in the rostral SC or the ►omnipause neuron area in the brain stem [7,8]. Since most SC neurons (both buildup and burst neurons) are silenced during the interrupted period, this subset of buildup cells may serve as the functional source that rekindles SC discharge at the active cite in the SC as the saccade resumes and ends on target.

Dorris et al. [9] also found that buildup and burst neurons overlapped in the level of their pre-saccadic buildup of discharge in a delayed saccade task. They proposed that two classes of neurons in the SC could better be distinguished based on the level of discharge present at the end of the gap period in a ►gap-saccade paradigm. Cells with significant prelude activity in the gap period were defined as buildup neurons. As the prelude activity occurred in the gap period before the location of the target for the saccade was known, and was correlated with saccade latency and the occurrence of express saccades, these authors hypothesized that buildup cell activity was related to the function of motor preparation for saccades.

Basso and Wurtz [10] defined a group of SC cells they called buildup neurons that showed significant discharge in the delay period in a memory-guided, delayed-saccade task. In their definition, the criterion level of activity that distinguished buildup neurons was determined by a metric aligned to the end of the delay period, in contrast to most previous measures that were aligned on saccade onset. In additional experiments, they manipulated the number of potential targets present as the animal maintained fixation on a central visual target before signaling goal location by dimming one of the potential targets (a target pre-specification period). Based on their observation that the discharge of buildup cells in the pre-specification period showed an inverse level of activity in relation to the number of potential targets, they hypothesized that buildup cells signaled the establishment of a motor set before target selection was possible.

The rostral region of the SC has neurons that decrease their discharge during saccades rather than show a saccade-related increase. Cells located in this region of the SC that pause for most saccades have been called fixation neurons [11]. Anderson et al. [6] argued that these cells, although they paused for most saccades, showed a burst of activity for very small contralaterally directed saccades. Thus, they hypothesized that fixation cells formed a rostral extension of the caudal buildup cells, with movement fields that became smaller and smaller and ever closer to the fovea for more rostral locations on the SC. Krauzlis et al. [12] recorded from these rostral SC cells under a wider range of experimental conditions, including smooth pursuit movements, small saccades and fixation. They found that these cells displayed increased discharge during small saccades, for small fixation errors and during smooth pursuit, when small errors between the target and the eyes existed. They hypothesized that the discharge of these rostral cells best signified the existence of near foveal position errors between the target and eye position, regardless of the type of eye

movement (saccade or pursuit) or lack of an eye movement (fixation) that might be used to correct the error.

McPeek and Keller [5] found that SC saccade-related cells displayed activity that was consistent with a role in target selection in a reaction time, popout visual search task. They found no difference in the behavior of buildup neurons and burst neurons in this task. They identified buildup cells in a manner similar to that used by Basso and Wurtz [10]. McPeek et al. [13] also found, in a reaction time, popout visual search task, that the pre-saccadic discharge of SC cells located at the collicular image location of visual field distractors was correlated with the amount of curvature present in saccades. They found no difference in the behavior of buildup or burst neurons in their results. Buildup cells were identified in a manner similar to that used by Basso and Wurtz [10].

In conclusion, a wide ranging succession of experiments have consistently identified SC neurons called buildup or prelude neurons that show considerable amounts of low level, pre-saccade discharge that can lead saccade onset by 100 ms or more. It has not been conclusively established if the cells with buildup discharge form a discrete subset of SC saccade-related neurons or whether they are better described as one end of a continuum of cells with respect to pre-saccadic discharge behavior. The method of Basso and Wurtz [10], which defines cells as buildup cells based on significant delay-period discharge relative to resting discharge, suggests a subset of SC cells may be distinguishable statistically. Cells that display higher amounts of pre-saccadic discharge also tend to be located more ventrally in the SC and have larger movement fields than cells with less pre-saccadic discharge. In particular, the outer edge of the movement field of many of these buildup cells may extend beyond the limit of the oculomotor range. It is also not clear if buildup cells, as discriminated by the Basso and Wurtz [10] criterion, have a separate functional role in the saccadic system. Separate roles in motor set, target selection or motor preparation have been suggested as the functional role of buildup neurons. Reaction time tasks tend to show no difference in the functional role of buildup and burst cells.

### Higher Order Structures

Buildup neurons are found in the intermediate and deep layers of the superior colliculus. They form part of the descending oculomotor saccadic system.

# SC – Interlayer Neurons

Adonis Moschovakis
Institute of Applied and Computational Mathematics, FO.R.T.H. and Department of Basic Sciences, University of Crete, Heraklion, Crete, Greece

### Definition

Neurons of the superficial SC layers *strata griseum superficiale* and *opticum* which project to the deeper SC layers.

### Characteristics

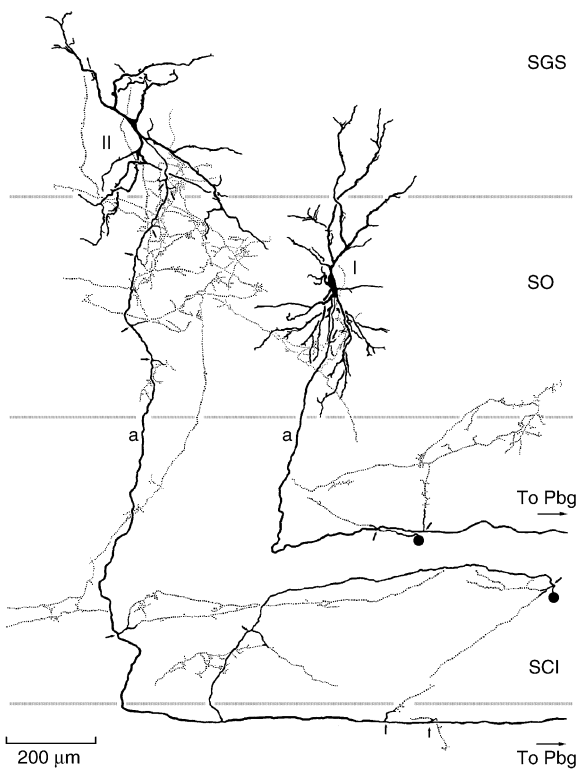
#### Higher Order Structure

Interlayer neurons are crucial components of the sensorimotor interface implemented inside the superior colliculus.

S

## Parts of the Structure

In primates, the projection from the superficial to the deeper SC layers largely originates from a particular class of neurons, designated L [1,2]. Fig. 1. provides two typical examples and illustrates the range of their morphological characteristics. Typical of such cells is the fact that one of them is located in the superficial gray layer (SGS) and the other in the stratum opticum (SO). Also typical of such cells is their somatodendritic morphology, which can be characterized as narrow field vertical in the case of cell I and wide field vertical in the case of cell II. Finally, typical of L cells is the fact that one of their axonal branches projects to the parabigeminal nucleus and even beyond it, presumably to the dorsolateral pontine gray. Fig. 1. also illustrates the considerable number of collaterals arising from the axons of L neurons. Some of them deploy terminal fields in the neighborhood of the soma they originate from in the SGS and SO, while others deploy terminal fields in the intermediate gray layer (SGI).



**SC – Interlayer Neurons. Figure 1** Complete camera lucida reconstruction of the dendritic (*solid*) and intratectal axonal termination patterns (*dotted*) of two primate L neurons in the frontal plane (modified from [2], with permission). The solid line indicates the surface of the superior colliculus and the stippled lines indicate borders between its layers. Small arrows point to the origin of intrinsic collaterals. Solid circles indicate the point where major axonal branches assume rostral trajectory. Abbreviations: *Pbg*, parabigeminal nucleus; *SGI*, stratum griseum intermediale; *SGS*, stratum griseum superficiale; *SO*, stratum opticum.

The origin of superficial to deeper collicular projections from cells displaying the somatodendritic features of L neurons (i.e. narrow and wide-field vertical cells) has been corroborated in other mammalian species. Narrow field vertical neurons of the SGS and SO of the rabbit were known to Cajal who was able to follow their axons to their bifurcation in the deeper tectal layers (Fig. 119 of [3]), but was unable to ascertain if they deployed any boutons. Examples of narrow and wide field vertical cells of the SGS and SO and their extensive axonal arborizations in the SGI have been documented in the hamster [4,5] and the rat [6]. However, L neurons are not the only ones to relay information from the superficial to the deeper SC layers. In both the monkey and the cat, the axons of tectotectal neurons of the SO (T neurons) also issue collaterals ramifying in the deeper tectal layers [7,2]. Additionally, axons of upper SGS neurons emit collaterals distributing terminals in the SGS, the SO, and the SGI in the neonate cat [8]. Unlike those originating from L or T neurons, the fairly long dendritic arbors of the feline neurons were seen to originate only from the dorsal pole of the soma and to branch profusely towards the surface of the SC. Axons of wide and narrow field vertical cells of the SGS and the SO, projecting to the nucleus lateralis posterior, have been also shown to deploy terminal fields in the deeper tectal layers of the hamster [9]. The axons of marginal, stellate, horizontal and unclassified cells of the superficial SC layers of this species have also been shown to deploy terminal fields in the deeper SC layers [5].

## Function of the Structure

In the rhesus monkey, the information carried from the superficial to the deeper SC layers can be surmised from the response properties of tectoparabigeminal cells; often these are directionally selective and respond with sustained discharges to stimuli crossing the center of their receptive field [10]. More varied information is conveyed from the superficial to the deeper SC layers in the hamster: the cells it originates from can respond to stationary flashed stimuli or not, they can be directionally selective or not and they can be sensitive to stimuli moving at high or low speeds [5]. Its importance is demonstrated by the fact that the visual responses of almost 90% of deeper SC neurons are reduced or abolished after injection of $CoCl_2$, which blocks synaptic transmission near the injection site in the superficial SC layers of the hamster [11]. The pattern of their projections to the deeper SC layers can have

important implications for the therein represented map of visual space. For example, in the hamster, visual receptive fields of deeper SC layer neurons are shifted laterally together, with the lateral shift of the projection from the superficial to the deeper tectal layers relative to projection lines normal to the SC surface [12].

Activation of the superficial layers (with brief electrical pulses) suffices to evoke excitatory postsynaptic potentials (EPSPs) in neurons of the deeper layers of frontally cut slices of the SC of young (8–28 old) tree shrews; their minimal latencies are monosynaptic but they can have multiple peaks and their duration, which can outlast the duration of the stimuli by 100-fold or more, is not related to the duration or the intensity of the stimulus [13]. Work in slices has been crucial in elucidating their pharmacology. Evoked EPSPs are glutamatergic [6,14,15] and are strongly enhanced when the target neurons are depolarized (either through activation of nicotinic ACh receptors or blockade of $GABA_A$ mediated inhibition).

The long bursts evoked in deeper SC neurons in response to electrical stimulation of the superficial SC, could be due to the reverberatory engagement of groups of deeper SC neurons mutually activated through their recurrent collaterals (described in the entry devoted to ►SC – tectal long-lead burst neurons). They could also be due to the reverberatory engagement of groups of superficial SC neurons contacted by the recurrent collaterals of their neighbors, which may or may not project directly to the deeper tectal layers. The density of the terminal fields deployed by axons of superficial SC neurons in the vicinity of the some they originate from can be appreciated from the examples shown in Fig. 1. Recurrent networks of similar complexity have been documented in several other mammalian species, i.e. cat [8,7], hamster [4,5], monkey [1,2] and the rat [6]. It is, therefore, hardly surprising that some of the deeper SC projecting superficial SC cells display similar long bursts of discharge in response to electrical stimulation of the superficial SC [14]. The multi-step projection of the superficial tectal layers to the deeper through several synapses may be the dominant path in some species. For example, small injections of biocytin in the SGS of the tree shrew (*Tupaia belangeri*) demonstrated the existence of a strong SGS projection to the SO, but not to the deeper layers [16].

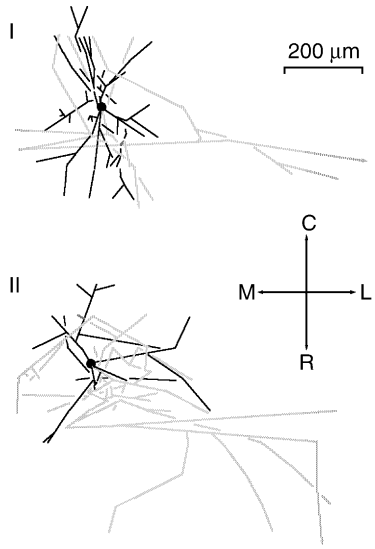
## Higher Order Function

Relatively direct relay of visual signals from the superficial to the deeper SC is implicit in the ►foveation hypothesis proposed by Schiller and Koerner [17] (see the entry devoted to the foveation hypothesis for a discussion of this, at one time dominant, account of information flow through the SC). Despite early efforts to determine its existence [18], the projection from the superficial to the deeper SC remained controversial until the mid-1980s. In a seminal review written in 1984, Chalupa [19] ranked this at the top of several questions that remained to be answered regarding the physiology of the SC. Soon after this review appeared, conclusive evidence of its existence began to appear, much in the manner that he had envisioned, i.e. with use of the intracellular HRP technique. This was accomplished first in the neonate [8] and adult [7] cat, and then in quick succession the adult hamster [4,5] and monkey [1,2]. Bulk tracer injections of an anterograde tracer generally thought not to be taken up and transported over significant distances by fibers of passage (*Phaseolus vulgaris* Leucoagglutinin, in short PHAL) were later employed to show that it exists on a larger scale in the hamster [12], and cat [20]. In ferrets, there is morphological evidence to suggest that its targets in the deeper tectal layers include cells of origin of the predorsal bundle [15].

The entry devoted to the foveation hypothesis also includes a summary of the reasons to doubt that transmission of visual information from the superficial to the deeper SC layers always suffices to accurately specify the metrics of saccades towards visual targets. Instead, relatively direct relay of visual signals from the superficial to the deeper SC could underlie the short latency of "express" saccades [2,21], as described in the entry SC-sensorimotor integration. Consistent with this notion, and the acetylcholinergic modulation of the efficacy of signal transmission along this route, injection of nicotine in the SC of the monkey increases the frequency of express saccades [22].

## Quantitative Measure for this Structure

About 40% of the neurons in the superficial SC have axons that deploy terminal fields in the deeper tectal layers [5]. Of the cell classes that participate in this projection, it is the primate L neurons whose appearance has been the object of detailed quantitative analysis [2]. Besides providing information about the range of values obtained by several morphological features (e.g. 3-D orientation of the dendritic tree, complexity of its branching pattern, etc.) this analysis allowed the formulation of canonical discriminant functions, which can objectively differentiate L neurons from other classes of SC cells. Moreover, given the manner in which visual space is represented in the superficial SC (along the mediolateral and rostrocaudal extent of the nucleus), the location and spatial distribution of the somatodendritic processes of L neurons on horizontal maps of the SC must have important implications for the size of their receptive fields, and thus the graininess with which they can represent the visible world. Examples of such horizontal rotations of camera lucida reconstructions of primate L neurons are shown in Fig. 2. The same figure also



**SC – Interlayer Neurons. Figure 2** Reconstruction of the primate L neurons of Fig. 1 in the horizontal plane (modified from [2], with permission). Stippled lines indicate the neurons' axonal systems.

illustrates the region occupied by their axonal terminations in the deeper layers of the SC. Consistent with their columnar arrangement, the fairly large number of *boutons* they deploy (sometimes more than 3,000) is largely confined to a cylinder that measures somewhat less than 1 mm in diameter, underlies the territory occupied by the dendrites of the same neurons, and is oriented normally to the surface of the SC.

# SC – Local Feedback

Edward L. Keller
Smith-Kettlewell Eye Research Institute, San Francisco, CA, USA

## Synonyms

Efference copy; Corollary discharge feedback

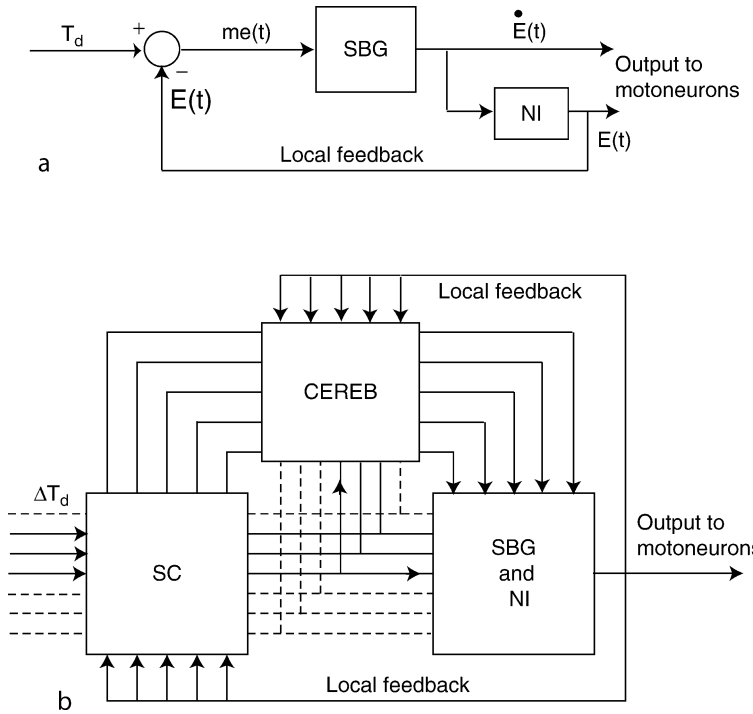
## Definitions

►Saccades are rapid eye movements that normally are very accurate. Their accuracy under varying conditions suggests that this class of movements is controlled by feedback mechanisms in contrast to a preprogrammed control. However, feedback of afferent visual information about the progression of the movement that could be used to control and adjust saccade trajectory in flight is not possible, due to the short temporal duration of saccades and the long latencies required to process visual input. Following theoretical ideas derived from the study of other movement control systems [1], Robinson [1] proposed that saccades were controlled by feedback information derived from the ►efferent motor commands. Such internal or local signals, as opposed to afferent feedback from the visual system, could continuously encode the current eye position during saccades with only minimal delay (►delayed saccade), and thus, play a role in controlling their accuracy.

## Description of the Theory

In Robinson's theory [3], a copy of the efferent saccadic motor command was integrated to produce an eye position signal. This signal was directed centrally (the local feedback signal) and was compared to a neural representation of the goal or target of the saccade (Fig. 1). The difference between the local feedback signal, which represented current eye position during the saccade, and the desired goal was a dynamic motor error signal that in turn continuously updated the motor command until the error signal dropped to zero and the eyes arrived on target. Since the local feedback signal was derived from neural signals very close (in a synaptic sense) to the motor outflow, delays (in the feedback loop could be very short and performance, in terms of terminal accuracy, was optimized [2]. As evidence for the existence of a local feedback loop in the saccadic system, van Gisbergen et al. [2] cited the results of perturbation experiments in which the normal stereotyped trajectories of saccades were halted in mid-flight by electrical ►microstimulation of the omnipause neuron region (►omnipause neuron area) in the brainstem. Such interrupted saccades resumed their trajectory and ended on target [3,4], and thus, were compensated for the trajectory perturbation. Robinson and his colleagues [2] hypothesized that the ►comparator that generated the dynamic motor error signal was located at the level of the ►saccadic burst generator in the brainstem, and further that the eye position local feedback signal used to close the feedback loop was generated by a ►neural integrator located in the brainstem close to the saccadic burst generator.

The concept of saccade control by local feedback remains a central hypothesis in all saccade system models, but the original model of Robinson has undergone considerable debate and modification since its promulgation. Jürgens et al. [5] argued that the desired saccade goal (desired target location) should be specified in retinotopic coordinates, not absolute position in head-centered coordinates as posited in the Robinson model. Implementation of this suggestion requires that the local feedback signal is displacement of eye position during the current saccade. An eye displacement signal could be generated by a separate neural integrator from the integrator that controlled the static, eye-position related discharge of oculomotor neurons. This second integrator would have to be reset after the end of each saccade. Scudder [6] proposed a model that posited that the superior colliculus was the source of the retinotopically coded desired target signal. In his model he integrated the difference between the SC input signal and a local feedback inhibitory signal from the saccadic burst generator that carried an instantaneous eye velocity signal in a group of brainstem neurons called long-lead bursters. Such an arrangement operated in displacement coordinates and avoided the specification of a resetable integrator by the incorporation of the inhibitory eye velocity signal. The output of the integrator in the Scudder model first increased in magnitude in the pre-saccadic period as the SC signal increased, but then declined in magnitude as the saccade progressed and returned to a zero level by saccade end under the influence of the inhibitory (negative sign in the model) eye velocity signal. No physical dynamic motor error signal exists in this model. Figure 1a shows a Robinson type local feedback model which specifically defines the signals discussed above: desired goal position ($T_d$); local feedback of eye position (E(t)); and dynamic motor error (me(t)). The inclusion of the time variable (t) in some model signals indicates that signal is updated continuously during a saccade. The schematic version shown here provides a lumped representation of the neural operations that are hypothesized to occur when saccades are generated. All the dynamic elements in the models described so far have single-input, single-output signals and well defined variables with exact physical meaning (e.g. motor error). These model elements (e.g. the comparator which computes the difference between the final goal and instantaneous eye position and outputs dynamic motor error) appear at discrete locations in the model topography, and



**SC – Local Feedback. Figure 1** Examples of models of saccade control that utilize local feedback to ensure movement accuracy. (a): Lumped model utilizing eye position feedback. A comparator continuously computes the difference between the saccade goal ($T_d$) and the local feedback signal (E(t)). The difference signal is dynamic motor error (me(t)). Dynamic motor error controls the activity of burst neurons in the saccadic burst generator (SBG) which produce an eye velocity ($\dot{E}(t)$) command signal to ocular motoneurons. The local feedback signal is current eye position that is computed by a neural integrator (NI) that also controls the eye-position related tonic discharge of ocular motoneurons. (b): A distributed model of saccade control. The boxes labeled SC and CEREB represent recurrent neural networks of the superior colliculus and the cerebellum, respectively. The box labeled SBG and NI represents the saccadic burst generator and a neural integrator. The saccade goal ($\Delta T_d$) is represented with a space code by which input lines to the SC are active (shown by solid lines). Dashed lines indicate inactive input lines. Spatiotemporal discharge in SC and CEREB are produced by interconnected feedforward and feedback lines between the two structures and each structure's own pattern of recurrent connections (not shown). Both structures control the activity of the SBG in parallel through spatially weighted input lines. Local feedback is derived from the SBG and NI and may include both eye position and eye velocity signals. Combinations of these latter signals are fed back in a spatially weighted, distributed fashion to all the units in SC and CEREB. Dynamic motor error is represented in the distributed activity of the units in both SC and CEREB. Not all known connections are shown, e.g. CEREB may receive a spatially distributed input of $\Delta T_d$ that is separate from that to SC.

hence the term "lumped model" that is used to classify this type of model. The single signal lines should not be confused to represent single neurons, rather they posit the existence of a group of neurons that carry a single physical signal with a temporal rate code.

More recently, several attempts have been made to represent the organization of the saccadic system and the local feedback concept with distributed models of signal processing (see [7] for a review). Biologically realistic models of this system require that at least the source of the desired goal, which originates in structures like the SC and the ►cortical frontal eye fields (FEF), be modeled in a distributed fashion. This is because these higher level sensorimotor structures primarily represent the desired target (saccade goal), with a space code in which a target position is represented by the discharge of a population of cells centered at a specific location in the SC and the FEF. The temporal discharge pattern of the activated population of cells may be the same for very different saccade goals. Only the anatomical location of the activated population changes with target location.

Figure 1b is a schematic model which illustrates that most of the structures involved in the control of saccades are interconnected with multiple distributed feedback loops. Each of the structures shown by box elements: the SC, the cerebellum and the saccadic burst generator (SBG and NI) are themselves dynamic, recurrent neural networks. Saccade-related neurons in the SC and cerebellum display both place and temporal

coding. A local feedback signal still exists, but it may consist of both eye displacement and eye velocity signals, and it is distributed in a weighted fashion to all the spatially distributed neurons in the SC and the cerebellum. There is no single place in the model where a physical signal coding dynamic motor error exists. Instead, error is represented in a distributed fashion as a property of the whole network.

Specific implementations of distributed control have focused on the SC or the cerebellum.

Depending on the symmetry and the parameters used to model the lateral interconnections in either of these two structures, two quite different types of distributed control mechanisms may be generated. In one type of distributed model, eye velocity local feedback drives a moving wave of activity from an originally active site in the SC or the cerebellum [8]. This original locus of activity codes the desired saccade vector. When the spreading activity reaches the rostral pole of the colliculus (in the SC model) or the mirror symmetric location in the opposite cerebellum (in the cerebellar model), the movement ends. The rate of movement of the wave is controlled by the local distributed feedback of eye velocity, so that at any time during the saccade the distance from the wave front to the end-point location in either colliculus or cerebellum spatially codes motor error. In this form of local feedback control, the distributed structure performs a spatial integration of the eye velocity feedback and represents motor error in a distributed spatial location.

In the other type of control scheme, a distributed population of cells in the SC becomes activated by spatially coded visual input and recurrent, excitatory connections among SC cells themselves [9, 10]. In the Arai [10] model, and to a lesser extent in the Bozis and Moschovakis [9] model, feedback of eye velocity and/or eye displacement to the SC drives the discharge of SC cells originally active down at a rate coupled to the progression of the saccade. Additional local feedback to the brainstem SBG or the cerebellum is needed to make either model function in an accurate fashion.

In conclusion, some type of local feedback about the ongoing eye movement during saccades controls saccade trajectory, and hence the accuracy of these rapid movements. The feedback signal may involve instantaneous eye displacement or eye velocity variables or both. Both the superior colliculus and the cerebellum are involved in the control of saccades, and both receive extensive inputs from brainstem structures that carry eye velocity and position signals. Both structures are themselves recurrently connected, distributed dynamic neural networks. Therefore, control by local feedback is certain to involve highly distributed control processes. With present day neuroscience recording techniques it will be difficult to isolate the location of, and the precise mechanisms, underlying local feedback control in this distributed system. Instead, local feedback and the motor error signals generated by local feedback are likely to be distributed properties of the entire network. Modern imaging techniques may be able to advance our knowledge of the mechanisms involved in the distributed control of saccades by local feedback.

# SC – Motor Map

Edward L. Keller
Smith-Kettlewell Eye Research Institute,
San Francisco, CA, USA

## Definition

The term motor map refers to a very general neuroscience concept in which movements with specific

spatial characteristics are represented topographically within a neural structure. The exposition here will be limited to gaze shifts (movements of the head and eyes) directed to targets presented in the visual surround of a subject. With this restriction, the topographical arrangement of movements on the map may be retinotopic or spatial. In a retinotopic motor map, the movements represented on the map are independent of the initial eye position in space, but vary smoothly in amplitude and direction as a function of the location of the target with respect to the fovea (the current line of sight). In a spatially coded motor map, specific locations in space are represented topographically in the neural structure. In this type of motor map, gaze comes to rest after a movement at a fixed location in space regardless of the initial position of gaze. For retinotopically coded motor maps, gaze shifts may be represented as movement vectors directed between the initial gaze position and the position of the target with respect to the fovea. Retinotopic movement vectors remain invariant for any initial position of gaze. In spatially coded maps, the movement is directed from any initial gaze position to an invariant point in the visual surround. Retinotopic motor maps in the SC are considered in detail below, but an example of a spatially coded map in SC in the cat is also described. Neurons in several gaze-related regions of the brain have a preferred movement vector for which they show the most vigorous peri-movement discharge. The level of their discharge declines systematically for movement vectors that are different in direction or amplitude from the preferred vector. Movement vectors are defined by the polar coordinates of movements to point targets in visual space, and therefore, can be alternately described as coordinates in a foveally centered visual space. If the movement-related neurons in a structure are organized in a topographical manner such that nearest neighbors anatomically also have nearest neighbor preferred vectors in the visual field, the structure contains a motor map. That is, neighboring points in the visual field (the movement vectors) are mapped to neighboring points in the motor map. In such motor maps, the amplitude and direction of the preferred movement vector in individual cells changes in a smooth manner as the anatomic locations of the cells being recorded are systematically altered within the neural structure. When the preferred movement vectors are plotted on an anatomical representation of the structure, a vector field emerges on which the preferred vector changes smoothly in direction and amplitude as a function of anatomic location.

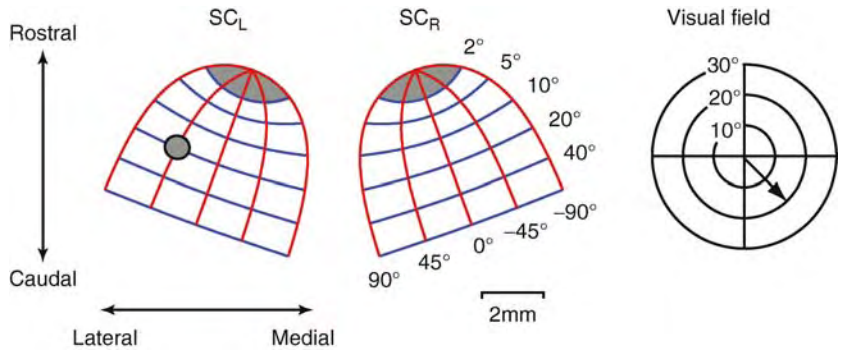
## Description of the Theory

A variety of techniques have shown that several structures in the brain contain retinotopically coded motor maps for saccadic eye movements. The two most thoroughly studied structures with ►saccade motor maps are the superior colliculus (SC) and the ►cortical frontal eye fields (FEF). The motor map in the SC will be described in detail in this exposition. The motor map in the SC has been well described because this midbrain structure is approximately flat and is not located in a cortical sulcus, which has allowed recording and electrical ►microstimulation experiments to more precisely characterize the topographical arrangement of saccade vectors in this structure. In initial studies of the motor map in the SC, the animals' heads were mechanically restrained so that only eye and not combined eye and head (gaze) movements were recorded.

The saccadic eye movement fields of neurons in the intermediate and deep layers of the SC were determined by recording their discharge during a temporal window aligned on saccade onset. The activity of cells was determined for a succession of targets presented at different positions in the animal's visual field. In a manner similar to that found for the visual response of cells in visual structures of the brain, these response fields contained a central location (a saccade of a fixed amplitude and direction) which was associated with the most intense saccade-related discharge. The saccade vector with the largest discharge was called the preferred vector. By recording this preferred vector for cells encountered at different locations in the SC, a retinotopically organized map of the contralateral visual field was found [1]. The horizontal meridian of the contralateral field was represented by cells located along a rostral to caudal strip of the middle portion of one colliculus. Cells with preferred movement vectors with small amplitudes were located at rostral locations on this medial strip, and cells with large-amplitude preferred vectors were located caudally. Cells that coded movement vectors with down components were located laterally on the colliculus, and cells with up preferred vectors were located near the midline. The motor map found in the deeper layers of the SC is in spatial register with the sensory map of visual cell responses found in the upper layers of the SC.

A more precise specification of this collicular motor map of preferred saccade vectors was provided by an electrical microstimulation study [2]. In this study, the colliculus was sampled with sufficient density of stimulation sites to show that the motor map was logarithmically warped, so that the space allotted to the representation of small saccades in the rostral SC was greatly magnified with respect to that allotted to large saccades in caudal SC.

Ottes et al. [3] used Robinson's stimulation data [2] to construct a set of equations that converted saccade vectors in visual space into location in collicular space. The motor map defined by their equations is shown in Fig. 1. This motor map in SC space can be quantified by



**SC – Motor Map. Figure 1** Motor map for saccadic eye movements in the monkey superior colliculus. The plot on the right shows a representation of the visual field in polar coordinates. An example of one saccade vector is shown by the arrow in this plot. The plot on the left shows the left superior colliculus ($SC_L$) and the right superior colliculus ($SC_R$) with inscribed saccadic isoamplitude curves (blue) and isodirectional curves (red). When the saccade vector shown in the visual field plot is made, the greatest activity will appear in the $SC_L$ at the location of the small gray disk. The gray sectors at the most rostral extent of both colliculi show the location of a hypothesized fixation zone.

a logarithmic transformation of amplitude coordinates in visual space along rostral to caudal strips (blue curves in Fig. 1) in SC space, and by an inverse tangent transformation of directional coordinates in visual space along the medial to lateral strips (red curves in Fig. 1) in SC space. Figure 1 shows that the conformal transformation of the coordinates of the saccade vector in visual space into rostrocaudal and mediolateral coordinates of associated activity in collicular space is single valued. That is, each saccade vector in retinotopically centered visual space maps to a unique point in collicular space. One example of the mapping is shown by a vector in visual space (black arrow) which illustrates a desired saccade goal with an amplitude of 20°, and a direction to the right and down at 45°. This goal is represented in the motor map of the left SC at the location of the small gray disk where activity would be the greatest during this particular saccade. However, the motor map in one colliculus represents only contralateral visual space, so the map has discontinuities along its medial and lateral edges that represent saccades with pure up (medial edges) or down (lateral edges) directions. The exact pattern of discharge in the SC for nearly vertical saccades has never been studied quantitatively, but most likely pure vertical saccades are coded by activity in both colliculi.

Another irregularity has been reported to exist in the SC motor map. Instead of the map representing progressively ever smaller saccades as the most rostral region of the colliculus is traversed, a rostral region called the fixation zone is found that codes instead the suppression of saccades [4]. This zone, as defined by these investigators, is shown in Fig. 1 as the gray-shaded sectors at the rostral poles of both colliculi. Gandhi and Keller [5] stimulated this rostral region of the SC, and showed that progressively smaller saccades could be evoked as the anatomic location of the stimulation site was moved further in the rostral direction. The direction of the small saccade evoked by stimulation at a particular rostral site with the animal fixating was first determined. They next stimulated with a short pulse train at the same site at the onset of large visually triggered saccades. If the direction of the small evoked saccade and the large visually guided saccade were the same, only a momentary interruption of the ongoing saccade occurred. This result would be expected if the site in the rostral SC were part of a fixation zone. In contrast, when the direction of the small evoked saccade was orthogonal to the direction of the large visual saccade, they found that, in addition to the slowing of the ongoing saccade, a spatial deviation of the two-dimensional trajectory of the ongoing saccade was produced. The direction of the deviation was consistent with the direction of the small saccade evoked by stimulation in the absence of an ongoing movement. The latter observation would be expected if the rostral region of the SC coded small saccade vectors that were averaged with the trajectory of the ongoing saccade during stimulation. Thus, although the rostral SC appears to play a role in maintaining gaze fixation (through the high level of tonic activity of cells located there and their connections to the omnipause cell region in the brain stem), it also plays a role in coding for smaller and smaller saccade vectors as location on the map is moved more rostral.

It is instructive to compare the single-valued transformation that characterizes the motor map in the SC with the motor map that exists in the FEF, in which the mapping from visual space to FEF space is not unique [6]. The precise form of this FEF map, which exists in the anterior bank of the arcuate sulcus, has not been quantified as well as that in the SC, but larger

amplitude saccades are represented dorsomedially and smaller saccades ventrolaterally. The representation of saccade direction changes systematically on radial penetrations down the anterior bank, but a given direction in visual space is often represented at multiple locations along the penetration.

Recently, movement mapping studies have been repeated in the SC of the monkey with its head unrestrained so that the possible representation of both head and eye movements could be ascertained. Both single-neuron recording studies [7] and microstimulation studies have demonstrated that the retinotopically organized motor map in the SC codes gaze (the sum of eye and head motion) instead of eye saccades. Based on their data from the head-unrestrained monkey, Freedman and his colleagues have suggested that the saccadic eye movement motor map shown in Fig. 1, which was obtained from recording and stimulation data in head-fixed animals, is badly distorted.

A motor map also exists in the SC of the cat as determined by electrical microstimulation experiments [8]. These investigators stimulated the deeper layers of the SC in the head-restrained cat, and reported that a map similar to that found in the monkey existed in the rostral half of the SC. Small saccades were presented rostrally and larger movement caudally, while saccades with a downward component were represented laterally and those with an up component were found medially. However, in contrast to the map found in the monkey, the map in the posterior half of the cat SC appeared to have a goal-directed (spatially coded) organization. Saccades evoked at a given site in this portion of the SC invariably ended at a fixed orientation in space, regardless of the initial position of the eyes at the start of the movement. Thus, the evoked saccade vector was highly dependent on the initial position of the eyes just before the saccade was initiated. The limited oculomotor range of the cat made the differentiation between goal-directed behavior and saturation effects near the limits of the oculomotor range difficult to make. Roucoux and Crommelinck [8] repeated the electrical stimulation study in the SC of the head-unrestrained cat and reported that a topologically organized gaze motor map existed throughout the structure. Small, eye only saccades were evoked from the rostral SC, while large gaze shifts that were composed of both eye and head movements were evoked from the caudal SC. The apparent goal-directed map found previously in the cat SC was apparently an artifact produced by restraining the head. A more recent study suggests that the rostral most portion of the cat SC contains a fixation zone [9] which codes for the suppression of saccades rather than smaller and smaller gaze vectors. Additional studies are required to check this suggestion against the conflicting results found in the monkey [5].

The movement fields of SC neurons can be quite large, i.e. these neurons discharge with the greatest intensity for a particular saccade vector, but also display significant activity over an extended range of neighboring saccade vectors. The result of this behavior in single cells is that a large population of cells in the SC will be active for any saccade. The location of this population of active cells shifts within the SC as a function of saccade vector [3,10]. The locus of population activity on the SC is an alternative way to describe the motor map for saccadic eye movements in the SC. Anderson et al. [10] estimated the two-dimensional loci of activity in the SC for a variety of saccades made to an extended region in contralateral visual space. The spatial extent of the population activity involved nearly 50% of the contralateral colliculus for any saccade. The spatial extent of the population activity was rather invariant with saccade size or direction, and the center of mass of this activity fit well with the motor map for saccades shown in Fig. 1, which was based on electrical microstimulation studies [2].

## Definition

►Saccade related burst neurons (SRBNs) of the ►superior colliculus (SC) are characterized by a high frequency burst that begins about 20 ms before ►saccades of appropriate amplitude and direction. In addition to the burst, some SRBNs have low frequency prelude activity preceding the burst. Although the onset of the burst is tightly coupled to the onset of the upcoming saccade (see below), the duration of the prelude activity varies from trial to trial and its onset is neither tightly coupled to the onset of the saccade nor to the onset of the target [1].

## Characteristics

### Higher Order Structures

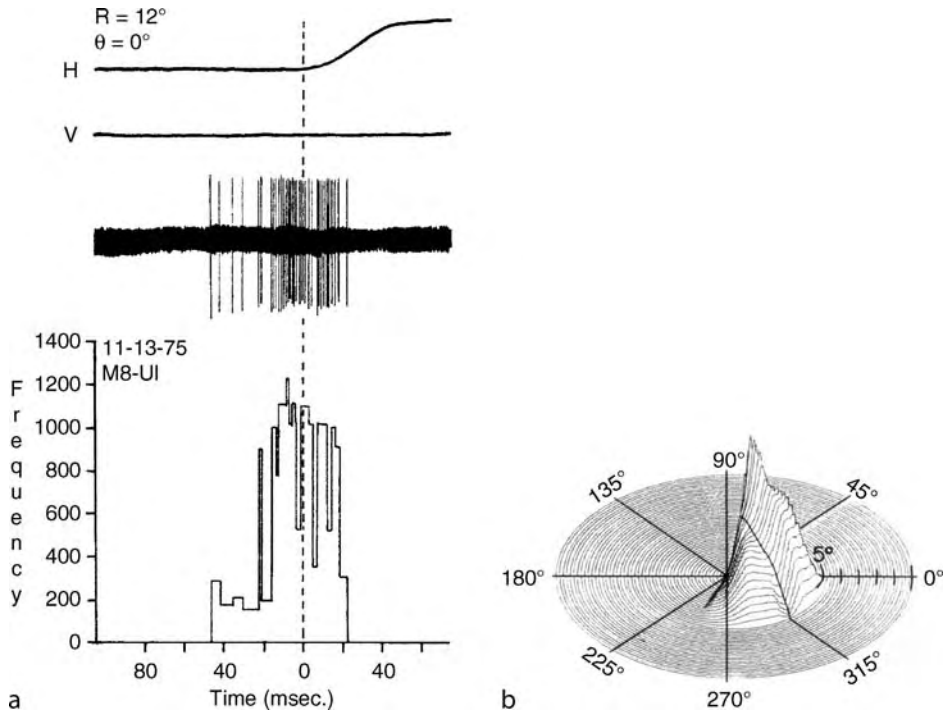
SRBNs are located in the deeper layers of SC and each of them has a movement field (each SRBN discharges optimally before saccades of a specific amplitude and direction, see below). They are organized topographically according to their movement fields. Neurons discharging before small saccades are found in the anterior part of SC, while those firing before large saccades are found in the posterior part of SC. Cells discharging before saccades with a downward component are located laterally in SC and those firing before saccades with an upward component are located medially [1]. In general, the distribution pattern of SRBNs movement fields in SC corresponds to the motor map obtained by microstimulation studies [2].

### Parts of This Structure

The deeper layers of SC receive inputs from cortical and subcortical regions serving both sensory and motor functions. For example, the frontal eye fields (FEF), the posterior parietal cortex and inferior colliculus project extensively to this part of SC. These signals are processed and integrated into motor commands here and outputted downstream for the control of orienting behavior of the animal. Converging lines of evidence indicate that the axons of SRBNs are an important component of SC efferent pathway. Keller [3] reported that 10 out of 10 SRBNs recorded in SC could be antidromically activated by stimulation of the ►paramedian pontine reticular formation (PPRF) and the area that contains ►omnipause neurons (OPNs). Only 1 of 12 non-burst SC neurons, which displayed saccade related activity but lacked the high frequency burst, was activated. In another experiment, Moschovakis et al. [4] recorded from the SC of squirrel monkeys making spontaneous eye movements and grouped the recorded neurons into different functional classes. One class, named vectorial long-lead burst neurons, has properties that are very similar to those of the SRBNs. Those vectorial long-lead burst neurons have a motor field, display very little spontaneous activity and burst intensively before saccades made into their motor field. Like SRBNs, the burst preceded saccade onset by about 20 ms. The axons were filled with HRP after the recording, permitting their morphological identification. In addition to projecting to the contralateral SC, axons of those vectorial long-lead burst neurons bifurcate in the midbrain. One branch crosses the midline and joins the predorsal bundle, which terminates in, among other targets, PPRF, the horizontal burst generator. There is evidence indicating that these axons of the vectorial long-lead burst neurons actually make synaptic connections with neurons in PPRF [5]. The other branch joins the ventral ascending efferent bundle (AV). The vertical burst generator, the rostral interstitial nucleus of the median longitudinal fasciculus (riMLF), is one of the targets of the AV pathway [6].

### Functions of This Structure

As mentioned above, SRBNs have movement fields. The SRBN shown in Fig. 1 is an example. This cell discharges before a range of saccades (amplitude < 5°) aimed to the right and down region in the visual field. As the positions of the saccadic end points in the movement field varies, a systematic change of the discharge rate and duration can be observed. Saccades directed to the center of the field are preceded by



**SC – Saccade Related Burst Neurons. Figure 1** (a) Discharge pattern of a typical SC saccade related burst neuron (SRBN). Top graph: horizontal eye position (H) and vertical eye position (V) as a function of time. Middle graph: Action potentials of the cell. Bottom graph: instantaneous firing rate as a function of time. Vertical dotted line: the onset of the saccade. (b) A 3D plot of the movement field of this cell. The optimal amplitude is 1 degree at an angle of 320 degree (Courtesy of Sparks and Jay, 1986).

more vigorous discharges with longer durations, while saccades deviating from the optimal direction and amplitude are accompanied by less vigorous discharges with shorter durations. In addition to this spatial gradient, the movement field is also characterized by a temporal gradient. The time between the onset of the burst and the onset of the saccade is longer for those movements to the center of the field than those to the periphery. The size of SRBNs' movement fields tends to increase with eccentricity. That is, neurons that discharge before small saccades have small and sharply defined movement fields, while those firing before large saccades have large and coarsely tuned fields [1,7].

SRBNs discharge before saccades of specific directions and amplitudes regardless of initial eye position. Therefore, the collicular command is not to move the eye to a particular position in the orbit, but to displace the eye in a specific direction and amplitude [1]. Unlike the motor neurons and excitatory burst neurons (EBNs) in the brain stem, SRBNs do not code the direction and amplitude of an upcoming saccade by firing rate. Identical bursts may occur in association with many saccades of different directions and amplitudes. Moreover, there is no distinguishable difference among the discharges of different SRBNs preferring different saccade sizes [7]. Thus, it is the location of the activated SRBNs in the SC motor map that determines saccade amplitude and direction. In other words, the direction and amplitude of a saccade are spatially coded in SC.

There is strong evidence indicating that the high frequency burst of SRBNs plays an important role in saccade initiation. First, the onset of the burst is tightly correlated to the saccade onset ($r = 0.99$). Second, when the experimental parameters are setup in such a way that sometimes the visual target elicits a saccade and sometimes does not, the occurrence of the burst of a SRBN is almost perfectly correlated with the occurrence of the saccade. Although SRBNs sometimes discharge a few spikes in the absence of a saccade, this kind of activity is far less vigorous than the least vigorous ones that accompany appropriate saccades [8]. A more recent experiment, in which the monkey was required to cancel an on going visually guided saccade in one third of the trials, also showed that SC neurons

play an important role in the decision process regulating whether a saccade is to be made [9]. In addition to initiating the normal visually guided saccade mentioned in the above two experiments, the burst of SRBNs could also serve as the trigger signal in express saccades (saccades that have very short latency, ranging from 80 to 100 ms). Under the "gap" condition in which express saccades are often observed, the interval between the onset of the visual target and onset of the burst is shortened and, as a result, the saccadic latency is shortened [10].

### Higher Order Function

The deeper layers of SC in which the SRBNs are located are an important component in a circuit transforming signals from different sensory and motor areas into motor commands that initiate and guide the ►orienting responses of the eyes, head and pinnae.

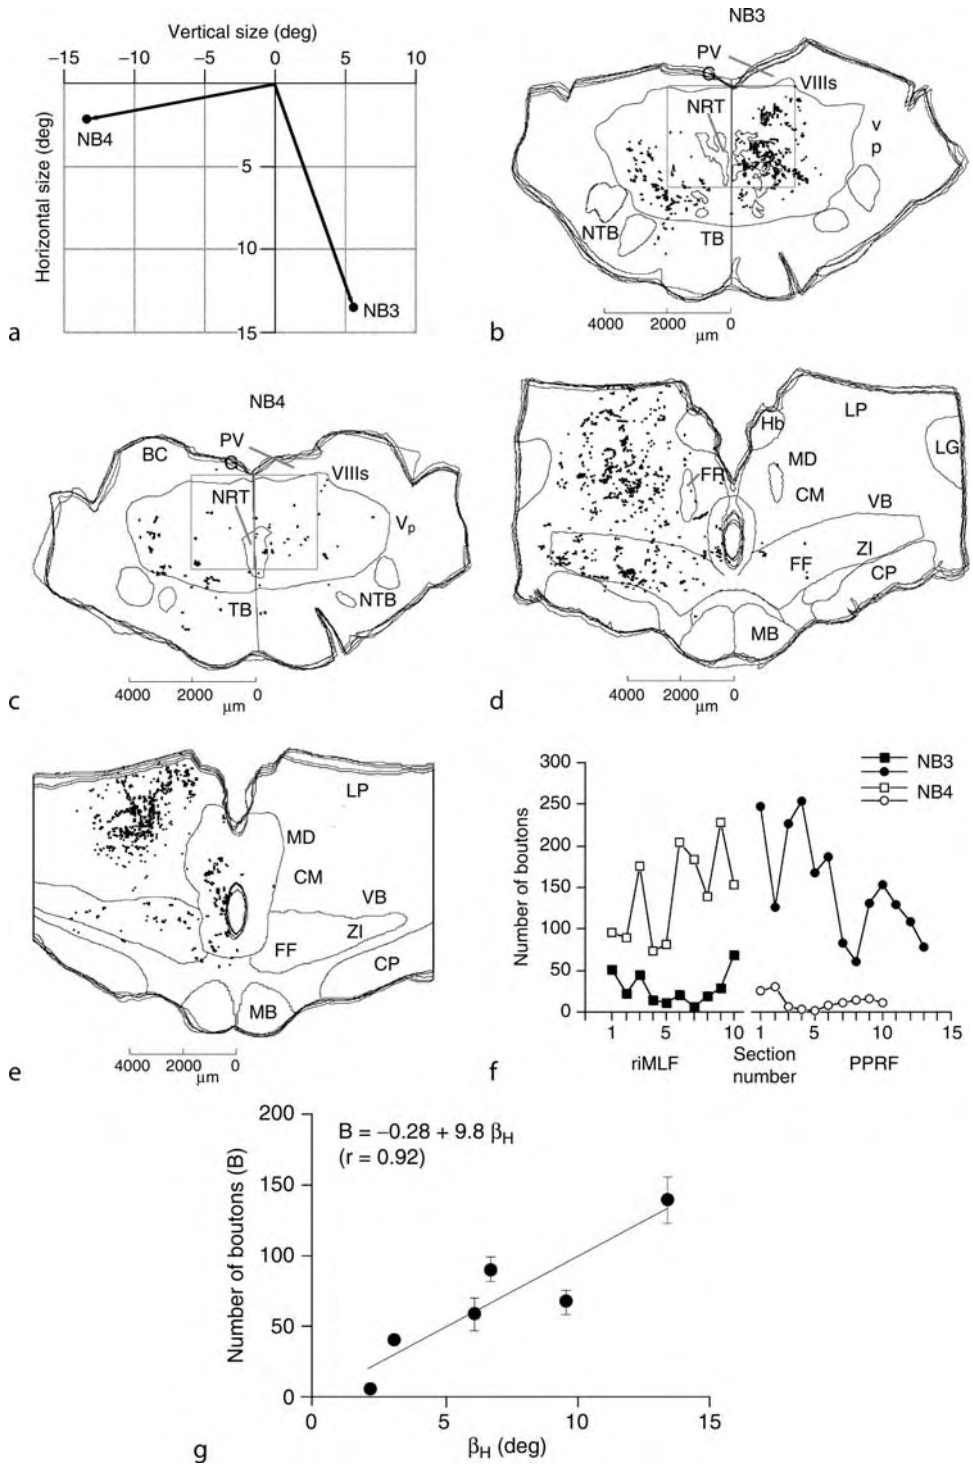
## Definition

The sequence of neural processes that enables the SC to use information about world events in order to issue motor commands guiding orienting responses to these events.

## Characteristics

### Description of the Theory

The front stage of the sensorimotor interface contained in the SC devotes neural space to represent the location of sensory stimuli. The neural mechanisms employed to this end are considered in some length in the entry ►SC – sensory maps. Since the SC uses different frames of reference to encode the spatial location of stimuli of different modalities, the sensorimotor interface must use coordinate transformations to bring them in register to one another, as well as to the frame of reference used to encode movement metrics. Further, because sensory information reaches the SC from a multitude of stimuli while orienting movements can be executed one at a time, the sensorimotor interface must also include a mechanism to decide when to launch a movement and which of several targets to favor with it. Once the decision to launch the appropriate movement is reached, a command that specifies its amplitude and direction is issued in the form of presaccadic bursts of SC neuron discharges. As the SC uses a place code, and premotoneuronal interneurons use a time code to specify these parameters, the movement related commands must be decomposed and spatio-temporally transformed. The coordinate transformations used in the SC are briefly considered in the entry devoted to the ►foveation hypothesis, while the representation of movement metrics is considered in some length in the entries ►SC – motor map, ►SC – role in eye movements, ►SC – saccade related burst neurons (SRBNs) and ►SC – tectal long lead burst neurons (TLLBs). The present entry is devoted to the following issues: (i) Transmission of sensory information to movement related cells of the SC; (ii) Decision processes; (iii) Burst generation; and (iv) Vector decomposition and spatiotemporal transformation.



**SC – Sensorimotor Integration. Figure 1** (a) 2-D plot of the amplitude and direction of saccade vectors (abscissa: horizontal, ordinate: vertical) evoked from two SC sites in cats NB3 and NB4. Consistent with the motor map of the SC, the horizontal contraversive component was big (13.5 deg) in the case of NB3 and small (2.1 deg) in the case of NB4. Similarly, a conspicuous difference in the size and direction of the vertical components (5.6 deg upward in NB3 and 13.4 deg downward in NB4) agreed well with the location of the stimulus sites on the motor map. (b, c) Distribution of *boutons* in five consecutive sections, at the level of the rostral border of the nucleus reticularis pontis caudalis (NRPc), after biocytin injections in areas of the feline SC encoding saccades with a big horizontal and a small vertical component (NB3, b), or saccades with a small horizontal and a big vertical component (NB4, c). (d, e) Distribution of

### Transmission of Sensory Information to Movement Related Cells

The classes of cells that convey visual information from the superficial to the deeper SC layers and the role they play in generating bursts of discharge in deeper SC layer neurons are examined in the entry devoted to ►SC – interlayer neurons. The direct superficial to deeper visual information transfer is supplemented by a massive cortical projection of visual information to the deeper SC. Information of other modalities (e.g. auditory or somatosensory) is similarly funneled to the deeper SC layers, as described in the entry SC – sensory maps. The intensity of SC neuron discharge depends on the properties of the stimuli employed. For example, moving stimuli are particularly effective in driving SC cells [1]. Moreover, multimodal stimuli are more efficient in driving SC neurons than unimodal ones; the vast majority (84%) of deeper SC cells respond much more strongly to stimuli involving two or more sensory modalities than would be expected on the basis of their responses to unimodal stimuli [2]. It also depends on the context in which such discharges are emitted. For example, visual responses of primate superficial SC cells can be enhanced if stimuli in their receptive fields are used as targets for saccades [3], and the same is true of the visual responses of deeper SC movement related cells for rewarded movements [4].

The biological means that the SC employs to encode the location of visual targets and match it to the metrics of the saccade related motor commands it sends to its targets are examined in the entry devoted to the foveation hypothesis. As discussed there, use of raw sense data to represent stimulus location does not always suffice to accurately specify the discharge of presaccadic SC neurons, and therefore the metrics of ensuing saccades. Instead, stimulus location must sometimes be reevaluated through the use of coordinate transformations; subsumed under the heading "vector subtraction hypothesis" they are also described in the entry foveation hypothesis, while neurons crucially relevant for its implementation are described in the entries devoted to the ►reticulotectal long-lead burst neurons and the ►SC – quasivisual neurons.

### Decision Processes

There is considerable evidence to suggest that the SC participates in processes which determine whether a saccade needs to be produced and if so when. Saccade reaction times offer a convenient means to assess the neural mechanisms leading to such a decision, in particular since their range can be readily influenced by experimental manipulation. For example, the latency of ►express saccades (often evoked with the use of the gap paradigm, in particular in trained subjects) is shorter than that of regular saccades [5]. Conversely, saccades to auditory [6] and somatosensory targets [7] and saccades away from targets (antisaccades [8]) take longer to initiate. Several parameters of the discharge of deeper SC neurons reflect these reaction time differences. For example, the number of deeper SC layer neurons bursting for saccades is larger [9], and the intensity of their discharge is greater [10], when saccade targets are visible rather than when they are not (such as in the case of antisaccades or spontaneous saccades). Also, the bursts of discharge of SC motor cells for longer latency saccades (e.g. to somatosensory targets) are delayed relative to those for saccades to visual targets [11].

It might be argued that the phasic sensory responses reaching the deeper SC layers are automatically translated into executable movement related phasic commands leading to quick decisions and early movements. This is probably not always the case, as indicated by the fact that ►tectoreticulospinal neurons (TRSNs) of the deeper SC of the cat emit short latency bursts of discharges for visual stimuli, yet these bursts do not accompany saccades [12]. Further, the motor responses of primate buildup neurons, which accompany correct anti-saccades of appropriate metrics, are weaker than their sensory responses to visual stimuli into their receptive field which are not followed by saccades (these would be erroneous prosaccades towards the stimulus rather than the correct anti-saccades away

*boutons* in five consecutive sections at the level of the rostral border of the Fields of Forel (FF) and, more precisely, their medial portion traversed by the retroflex bundle (homologous to the riMLF of the monkey) in the same cases (NB4, d; NB3, e). (f) Number of *boutons* that were recovered in the ipsilateral riMLF of NB3 (*solid squares*) and NB4 (*open squares*), and the contralateral PPRF of NB3 (*solid circles*) and NB4 (*open circles*) in several individual consecutive sections through these nuclei. (g) Plot of the average number of *boutons* deployed in the feline PPRF per 100 fibers per section (B; *ordinate*) from each one of several SC injection sites versus the size of the horizontal component of the characteristic vector (i.e. the saccade vector that would have been evoked had the eyes started from a straight ahead position) of the saccades evoked from the same site ($\beta_H$; *abscissa*) after bulk injections of a tracer in collicular microzones of the cat. Error bars indicate the standard error of the mean. The solid line is the linear regression line through the data and obeys the equation displayed. Abbreviations: *Vp*, principal sensory nucleus of the trigeminal nerve; *VIIIs*, superior vestibular nucleus; *BC*, brachium conjuctivum; *CM*, central median nucleus; *CP*, cerebral peduncle; *FF*, fields of Forel; *FR*, fasciculus retroflexus; *Hb*, habenula; *LG*, lateral geniculate nucleus; *LP*, lateral posterior complex; *MB*, mammillary bodies; *MD*, mediodorsal nucleus; *NRT*, nucleus reticularis tegmenti pontis; *NTB*, nucleus of the trapezoid body; *PVG*, periventricular gray; *TB*, trapezoid body; *ZI*, zona incerta.

from the stimulus which are actually executed [10]). Conceivably, the visual responses of omnipause neurons [13] transiently raise the threshold for initiating eye movements and thus bursts exiting the SC shortly after the appearance of salient stimuli are rendered ineffective. The notion that the visual bursts of deeper SC neurons could elicit saccades at least in some circumstances, such as those favoring express saccades (visuo-motor hypothesis [14]), has been explored, and shown to be unlikely in monkeys executing saccades of a particularly wide range of reaction times (engendered by interleaving trials in which target onset preceded -delayed saccade task, coincided with -step task, or followed -gap task, fixation target offset). Most SC cells emit only one burst which is tightly coupled either with the appearance of the target (visual cells) or with the onset of the saccade (movement cells). However, visuo-motor cells of the deeper SC generate two bursts of discharge, an early visual one and a second, motor one. The interval between the two decreased with the latency of the saccades until extremely short latencies were reached, in which case the motor burst fused with the visual one. The tight coupling between the onset of the motor burst and the onset of saccades extended into the express saccade range for both the visuo-motor and the motor cells, while no range of saccade reaction times was found in which visual rather than motor responses were tightly coupled to saccade onset [15].

A large range of reaction times can also be found in experiments employing a two choice discrimination task in which subject decision is declared by making a saccade in one of two directions. In such experiments, the latency of the movement varies almost continuously with task difficulty (a function of the separability of the cues employed to instruct movements in one or the other direction). Of the models proposed to account for the variability of saccade reaction times, diffusion models have been particularly useful in that they capture essential features of both subject performance and of cell discharge. Such models assume that to initiate a saccade, information starts from a baseline and drifts over time until it reaches a boundary [16]; reaction time (as well as the number of correct and erroneous responses) could in principle depend on the baseline, boundary and rate of the drift values. Indeed, the post-target presentation rate of rise of the firing of prelude neurons has been shown to reflect the dynamics of the decision process [16]. Moreover, there is some evidence to suggest that when the discharge of saccade related SC neurons exceeds a certain intensity (threshold), saccades in their movement field must be executed [17]. Finally, the intensity of discharge of prelude neurons, before target presentation (baseline), is influenced by the probability of reward [4] and of a target present in their receptive field [18], increases in the gap period [10], and is inversely correlated with the latency of saccades [18]. It also determines whether a correct or erroneous movement will be executed in the anti-saccade task; high level prestimulus activity of prelude cells located near the SC site where visual stimuli are represented gives rise to reflexive saccades towards them [10]. Apparently, several factors can increase the excitability of deeper SC neurons; whenever this is the case, and depending on the strength and timing of superimposed sensory signals, SC cells can emit motor bursts leading to extremely short latency and maybe even inappropriate movements.

### Burst Generation

To some extent, the saccade related bursts of SC neurons are due to movement related signals they receive from the ►frontal and ►supplementary eye fields. However, since saccades can still be executed after lesions of the frontal lobes, the SC must be able to generate presaccadic bursts from signals which need not be either phasic or saccade related. Here, we consider two mechanisms: (i) synaptically modulated non-linear responses of deeper layer SC neurons, and (ii) the recurrent excitatory network deployed by TLLBs.

Under certain circumstances, the synaptic influence of fibers carrying sensory information to the deeper SC layers might evoke intense bursts in their targets. For example, application of the GABAergic antagonist bicuculline can evoke prolonged bursts of action potentials, which ride on top of large amplitude EPSPs produced in deeper SC neurons in response to electrical stimulation of the superficial layers of rat SC slices [19,20]. These are presumably due to NMDA receptor mediated regenerative processes switched on by the depolarization of the deeper SC cells due to the removal of synaptic inhibition. The source of GABA in such preparations is probably local interneurons [21], but the SC of intact animals has several additional ones. The best studied of these is the pars reticulata of the substantia nigra, and is examined in detail in the entry ►Substantia nigra – role in eye movements.

The recurrent plexus of TLLBs is described in the entry devoted to the ►SC – Tectal Long Lead Burst Neurons. The notion that it mediates excitatory synaptic influences between adjacent TLLBs is consistent with the fact that the main axon of such neurons joins the predorsal bundle [22] and the fact that predorsal bundle fibers are glutamatergic [23]. It is also consistent with the fact that brief inward currents superimposed on long-lasting ones can be recorded from SGI neurons in response to the photorelease of caged glutamate [24]. Similar bursting discharges of SGI neurons in rat slices could not be accounted for by the relationship between the firing rate and the intensity of the current injected into the neurons studied. Instead, consistent with the above described network of interacting TLLBs, they could be reproduced (abolished) by NMDA receptor activation (block) [25].

### *Spatiotemporal Transformation and Vector Decomposition*

As with other motor systems, the saccadic one is characterized by a profound transformation of its signals as they pass from higher order supranuclear structures to motoneurons. The "place" code used by the motor SC to specify saccade vectors is described in the entry devoted to ►SC – tectal long lead burst neurons. Its adoption makes eminent sense, as it allows the front end of the saccadic system (the motor SC) to use a code favored by sensory systems. However, because neural circuits interposed between the SC and the extraocular motoneurons use a time code to specify the same parameters (considered in the entries devoted to the ►horizontal and ►vertical medium lead burst neurons), this choice engenders two transformations of the movement related commands exiting the SC. Firstly, the vector of saccadic displacement represented in the SC must be "decomposed" into the vertical and horizontal saccadic components specified by the burst generators. Conceivably, this could be implemented by the Av and PDB branches of the axons of single TLLB neurons (described in the entry ►SC – tectal long lead burst neurons) which target the ipsilateral riMLF (the Av branch) and the contralateral PPRF (the PDB branch), respectively. The differential weighing of the simultaneous projections of single SC sites onto the vertical and horizontal burst generators could provide an anatomical substrate for "vector decomposition". Consistent with this scheme, and as documented in Fig. 1b–f, collicular regions encoding saccades with a big horizontal and a small vertical component project strongly upon the horizontal burst generator and weakly upon the vertical burst generator, while regions encoding saccades with a small horizontal and a big vertical component give rise to the opposite pattern of projections [26].

Following vector decomposition, the spatial code employed by the SC must be further transformed to obtain a matching temporal code at the level of the burst generators. Such a "spatio-temporal" transformation could rely on the graded strength of anatomical projections of distinct SC sites onto the burst generators. Figure 1g illustrates experimental evidence consistent with this scheme [27]. As shown here, the number of *boutons* that tectal efferent fibers deploy within the confines of regions housing the horizontal burst generators (B) increases in proportion to the amplitude of the horizontal component of the saccade vector ($\beta_H$) encoded by the collicular sites from which they originate. The relation between the two variables obeys the expression indicated on the figure. Its slope is equal to about ten *boutons* per degree of horizontal eye displacement per 100 fibers per section, while the high correlation coefficient ($r = 0.92$) indicates that about 85% of the variance of the dependent variable (number of *boutons*) can be accounted for by the independent variable (saccade size).

## Definition

A topographic arrangement of visual, somatosensory, and auditory signals can be found in the ►superior colliculus. When the eyes are centered in the orbits, these maps lie approximately in spatial register with each other, and with saccade-related motor maps. When the eyes are not centered in the orbits, however, a map organized in body or head-centered coordinates will provide an inappropriate input to the oculomotor system, which requires that target position be specified in ►motor coordinates (i.e. the change in eye position required to look to the target). Consistent with this view, the spatial alignment of sensory maps in superior colliculus appears to shift with changes in the orientation of the eyes, head, and body.

## Characteristics

### Higher Order Structures

The superior colliculus is a layered structure in the midbrain, consisting of three cellular layers, alternating with four fibrous layers. Layer II contains the cell bodies of visual neurons, arranged in a topographic map of the contralateral visual hemifield. Multimodal sensory and motor signals are found in the intermediate and deep layers.

### Parts of This Structure

Topographic maps have been identified in the superior colliculus for several sensory modalities. Visual, somatosensory, and auditory maps lie approximately in register when the eyes are centered in the orbits.

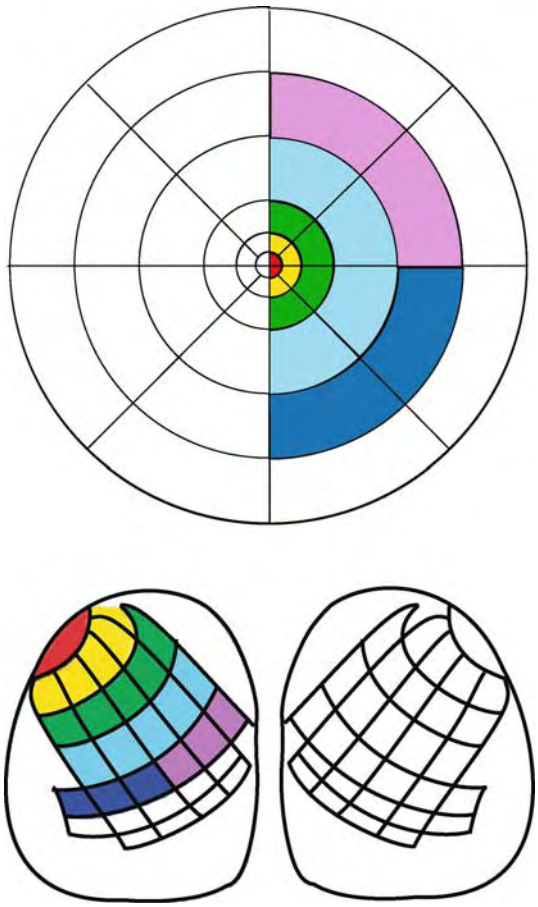
### Functions of This Structure

#### *Sensory Maps and Map Alignment*

The ease with which we can reach out and grab our morning cup of coffee belies the complexity of the neural processing required to compute the location of the coffee cup in space. Cells in a specific region of the retina will be activated by light reflected from the cup, but there is not a one- to-one correspondence between which region of the retina is activated and the location of the cup in space. The positions of the eyes in the orbits, the position of the head, and the position of the body all affect the region of retinal activation. Thus, the location of a visual target cannot be computed using only signals that reach the brain through the optic nerve: localization requires that visual signals be combined with information about eye, head, and body positions. Localization of somatosensory and auditory stimuli also requires complex neural computations.

The superior colliculus (SC) provides an excellent model system for studying the neural processing involved in spatially-directed action. Signals from several sensory modalities converge in the deeper layers of SC, a region that also contains cells generating commands for orienting movements of the eyes, head, and pinnae. In mammals, many neurons residing in the deep division of SC are responsive to auditory, somatosensory and/or visual stimuli. Each sensory cell has a spatial receptive field and the sensory cells are organized according to the location of their receptive fields, thereby forming topographical sensory maps.

Visually responsive cells are activated by stimuli appearing in the contralateral visual field. Neurons with receptive fields in the upper visual field are located medially; those with receptive fields in the lower visual field are found laterally. Cells with receptive fields near the center of the visual field reside anteriorly; those responsive to peripheral stimuli are located posteriorly (Fig. 1). Tactile receptive fields are also organized topographically in the SC [1,2]. In each colliculus, representation of the contralateral forelimb and head is extensive, whereas only a small part of the colliculus is allocated to representation of the large cutaneous surface area of the trunk and hindlimb. The acoustic receptive fields of collicular neurons are large, but each



**SC – Sensory Maps. Figure 1** Top: color coded diagram of visual space. Bottom: schematic diagram of superior colliculus, showing the representation of the contralateral visual hemifield. Colors on the SC map correspond to the colors in the top panel. The area of visual space near the fovea is represented near the rostral end of superior colliculus; peripheral locations are represented caudally. Note that the area of visual space near the fovea is represented by a disproportionately large area of the SC map.

cell has a "best area," defined as the range of stimulus locations which elicit responses greater than 75% of maximum. The best areas of cells vary systematically with cell location, forming a map of auditory space in the SC [3].

Thus, cells responsive to each modality are organized in an anatomical map and in anesthetized or paralyzed preparations; the visual, somatosensory, and auditory maps appear to be aligned. For example, in the paralyzed cat, collicular neurons responding to both auditory and visual stimuli have visual and auditory receptive fields that overlap spatially. For cells responding to auditory but not to visual stimuli, the location of the auditory receptive field is correlated with the spatial location of the receptive fields of nearby visually responsive neurons. Observations such as these led to the assumption that the SC contains a general, modality independent map of the external environment. In such a map, stimuli originating from a particular region of the external world (regardless of sensory modality) would activate a particular subset of multimodal neurons (neurons that respond to visual, auditory, or tactile stimuli). The activation of these sensory neurons, in turn, could initiate ►orienting responses by exciting adjacent cells with movement- related activity organized in a motor map aligned with the multimodal map of sensory space.

But what happens to the alignment of the visual and somatosensory maps in the unanesthetized, freely moving animal when the direction of ►gaze and the position of the limbs in space do not maintain a fixed relationship, or to the alignment of the visual and auditory maps when the positions of the eyes change, with respect to the head? Jay and Sparks [4] noted that collicular neurons with saccade-related activity are organized topographically and it is the location of active neurons within the topographical map of movement fields that specifies the change in eye position required to direct gaze to the target location. They reasoned that the task of sensory systems is to specify the change in eye position required to look to a target, not merely the location of the target in head, body or ►retinal coordinates. Consider, for example, a monkey with the head positioned "straight ahead" but with gaze directed 24° to the left of center. When an auditory stimulus is presented 10° to the right of center, interaural cues are used to localize the acoustic target in ►head coordinates ("target is 10° right"). However, since the eyes are directed 24° left of center, a 34° rightward saccade is required to look to the target, and neurons in caudal regions of the left SC must be activated to produce this movement. If an auditory target is presented in the same location on another occasion with gaze directed 24° to the right of center, cells in the right SC must be activated to produce the 14° leftward saccade required to look to stimulus. Based upon these observations, they hypothesized that the maps of sensory space observed in the deeper layers of the SC were not static, and that the activity of the cells are encoded in motor, rather than sensory, coordinates.

To test this hypothesis, Jay and Sparks [4] plotted the receptive fields of neurons responsive to auditory and visual stimuli while the eye position of trained, alert monkeys was systematically varied. If auditory signals are organized in head coordinates, then in these experiments in which the head is fixed, the discharge of acoustically responsive neurons should be independent of initial fixation position and depend entirely upon the azimuth and elevation of the sound source. However, if auditory signals have been translated into motor coordinates, then the response of collicular

neurons to acoustic stimuli should be sensitive to both the position of the speaker in space and the position of the eyes in the orbits. They found that the auditory receptive fields shifted with changes in eye position and that, in the monkey, the map of auditory space in the deeper layers of the SC is not static. With each change in eye position, the site of neural activity induced by a fixed auditory stimulus shifts to a new location – a location that specifies the metrics of the movement that would direct gaze to the target location. A similar effect of eye position on the responses of collicular neurons to acoustic [5–7] and somatosensory [8] stimuli has been observed by other researchers.

### *Multimodal Interactions*

Many cells in the intermediate layers of SC respond to sensory stimuli of more than one modality. In anesthetized animals, dramatic enhancement and inhibitory effects on the responses of multimodal cells have been reported to occur when combinations of visual, somatic and auditory stimuli are presented to cat [2]. These interaction effects depend upon the spatial and temporal overlap of the multimodal stimuli. Enhancement usually occurs if each stimulus is in the center of its receptive field and if the two stimuli are temporally contiguous. Response depression occurs most commonly when one of the two stimuli is outside or on the fringe of the cell's receptive field, or if there is a large temporal disparity in the onset of the two stimuli [9]. A reasonable hypothesis is that ►multimodal enhancement, assumed to occur when two stimuli from the same region in external space appear simultaneously, facilitates orienting movements to that part of the environment. The physiological studies describing bimodal enhancement were performed in anesthetized animals. Populin and Yin [7] tested for bimodal enhancement in the superior colliculus of behaving cats trained to orient to acoustic, visual, and bimodal stimuli. They failed to observe the large enhanced responses reported in anesthetized animals, even when the time between presentation of the visual and acoustic stimuli was varied systematically and/or the relative intensity of the two stimuli was varied. They did, however, observe prominent depressive effects when the cats were required to fixate a visual target during presentation of an acoustic stimulus. Much remains to be learned about the role of multimodal cells in SC in the initiation and guidance of orienting movements of the eyes, head, and external ears.

## Higher Order Function

Although most neuroscientists studying sensory processing view the problem from the perspective of perception, perception is not the only end point of sensory processing. Movements are often initiated by and guided by sensory signals. Studies of the sensory maps in SC have been influenced by the realization that the format of the motor command imposes constraints on the types of sensory processing that must occur. In the case of orienting movements of the eyes, the motor map in the SC is organized in relative coordinates – the signals specify the change in eye position required to look to a target. Thus, input signals that initiate a movement must also specify the location of the target with respect to the current gaze position, not the location of the target in body or head coordinates. According to this view, the sensory maps are dynamic and the receptive fields of collicular neurons shift with relative movements of the eyes, head, and body. A dynamic mapping of sensory space is required because of constraints imposed by the organization of the motor map. It seems likely that other motor systems will require specialized sensory processing to transform sensory signals into the format of the motor commands.

## Quantitative Measure for This Structure

Approximately 50% of neurons in the intermediate layers of SC are multisensory. Visual responses in superior colliculus occur at latencies of approximately 70 ms, and auditory responses occur at latencies of 20 ms or less [7]. In anesthetized cats, bimodal enhancement can exceed 300%; bimodal suppression can be nearly a complete suppression (99%) [2]. However, in the awake animal, Populin and Yin [7] reported that the responses to bimodal stimuli approximated, but generally did not exceed, the sum of the responses to the two single modality stimuli.

## Definition

The best studied saccade related efferent cells of the primate SC. They emit high frequency bursts for all saccades in their ►movement field (of saccade related neurons), including spontaneous ones. Their medium size somata occupy fairly superficial locations in the deeper layers of the SC, and give rise to vertically oriented dendritic fields of average complexity. Finally, their rather delicate axons deploy recurrent collaterals and participate in several tectofugal fiber bundles reaching a multitude of brainstem oculomotor related nuclei. Due to their pattern of discharge, TLLBs can be thought to correspond to the saccade related burst neurons (SRBNs), a subclass of SC movement cells described in detail by Sparks and his colleagues [1]. Also, due to their rather short lasting bursts, TLLBs cannot correspond to the ►SRBN type II neurons also first described by Sparks and his colleagues [2] and more recently by Wurtz and his colleagues [3] (the build-up neurons of these authors). The same is true for visually triggered movement cells, and ►fixation neurons.

## Characteristics

### Higher Order Structure

The TLLBs are crucial components of the metric computer in the superior colliculus, the output of which they convey to the burst generators.

### Parts of this Structure

The morphological features of TLLBs were elucidated after recording their discharges intraaxonally in alert behaving monkeys and then injecting them with HRP [4]. A typical example is illustrated in Fig. 1. The shape and small or medium size of TLLB somata allows their assignment to the T class of tectal efferent neurons. This identification is consistent with their fairly superficial location in the SC, namely in the ventral stratum opticum and the dorsal stratum griseum intermediate. Further, it is consistent with the moderate complexity of their dendritic trees, which are oriented normally to the surface of the SC. Finally, it is consistent with the fact that their axons are rather thin (2.5–3.5 mm) and give rise to recurrent (Fig. 1, arrowhead) and commissural (Fig. 1, arrow) fibers. The axonal system of TLLBs participates in several efferent systems of the SC. As shown in Fig. 1, their main axon travels along the borders of the periaqueductal gray and crosses to the

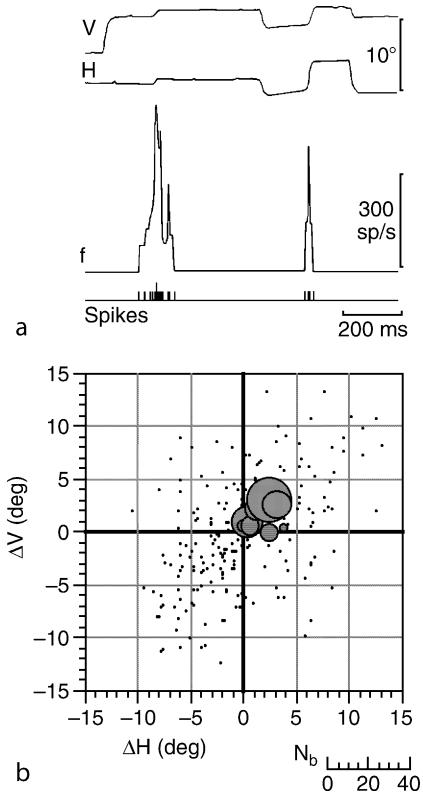
opposite side in the dorsal tegmental decussation of Meynert. Before crossing, it emits one or two major branches that follow the ventral ascending (Av) tectofugal fiber bundle on its way toward the riMLF. It also emits several thin collaterals which deploy terminal fields in the mesencephalic reticular formation. Fig. 2 illustrates the distal trajectory and patterns of termination of PDB branches of single identified TLLBs [5]. Their distal targets include the nucleus reticularis tegmenti pontis (NRTP), the nuclei reticularis pontis oralis (NRPo) and caudalis (NRPc), the nucleus paragigantocellularis dorsalis, and the nucleus raphe interpositus (rip).

## Functions of the Structure

TLLBs emit high frequency bursts for contraversive spontaneous saccades of the appropriate metrics (Fig. 3a). As the latency of their bursts is in the long lead range (21–46 ms on the average), such SC cells are called tectal long lead burst neurons (in short TLLBs). Saccades preceded by TLLB discharges collectively define the cell's movement field; in the case of the neuron illustrated in Fig. 1, it encompasses small (about 3°) right-up saccades (Fig. 3b). It is via their movement fields that TLLBs can encode the vector (amplitude and direction) of desired saccade displacement. As expected of cells causally relevant for saccades, TLLBs are generally silent both between saccades and for saccades outside their movement field (Fig. 1a). Nevertheless, the relationship between cell discharge and the execution of saccades is not as obligate as originally thought. For example, cell discharge does not reflect the actual displacement of the eyes during saccades that have been adapted, are executed toward remembered targets, or participate in gaze shifts accomplished through a combination of eye and head movements. In all these cases, TLLB discharge is better related to the distance between target and fovea (i.e. the metrics of saccades that would have foveated the target had they been executed) rather than to the metrics of the saccades that are in fact executed.



**SC – Tectal Long-Lead Burst Neurons.**
**Figure 3** Salient physiological features of TLLBs (modified from [4], with permission). (a) Neuronal discharge pattern in relation to saccades. (b) Bubble diagram of the neuron's movement field. Circles are centered over the end points of saccades (in retinotopic coordinates) and their diameter is proportional to the number of spikes in the accompanying burst ($N_b$). Dots indicate saccades not accompanied by spikes. Abbreviations: *f*, instantaneous firing rate; *H, V*, instantaneous horizontal (H) and vertical (V) eye position.

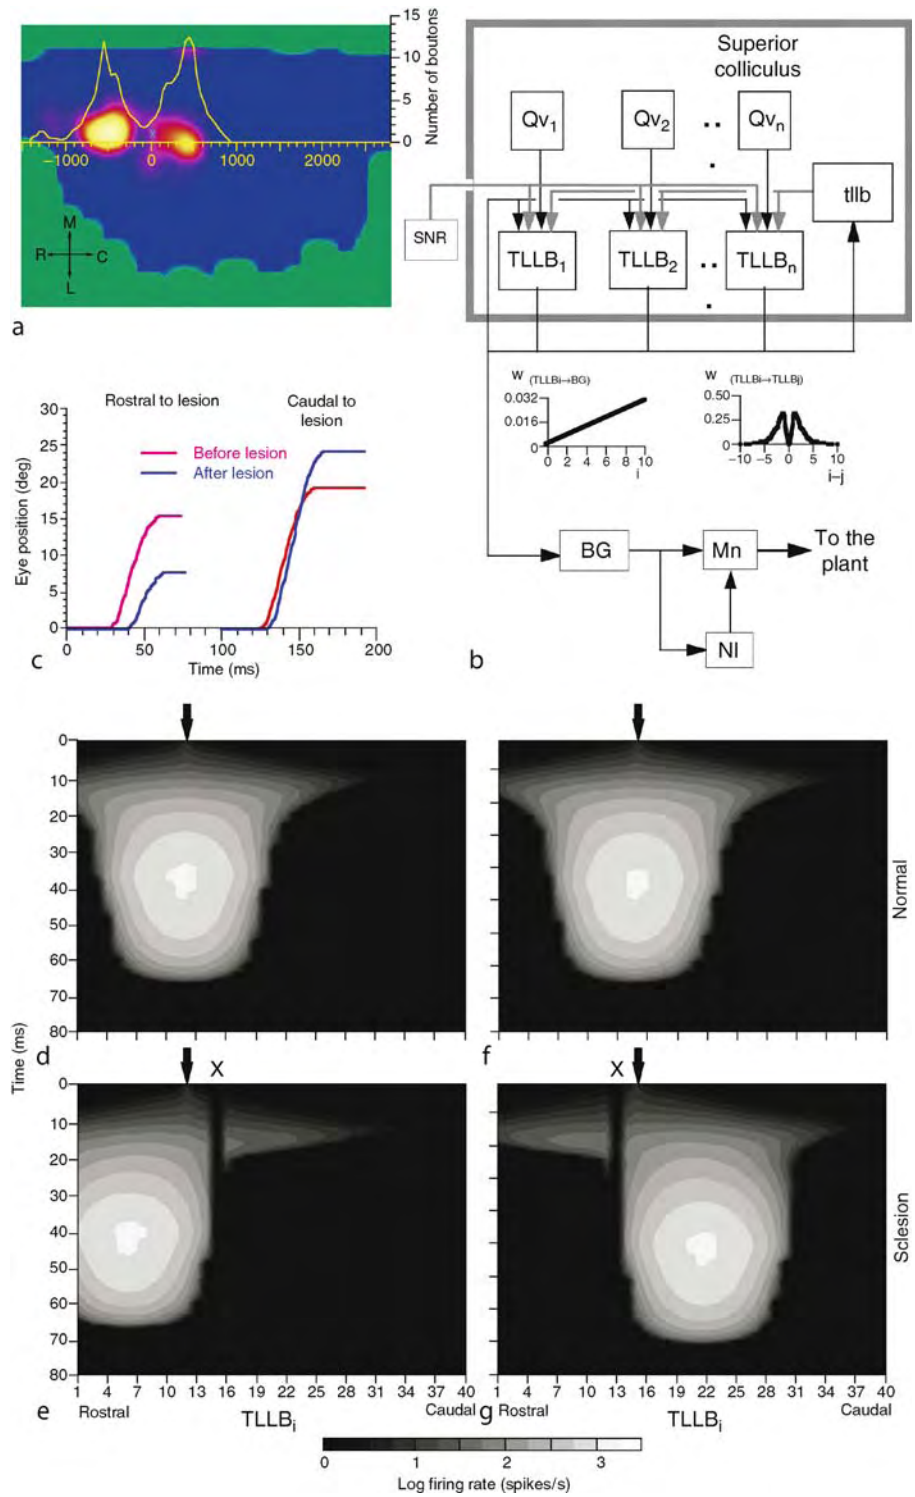
The highly distributed axonal system of TLLBs is eminently suitable for conveying a saccade related command to targets of the SC. Firstly, the terminal fields they deploy in the central mesencephalic reticular formation occupy a region housing the somata of ►reticulo-tectal long-lead burst (RTLLB). Moreover, the nuclei targeted by Av and PDB fibers contain most of the premotoneuronal interneurons that comprise the burst generators: the Av branch supplies an area that houses ►vertical medium lead burst neurons (VMLBs), while the PDB branch supplies an area that houses ►horizontal ones (HMLBs). In this manner, each TLLB can simultaneously influence both the vertical and the horizontal burst generators. Also, the commissural collaterals of TLLBs could couple the two colliculi in a push-pull fashion so that saccades in opposite on-directions are not programmed simultaneously. This is consistent with the observation that cells of the feline SC, which burst before saccades in one direction, are inhibited during saccades in the opposite direction [7]. Finally, as discussed in the entry ►SC – sensorimotor integration, the plexus of recurrent connections deployed by TLLBs could ensure the reciprocal excitation of neighboring TLLBs and give rise to their intense bursts.

## Higher Order Function

As different TLLBs encode different saccade vectors, the SC can be thought to implement a labeled line code. Moreover, TLLBs are topographically organized over the mediolateral and rostrocaudal extent of the SC, such that cells preferring small saccades are located in the rostral SC, while cells that prefer big saccades are located more caudally. Also, cells that discharge before upward saccades are located medially in the SC, whereas cells that discharge before downward saccades are located laterally [4]. It is for this reason that the SC is said to also use a place code to specify movement parameters. Adoption of a code generally preferred by sensory systems (the "place" code), provides an elegant biological solution to the problem of how to interface the front end of the saccadic system (the motor SC) with systems carrying sensory information about outside world events.

## Quantitative Measure for this Structure

The appearance of the class of primate collicular efferent neurons (T neurons) to which TLLBs belong has been the object of detailed quantitative analysis [8]. Besides providing information about the range of values obtained by several morphological features (e.g. 3-D orientation of their dendritic tree, complexity of its branching pattern, etc.), this analysis allowed the formulation of canonical discriminant functions that can objectively discriminate T neurons from other classes of collicular efferent cells. Moreover, there is some quantitative information regarding the differential strength of descending projections of intraaxonally labeled TLLBs to several of their target nuclei [5]. Due to the important role it could play in the generation of TLLB bursts, the spatial distribution of the boutons they deploy inside the SC has also attracted quantitative attention. Figure 4a illustrates the spatial distribution of the recurrent terminal field of one TLLB that was intraaxonally injected with HRP following its functional identification in an alert behaving squirrel monkey [9]. As shown here, TLLB recurrent projections (plotted in the inset of $w_{(TLLBi \rightarrow TLLBj)}$ versus i–j; Fig. 4b) cover a considerable proportion of the ipsilateral SC, and are spatially distributed in a bi-lobe fashion centered around the cell body they originate from. Such information has been used to generate a computational model of the SC, (schematically illustrated in Fig. 4b) that accounts for several counterintuitive results [9]. Firstly, it accounts



**SC – Tectal Long-Lead Burst Neurons. Figure 4** (a) Horizontal spatial distribution of terminals deployed in the deeper layers of the primate SC by a single functionally identified TLLB that was intraaxonally injected with HRP (reproduced from [9], with permission). Colors range from dark to light in proportion to the small or large number of boutons deployed in the corresponding point of the horizontal map of the SC. The yellow line is a plot of the number of boutons (*ordinate*) within 80 μm of a plane through the soma and normal to the SC surface as a function of the rostrocaudal distance from the soma (*abscissa*). (b) Model of distributed population coding of saccade metrics in the motor layers of the SC (modified from [9], with permission). Solid lines indicate excitatory connections.

for the fact that simultaneous electrical stimulation of two collicular sites generates saccades equal to the average of the saccades that are generated when the two sites are stimulated separately, rather than to their sum. Further, it provides an intuitive understanding of why this is so, in that the spatial distribution of its engaged TLLB units shifts to a site intermediate between those activated when the two sites are stimulated separately. It also accounts for the fact that saccades can be hypermetric as well as hypometric after lesions of the superior colliculus (Fig. 4c), and demonstrates that the spatiotemporal profile of TLLB activation shifts in the requisite manner depending on the relative location of the stimulus and lesion sites (Fig. 4d–g). Finally, it accounts for the generation of staircases of saccades in response to long trains of constant stimulation, thus implying that the superior colliculus contains a biological oscillator. Evidence consistent with the involvement of a recurrent network of mutually excited TLLBs in burst generation is considered in the entry SC – sensorimotor integration. The same entry also includes a description of quantitative estimates of the spatial distribution of *boutons* deployed by efferent neurons of the SC in regions housing the burst generators and their implications for the "spatio-temporal transformation."

# SC – Tectoreticulospinal Neurons

Alexej Grantyn
Laboratoire de Physiologie de la Perception et de l'Action (LPPA), CNRS – Collège de France, Paris, France

## Synonyms

X neurons, TRSNs

## Definition

"Tectoreticulospinal neurons (TRSNs)" are large or medium-size superior colliculus (SC) ►projection neurons. Their long axons cross the midline in the dorsal tegmental decussation, descend in the ►predorsal bundle (►tectobulbospinal tract) and make extensive connections with the midbrain, pontobulbar ►tegmentum (Midbrain, Pontobulbar) and the spinal cord by virtue of multiple axon collaterals. TRSNs are a subset of a larger class of the SC projection neurons, called "X neurons" [1] (Figs. 1 and 2).

## Characteristics

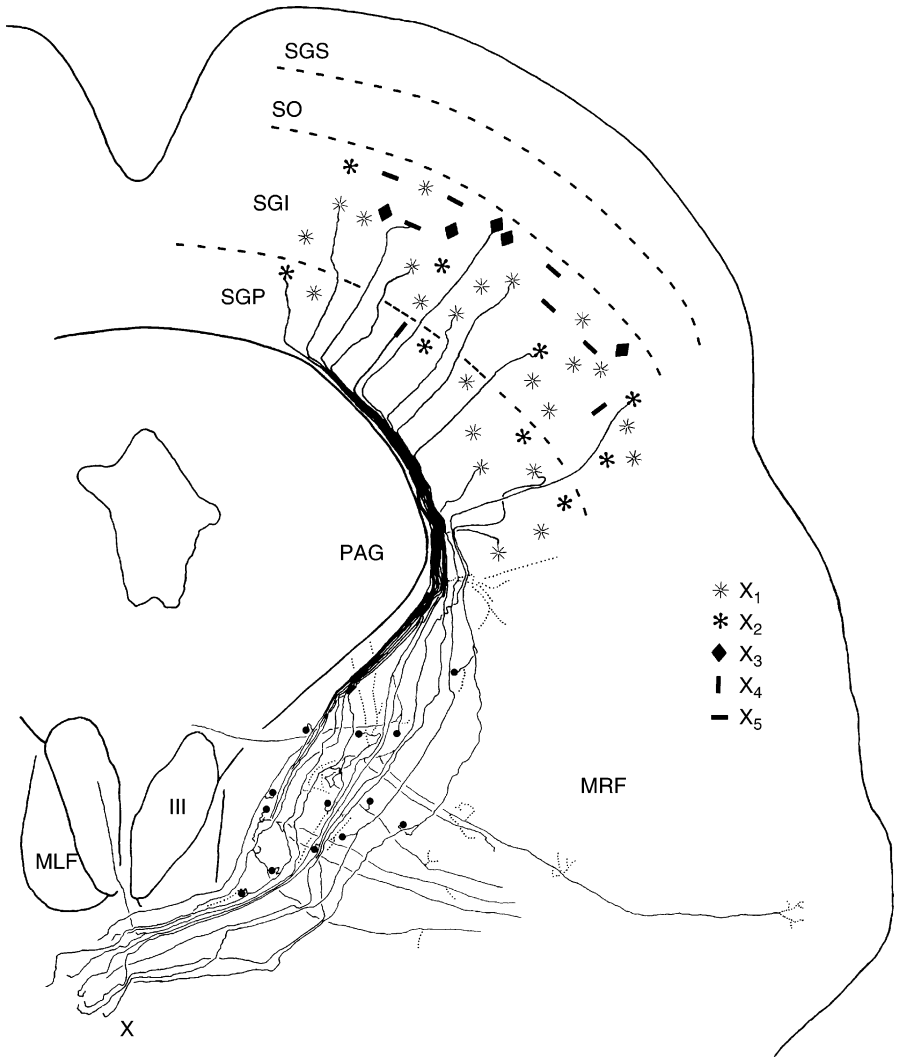
### Higher Order Structures

#### *The Superior Colliculus: An Overview*

Cell bodies (somata) of TRSNs are located in the deep division of the SC, a laminated structure (Fig. 1)

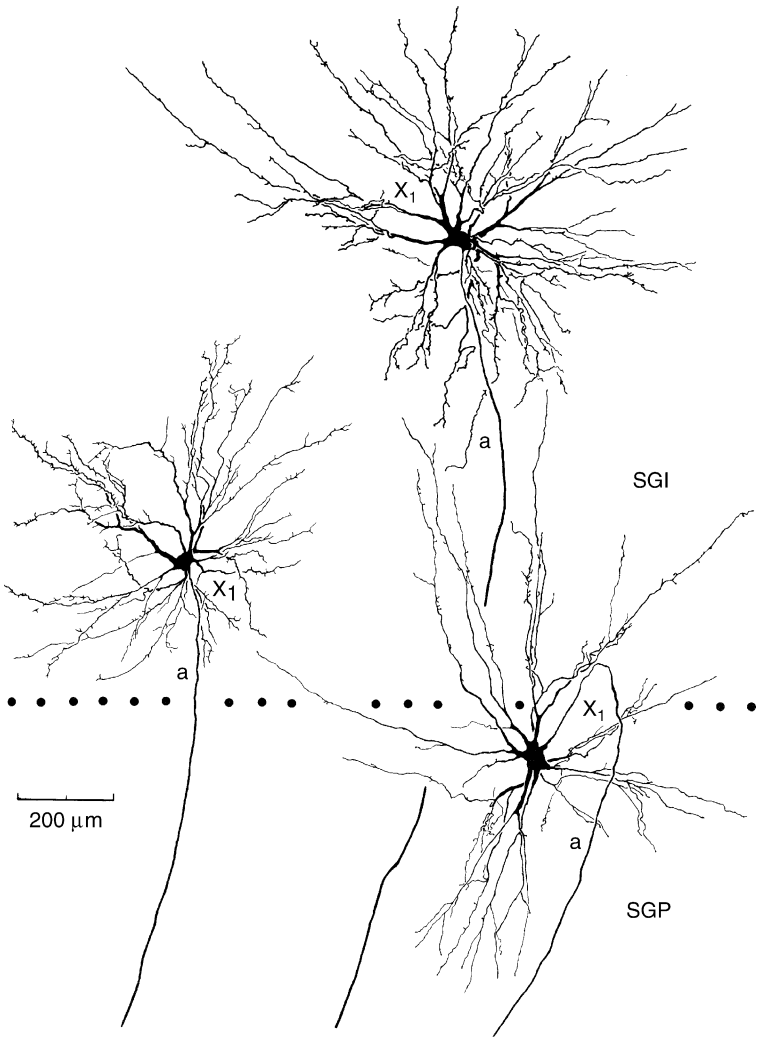
All other connections are inhibitory. Numbers indicate connection strengths. Insets indicate spatially varying connection strengths (w), plotted as a function of the location of source (i), or the target (j) neurons within their respective arrays, or in terms of the distance between them (i–j). (c) Two examples of saccades produced before (blue) and after (red) simulated focal TLLB "lesion" experiments in response to activation of the same Qv unit. (d–g) Gray scale contour plot of the spatio-temporal profile of all TLLB units employed in the model as a function of their index (*abscissa*) and time (*ordinate*) for saccades evoked from a normal (d and f) or a "focally lesioned" (e and g) SC. Small index numbers correspond to rostral SC sites and big index numbers correspond to caudal SC sites. The gray scale is proportional to the Logarithm of the TLLB activation function. In (d) and (e), the stimulation point (*arrowheads*) is rostral to the lesion (x), while in (f) and (g), the stimulation point is caudal to the lesion. Abbreviations: *BG*, burst generator; *C*, caudal; *L*, lateral; *M*, medial; *Mn*, motoneuron; *NI*, neural integrator; *R*, rostral; *SNR*, neuron of the substantia nigra pars reticulata that pauses for saccades; *Qv*, quasivisual neuron; *TLLB and tllb*, excitatory and inhibitory tectal long-lead burst neurons.

S



**SC – Tectoreticulospinal Neurons. Figure 1** Tracing of a representative coronal section through the midbrain to show the location of the superior colliculus, its principal layers, and the distribution of different subclasses of X neurons ($X_1 - X_5$, as indicated by symbols in the *inset*). Also shown are the initial axon trajectories till the decussation and proximal axon collaterals supplying the central mesencephalic reticular formation. (from [1], with permission of the Authors and Wiley & Sons, Inc.). Abbreviations: *MLF*, medial longitudinal fasciculus; *MRF*, mesencephalic reticular formation; *PAG*, periaqueductal gray substance; *SGS*, superficial gray layer; *SO*, optic layer; *SGI*, intermediate gray layer; *SGP*, deep gray layer; *X*, dorsal tegmental decussation; *III*, oculomotor nucleus. The fiber rich intermediate white layer in the lower SGI and the deep white layer in the lowermost SGP are not labeled. The latter can be recognized as the site of collection of outgoing X neuron axons on their course along the border of the periaqueductal gray.

occupying the anterior portion of the roof of the midbrain, the tectum. Its superficial layers (SGS, SO, Fig. 1) receive a direct pathway from the retina and contain a topographic map of the contralateral visual hemifield. The deeper SC is subdivided in the intermediate and deep layers (SGI, SGP, Fig. 1), which differ in their cell composition and afferent connections. Common to them is the convergence of afferent pathways from a great number of sources, including both higher order structures, such as the cerebral cortex and basal ganglia, and ascending sensory pathways. Besides their well established role in the ►visuomotor transformation, the deeper layers are thus also the site of ►multisensory (convergence, integration). Besides neurons with local connections inside the SC, all layers contain projection neurons which form several pathways with different trajectories and different combinations of target regions. TRSNs are one of the classes of projection neurons. They send their axons in the predorsal bundle and establish the most extensive extrinsic connections.



**SC – Tectoreticulospinal Neurons. Figure 2** Reconstruction of somatodenritic profiles of HRP-labeled $X_1$ neurons. These exemplary neurons illustrate common features of $X_1$ subclass (large dendritic extension, central position of the cell body with respect to radially oriented dendrites, approximately symmetrical dendritic field). Also the range of variation of soma size and dendritic extension can be readily recognized. See Table 1 for a summary of morphometric data. (from [1], with permission of the Authors and Wiley & Sons, Inc.).

S

## *Morphology of TRSNs*

### *Laminar Location*

A majority (66% [2] to 73% [1]) of TRSN cell bodies are located in the intermediate gray layer of the SC (SGI), the remaining ones being found in the deeper layers (Fig. 1). They are distributed over the entire rostrocaudal and mediolateral extent of the SC, but their density is somewhat higher in the caudolateral quadrant. The complete ►motor map of the SC can therefore gain access to the downstream areas contacted by TRSN axons, with some bias in favor of the representation of the lower half of the visual field.

### *Size and Dendritic Pattern*

X neurons (see Definition "Tectoreticulospinal Neurons (TRSNs)") intracellularly labeled with ►horseradish peroxidase (HRP) have been subdivided in five subclasses ($X_1$–$X_5$), based on the size of cell bodies and the shape and orientation of the dendritic trees [1]. Some morphometric data underlying the classification are summarized in Table 1 (see ►Quantitative measures). The first three subclasses ($X_1$–$X_3$) comprise medium-size and large cells, and correspond best to TRSNs identified by their crossed projection to the lower brainstem and to the spinal cord, and by their firing patterns during ►orienting movements [2,3]. Smaller neurons ($X_4$, $X_5$) with vertically or horizontally oriented dendritic trees are unlikely to be present in the TRSN population. Judging from their spherical dendritic fields, a great majority of TRSNs belong to the $X_1$ subclass (Fig. 2), characterized as "large multipolar wide field neurons" in preceding studies with

Golgi method in the cat. Typically, they have 5–10 stem dendrites arranged radially and occupying an approximately spherical space of considerable size (800–1,400 µm) (Table 1). Distal portions of dendrites often cross the borders of collicular layers, which explains the capacity of TRSNs to sample and integrate ascending, descending and interlaminar inputs to the deeper layers of the SC.

## Parts of this Structure

### Main Axons, Axon Collaterals and Termination

Morphometric data on TRSN fiber system are summarized in Table 2 (see ►Quantitative measures). To-date, only a qualitative description of target areas is available for midbrain portions of TRSN axons [1,2]. In the pontobulbar tegmentum, the anatomical strength of connections could be evaluated for a few orienting-related TRSNs [3]. These data are collected in Table 3.

#### Midbrain

Axons of TRSNs, at their exit from the SC, range 3–8 µm in diameter but more than 90% are thicker than 4 µm. They course along the border of the periaqueductal gray substance (PAG) (Fig. 1), cross the midline and join the contralateral predorsal bundle (PDB). Before crossing, all TRSNs emit a long "main ascending collateral" that goes rostrally and reaches the field of Forel (FF) and the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). TRSNs have no recurrent collaterals terminating in the SC but they do issue several ipsilateral collaterals which supply with terminals the central mesencephalic reticular formation (cMRF) (Fig. 1). Other tegmental regions are "facultative" targets of TRSNs, supplied by some but not all TRSNs. The supraoculomotor region of the PAG receives projection from about one third of TRSNs, whereas collaterals terminating in the interstitial

nucleus of Cajal (INC) are rare and no terminations have been traced in the oculomotor nucleus. Some fibers enter the nucleus of the posterior commissure (NPC) and other pretectal nuclei. From the functional point of view, it is important to note that all cells of this class project not only in the contralateral PDB but also to midbrain regions containing the vertical saccade generator (riMLF, INC, NPC), some intermediate circuits involved in horizontal saccades (cMRF, supraoculomotor PAG), and neurons projecting to the spinal cord and participating in the control of ►head movements in the vertical plane (FF).

### *Pons and Medulla*

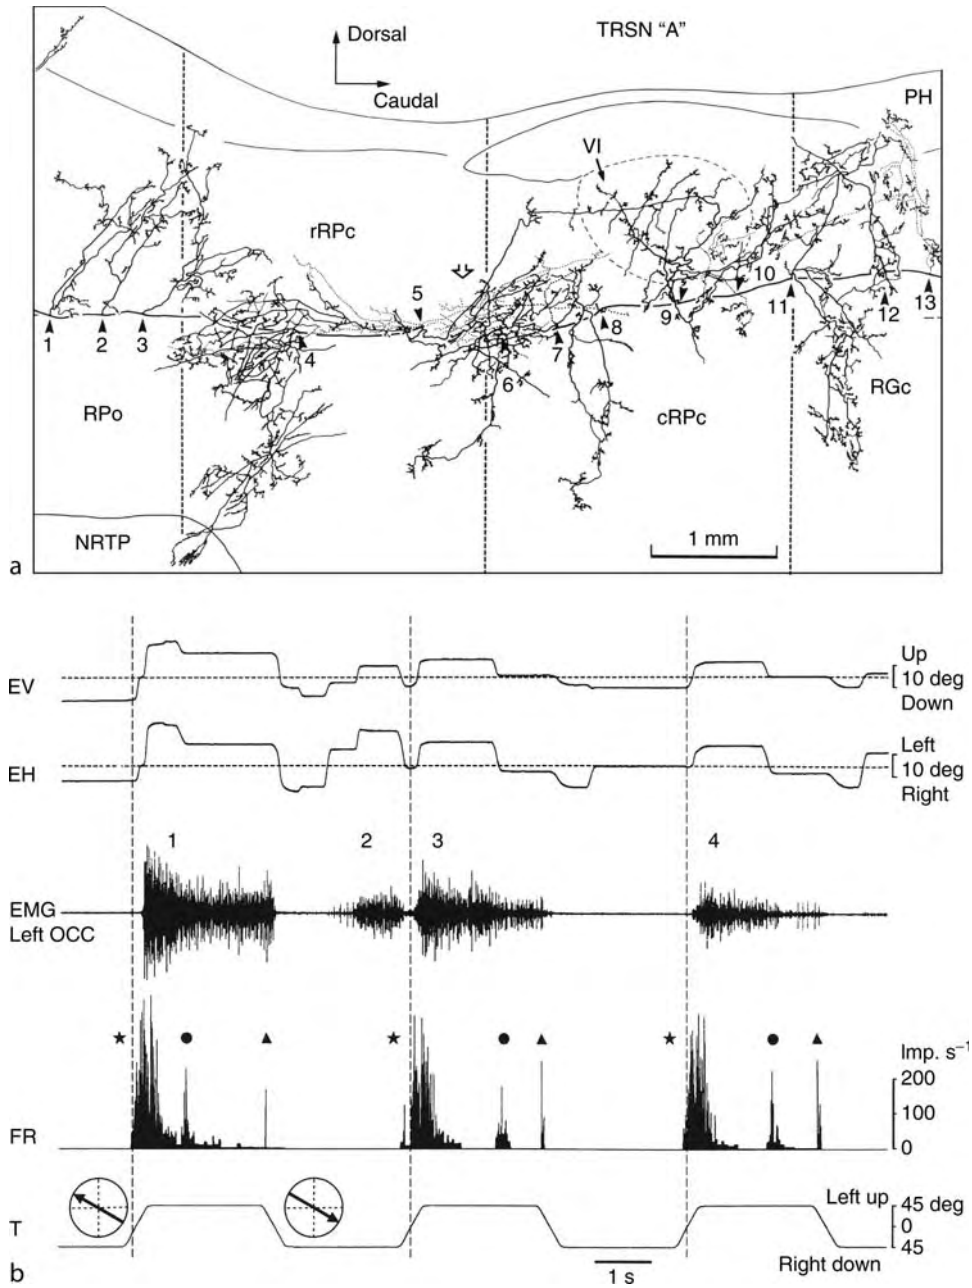
"Visuomotor TRSNs" (vm-TRSNs, see below) labeled by intra-axonal HRP injections [3,4] have axons of 4.6–9.3 μm in diameter. Collaterals are issued at all levels of the pons and medulla at variable inter-collateral distances, but their branching domains usually overlap along the longitudinal axis of the brainstem tegmentum (Table 2). The neuron illustrated in Fig. 3a is representative because the regions of its densest ramifications correspond to common terminal regions of all studied vm-TRSNs. The first of them (collateral 3 and 4) is in the rostral pole of the caudal pontine reticular nucleus (RPc), with a denser innervation of its central portion. The second (collaterals 5–8) is just rostral to the AbdN. The third one (collaterals 9, 10) corresponds to the caudal extremity of the dorsal RPc, where the terminations of vm-TRSNs become particularly dense near the border of the AbdN before entering in this nucleus as well. In the medulla, axons of vm-TRSNs ramify and terminate in the gigantocellular reticular nucleus (RGc) (e.g., Fig. 3a, collaterals 11–13). Superposition of terminal domains makes it clear that, taken together, vm-TRSNs make connections with the entire medial reticular formation in the pons and in the rostral medulla. Besides this termination domain in common, individual neurons make selective connections with some but not other areas. Among such facultative targets are the precerebellar nucleus reticularis tegmenti pontis (NRT), nucleus prepositus hypoglossi (PH) and the motor nucleus of the facial nerve (VII). The strength of projections to the areas containing excitatory and inhibitory ►burst neurons (Saccadic, Excitatory, Inhibitory) of the ►horizontal saccade generator also differs between the vm-TRSNs (Table 3). Differences in local connection strengths between TRSNs may suggest that they fulfill specialized tasks in the selection of neural populations controlling different moving segments, e.g., eyes, head, spine and limbs, during complex orienting movements (synergies).

### *Spinal Cord*

Compared to pontobulbar axons of vm-TRSNs, spinal portions of axons, presumably originating from X neurons, have sparser collaterals and a smaller number of boutons per collateral in the spinal grey of C1 and C2 segments [6]. Although terminals in the motor nuclei of neck muscles have been previously reported, no terminations of X neurons have been found on retrogradely labeled motoneurons [6]. This latter study demonstrated an indirect connection through interneurons in the laminae V–VIII. Some electrophysiological studies affirmed, others denied, a direct SC connection with neck motoneurons, so that the question remains unresolved [5]. There is a general agreement, however, as to a powerful disynaptic tecto-reticulo-spinal connection through the caudal pontine (RPc) and rostral bulbar (RGc) reticular formations, as well as through spinal segmental interneurons.

### *Summary*

Connections of individual TRSNs in the brainstem are very extensive, suggesting, at a first glance, a fairly unspecific function. On the other hand, when regarded



**SC – Tectoreticulospinal Neurons. Figure 3** Axonal morphology and discharge patterns of a "visuomotor" TRSN recorded and labeled in alert cat. *A*, Reconstruction in the parasagittal plane of axon collaterals in the pons and in the rostral medulla. Open arrow indicates the point of intraaxonal HRP injection. Quantitative data on terminations within three segments of the pontobulbar tegmentum (vertical interrupted lines) are presented in Table 3 (TRSN "A"). Abbreviations: *NRTP*, nucl. reticularis tegmenti pontis; *RGc*, nucl. reticularis gigantocellularis; *RPc*, nucl. reticularis pontis caudalis (*r*, rostral; *c*, caudal halves); *RPo*, nucl. reticularis pontis oralis; *VI*, abducens nucleus. (1993), Multisensory Control of Movement, Oxford University Press, pp. 185–200, with permission). *B*, Discharge pattern of the same neuron during tracking of a moving target. From *top to bottom*: vertical (EV) and horizontal (EH) eye position, electromyogram (EMG) of the left m. obliquus capitis cranialis (OCC), instantaneous firing rate (FR) of the neuron and position of the target (T). *Insets* show the direction of target motion. Stars: "visuomotor" bursts during target motion in the neuron's preferred direction, associated with tracking saccades, slow drifts (event 4) and neck muscle contractions. Vertical interrupted lines are drawn through the onset of high frequency firing before the saccades. Note weaker bursts of visual origin during return saccades (*circles*) and at the onset of target motion in the direction, opposite to the preferred one (*triangles*). Event 2 demonstrates the absence of discharge during spontaneous gaze shift in the preferred direction of the neuron. (Modified from [5], with permission).

as a population, they supply with terminals all areas known to harbor premotor neurons controlling eye and head movements toward the contralateral visual field. In the lower brainstem, terminals are distributed to the regions of long-lead and medium lead excitatory burst neurons of the horizontal saccade generator (RPc). Caudal RPc and RGc contain reticulospinal neurons (RSNs) controlling horizontal head movements, and strong monosynaptic connections of TRSNs to such cells have been proven by intracellular recordings (►intracellular labeling). In the midbrain, TRSNs distribute terminals in the region of the vertical saccade generator (riMLF) and in the field of Forel, the site of location of RSNs controlling vertical components of head movements. TRSNs contact directly not only premotor areas but also motor nuclei participating in orienting movements. Monosynaptic excitatory effects of TRSNs on abducens (eye muscle), facial (ear muscles) and neck motoneurons are admittedly weak. Nevertheless, it is worth underscoring such a divergence to motor nuclei, all participating in complex orienting synergies, but very different according to biomechanical properties of moving organs (effectors) they control.

## Higher Order Function

### *The Role of the Superior Colliculus in the Control of Gaze Shifts–An Overview*

The role of TRSNs is to transmit output signals of the SC to premotor structures of the brainstem tegmentum. The SC is commonly referred to as a subcortical "center" controlling orienting movements. Under orienting movements we understand rapid ►gaze shifts toward novel or otherwise biologically significant events in the surroundings. Under natural conditions, such changes of gaze direction are achieved by coordinated saccadic movements of the eyes and rapid head movements. When large gaze displacements are required, movements of the trunk and of extremities do participate in orienting synergies. The most studied function of the SC consists of providing an output signal specifying the desired direction, amplitude and, to some extent, the speed of gaze shifts. These parameters are encoded in the location of the active population of SC output neurons with respect to coordinates of the motor map, as well as in the size and the level of excitation of the population. For a detailed description of neural processes underlying the control of gaze by the SC see ►SC – Role in eye movements, ►SC-Motor map, ►SC-Sensorimotor integration.

### *Physiology of TRSNs*

#### *Visuomotor Properties*

Typical activity pattern of a morphologically identified (Fig. 3a) visuomotor TRSN (vm-TRSN) [3–5] is shown in Fig. 3b. This TRSN generated the strongest activity during ►tracking of a target when it moved in the direction, opposite to the side of the cell's location in the SC. Preferred directions of other TRSNs are usually within 50–60° from horizontal, but a few cells respond stronger to nearly vertical target motion. The earliest portions of the bursts (Fig. 3b, stars) are visual responses to the target, when it is close to entering the contralateral visual hemifield. Increments of the spike rate to 150–200 $s^{-1}$ precede first tracking saccades by about 100 ms but bursts continue beyond the saccade ends. They often coincide in time with sequences of saccades (Fig. 3b, event 1) or post-saccadic slow eye movements (e.g., Fig. 3b, event 4). Burst duration is similar to the duration of the dynamic component of the electromyogram (EMG) of neck muscles participating in an attempted head movement.

Discharge characteristics of vm-TRSNs, illustrated by an individual example of Fig. 3, vary in a broad range. Bursts start in advance of the onsets of gaze movement or EMG activation with lead times as short as 30 ms in some neurons and as long as 200 ms in others. Some cells generate bursts of relatively short duration (50–400 ms) and terminating before the end of eye saccades, others are able to generate sustained bursts in the range of 0.5–2.0 s. Temporal relationships of bursts with motor events of different duration (saccades, slow eye movements, activation of neck EMG) differ accordingly. Firing rate within the bursts is maximal in association with saccades in the neuron's preferred direction and, particularly, when movements are very fast, as it happens when the level of the animal's motivation for visual "capturing" of the target is high. However, the maximum firing rates vary considerably among vm-TRSNs (100–500 imp $s^{-1}$), even when tested in neuron's optimal behavioral conditions. The differences in burst durations, spike frequency during visuomotor bursts, and the probability of neuron's recruitment during the movement can be explained by the differences in membrane excitability of TRSNs [7].

The above description, based on experiments on cats with immobilized heads, is in perfect agreement with the results obtained in head-free cats [8,9]. The study clearly demonstrated the contribution of TRSN discharges to the generation of eye and head components of the orienting synergy. In particular, there exists a tight temporal coupling between increments of the firing rate and accelerations of eye (delay 10–12 ms) and head (delay 24–32 ms) movements. Using stationary instead of moving targets for orienting, Munoz and coworkers [9] were able to further analyze spatial properties of movement-related TRSN discharges. They found that maximal firing rates are always associated with a particular vector of gaze shifts, corresponding to the optimal ►gaze motor error (of a

neuron). However, all neurons will produce some firing for smaller or larger gaze displacements. Besides burst-like (phasic) movement-related discharges, about 75% of TRSNs generate sustained discharges during preparation of gaze shifts toward the location in space roughly corresponding to the location of neuron's visual receptive field. The size of the field is large (up to 70° horizontally and 40° vertically). The strongest preparatory firing is observed when target location corresponds to the optimal gaze motor error (►Gaze Motor Error-Static) of the neuron.

#### *Multisensory Properties*

Practically all TRSNs tested in alert animals with visual, auditory and somesthetic stimuli display a multisensory convergence [8,10]. Visual responses to stationary targets have mean latencies of 50–95 ms, but the majority of neurons respond at less than 60 ms. Such responses usually consist of a few spikes, and they are weaker than responses to moving targets. Different sensory modalities interact on TRSNs in a complex way. Although the most consistent excitatory effects are provided by vision, via the retinotectal connections, auditory and somesthetic modalities can enhance or suppress visual responses, depending on the spatial coincidence or disparity of the stimulus sources in the surrounding space. Such interactions are considered as a part of the processes underlying the selection of targets for orienting movements [10].

#### *Summary*

TRSNs identified both by morphological and by behavioral criteria in head-fixed cats have the following properties: (i) Broad spatial tuning of visual and movement-related discharges; (ii) Responsiveness to sensory stimuli of different modalities and a superposition of sensory (predominantly visual) and motor components in their bursts; (iii) Unequal capability to generate high frequency firing; (iv) Broad range burst durations, such that discharges of some neurons coincide in time with saccades only, while discharges of other neurons can contribute to all dynamic components of orienting synergies (saccades, slow eye drifts and contractions of neck muscles); (v) Nonobligatory association of vm-TRSN bursts with gaze shifts: they discharge only when the animal moves its gaze toward an object of its choice, but not during scanning gaze movements across a uniform visual background or in darkness. They also generate visual responses when a moving target is neglected and not tracked. By their location on the collicular motor map, TRSNs encode the gaze motor error and they also contribute to the control of dynamic parameters of both eye and head movements (►eye-head tracking). Considering the behavioral properties of individual TRSNs, their function should be defined as a fairly generalized facilitation of premotor extracollicular circuits, whose activation is required to realign the head and the eyes to a relatively large albeit circumscribed area of the environment. This conclusion is well corroborated by the broad divergence of TRSN projections to the brainstem tegmentum. More specific functions of individual TRSNs are suggested by anatomical data, such as regional differences in the strength of connections and differences in patterns of multisensory integration. This aspect of "specificity" has, however, not been sufficiently studied.

## Quantitative Measure for this Structure

### *Cell Bodies and Dendrites*

Table 1 presents a selection of morphometric characteristics compiled from references [1,2]. TRSNs and X neurons have similar trajectory and branching patterns of axons in the midbrain, but the definition of TRSNs is further restricted by adding an identified descending projection to the lower medulla and to the spinal cord. According to their size (As) TRSNs are well comparable to $X_1$–$X_3$ neurons. It should be noted that $X_2$ and $X_3$ neurons have a vertical orientation of dendritic fields, whereas radially symmetrical fields have only been reported for TRSNs. The available sample of completely reconstructed TRSNs is, however, smaller than that of X neurons, and it is premature to affirm that all of them belong to the $X_1$ subclass. On the other hand, all X neurons, including TRSNs, can be clearly distinguished from another class of SC neurons projecting in the PDB, the T neurons [1]. Firstly, T neurons are of consistently smaller size and, secondly, they emit recurrent collaterals passing to the opposite SC in the collicular commissure. Such collaterals have not been observed, either on X neurons or on TRSNs.

### *Axons and Axon Collaterals*

Table 2 summarizes quantitative data on axons and collaterals of TRSNs [2,3]. A broader range (3.0–8.0 μm) has been reported for the whole population of X neurons [1], but the thinnest axons (3.0–4.5 μm) were not observed among TRSNs. An HRP study of TRSN axons in the pontomedullary region of anesthetized cats suggested an increase of axon diameters on their descending course to the spinal cord [2]. The range of behaviorally identified visuomotor TRSNs also includes, however, smaller diameters. Conduction velocities of TRSN axons between the SC and the pons are in the range of 35.7–57.2 m $s^{-1}$ whereas the range of ponto-spinal portions of axons is broader (39.0–80 m $s^{-1}$). Axon diameters and the related parameter, conduction velocities, are appropriate for a rapid and fairly synchronous transmission of spike volleys to target areas separated by long distances. Intracellular recordings have indeed demonstrated that minimal latencies of synaptic responses to SC stimulation are

0.5–1.0 ms in the pontine reticular formation neurons, 0.8–1.0 ms in abducens motoneurons and 1.4–1.6 ms in motoneurons of neck muscles in the upper spinal segments.

The presence of axon collaterals along the total length of main axons is common to all TRSNs. The richness of the collateralization varies between individual neurons, as shown in Table 2 by the numbers of collaterals issued over axon segments of a comparable length. Although some inter-collateral distances are quite long, termination domains of successive individual collaterals show practically no gaps. This is due to a great antero-posterior extension of collateral trees formed by second and higher order branches. The number of terminals issued by each collateral is variable and depends on the profuseness of branching which, in turn, is related to the diameter of collaterals at their origin.

### *Topographic Distribution of Terminal Boutons in the Pontobulbar Tegmentum*

The numbers of terminals and, in particular, their regional densities serve as a measure of the anatomical strength of connections. To obtain reliable data, the labeling of collaterals must be complete, i.e., one should be able to identify terminal boutons on all preterminal fibers. Table 3 shows bouton counts from three behaviorally identified vm-TRSNs [3]. To satisfy the above criterion of labeling quality, only a limited length of axons has been used for counts. Similar data are not available for the midbrain portion of TRSN axons.

Table 3 includes three well known areas involved in the control of saccadic eye movements which represent common targets of TRSNs. It can be seen that, in spite of considerable differences in local bouton numbers, their densities in the area of excitatory saccadic burst neurons are consistently higher than over the total innervation domain at the same brainstem level. It is not so in the case of the Abducens nucleus for which only TRSN "A" shows a high selectivity while it is small for TRSN "K", and absent for TRSN "S". Finally, TRSN "S" is the only one showing an over-proportional density of terminations in the region of inhibitory saccadic burst neurons.

# SC – Visually Triggered Movement Cells

Robert H. Wurtz
Laboratory of Sensorimotor Research, National Eye Institute, National Institutes of Health, Bethesda, MD, USA

## Definition

Visually guided saccades (►saccade, ►saccadic eye movement) are those rapid eye movements that direct the eye to a visual target. This is in contrast to saccades occurring under other conditions, such as those made without any overt target termed spontaneous saccades or those made to targets that are no longer present, which are referred to as memory guided saccades. Neurons in the brain of a monkey that are active *only* when the saccade is made to a visual target that is present in the field of view are visually triggered movement cells. Neurons of this type were first identified in the ►superior colliculus (SC) and study of them has concentrated on that structure.

## Characteristics

### Higher Order Structures

The inputs to the superior colliculus that could contribute to the activity of the visually triggered

movement cells include large regions of cerebral cortex, but several areas in particular have neuronal responses to visual stimuli and increased activity before saccadic eye movements [1]. Neurons in the lateral intraparietal area of parietal cortex have strong responses to visual targets for saccades and are modestly active before saccades, while neurons in the frontal eye field area of frontal cortex have both visual responses to targets and clear bursts of activity before saccades. For the visually triggered movement cells in the superior colliculus, it may well be the nature of the visual activity in the cortex that is most important for understanding their function. Both cortical areas have strong direct projections to the superior colliculus, and the frontal eye field has an indirect pathway through the basal ganglia.

## Parts of This Structure

The superior colliculus has multiple layers including the superficial layers in which all of the neurons have visual responses, and the intermediate layers in which the neurons have not only visual responses but many also have a burst of activity preceding the saccadic eye movement [2]. The visually triggered movement cells lie in the intermediate layers and generally have both increased activity in response to the stimulus and the burst of activity before the onset of the saccade.

## Functions of This Structure

The visually triggered movement cells were first identified by comparing their activity when the monkey made a saccade to a visual target, with the activity before a saccade of the same amplitude and direction made in total darkness [3]. The visual response was of course absent in the dark, but the burst before the saccade was also absent even though the saccade in the dark and the saccade to a visual target were nearly identical. Such an absence of presaccadic bursts of activity were subsequently seen in experiments in which the monkey made a series of two saccades [4], or in which it made an anti-saccade away from a visual target [5]. More recently, the role of the visual target has been investigated systematically, and the presence of a visual target was found to alter the presaccadic burst of many collicular neurons [6]. In these tasks, monkeys made saccades to visual targets, to the location of remembered visual targets, and to locations where the targets had not appeared at all (a task referred to as the anti-saccade task). What these experiments showed was that the collicular neurons fell along a continuum, from those at one end that only showed the burst of activity before saccades to visual targets to those at the other end where the burst was the same whether or not the saccade was to a visual target. The visually triggered movement cells were simply those lying at one end of a continuum, not a unique class of neurons. It should be emphasized that this effect of the visual target was independent of the intensity of the visual response of the neuron; weak visual responses could be followed by strong potentiation of the burst before the saccade. The strength of the visual effect on the presaccadic burst tended to decrease over several hundred milliseconds after the visual target had disappeared. Even though the velocity of the saccades in the absence of a visual target is lower, this variable did not fully account for the reduced presaccadic burst in the absence of the visual target. In net, the presence of the visual target seemed to have an effect on the vigor of the presaccadic burst that was second only to the effect of the amplitude and direction of the saccade to be made. Furthermore, at the same time as the presence of a visual target increased the presaccadic bursts, the presence of the target also reduced the scatter in the saccadic end points around the target, which is consistent with a contribution of the increased bursts to the greater precision of the saccades to visual targets.

## Higher Order Function

The superior colliculus is a homologue of the optic tectum found in other vertebrate animals, and across species these structures are clearly related to the control of eye and head movements. As the eyes are shifted to more frontal positions in the head and the high resolution fovea develops in the retina, the need for greater precision in directing saccades to visual targets becomes more critical for the animal's survival. It has been suggested [6] that the enhanced burst of activity in the superior colliculus that accompanies saccades to visual targets is part of this adaptation for greater precision in the visual guidance of saccades.

## Quantitative Measure for This Structure

Progress on the nature of the effect of the visual stimulus on neuronal activity has been made possible by the use of tasks that separate out the variables that alter the neuronal activity. A second critical factor in studying the awake monkeys results from the accurate recording of movements using the magnetic search coil method, which gives precise indication of eye position, velocity, and acceleration. The entire experiment is controlled by online computer systems that also collect and store all the data from the experiments.

# Scaffold Protein

Yutaka Hata, Junko Iida
Department of Medical Biochemistry, Graduate School of Medicine, Tokyo Medical and Dental University, Tokyo, Japan

## Synonyms

The words "adaptor" and "linker" are sometimes used to mean a scaffold protein; Although scaffold proteins have more varied functions than adaptor and linker

## Definition

Scaffold proteins are proteins that simultaneously bind two or more other proteins, and organize binding partners into a functional unit to enhance signaling efficiency and fidelity.

Signaling molecules interact with each other to form large complexes, and most of those complexes do not diffuse in the cytoplasm, but rather are attached to cell membranes. The complex is called signalsome or transducisome. Among components of a signalsome, a protein that binds to more than one protein and has no enzymatic activity is defined as a scaffold protein, because the primary function of such a molecule is to provide other components with a framework on which they efficiently work.

## Characteristics

### Higher Level Structures

As biological signals come from outside a cell, many signalsomes are localized under the plasma membranes with receptors for the external signals. In the field of neurobiology, scaffold proteins at synapses are the most extensively studied. However, scaffold proteins can also form signalsomes in other subcellular structures including the nucleus, the Golgi apparatus, mitochondria, and centrosome.

### Lower Level Components

Scaffold proteins are composed of multiple protein modules. Modules are compact folded portions of proteins with 30–200 amino acids that recognize short continuous peptide sequences in their binding partners. ►PSD-95/Discs large-A/ZO-1 (PDZ), Src-homology (SH) 2, SH3, WW, and phosphotyrosine binding, and guanylate kinase homologue domains are frequently recognized in scaffold proteins. Sterile alpha motif (SAM), WASP homology 1, ARM, and LIM domains are also detected in scaffold proteins. L27 and protein kinase A anchor domains are present in scaffold proteins binding to Lin-2/Lin-7 and protein kinase A, respectively. Scaffold proteins often have sequences involved in multimerization such as a coiled-coil domain and leucine-rich repeats. Furthermore, some scaffold proteins have short target motifs that bind to modules of other scaffold proteins.

### Structural Regulation

Alternative splicing is a source of diversity of scaffold proteins. Variants with different combinations of modules and motifs mediate distinct protein–protein interactions. Synapse-associated protein 97 (SAP97) has alternatively spliced insertions in the N-terminal domain, and in the region (HOOK domain) between the SH3 and the GK domains. The N-terminal insertions determine the ability of SAP97 to cluster potassium channels. The interaction of human Discs large (hDLG; human homologue of SAP97) with protein 4.1 depends on the insertion in the HOOK domain, and is involved in the localization of hDLG at cell junctions in epithelial cells. SAP97 with the same insertion is targeted to synapses in neurons, and delivers AMPA receptor subunit GluR1 to the cell surface. Posttranslational modifications also contribute to diversity and regulation of scaffold proteins. Phosphorylation regulates the interaction of the AMPA receptor subunit GluR2 with ►Glutamate Receptor Interacting Protein (GRIP) and PICK1. Phosphorylation by cyclin-dependent kinase 5 regulates the clustering (►receptor regulation, clustering) of PSD-95. Phosphorylation by calcium/calmodulin-dependent kinase II (CaMKII) induces synaptic targeting of SAP97. Palmitoylation is involved in synaptic targeting and interaction with ion channels of PSD-95 and localization at spine heads of GRIP. Axin needs sumoylation to activate c-Jun N-terminal kinase. Finally, activity-dependent polyubiquitination regulates the amount of scaffold proteins in neurons.

### Higher Level Processes

Scaffold proteins function in a wide variety of receptor, channel, and cell adhesion molecule signalings. Major research efforts by neurobiologists have been made to demonstrate that synaptic activity modulates protein-protein interactions mediated by synaptic scaffold proteins. For instance, activity-dependent phosphorylation of NMDA receptor subunit 2B disrupts the interaction with PSD-95. Activation of NMDA receptors induces

redistribution of A kinase-anchoring protein (AKAP) 79/150 through calcium signaling and F-actin organization. Studies on PSD-95 suggest that higher level processes may regulate the amount of scaffold proteins at translation and transcription levels. Estrogen stimulates translation of PSD-95. Activation of type I metabotropic glutamate receptors induces translation of PSD-95. Neuronal depolarization of spiral ganglion cells upregulates transcription of PSD-95 through neuregulin-1. Activity-dependent protein degradation also regulates the amount of synaptic scaffold proteins.

## Lower Level Processes

Scaffold proteins are involved in many biological processes including cell proliferation, apoptosis, endocytosis, and regulation of cytoskeletons. In neurons, scaffold proteins are involved in membrane traffic and endocytosis of neurotransmitter receptors, accumulation of synaptic components, and regulation of actin cytoskeleton. Researchers consider that scaffold proteins play roles through these processes in synaptogenesis and synaptic plasticity.

## Function

### *Function of Scaffold Proteins in Signaling*

Scaffold proteins form signalsome to enhance signaling efficiency, ensure signaling fidelity, increase signaling sensitivity, and coordinate different signaling pathways. These biological advantages of signalsome were first delineated for *Drosophila* INAD. INAD is a multivalent PDZ protein that functions as a scaffold in the phototransduction pathway. It assembles TRP, protein kinase C, and phospholipase C, and promotes signaling specificity and speed. The importance of scaffold proteins in mitogen activated protein kinase (MAPK) and cyclic AMP-dependent signalings is well documented.

#### *Scaffold Proteins in MAPK Pathway*

In yeast, Ste5 assembles components of MAPK including Ste11 (MAPK kinase), Ste7 (MAPK kinase), and Fus3 (MAPK) so that the kinases are efficiently activated. Another MAPK, Kss1, is also activated by Ste11 and Ste7. However, Ste5 only weakly binds Kss1, so that Fus3 is preferentially activated in response to pheromone. In other animals, Kinase suppressor of Ras (KSR) is a well-characterized scaffold in MAPK cascade. KSR has a multiple modular structure and binds many proteins, for example, Raf, MEK, ERK, and others. Although KSR has no kinase activity, loss-of-function studies in *Drosophila* and nematode indicate that KSR is a positive component of Ras/MAPK pathway. Gene targeting in mice supports that KSR is a requirement of the MAPK pathway in mammals. The connector enhancer of KSR (CNK) is a potential scaffold in MAPK pathway, and has SAM, PDZ, and pleckstrin homology domains and interacts with Ras, Raf, and Rassf1. Synapses have a neuronal isoform of CNK named MAGUIN/CNK2. MAGUIN/CNK2 interacts with Raf and is necessary for NGF-mediated MAPK signaling. Jun-N terminal kinase (JNK)-interacting proteins (JIPs) are scaffold proteins for JNK and bind JNK, MKK7 (MAPK kinase), and MLK (MAPK kinase) [1].

#### *Scaffold Proteins in cAMP Signaling*

As its name implies, AKAP family proteins anchor PKA at specific subcellular structures, and regulate the temporal and spatial organization of signalings mediated by PKA. AKAP79/150 directly binds to PSD-95 and SAP97 in neurons, and forms a PKA-containing macromolecular complex that is associated with NMDA and AMPA receptors. Moreover,AKAP79/150 binds PKA, PKC, and calcium/calmodulin-dependent phosphatase, and provides a platform on which different signaling pathwayscross-taf [2].

#### *Scaffold Proteins Associated with Membrane Receptors*

Scaffold proteins modulate receptor-dependent signaling in two ways: by clustering of receptors and through the assembly of signalsome physically associated to receptors. Scaffold proteins often cluster different categories of membrane proteins such as receptors, channels, and transporters. $Na^+/H^+$ exchanger regulatory factor (NHERF) binds to $\beta_2$-adrenergic receptor in an agonist-dependent manner and mediates the change of cellular pH after stimulation of adrenergic receptor. Likewise, synaptic scaffold proteins link different receptors. PSD-95 directly binds to NMDA receptors, and indirectly associates with AMPA receptors through its interaction with stargazin. NMDA receptors are also linked to metabotropic glutamate receptors by sequential interactions of PSD-95, GKAP/SAPAP, Shank, and Homer/Vesl. PSD-95 also links $\beta_1$-adrenergic receptor to NMDA receptors. GRIP binds AMPA receptors and Eph receptor kinases by different PDZ domains. Moreover, GRIP binds EphrinB, a transmembrane ligand for Eph, and LAR family of receptor tyrosine phosphatase *via* liprin-α proteins. Tamalin interacts with metabotropic glutamate receptors and $GABA_{B2}$ receptor. As tamalin was also identified as a GRIP-associated protein, it may interact indirectly with AMPA receptors. In Purkinje cells, Shank that is associated with metabotropic glutamate receptors through Homer/Vesl directly binds glutamate receptor delta2. Although it needs to be determined which interactions can occur simultaneously, synaptic scaffold proteins may form a functional unit composed of various membrane proteins on specific cell surface domains.

As receptor density affects receptor properties, scaffold proteins can directly modulate receptor functions by cluster formation. For instance, NEHRF and cystic fibrosis transmembrane conductance regulator (CFTR)-associated protein 70 both interact with CFTR, and

directly affect CFTR gating using tandem PDZ domains. In contrast, precise details of synaptic scaffold proteins on neurotransmitter receptors are not clear enough. NHERF binds platelet-derived growth factor receptor (PDGFR) and potentiates autophosphorylation of the receptor by oligomerization. PSD-95 induces clustering of ErbB4 and enhances ErbB4-mediated ERK signaling, although it is not shown whether PSD-95 affects autophosphorylation of ErbB4.

In addition to receptor-level regulation, scaffold proteins facilitate signal transduction through tethering signal molecules to physical proximity of receptors. β–Arrestin is a scaffold protein in G protein-coupled receptor (GPCR) signaling. The list of β-arrestin-interacting molecules includes JNK signaling molecules, tyrosine kinase, and components involved in endocytosis. β-Arrestin binds to GPCR phosphorylated by GPCR kinase and recruits interacting molecules to activated receptors. Recent intense studies have revealed that PSD-95 and other synaptic scaffold proteins bind various signaling proteins implicated in synaptic plasticity. PSD-95 interacts with GTPase-activating protein for Rap1 (synGAP-α), GDP/GTP exchange factors for Rap1 (SPAR) and Rac (Kalirin-7), tyrosine kinase fyn, and Rho target protein (Citron kinase). GRIP, tamalin, and ▶gephyrin bind GDP/GTP exchange factors for Ras (GRASP-1), ARF (ARNO), and CDC42 (collybistin), respectively. GRIP also interacts with GAP for ARF (GIT1) through liprin-α. Studies using mutant mice support that synaptic scaffold proteins are crucial for signaling of synaptic plasticity. Collectively, the data suggest that signaling molecules, only when assembled by scaffold proteins, can respond quickly to receptor activation, interact with each other efficiently to produce down-stream signals, and modulate receptor functions through the regulation of cytoskeleton and phosphorylation of receptors. A recent study has demonstrated that MUPP1 directly binds synGAP-α and CaMKII, and that CaMKII phosphorylates synGAP and suppresses its activity. Upon NMDAR stimulation, the elevation of calcium ions induces dephosphorylation of synGAP and dissociation of CaMKII from MUPP1. synGAP is then activated and inhibits p38 MAP kinase by inactivation of Rap1. The authors have demonstrated that synGAP-α phosphorylation requires the binding to MUPP1. Although how CaMKII regulates the activity of synGAP is not free of controversy, this report depicts the function of a scaffold protein in signaling well [3,4].

## Function of Scaffold Proteins to Organize the Molecular Architectures in Cells

### Scaffold Proteins and Cell Polarity

Scaffold proteins are important to establish, maintain, and remodel the molecular architecture of specific membrane domains. Three complexes composed of scaffold proteins and their binding partners are essential for cell polarity in epithelial cells. The first complex is Par3/Par6/aPKC. The second and the third complexes are Crumb/Pals1/PATJ and Scrib/Dlg/Lgl. Par3 have three PDZ domains, whereas Par6 has one PDZ domain and a CRIB motif to bind CDC42. PATJ is similar to MUPP1 and has L27 and thirteen PDZ domains. Dlg is SAP97 orthologue. Pals1 has L27, SH3, PDZ, and guanylate kinase domains. Scrib has a leucine-rich repeat and one PDZ domain. All these proteins function as scaffold proteins. The first and the second complexes are essential for proper formation of tight junctions in epithelial cells. The third complex is involved in the establishment of basolateral membranes. These polarity complexes link to each other. Par6 directly binds to Pals1. aPKC phosphorylates Lgl. In neurons, Par complex is involved in axon specification. The complex is localized at the tip of a newly formed axon depending on PI3-kinase, Rap1B, and CDC42, and interacts with kinesin [5].

### Scaffold Proteins and Receptor Localization

Scaffold proteins regulate receptor localization on the cell surface. Receptor trafficking has been investigated most extensively for AMPA receptors. Newly synthesized AMPA receptors interact with scaffold proteins when they are still present at the ER. GluR2 interacts with PICK1, and this interaction is necessary for the export of GluR2 from the ER to the Golgi apparatus. Trafficking from cell bodies to dendrites is also regulated by scaffold proteins. GRIP binds to kinesin heavy chain and KIF5 transports GluR2 to dendrites. Although the precise details are unknown, SAP97 binds GluR1 and regulates the synaptic delivery. Stargazin and its isoforms are tetraspanins and bind all AMPA receptors. Stargazer mice, which do not have AMPA receptors on the cell surface in cerebellar granule neurons, support the essential role of stargazin in AMPA receptor trafficking. Furthermore, stargazin mediates synaptic targeting of AMPA receptors through binding to PSD-95. Additional factors that regulate synaptic targeting and clustering of AMPA receptors are cytoskeletal protein 4.1N, nPIST, and RIL. Among them, nPIST and RIL are regarded as scaffold proteins. nPIST binds to NMDA receptor subunit 2A by a PDZ domain and to stargazin by a different region. RIL binds to α-actinin by a PDZ domain and GluR1 by a LIM domain. LTP correlates with the insertion of AMPA receptors into the cell surface membranes, while LTD involves the retrieval of receptors by endocytosis. The phosphorylation state of GluR1 is important for LTP and LTD, but the effect of phosphorylation and dephosphorylation of GluR1 on the interaction with SAP97 is not well characterized. In terms of GluR2, it is proposed that dephosphorylation following the modest elevation of calcium ion triggers dissociation of GRIP

from GluR2, so that GluR2 binds to PICK1 and is removed from the cell surface. Recent studies have shed light on NMDA receptor trafficking. NMDA receptor subunit 2B is transported to dendrites by a cargo composed of CASK/Lin-7/Lin-10 that binds to KIF17. The complex of Sec8 and SAP102 is important for NMDA receptor trafficking. NMDA receptors are internalized by clathrin-coated pits. This internalization is inhibited by PSD-95 and its isoforms. Activity-dependent serine phosphorylation of NMDA receptor subunit 2B by casein kinase II inhibits the interaction with PSD-95 and SAP102, and decreases the number of receptors on the cell's surface. Tyrosine dephosphorylation is also reported to regulate the endocytosis of NMDA receptors. At inhibitory postsynaptic sites, gephyrin plays a key role in the localization of glycine and $GABA_A$ receptors. Deletion of gephyrin reduces clusters of both receptors. Gephyrin interacts with tubulin and $GABA_A$ receptor-associated protein (GABARAP) that binds to γ2 subunit. The later protein is small and does not fit the criteria of a scaffold protein, but is involved in the intracellular transport of the receptor [6–8].

### *Scaffold Proteins and Membrane Transport*

Scaffold proteins are implicated in the transport of other proteins besides receptors. The presynaptic active zone is the membrane domain specialized for vesicle release. The active zone is composed of the matrix proteins (Bassoon, Piccolo, CAST/ERC) and functional units implicated in exocytosis (RIM, Munc13, Munc18). Most of them have modular structures and interact with each other in multiple ways. For instance, Piccolo has a PDZ domain and C2 domains, and interacts with signaling molecules (GAP for ARF (GIT1), and cAMP-GEF), a cytoskeleton-related protein (profilin and Abp), and other scaffold proteins (liprin-α, RIM, and CAST/ERC). In the synapse formation, vesicles containing scaffold proteins like Bassoon and Piccolo transport components of the active zone as packets to a nascent synapse. Furthermore, some scaffold proteins interact with motor proteins. Liprin-α has coiled-coil and SAM domains and interacts with LAR, Piccolo, RIM, CAST, GIT1, and GRIP. It also interacts with KIF1A that transports synaptic vesicles. JIPs bind to kinesin light chain and link amyloid precursor protein and ApoER2 to KIF5. Thereby, scaffold proteins may be important to ensure that distinct combinations of proteins are delivered efficiently to a specific membrane domain [9,10].

### *Scaffold Proteins and the Cytoskeleton*

One of the major outputs of signal transduction is the morphological change of cells. As mentioned above, synaptic scaffold proteins assemble various regulator proteins for the actin cytoskeleton, and are directly or indirectly associated with the cytoskeleton. For instance, AKAP79/150 directly binds F-actin. Shank binds α-fodrin, βPIX (GEF for Rac and CDC42), and cortactin (regulator for the cortical actin cytoskeleton). RIL binds α-actinin. Cupidin, an isoform of Homer/Vesl, directly interacts with F-actin and CDC42. These scaffold proteins are positioned to transmit signals from receptors to the cytoskeleton and modify the receptor activity through the remodeling of the cytoskeleton.

## Pathology

As scaffold proteins have various functions in neurons, they should be implicated in the pathophysiology of many neuronal diseases. However, to date, the number of reports is still limited. Human DLG3 encoding SAP102 was recently identified as a nonsyndromic X-linked mental retardation gene. Filamin is a scaffold protein associated with cortical actin and interacts with a large number of proteins including receptors and kinases. Filamin comprises of three members. One of the filamin genes, *FLNA*, is X-linked and its mutations cause brain malformation. Several mutant mice generated by gene targeting show phenotypes similar to human congenital diseases. The mutation of GRIP1 alters the localization of ECM protein, Fras, in keratinocytes, and leads to a phenotype that is reminiscent of Fraser syndrome with the blistered skin. Future studies may uncover mutations of scaffold protein genes in human diseases.

## Schizophrenia

Bernhard Bogerts
Universitätsklinik für Psychiatrie, Psychotherapie und Psychosomatische Medizin, Otto-von-Guericke Universität Magdeburg, Magdeburg, Germany

### Synonyms
Schizophrenic psychosis; Morbus Bleuler

### Definition
The term "schizophrenia" was introduced in 1911 by E. Bleuler meaning a splitting of emotional and cognitive functions in the affected patients. Today the international classification systems ICD-10 and DSM IV-R provide consensus criteria on symptom constellations required for this diagnosis. Leading symptoms in the acute periods of the disease are

1. Reality distortions such as hallucinations (mainly auditory and somatosensory)
2. Delusions and paranoid symptoms such as feelings of being observed or persecuted often associated with anxiety
3. Disorganization of thinking and behaviour

These symptoms are summarized as so-called ►positive schizophrenic symptoms.

Patients can also suffer from ►negative schizophrenic symptoms such as

1. Emotional flattening
2. Loss of drive and initiative
3. Social withdrawal
4. Depression

as well as from psychomotor alterations such as stupor and mutism (inability to move or to speak). Positive and negative symptoms can occur alternatively during the course of the disease or simultaneously in acute stages. Symptom constellation and the long term course of the illness vary considerably. If hallucinations and delusions prevail, the paranoid-hallucinatory subtype (reality distortion subtype) of schizophrenia has to be diagnosed, if psychomotor symptoms (often combined with anxiety) dominate, the catatonic subtype (►catatonia), if affective flattening and avolition are the leading syndrome, the hebephrenic subtype (►hebephrenia), if disorganization of thinking and behaviour are the prominent clinical signs the disorganized subtype has to be diagnosed.

There are persons – often close relatives of schizophrenics – with eccentric behaviour and anomalies of thinking and emotions that have some similarities with schizophrenia but do not reach the extent of a real schizophrenic psychosis. Such very weak forms of positive or negative symptoms are usually diagnosed as ►schizotypal personality disorder.

The typical "positive" symptoms usually start in young adulthood or late adolescence, males in general earlier and more severely affected then females. Hebephrenia often becomes obvious during or shortly after puberty. With regard to the long term course, about one third of the patients show a rather benign outcome, i.e., symptoms disappear after one or two episodes; one third has an unfavourable outcome with progressive impairment of psychotic or residual symptoms (worsening of cognitive and emotional functions) and one third has a fluctuating course with exacerbations and remissions.

It should be emphasized that the enormous variety of psychopathological alterations summarized under the term "schizophrenia" do not represent a disease entity, but rather a hypothetical construct that was created many decades ago by leading authorities in the field and is now defined by international classifications committees, whose inclusion criteria changed from issue to issue, there are moreover differences between schizophrenia definitions in ICD and DSM criteria.

### Characteristics
#### Epidemiology and Genetics, Risk Factors
About one percent of the world's population has a lifetime prevalence of schizophrenia, this is independent from the cultural or geographical background.

Schizophrenia very seldom begins during childhood on beyond the forth decade of life. The disease has a strong genetic component. Monozygotic twins have a concordance rate of about 50%, even if they grow up in different families, first degree relatives have a concordance rate of 10–20%. This indicates that genetic and non-genetic components play an essential role in pathogenesis of schizophrenia.

Several research groups recently demonstrated that polymorphisms in the neuregulin-1 gene (chromosome 8p12) and dysbindin (DPNBP, chromosome 6p23.3) predispose to the disease. Because of the clinical complexity of psychotic symptoms, other genes might also have a pathogenetic significance. Neuregulin is important for neurodevelopmental processes, myelination and for NMDA-neurotransmission, Dysbindin is localized in the postsynaptic membranes and plays a role in neuronal signal transduction. All of these functions are believed to be disturbed in schizophrenia [1,2].

The following risk factors for later development of schizophrenia are now well established:

1. Genetic disposition (50% concordance in monozygotic twins)
2. Prenatal neurodevelopmental disorder (as indicated by, abnormal cytoarchitecture in frontal and temporal cortex) [3]
3. Birth complications (obstetric complications, hypoxia during birth)
4. Winter birth (increased risk of viral infections)
5. Chronic cannabis consumption
6. Migration (increased frequency in first and second generation Afro-Caribbean immigrants) [3]

In contrast to earlier psychodynamic oriented opinions, parental influences during childhood or educational styles do not predispose to later development of schizophrenic psychoses.

## Changes in Brain Structure of Schizophrenics

Numerous structural imaging studies by computed tomography (CT) or magnetic resonance imaging (MRI) reported a broad variety of subtle structural alterations in the brains of schizophrenics. The most consistent statistical findings are [4,5]:

1. Lateral ventricular enlargement (by about 20%)
2. Enlargement of frontal, temporal and parietal sulci
3. Smaller volume of hippocampus and parahippocampal gyrus (by about 10%)
4. Decreased thickness of frontal, temporal and parietal association cortex (by 5%)
5. Reduced asymmetry between right and left hemisphere

Post mortem studies also found changes at the microscopical level [4]:

1. Cellular disarray and abnormally positioned neurons in entorhinal cortex, hippocampus and prefrontal brain, as an indicator of a prenatal disorder of neurodevelopment
2. Reduced neuropil and synaptic markers, while the number of nerve cells is unchanged
3. Alterations in myelin and oligodendroglia components [6]
4. Reduction of inhibitory interneuron terminals [7]

While cellular disarray in limbic mesiotemporal structures and frontal cortex as well as reduced cortical asymmetry are a strong argument for a prenatal developmental disorder, several MRI-studies could demonstrate a progressive loss of cortical tissue in the first years after the onset of clinical symptoms. This points to an additional degenerative component that adds to a primary neurodevelopmental disorder [3].

## Neurotransmitter Theories

### *Dopamine*

The most prominent theory on neurotransmitter dysfunctions causing schizophrenic symptoms is the dopamine theory, according to which dopaminergic functions are in some way overactive in the schizophrenic brain. This theory is essentially based on the observation that antagonists on the D2-receptor have antipsychotic properties and that dopaminergic substances like amphetamine, cocaine or L-DOPA can induce a schizophrenia-like psychosis. However, earlier reports of increased concentration of dopamine receptors in the schizophrenic brain proved to be an artefact of antipsychotic treatment. On the other hand there are reports that schizophrenics have increased dopamine release after application of amphetamine and animal models after lesions in prefrontal and limbic structures show changes in dopamine turnover similar to those observed in psychotic patients [8,9].

### *Glutamat*

The best drug induced model for schizophrenic symptoms is the phencyclidin-(PCP)-psychosis. After PCP consumption, the full spectrum of schizophrenic symptoms (hallucinations, paranoid ideas, catatonia, disorganized behaviour) can occur. PCP, like ketamine, is an antagonist of the NMDA-subtype of glutamate receptors. Several postmortem studies found a decreased concentration of the NMDA-subreceptor NR1 in temporal cortex or thalamus. Thus, a hypofunction of NMDA-linked neurotransmission can be postulated. The glutamate agonists Glycin and D-Serine are reported to have moderate antipsychotic effects [9].

### *GABA*

Inhibitory interneurons containing GABA as neurotransmitter are another important candidate in current neurotransmitter theories of schizophrenia. GABA-cells are responsible for the bulk of neuronal inhibition in all cortical and subcortical structures. There are

several clinical indicators of disturbed neuronal inhibition in schizophrenic patients; these are:

1. Deficits in sensory gating
2. Hallucinations (explainable as dysinhibition of sensory cortical areas)
3. Reduced latent inhibition
4. Reduced prepulse inhibition

Some studies showed decreased mRNA for the GABA-synthesizing enzymes GAD65 and GAD67 in hippocampus and frontal cortex and of the GABA-transporter GAT in inhibitory cortical synapses. The peptides parvalbumin and reelin, that are co-localized in special subclasses of GABA-interneurons, are also diminished in frontal and temporal cortex [7].

### *Therapy*

After treatment with ►antischizophrenic drugs (synonyms: antipsychotic drugs, neuroleptics), acute symptoms usually improve within a few weeks. In many patients, prophylactic long term treatment with these drugs over years is necessary to prevent relapses.

Antipsychotic drugs or neuroleptics are dopamine antagonists whose therapeutic efficacy correlates essentially with their affinity to the Dopamine-2 (D2) receptor.

Antipsychotics can be divided into first generation or typical neuroleptics (prototype: haloperidol) and second generation or atypical neuroleptics (prototype: clozapine). The first generation neuroleptics block D2 receptors in all dopaminergic brain systems. By D2-receptor antagonism in the nigrostriatal system they often cause their "typical" extrapyramidal side effects like Parkinson symptoms and other forms of abnormal movements (dyskinesias), while their action in the mesolimbic and mesocortical dopamine system is believed to be responsible for the antischizophrenic properties. The second generation (atypical) neuroleptics have a higher affinity to the mesolimbic than to the nigrostriatal dopamine system, therefore they have much weaker or no extrapyramidal side effects, but they have antipsychotic actions that are comparable to that of the typical antipsychotics [8]. However, some of the second generation antipsychotics have other unfavourable side effects such as weight gain and other signs of a metabolic syndrome. This could be due to their affinity to multiple receptors including the histamine and serotonin receptors

Beside pharmacological treatment and after remission from acute psychosis, additional psychotherapeutic and psycho/socioeducational treatment strategies are helpful.

## Schwann Cells in Nerve Regeneration

Hidenori Horie
Advanced Research Institute for Biological Science, Waseda University, Nishitokyo, Tokyo, Japan

### Definition

The Schwann cell is a type of peripheral nerve glial cell that surrounds and interacts with axons. There are two types of Schwann cells: myelinating and non-myelinating. Whereas myelinating Schwann cells form myelin around fast-conducting, large-diameter axons, non-myelinating Schwann cells surround smaller-diameter axons without forming a myelin sheath.

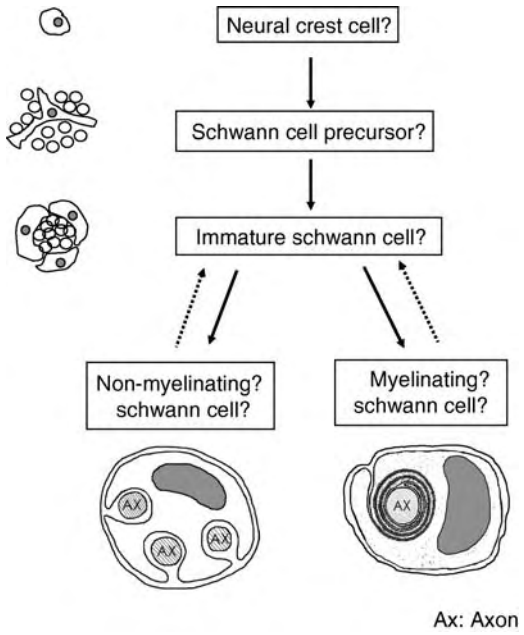
### Characteristics

#### Development and Classification of Schwann Cells

Studies in rats and mice have led to an understanding of the process of Schwann cell maturation. Most Schwann cells develop from cells derived from the ►neural crest. The neural crest is a transient group of cells that delaminates from the dorsal part of the neural tube during embryonic development. In the trunk region, cells of the neural crest give rise to glial cells, neurons of sensory, sympathetic, and parasympathetic ganglia, chromaffin cells, and melanocytes. Between undifferentiated migrating crest cells and mature Schwann cells lie three main developmental transitions: first, the formation of ►Schwann cell precursors; second, the formation of immature Schwann cells; and lastly, the reversible generation of myelinating and non-myelinating cells (Fig. 1).

Schwann cell precursors are the most prevalent cell type in peripheral nerves at embryonic day (E-) 14/15 in rats (E12/13 in mice), and by E17/18 in rats (E15/16 in mice), nearly all cells resident in peripheral nerves are Schwann cells or their precursors. Immature Schwann cells differentiate into myelinating Schwann cells initially, and form mature non-myelinating cells as development progresses. These Schwann cells regulate the development of the three main components of peripheral nerves – the neurons, connective tissue cells, and the Schwann cells themselves – to construct the peripheral nervous system (PNS).

Various proteins are markers of Schwann cell differentiation during embryonic development [2]. Use of these markers has been crucial for the characterization of the differentiation of Schwann cells from precursors to mature myelinating or non-myelinating cells, and for defining the roles of Schwann cells in the developing and adult PNS. The markers can be classified into four categories. The first category consists of markers that are found on embryonic PNS glia, but do not differentiate between developmental stages as these proteins are also expressed at later stages of Schwann cell development. An example of this type of marker is the cell adhesion molecule ►L1. A second class of markers are those that are found on crest cells and Schwann cell precursors but at very low levels on immature Schwann cells, including N-cadherin and the transcription factor ►AP2α. The third class of markers includes proteins that allow for the differentiation of Schwann cell precursors and immature Schwann cells from crest cells. This class is comprised of fatty acid binding protein ►B-FABP, ►protein zero (P0) and desert hedgehog (►Dhh), which are also not found on



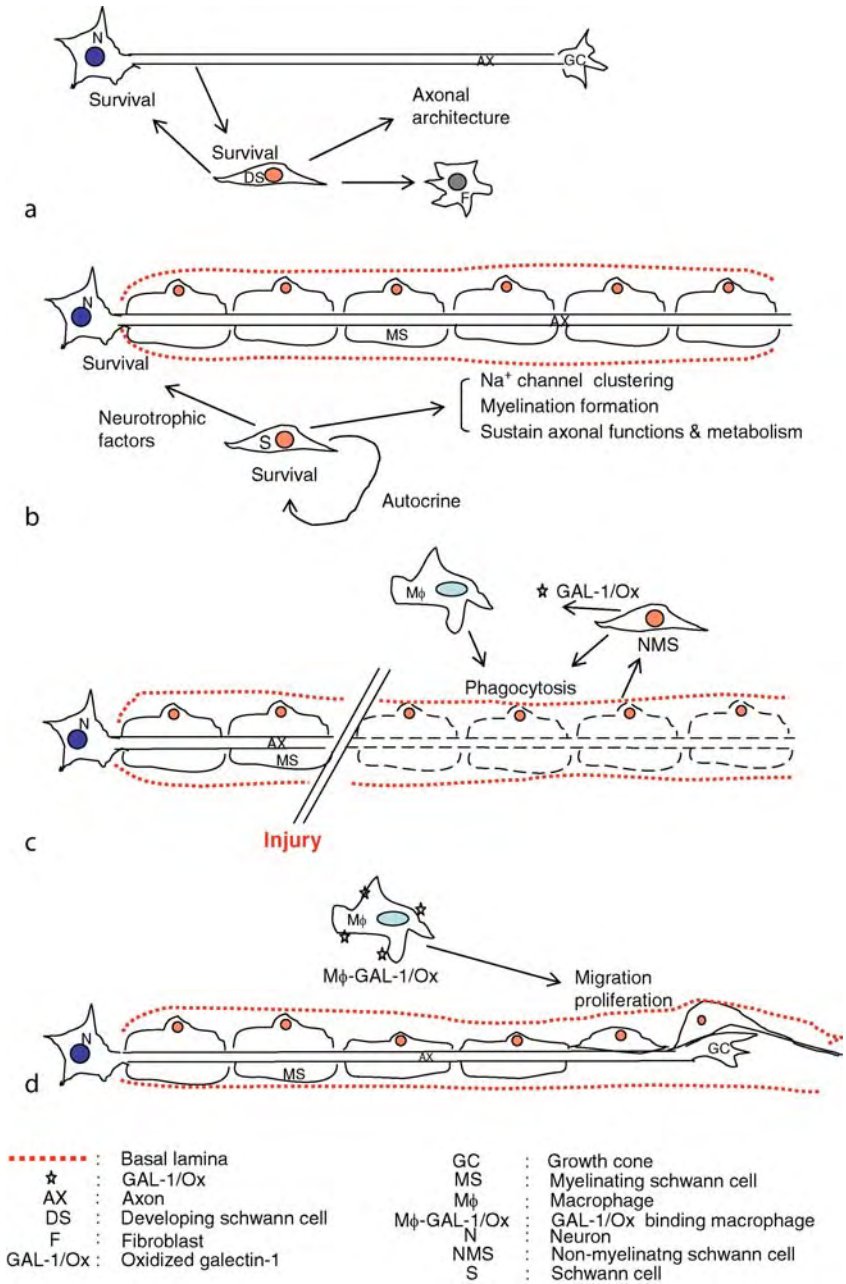
**Schwann Cells in Nerve Regeneration. Figure 1** The Schwann cell lineage in the rat and mouse. Most Schwann cells develop from cells derived from the neural crest. Between migrating crest cells and mature Schwann cells lie three main developmental transitions: first, the formation of Schwann cell precursors; second, the formation of immature Schwann cells; and last, the reversible generation of myelinating and non-myelinating cells [1]. The Schwann cell precursors are always in close apposition to axons that are of similar size. They possess extensive sheet-like processes that contact and form junctions with processes from neighboring cells, thereby surrounding large groups of axons. These precursors differentiate into immature Schwann cells which display a large number of phenotypic differences from the precursor cells. The immature cells subsequently differentiate into two kinds of mature Schwann cells, myelinating and non-myelinating. Whereas myelinating Schwann cells associate with large diameter axons (Ax) in a 1:1 ratio, non-myelinating Schwann cells loosely ensheath numerous small diameter axons. Since Schwann cells are labile throughout their life cycle, differentiation into myelinating Schwann cells and non-myelinating Schwann cells is reversible [1].

early developing neurons and therefore provide a distinction between the neuronal and glial lineage at an early stage. The fourth group of markers consists of those that are found exclusively on immature and mature Schwann cells, and can therefore be used to distinguish these cells from Schwann cell precursors or crest cells. Markers in this class include calcium binding protein ►S-100 and glial fibrillary acidic protein (GFAP). Studies on the expression patterns of the aforementioned markers have led to the conclusion that immature Schwann cells reversibly differentiate into two types of cells, myelinating Schwann cells and non-myelinating Schwann cells. Both of these cell types closely associate with axons in mature PNS, and they have essential roles in maintaining the appropriate structure and function of the PNS. They are also critical players in the processes of degeneration and regeneration following nerve injury.

## Function

Schwann cells have been implicated in the development of various components of the peripheral nerve. Factors secreted by Schwann cells are important in the survival of immature neurons, and in the development of the connective tissues that provide protection and mechanical support for peripheral nerves (Fig. 2a). Schwann cells and their precursors regulate nerve development actively through their interactions with axons. Likewise, axons release factors that have effects on the survival and development of immature Schwann cells. One example of this reciprocal interaction is provided by mice that lack the neuregulin-1 receptor. Neuregulin-1 is the major axonally derived Schwann cell mitogen and survival factor, and it supports the survival of Schwann cell precursors [3]. Schwann cells and their precursors are severely depleted in peripheral nerves of mice lacking the receptor for neuregulin-1. Another phenotypic abnormality is also apparent in these mice: most sensory neurons and cervical and lumbar motoneurons are lost during the second half of embryonic development [4]. This suggests that Schwann cells and their precursors act as a source of developmental signals that are crucial for the survival of peripherally projecting neurons and the generation of peripheral nerves. Recent research has also implicated Schwann cells in the formation of the connective tissue structure of the nerve, which includes the endoneurium, perineurium, and epineurium. These act as protective diffusion barriers [5]. Thus, Schwann cells and their precursors have key roles both in the survival of developing neurons, and in the production of the connective tissue sheaths of peripheral nerves (Fig. 2a).

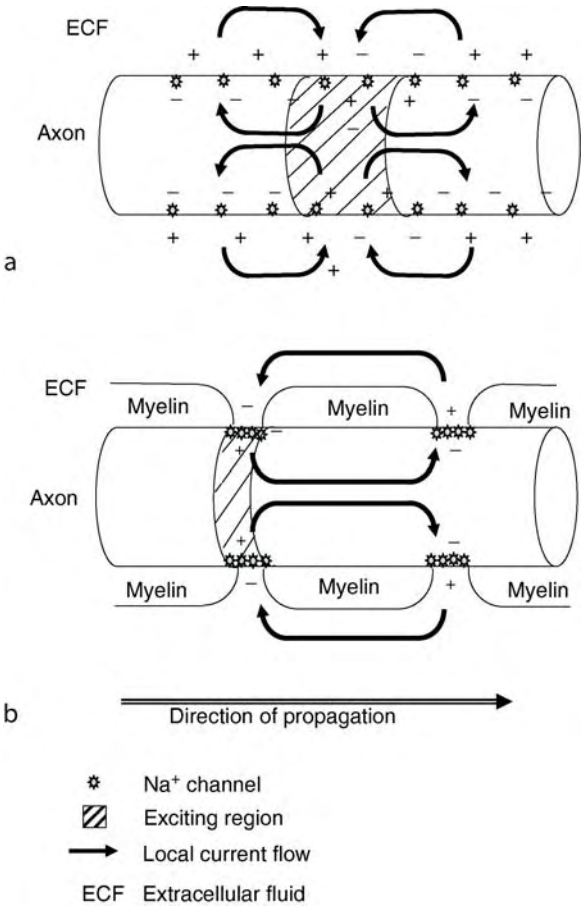
As mentioned above, myelinating and non-myelinating Schwann cells represent the terminal step of Schwann cell differentiation. These cells express distinct sets of proteins involved in cytoskeletal dynamics, associate with different sizes and numbers of axons, and have some disparate effects on the axons that they ensheath. Non-myelinating Schwann cells express high levels of the neural cell adhesion molecule (NCAM) and L1, modest levels of the neurotrophin receptor ►$p75^{NTR}$ and the growth-associated protein-43 kDa (GAP-43), and contain a distinct set of cytoskeletal proteins including glial GFAP. These cells do not express myelin-related proteins. In contrast, myelinating Schwann cells express little or no NCAM, L1, $p75^{NTR}$, GAP-43, and GFAP. Instead, these cells express high levels of the structural components



**Schwann Cells in Nerve Regeneration. Figure 2** Roles of Schwann cells in peripheral nerve during development, in the adult animal, and following nerve injury (Wallerian degeneration and subsequent axonal regeneration). (a) Developmental stage; (b) Mature stage; (c) Degeneration; (d) Regeneration. During developmental stages (a), Schwann cells and their precursors provide survival signals to neurons, and contribute to constructing the connective tissue sheaths of the nerves. Their survival is supported by axons via neuregulin-1. Upon maturation of the nerve and its cells (b), Schwann cells can survive by themselves and support neurons via neurotrophic factors. At this stage, Schwann cells have also formed myelin sheath around axons to propagate action potentials more quickly via saltatory conduction. After nerve injury, Wallerian degeneration (c) occurs distal to the site of axotomy. Axons and myelin sheaths are fragmented into debris and are phagocytosed by cells in the local microenvironment. Denervated myelin-forming Schwann cells de-differentiate into immature Schwann cells. The debris is phagocytosed in part by Schwann cells, but mainly by invading hematogenous macrophages. The Schwann cells secrete GAL-1/Ox. During the regeneration phase (d), the secreted GAL-1/Ox binds to macrophages and induces the release an unidentified factor that promotes Schwann cell migration. Regrowing axons from proximal stumps can then extend their processes along migrating Schwann cells towards their peripheral targets.

of the myelin sheath, including P0, myelin basic protein (MBP), peripheral myelin protein 22kDa (PMP22), connexin32, myelin-associated glycoprotein (MAG), and ►periaxin [2]. Both types of Schwann cells surround axons to support neuronal survival by supplying trophic factors; however, unlike developing Schwann cells, mature Schwann cells can survive without support provided by axons (Fig. 2b).

Whereas non-myelinating Schwann cells loosely ensheath and support numerous small-diameter axons, myelinating Schwann cells surround large-diameter axons to furnish the myelin sheaths that insulate specific axonal populations in the PNS. Each individual myelinating Schwann cell forms a segment of myelin sheath about 1mm long on a single axon. The sheath assumes its form as the inner tongue of the Schwann cell and turns around the axon several times, wrapping it in concentric layers of membrane (Fig. 1). The intervals between segments of myelin are known as nodes of Ranvier. Myelination increases the diameter of axons and helps to direct $Na^+$ channels to the ►node of Ranvier [6]. $Na^+$ channels, which homogeneously distribute in the axonal membrane of unmyelinated axons (Fig. 3a), accumulate at these nodes. This accumulation essentially enables action potentials to "jump" from one node of Ranvier to the next (Fig. 3b). This jumping of action potential from node to node is called ►saltatory conduction. It is a rapid process, as it allows myelinated axons to conduct up to 50 times faster than the fastest unmyelinated fibers. Myelination results in significant increases in the total number of neurofilaments and the proportion of phosphorylated neurofilaments, which comprise the majority of the axonal cytoskeleton [7].



**Schwann Cells in Nerve Regeneration. Figure 3** Local current flow (movement of positive charges) around an impulse in unmyelinated and myelinated axons. (a) Unmyelinated axon, (b) myelinated axon. $Na^+$ channels, which distribute homogeneously in the membranes of unmyelinated axons, cluster at nodes of Ranvier in myelinated axons. Action potentials are transmitted differently in the two axons. Unmyelinated axons propagate action potentials by electronically depolarizing the membrane directly ahead of the charge. In contrast, myelinated axons propagate the signal by depolarizing the membrane present in the next node of Ranvier, effectively allowing the charge to "jump" down the axon at high velocity (saltatory conduction).

## Pathology

Two basic pathologies can occur in the PNS: Wallerian degeneration resulting from nerve injury and segmental demyelination caused by autoimmunity to peripheral nerve myelin. Wallerian degeneration refers to all of the events that occur distal to the site of axotomy, and is a feature of any insult that causes axonal degeneration. During the first week post-axotomy, axons fragment and disappear, and the myelin sheaths separate at incisures, breaking up into debris. Both myelinating and non-myelinating Schwann cells are denervated and are affected significantly by nerve injury. Denervated myelinating Schwann cells are plastic and change to become immature Schwann cells (Fig. 2c). Over the next few weeks, this myelin debris is phagocytosed in part by Schwann cells but mainly by macrophages that invade the degenerating nerve from blood vessels. The clearance of myelin debris, which contains proteins that inhibit axonal regeneration, is required for regenerating axons to enter and grow into the degenerated nerve. Schwann cells undergo extensive proliferation between 3 and 5 days post-axotomy, and those that phagocytose myelin are activated to produce factors that promote axonal extension. The basal lamina persists and surrounds the column of denervated Schwann cells. Denervated, previously myelinating Schwann cells express many of the proteins that are characteristic of non-myelinating Schwann cells such as NCAM, L1, $p75^{NTR}$, and GAP-43, and dramatically decrease their synthesis of myelin-related proteins and glycolipids. These observations indicate that axonal signals are required to maintain the phenotype of mature Schwann cells.

Autoimmune demyelinating peripheral neuropathies, like ►Guillain-Barre syndrome (GBS) and chronic inflammatory demyelinating polyneuropathy (CIDP), are characterized by local inflammation and demyelination of peripheral nerves. Both sensory and motor axons are often affected, resulting in acute motor weakness affecting at least one limb associated with areflexia. Since most patients respond well to treatment with high dose intravenous immunoglobulin G or to plasma exchange [8], circulating self-recognizing antibodies are presumably involved in these disorders.

## Therapy

Schwann cells play essential roles in the regeneration of peripheral nerves, and have been used as a cellular source for factors that promote the regeneration and remyelination of injured axons in the central nervous system (CNS) [9]. Successful peripheral nerve regeneration requires the concerted interplay of non-neuronal cells, growth factors, cell adhesion molecules, extracellular matrix components, regenerating axons, and recruited macrophages [10]. In the past, initiation of axonal outgrowth after axotomy was thought to be regulated mainly by neurotrophic factors; however, more recent studies have identified another factor that is important in this process. This factor is the oxidized form of ►galectin-1 (GAL-1/Ox), which has been shown to increase the rate of initial axonal regrowth by facilitating the interaction of neuronal and non-neuronal cells after injury [11].

The pattern of expression of GAL-1 in cells of the peripheral nerve is consistent with its potential role in enhancing axonal regrowth following insult. A common model for peripheral axotomy involves injury to the sciatic nerve, which contains axons projecting from dorsal root ganglion neurons and motoneurons. These axons, along with Schwann cells, express the reduced form of GAL-1 (GAL-1/Red) and subsequently release these molecules into the extracellular space via a non-classical pathway. After sciatic nerve injury, axons are damaged and Schwann cells become reactive. Axons in the proximal nerve stump are sealed at the injury site. The secretion of GAL-1/Red is increased by these injured axons, especially from their growth cones. Reactive Schwann cells likely secrete GAL-1/Red in the same manner following axotomy. The GAL-1 molecules that are released into the extracellular milieu have two potential fates. First, some GAL-1/Red will bind to β-galactosides located on cell surfaces. A second event may also occur: some GAL-1/Red molecules may not interact with carbohydrate moieties and can enter the extracellular space, where they could be oxidized in the presence of agents such as NO that are induced by injury. Oxidation of GAL-1 involves the formation of three disulfide bonds and the loss of lectin (carbohydrate-binding) activity. It is this form of GAL-1 that has been shown to enhance initial axonal outgrowth following peripheral nerve injury.

The major cellular target of GAL-1/Ox appears to be macrophages, and it is through events downstream of this interaction that axonal regrowth is accelerated. Target macrophages include those endogenous to the nerve itself, and those that are recruited from the blood in response to injury. The binding of GAL-1/Ox to a specific receptor on the plasma membrane of macrophages initiates a signal transduction cascade that leads to the secretion of an unidentified factor, which has been shown to promote axonal regrowth and Schwann cell migration after nerve injury. Migration of Schwann cells and fibroblasts from both proximal and distal stumps is important for the formation of cellular scaffolds that support regenerating axons. Treatment with GAL-1/Ox promotes Schwann cell migration from both stumps and accelerates axonal extension following injury, resulting in the promotion of functional recovery (Fig. 2d) [12]. Thus, GAL-1/Ox promotes the initiation of axonal regeneration in the PNS in animal models of neuropathy, suggesting that the factor may be useful therapeutically to enhance peripheral nerve regeneration.

The interaction between injured axons and cells in their microenvironment, including denervated Schwann cells, is critical for the successful regeneration of these axons. After injury and axonal sealing, growth cones are produced at the node of Ranvier located close to the proximal stump of the lesion. They must reach the distal nerve stump, which is possible even if there is a small gap between the proximal and distal nerve stumps. Upon arrival at the distal nerve stump, growth cones enter "Schwann tubes" (bands of Büngner), which consist of ordered columns of Schwann cells and their basal laminae. These bands provide the sole pathway for growth of regenerating axons in the distal nerve stump. Subsequent axon-Schwann cell interactions during nerve regeneration are fundamentally similar to those that occur during development. During early stages of regrowth, Schwann cells surround bundles of regenerating axons. As regeneration progresses, myelinating Schwann cells segregate with larger fibers into a 1:1 relationship, elaborate new basal laminae, and form new myelin sheaths. Much of the cholesterol and even a portion of the phospholipids of the original myelin sheaths are reincorporated into these new myelin sheaths. Macrophages and endoneurial fibroblasts are the key to this process, as they secrete lipoproteins that contain the recycled cholesterol and fatty acids, which are taken up by Schwann cells via low-density lipoprotein receptors [13]. With time, remyelinated axons may enlarge to nearly normal diameter, but the thickness of myelin sheaths and length of the myelin internodes do not recover to their uninjured sizes [14].

The pathway taken by regenerating axons to the targets depends largely on the nature of the lesion. After crush or freeze injury, the basal laminae of the Schwann cells remains intact at the site of injury. Growth cones usually remain within their basal lamina tubes, which guide them to their original targets. In contrast, nerve transection disrupts the continuity of the basal laminae. In this situation, axons usually do not enter their original Schwann tubes, and therefore do not reinnervate their original targets selectively. During the final stage of axonal regeneration, growth cones of regenerating axons passing through the distal nerve are guided to their targets by Schwann cells, resulting in the formation of functional neural networks.

## Scotoma

### Definition

A scotoma is an area within the visual field in which a person is blind. Scotomata may be caused by damage to the retina or damage to visual areas within the brain.

When a scotoma is relatively small patients may not even notice that they have a visual defect (just as we do not typically notice that we have a blindspot in the region of the retina where the optic nerve leaves the eye).

### Synonyms

Scratch reflex; Wiping reflex

### Definition

Scratching is a motor behavior elicited by tactile stimulation of a site on the body surface [1–10]. During a scratch, a nearby limb reaches towards and rubs against the stimulated site.

An organism can scratch using a variety of strategies, or forms, according to the biomechanical demands of the task [10]. A human can use an elbow-over-the-shoulder strategy to scratch a site on the person's upper back and an elbow-under-the-shoulder strategy to scratch a site on the person's lower back. While only one strategy may be used to scratch each site on the back, a site located elsewhere may be scratched using more than one strategy. Either the hand or the elbow can successfully rub against a lateral site on a person's thorax. This is an example of motor equivalence.

A vertebrate with a complete transection of the spinal cord, termed a ►spinal vertebrate, may produce successful scratching [7]. Supraspinal neuronal structures are not required for the generation of scratching behavior in these spinal vertebrates. Scratching has been studied in several spinal organisms: frog, turtle, cat, and dog. The spinal cord can select the appropriate strategy or form required to rub against a specific site.

For hindlimb scratching in frog [3] and in turtle [5,10], rostral scratching is used to rub against sites anterior to the hip in the midbody, lateral or pocket scratching is used to rub against sites near the hip, and caudal scratching is used to rub sites posterior to the hip near the anus.

A ►motor pattern is a specific sequence of motor neuron and/or muscle activations that occur during a behavior. In response to tactile stimulation of a site on the body surface, scratch motor patterns have been obtained with ►electromyographic recordings (EMGs) of muscle action potentials from specific muscles [5], as well as with ►electroneurographic recordings (ENGs) from nerves innervating these muscles [4,6,8]. For each scratch form, there is a specific motor pattern [4–6].

Movement-related sensory feedback can strongly modulate the characteristics of scratch motor patterns; such feedback is not required for the production of a scratch motor pattern, however. In an immobilized spinal vertebrate with all movement-related sensory feedback removed following blockade of neuromuscular synapses with a nicotinic acetylcholine receptor antagonist such as curare or gallamine, tactile stimulation evokes an excellent scratch motor pattern of ENG activation [4,6,8]. In response to stimulation of a specific site, the ENG motor pattern in the immobilized spinal preparation is an excellent replica of the EMG motor pattern in the spinal preparation with movement.

The neuronal networks in the spinal cord that produce scratch motor patterns in the absence of movement-related sensory feedback are termed ►central pattern generators (CPGs). Since these ENG motor patterns are produced in the absence of actual movements, they are termed "►fictive" motor patterns.

## Characteristics

### Quantitative Description

Scratching is often rhythmic. The rhythmic scratch motor pattern can be generated by a spinal CPG without movement-related sensory feedback; this establishes that the spinal CPG network is a neuronal oscillator.

The specific phase of the rhythmic scratch cycle during which a portion of the limb rubs against the stimulated site is a key feature of the scratch cycle [10]. The position of a toe in space as a function of time can be used to measure the scratch rhythm. The angles of several joints, e.g. hip and knee, are additional measures of the rhythm. The relative timing of knee angle in the cycle of movement of hip angle is a sensitive measure of the specific form of the scratch. In the turtle, the timing of the knee angle in the cycle of the hip is distinct for each form. The hip motor rhythm, the timing of activation of hip flexors and hip extensors as measured with EMGs or ENGs, is an important measure. The relative timing of knee extensor activity in the hip motor rhythm is distinct for each form of the scratch in the turtle [4–6].

### Higher Level Structures

Scratch motor patterns are produced by CPGs. CPG neuronal networks are found in many organisms and produce a wide variety of rhythmic behaviors such as breathing, ►scratching, stepping, and swimming [9]. Current research programs in many laboratories include studies designed to reveal characteristics of these neuronal networks.

### Lower Level components

Tactile stimulation of a site on the body surface activates cutaneous afferent neurons whose axons enter the spinal cord via dorsal roots. Cutaneous afferents activate cutaneous interneurons. The scratch CPG includes the spinal cord interneurons that generate the scratch motor pattern. CPG interneurons are activated by cutaneous afferents and cutaneous interneurons. Some CPG interneurons have outputs that synapse upon limb motor neurons. These limb motor neurons synapse in turn upon the specific muscles of the limb that are activated during a scratch.

### Structural Regulation

Stimulation of a distinct set of cutaneous afferents activates the scratch CPG to generate a specific scratch motor pattern. The dynamic physiological structure of the scratch CPG is regulated by the activation pattern of tactile afferent inputs.

During the normal pattern of scratching, each agonist at a joint rhythmically alternates between activation and quiescence. During a normal scratch, each antagonist at a joint is active during agonist quiescence. During an antagonist deletion variation of scratching, the antagonist is quiet and there is no quiescence between successive bursts of agonist activation. The best-studied deletion is the hip-extensor deletion variation of rostral scratching in the turtle [6,8]. Knee-related deletions have also been described in the turtle. The occurrence of deletions demonstrates considerable flexibility in the dynamic structure of the scratch CPG.

### Higher Level Processes

CPGs for rhythmic scratching have properties shared with CPGs for other rhythmic behaviors, e.g. breathing, stepping, or swimming. What the neuronal mechanisms are that are responsible for generation of the motor rhythm and the specific sets of motor patterns is a fundamental issue for all CPGs.

## Lower Level Processes

Intracellular recordings from motor neurons and extracellular single-unit recordings from spinal interneurons during fictive scratching have provided important insights into the processes responsible for the production of the scratch motor pattern [1,2,4,6,8]. These recordings provide support for a modular organization of the scratch CPG.

Some studies of CPGs have focused upon evidence for a half-center modular organization; other studies of CPGs have focused upon evidence for a unit-burst-generator modular organization [6,8,9]. In the hypothesis of a half-center organization of a CPG, all the flexors of a limb are active at one phase of the cycle and all the extensors of a limb are active at a different phase of the cycle. Reciprocal inhibition between the flexor half-center and the extensor half-center is postulated to be the sole basis for CPG rhythmicity. This half-center organization does not apply to the rostral scratch in the turtle, since monoarticular knee-extensor motor activity is active during the latter portion of hip-flexor motor activity.

In the hypothesis of a unit-burst-generator organization of a turtle rostral scratch CPG, there is a hip-flexor ►module, a hip-extensor module, a knee-flexor module, and a knee-extensor module, etc. Reciprocal inhibition between agonist and antagonist modules at the hip joint is postulated to be one of the bases for CPG rhythmicity. Additional bases for CPG rhythmicity are reciprocal inhibition between agonist and antagonist modules at each other joint of the limb. Still other bases for rhythmicity are the intrinsic oscillations of each module (="unit-burst-generator"), e.g. the hip-flexor module is postulated to be rhythmogenic even when the hip-extensor module is quiet.

Studies of normal rostral scratching as well as deletion variations of rostral scratching provide support for the unit-burst-generator hypothesis of CPG organization [6,8,9]. During normal rostral scratching, hip-extensor interneurons are active during hip-flexor motor neuron quiescence. During the hip-extensor deletion variation of rostral scratching, hip-extensor interneurons as well as hip-extensor motor neurons are quiet [8]. This supports the concept that hip-extensor interneurons belong to a hip-extensor module that acts in concert. These interneurons are active during hip-flexor quiescence of normal rostral scratching, and these interneurons are quiet during the hip-extensor deletion variation of rostral scratching. In addition, these results provide support for the idea that the hip-flexor module is rhythmogenic and its rhythmicity does not depend upon interneuronal activity in the hip-extensor module. Further support for the unit-burst-generator concept of the scratch CPG has been obtained with intracellular recordings from hip motor neurons during normal rostral scratching and during the hip-extensor deletion variation of rostral scratching [6]. There is also support for rhythmogenic knee-flexor and knee-extensor modules.

## Process Regulation

Scratch CPG interneurons are broadly tuned [4,9]. They fire with maximal frequency in response to stimulation of a specific site on the body surface. For example, a rostral-tuned interneuron fires with maximal frequency in response to stimulation of a site in the rostral scratch receptive field. The interneuron responds with lower frequencies in response to stimulation of other sites on the body surface. Many scratch CPG interneurons are active during more than one form of the scratch. For example, many rostral-tuned interneurons are also activated in response to stimulation of a site in the pocket scratch receptive field. This suggests that the CPG interneurons for one form of scratch are also members of the CPG for other forms of scratch. Selective output of broadly tuned interneurons has been proposed as a mechanism that contributes to the production of specific scratch forms. In this hypothesis, the outputs of rostral-tuned interneurons support the co-activation of knee extensors and hip flexors that occurs during rostral scratching.

There are multisecond excitability changes that occur in the scratch CPG in response to tactile stimulation of a site on the body surface. In response to a brief stimulus, there is often a motor after discharge that outlasts the stimulus by several seconds [1]. After the motor after discharge has ended, there may also be activation of long afterdischarge interneurons in the spinal cord that fire for many seconds after the motor afterdischarge has ended. The firing of these interneurons may be a basis for a multisecond "memory" of cutaneous activation in the spinal cord. Intrinsic modulation of voltage-gated calcium channels in spinal circuitry may also occur following the activation of metabotropic glutamate receptors in response to a tactile stimulus [1]. Future experiments are needed to understand the roles of this intrinsic modulation in the production of scratch motor patterns.

## Function

Scratching serves to generate force against a site on the body surface that has received a tactile stimulus. One function of a scratch is to remove the object that has generated the tactile stimulus. For scratching to be successful, the nervous system must be able to calculate the location in space of the stimulated site on the body surface, and control the musculature of a limb so that a portion of the limb is moved to that same location in space. Scratching is an example of a ►sensorimotor transformation. Since scratching can be produced in animals with a complete transection of the spinal cord, spinal structures can perform sensorimotor transformations without neuronal interactions with supraspinal structures.

### Therapy

Studies of scratching provide support for the concept that spinal cord CPGs have considerable complexity. Rehabilitation strategies for spinal-injured humans based upon the assumption of spinal CPGs show considerable promise.

## Seasonal Affective Disorder (SAD)

### Definition

Seasonal affective disorder (SAD) is another term for winter depression. SAD occurs in the same person every fall/winter and remits every spring. The treatment of choice is bright light exposure scheduled in the morning. However, low-dose melatonin administration in the afternoon/evening may also be effective. For some patients, bright light should be scheduled in the evening and melatonin should be taken in the morning.

SAD is the most common affective disorder unremittingly experienced year after year in women of childbearing age living at temperate latitudes.

## Seasonality

Antonio A. Nunez, Laura Smale
Department of Psychology and Neuroscience Program, Michigan State University, East Lansing, MI, USA

### Definition

Seasonal changes that animals undergo in order to adapt to environmental circumstances as they vary across the year.

### Characteristics

Species from temperate zones experience considerable seasonal variation in their environments and many have developed complex adaptations to match their physiology and behavior to particular seasonal demands and opportunities. In mammals, the most prominent seasonal changes are seen in systems devoted to the control of energy balance and reproduction, but some species also show seasonality in non-reproductive social behaviors [e.g., aggression [1]] and immune competency [2], among other traits. There are many cues that animals can use to synchronize their seasonal cycles to environmental changes; fluctuations in average ambient temperature, rain fall and food availability are all possible candidates, but none of these is as reliable as progressive changes in daylength in predicting the flow of the seasons. Given this fact, it is perhaps not surprising to find that many species use daylength (►photoperiod) to phase their seasonal rhythms.

#### Photoperiodism

The term ►photoperiodism has been adopted to refer to the use of daylength by a species to orchestrate seasonal cycles in physiology and behavior. Although the vast majority of the mechanistic studies on mammalian seasonality has focused on photoperiodic species such as hamsters, sheep and ferrets, there are examples of seasonal rhythms that are independent of photoperiod and which continue with a period close to a year under constant laboratory conditions. The annual cycle of body weight and body adiposity displayed by ground

squirrels is an example of an endogenous, ►circannual rhythm that does not depend upon photoperiod [3].

Among the traits that show photoperiod-dependent seasonal cycles, reproductive physiology has received preferential attention. Work with a variety of animal models show how the shortening of the photoperiod, which signals that winter is approaching, and its lengthening in early spring can suppress gonadal function in spring and autumn breeders, respectively. Interestingly, this suppression is not maintained indefinitely, even if the animals are kept under the same daylength; after several weeks gonadal function returns to the level seen before the exposure to the non-stimulatory photoperiod. This rebound of reproductive competence is known as spontaneous recrudescence. That label implies that the recrudescence depends upon an endogenous mechanism but it also reflects our current lack of a mechanistic explanation for this phenomenon. The fact that there is a relatively fixed amount of time between gonadal regression and spontaneous recrudescence points to the existence of an ►internal interval timer that is set by exposure to a non-stimulatory photoperiod (i.e., short days for spring breeders) or by a physiological change triggered by such photoperiod (e.g., a drop in the levels of gonadal or pituitary hormones).

## Photoperiodic Time Measurement and Melatonin

Pineal ►melatonin has been shown to play a central role in the transduction of photoperiod into a physiological signal. Regardless of the species-specific distribution of sleep and wakefulness across the day–night cycle, the secretion of melatonin shows a nocturnal elevation that matches the length of the dark period. The duration of this nocturnal melatonin pulse is used by photoperiodic species to measure daylength and with very rare exceptions, ►pinealectomy renders these animals insensitive to changes in photoperiod. The data from experiments with timed infusions of melatonin delivered to pinealectomized animals provide compelling evidence that the duration of the melatonin pulse drives the photoperiodic responses of the reproductive system. In hamsters relatively long-duration melatonin infusions result in gonadal regression regardless of the length of the prevailing photoperiod or the phase of the timed infusion with respect to the light dark cycle [4].

Light has two separate effects on the ►pineal gland. It ►entrains the ►circadian rhythm of melatonin secretion to the light dark cycle and it can acutely suppress melatonin production during the night. The mammalian pineal gland is not itself photosensitive. It depends upon neural inputs for its responsiveness to light. The pathway that conveys both circadian and photic information to the pineal has been described in detail in several species. It starts in the retina where a set of retinal ganglion cells that express the ►photopigment melanopsin give rise to the ►retino-hypothalamic tract, which projects preferentially to the ►suprachiasmatic nucleus (►SCN). The SCN is the main ►circadian pacemaker in mammals and it influences the pineal via a multisynaptic pathway that includes the hypothalamic ►paraventricular nucleus and its long descending projections to pre-ganglionic sympathetic neurons of the spinal cord, which in turn contact the sympathetic units of the ►superior cervical ganglia (►SCG). Axons from the SCG reach the pineal and via the release of ►norepinephrine regulate the synthesis and secretion of melatonin. Removing the eyes or transecting the optic nerve is equivalent to placing animals in short photoperiods or constant darkness. However, just like a pinealectomy, interruption of the pathway from the SCN to the pineal abolishes photoperiodic responses of most photoperiodic traits [2]. Notable exceptions are the short-day reduction in sexual behavior [5] and prolactin secretion [6] in female hamsters. These responses continue to be seen after the interruption of projections from the SCN to the paraventricular nucleus of the hypothalamus and may represent pineal-independent effects of photoperiod.

## Reading and Responding to the Melatonin Signal

Even though there is universal agreement that the length of the melatonin pulse serves to encode information about daylength in photoperiodic species, there is no consensus about where in the brain this signal is read and interpreted to induce remarkable changes in multiple systems. Brain lesions in several hypothalamic sites and central infusions of melatonin directed at specific targets have identified possible candidate sites for melatonin action. However, that literature features many species differences and contradictory results even within the same species. Often the effects of central melatonin infusions are specific to a particular trait, which indicates that there may be multiple sites that respond to melatonin in parallel for the photoperiodic control of specific systems. That the critical amount of daylength necessary to support summer like features differs for different traits in the same individual [7], also argues for multiple melatonin sensitive substrates with different thresholds.

Although there is no consensus about where melatonin acts in the brain to induce gonadal regression in spring breeders such as hamsters, it is clear that part of the cause for the collapse of the reproductive system is an increase in the effectiveness of gonadal hormone inhibition of ►gonadotropin release from the anterior pituitary. This increased sensitivity to the negative feedback of gonadal steroids is a central effect, which results in diminished stimulation of the pituitary by ►gonadotropin releasing hormone (GnRH). In short

days, the pituitary remains sensitive to GnRH stimulation as shown by the activation of gonadotropin release when gonadally regressed animals receive injections of the peptide. The recently discovered brain peptide kisspeptin, which directly stimulates GnRH neurons, may also play a role in the photoperiodic regulation of the reproductive system. In hamsters seasonal gonadal regression is correlated with a reduction of kisspeptin content in the anteroventral periventricular nucleus [8].

While the central sensitivity to the negative feedback of gonadal hormones increases in short days, male and female hamsters show a partial refractoriness to the activational effects of testicular and ovarian hormones on reproductive behavior. Thus, gonadectomized male hamsters treated with identical doses of exogenous testosterone only show full activation of the male copulatory pattern when exposed to long days [9]. Similarly, ovariectomized female hamsters treated with estradiol and tested with sexually active male hamsters rarely show ►lordosis if they are kept in short days [10]. Therefore, in at least this species, seasonal infertility is achieved by suppressing the hormones of reproduction and by reducing the behavioral responsiveness to hormones that stimulate sexual behavior.

### Summary and Significance for Humans

The study of seasonality and particularly photoperiodic seasonality has identified a system that extends from the ►retina to the pineal and that appears to serve as a transducer of information about daylength. This information, in the form of a nocturnal melatonin pulse, is used in a multitude of ways to produce seasonally appropriate adaptations, which increase survival and reproductive efficacy. All the components of this system have been conserved in humans, and there is evidence that humans show seasonality on a variety of traits and that these seasonal changes are driven by photoperiod. Some of us show seasonal changes in physiology and behavior, but for a few individuals these changes are extreme enough as to be considered a form of seasonal depression or ►seasonal affective disorder (►SAD). Knowledge derived from work with photoperiodic animal models is informing therapeutic interventions for SAD patients and is providing insights about milder forms of seasonal cycles in our species.

## Second Messenger

### Definition

When a signal (protein hormones, growth factors, etc.) is received at the cell surface, second messengers are molecules that relay signals to target molecules inside the cell.

## Second Messenger Cascade

### Definition

Cascade of biochemical reaction activated by membrane receptors via trimeric G-protein leading to the generation of intracellular messengers, which in turn activate effector systems. Often mediate a considerable signal amplification.

## Second Messenger Pathway

### Definition

A general term indicating any of a number of intracellular signaling pathways activated by G protein-coupled receptors.

►G Protein-Coupled Receptor (Metabotropic Receptor)
►G-Protein Coupled Receptors (GPCRs) in Sensory Neuron Function and Pain
►G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages

## Second Somatosensory Cortex

►Somatosensory Cortex II

## Secondary Hyperalgesia

### Definition

Hyperalgesia at sites surrounding injured or inflamed areas.

►Hyperalgesia and Allodynia

## Secondary Motor Areas

### Definition

Motor areas of the cerebral cortex, other than primary motor cortex, located in the frontal lobe. These areas all contain corticospinal neurons and make synaptic connections with primary motor cortex. Six areas have been identified in primates including two areas on the lateral surface of hemisphere (dorsal premotor area, PMd and ventral premotor area, PMv) and four areas on the medial wall of the frontal lobe including supplementary motor area (SMA) and three cingulate motor areas (CMAr, CMAd, CMAv).

## Secondary Neurodegeneration

### Definition

Progressive post-injury degenerative damage or death of neural tissue that escaped primary damage. It is mediated by many compounds and processes: for example, increased content of excitatory amino acids in the extracellular milieu; deprivation of growth factors; impairment of blood supply; increase in reactive oxygen species; and general ionic imbalance. The process is common to many neurodegenerative disorders and acute injuries of the central nervous system (CNS).

## Secondary Neurogenesis

►Adult Neurogenesis

## Secondary Prosencephalon

### Definition

Rostral subdivision of the embryonic forebrain that gives rise to the hypothalamus (ventrally), the telencephalon (dorsally) and the eye vesicle (laterally).

►Evolution and Embryological Development of the Forebrain

## Secondary Receptor Cell

### Definition

Specialized, non-neural sensory cell.

►Electroreceptor Organs

## Secondary Reinforcer

### Definition

Initially neutral sensory stimulus that obtained rewarding properties by previous association with a primary reinforcer.

►Operant Conditioning

## Secondary Sensory System

### Definition

►Sensory Systems

## Secondary Somatosensory Cortex (S2)

### Definition

A higher order sensory area, located within the depths of the lateral sulcus. Its inputs arise from a variety of sources, including S1 cortex and regions of the posterior parietal cortex. Receptive fields are often bilateral; inputs can be cutaneous or deep. There appear to be two body representations here: S2 proper is located caudally, while PV (parietal ventral area) is located rostrally.

►Primary Somatosensory Cortex (S1)
►Somatosensory Cortex, Plasticity

## Secondary Structure of Proteins

### Definition

The tendency of certain amino acid sequences to form ordered structures such as alpha helices or beta sheets. The amino acid sequence of an entire protein may be analyzed to determine those segments having a high probability of forming such structures (e.g. using the method of Chou and Fasman). For transmembrane proteins such as transmitter receptors or ion channels, these predictions may be combined with those of hydropathy analysis to identify regions that might form transmembrane pores or gating structures.

## Secondary Vestibular Circuitry

►Vision

## Segment in Body Structure

### Definition

Many animals are organized with repeated body units called segments. In annelid worms, like the leech, each segment is much like the next, both in its external features, musculature, and internal organs. In vertebrate animals, the segments are not so recognizable externally or in visceral organs, but are easily seen in the organization of the musculature, in the spinal cord and its peripheral nerves, and in the pattern of their sensory and motor innervation. In fishes, the chevron-shaped bands of axial muscle that flake when we cook their flesh are called myotomes and correspond to segments.

Each myotome receives its motor (and sensory) innervation from a different spinal segment via it associated segmental nerves.

## Segmental Reflexes

### Definition

A short-latency electromyogram (EMG) response to muscle stretch or cutaneous stimulation that depends on rapid transmission of the sensory volley and evoked motor volley and involves monosynaptic or oligosynaptic pathways within the spinal cord. Also known as spinal reflexes.

►Electromyography
►Electric Fish

## Segmentation

### Definition

Segmentation is characterized by closely spaced contractions of the circular muscle layer, dividing the small bowel into small segments adjacent each other. Since these movements rhythmically alternate the sites of contractions (alternating contraction), the segmentation effectively mixes and circulates chyme.

## Segmentation of the Small Bowel

### Definition

Segmentation is characterized by closely spaced contractions of the circular muscle layer, dividing the small bowel into small segments adjacent each other. Since these movements rhythmically alternate the sites of contractions (alternating contraction), the segmentation effectively mixes and circulates chyme.

►Bowel Disorders

## Seizure

### Definition

Paroxysmal, abnormal, often excessive, repetitive, stereotypical pattern of brainwave activity. Can be provoked by fever, infection or other metabolic derangement or happen spontaneously as in epilepsy.

►Anticonvulsants
►Epilepsy

## Selective Feature Enhancement

►Contrast Enhancement

## Selective Vulnerability

### Definition

Selective vulnerability refers to the susceptibility of particular groups of neurons in the central and peripheral nervous system to age-associated neurodegeneration and death.

## Selective Working Memory

### Definition

Allows the formation of working memory, where task-relevant information is maintained in mind over a delay period while task-irrelevant information is filtered out through an attentional mechanism.

# Self

Albert Newen
Institut für Philosophie, Ruhr Universitat Bodium, Bodium, Germany

## Synonyms

The term 'self' is often used interchangeably with the term 'I' and 'person' to refer to human beings by characterizing the special epistemic or normative status of human beings.

## Definition

The self can be defined as the bearer of self-conscious states. From a naturalistic view the self is a cognitive system that enjoys some form of self-consciousness. Self-consciousness can be defined as the ability to consciously represent one's own states, especially (but not only) mental states, *as one's own* (Newen & Vogeley 2003). In the case of competent speakers this involves an indexical representation typically expressed by the word "I". If the relevant representation of my own states does involve neither language competence nor consciousness then we still have to presuppose a characteristic immediate self-representation. While "self" is mainly used to characterize the epistemic dimension of self-consciousness, i.e. the capacity to grasp first-person thoughts, "person" is used in debates searching for criteria of being a person which could serve as a basis for having rights and duties in society. From a linguistic point of view the term "self" is an artificial term which was constructed by nominalization of variants of the first-person pronoun "I" in natural language. We use expressions like "It's me," "myself," "she herself/he himself." "Self" was introduced to denote the bearer of the mental states of a self-conscious human being.

## Description of the Theory

We can distinguish four central questions concerning self-consciousness:

*The epistemological question:* Do we have a privileged access to our own mental phenomena such that only we can know with certainty which mental phenomena we have?

*The ontological question:* Is there a self as an ontologically nonreducible entity or can we explain all phenomena of self-consciousness without presupposing a self as a nonreducible entity?

*The Cognitive question*: How can we investigate the natural basis of self-consciousness with the methods of empirical psychology and cognitive neuroscience?

*The question about personal identity:* What is the criterion of being a person and of remaining the same person?

Philosophical thinking about self-consciousness was not invented by Descartes – as often stated or implicitly presupposed – but is already present in ancient philosophy. The first book discussing important aspects of a theory of self-consciousness is Platon's early dialogue *Charmides*. Since the history of self-consciousness is already presented in other overviews, let me illustrate these three dimensions of self-consciousness while concentrating mainly on the modern discussions:

1. The epistemological dimension: Do we have self-knowledge on the basis of a privileged access? The philosophers of the period from Descartes to Kant took two claims to be evident: the transparency and the infallibility of the mind. If someone is in the mental state M then he/she knows that he/she has that state (transparency). If someone believes that he himself/she herself is in the mental state M then he/she knows that this is so (infallibility). Both claims are no longer acceptable as general claims. Given that mental phenomena can be divided into mental dispositions, (mental traits like being jealous, being anxious etc.) on the one hand and mental events (occurrences of thinking, feeling or perception) on the other, the transparency of the mind is undermined by several systematic observations. It is obvious that my mental dispositions can often be more reliably evaluated by other persons observing me than by myself. Furthermore, there is evidence that the same is also true for certain occurrences of my beliefs and desires, namely unconscious ones (as e.g. presupposed in Freud's psychoanalysis). Unconscious occurrences of feeling and perception are presupposed in modern theories of selective attention. But not only the transparency thesis, also the infallibility thesis has to go: There are cases in which we consciously think that we are in a certain mental state M1 when in fact we are in a different state M2. Concerning feelings psychological studies show that we can characterize a special class of people (repressors) who systematically misclassify their own feelings when they are in situations which make them feel personally concerned (Weinberger & Davidson 1994). In such situations repressors report being perfectly calm even though their palms are sweating, their hearts are racing at 180 beats per minute etc. This demonstrates that one can have a basic emotion while lacking a conscious representation of it. Furthermore, there is a general argument against the infallibility of self-knowledge, which shows that even basic perceptual impressions can be misclassified and that we therefore do not always enjoy self-knowledge of these impressions: In order to have self-knowledge we must classify our mental states on the basis of concepts. If

there are circumstances in which I have partially inadequate concepts or in which I may misuse my correct concepts due to psychological disorders or mental traits, I will misclassify my own mental events. Self-knowledge of our own mental states presupposes a correct classification on the basis of our concepts and this is not infallible but only *de facto* often given under normal circumstances. By the way, it should have become clear that we do not enjoy any privileged access such that only we know with certainty which mental state we have. The only privilege we enjoy concerning our mental states is called familiarity (Ryle 1949): We have much more information about ourselves than other people because we recognize a lot of our mental states during our life while other people only share a part of it. But such a situation of familiarity has to be learned: Parents often are more familiar with their children's mental states then the children themselves. Presupposing that we have standard conceptual competence and psychological conditions, there is one further principal challenge to the possibility of self-knowledge. This challenge is mainly based on the claim that the content of our thought is partly dependent on the environment. Putnam's famous thought-experiment distinguishes Tom who lives on earth and Twin-Tom, a psychophysical *Doppelgänger* living on Twin-earth. The only difference between earth and Twin-earth is that in using the word "water" on earth we refer to the well-known substance $H_2O$ while Twin-Tom using the word "water" on Twin-earth refers to a substance which has the same superficial properties but nevertheless is chemically based on molecules XYZ. Independent of the question whether this difference in the essential properties is known to the speakers, the reference of "water" is a different substance. Therefore, if Tom utters "Water is a tasteless liquid" he is expressing a thought about $H_2O$ while Twin-Tom using the same words expresses a thought about XYZ. The conclusion of this thought experiment is that the content of thoughts is dependent on the environment. This is called externalism of thought. The challenge to self-knowledge is produced by the following claims: (a1) Self-knowledge about the content of our thoughts is only based on introspection and therefore is independent of the environment. (a2) The content of our thoughts is dependent on the environment (externalism).

The conclusion is: Either self-knowledge is impossible or externalism is wrong. Which part of the conclusion is the correct one is still part of the recent debate, but, the problematic preaise is the externalism of thoughts while the externalism of utterances is widely accepted (Newen & Vogeley 2007).

2. The ontological dimension: Is there a self as an ontologically nonreducible entity? The *locus classicus* for a positive answer is the work of Rene Descartes. He claims that a person is constituted by a self as a purely mental entity (*res cogitans*) and a distinct body as a purely material entity (*res extensa*). An alternative traditional view was developed by David Hume. According to his view the self is nothing but a bundle of impressions (or ideas) such that there is no nonreducible entity in addition to the impressions which are the basic entities in his framework. A third important traditional view is that of Immanuel Kant. He claims that the self is not an entity at all but only a condition of the possibility of experience, i.e. the self is something that has an important status, but it can only be characterized negatively and as a consequence of conceptual considerations: There has to be a self as a precondition of experience, because otherwise we do not have an explanation for the unity of our experiences.

We have thereby already outlined the three vivid options which still dominate the recent debate in the twentieth century. Thomas Nagel argued for the Cartesian view that any person has an objective self as a nonreducible entity, because he claims that without such a presupposition we could not account for the first-person-perspective which is characteristic for our experiences. Dennett, in the spirit of the Kantian strategy, developed the view that the self is a special abstract entity: It is the centre of gravity of the stories which a person tells about herself, because we have to account for the self-ascription of beliefs and desires in our autobiographical memory. The special status of the self is then parallel to the special status of the centre of gravity which a bike has: It is a theoretical abstract entity which is a consequence of physical theory in the case of the bike and theory of mind in the case of the self. Since this analogy is rather unspecific it remains unclear what status the self has in more detail.

Furthermore, there is a modern radicalization of the Humean view, the claim that the self is not an entity at all: According to Wittgenstein and Anscombe the self is nothing but a fiction we introduced because of grammatical fallacies: In natural language we use sentences like "I am in pain" which express the fact that we are suffering from pain. Wittgenstein insisted that we would express exactly the same just by uttering the vowel "AUA!". Since it does not even make sense to ask what the reference of such vowels is, Wittgenstein concludes that the impression that there is a reference of "I" is just a consequence of drawing wrong conclusions from the grammatical surface structure of natural language to the ontological structure of the world. Although this argument – relying on the synonymy of vowels and normal utterances – is very weak (because such a synonymy exists only in some special cases), the general position that the self is only a fiction has become supported by new arguments. Metzinger (2003) presented the self-model theory of self-consciousness, claiming that the human being is a neural machine which is able to construct a self-model.

The self-model is nothing but all the contents of the stream of consciousness a human being experiences at one moment. Since the self is identified with a *content*, i.e. the content of our phenomenal consciousness, it is just a fiction, an epiphenomenal product of our neural machinery. Theories which claim that the self is a content cannot account for the basic fact that we use the word "I" to talk about persons as human beings. Therefore, there is still the option of identifying the self with the person as human being. According to Peter Strawson the self is nothing but a person, i.e. a primitive natural entity which has both mental and physical properties. In this framework self-consciousness is not explained away as a fiction but treated as a special property of human beings. According to the philosophy of language we know that uttering I-sentences is a standard way of expressing self-conscious thoughts. The property of expressing self-conscious thoughts is closely connected to the so-called essential indexicality of the first-person pronoun "I" (Perry 1979): The thought expressed by uttering an "I"-sentence (e.g. "I am hungry" uttered by Ernst Mach) is different from the thoughts expressed by utterances in which only the word "I" is substituted by a term having the same reference (e.g. "Ernst Mach is hungry") because only I-thoughts can have special motivational role. I will start to search for food only if I think that I am hungry. "I"-sentences have the feature of essential indexicality which is based on a property of self-conscious thoughts, namely the property of an immediate self-representation. The challenge for this common sense view is to explain the property of having an immediate self-representation.

3. The cognitive diveasion: There are atleast two ways of investigating this core property, taking an ontogenetic perspective, on the one hand, and measuring neural correlates, on the other. Developmental psychologists started to investigate the development of human self-consciousness (Neisser 1998). This led to different models of distinguishing types of self-consciousness (e.g. Bermúdez, 1998). The challenge is that there are several intuition-based distinctions on the market, but what we need is a systematically founded typology (Newen & Vogeley, 2003). The general line of this research is to understand full-fledged self-consciousness by understanding the way it is developed in human ontogenesis and in principle also in evolution. A presupposition of these investigations is an analysis of the complex phenomenon self-consciousness into several cognitive competences which are necessary to have self-conscious thoughts. We can distinguish (i) perspectivity, (ii) agency, and (iii) mineness. Perspectivity includes the first-person-perspective we have in human perception but also in the case of self-ascribing beliefs. Agency means the feeling that we are causing an action, the feeling that the action is performed because we want to perform it. Mineness can be characterized as the feeling that a bodily part (an arm, a leg) belongs to me, but also the feeling that a thought is *my* thought. The aim is to understand these fundamental cognitive capacities by investigating their development and explaining cases of malfunction in the case of mental diseases.

The second line of research aims at discovering the neural correlates of human self-consciousness. To measure neural correlates the general strategy runs as follows: On the basis of the conceptual analysis distinguishing perspectivity, agency and mineness, experimental paradigms to investigate different types of each capacity have to be developed. If an experimental design is validated then it can be used to measure the neural correlates. The first measurement of cognitive first-person-perspective was done by Vogeley, Bussfeld, Newen et al. (2001) measuring the neural correlates of the capacity to self-ascribing beliefs. There are further measurements of neural correlates of first-person-perspectives (Newen & Vogeley 2003, Ruby & Decety 2001 & 2003, Vogeley & Fink 2003).

Concerning the general strategy to naturalize human self-consciousness there is one basic argument which shows that we have to account for nonconceptual self-consciousness as a form of basic self-consciousness which is independent of and prior to linguistic competence. The argument is called the paradox of self-consciousness. It consists in the following incompatible propositions (Bermúdez 1998):

1. The only way to analyze the capacity to think a particular range of thoughts is by analyzing the capacity for the canonical linguistic expression of those thoughts (the Thought-Language-Principle).
2. The key to analyzing self-consciousness is to analyze the capacity to think "I"-thoughts.
3. "I"-thoughts are canonically expressed by means of the first-person pronoun and mastery of the first-person pronoun requires the capacity to think "I"-thoughts.
4. A noncircular account of self-consciousness is possible.

There is the additional background assumption that the capacity to think "I"-thoughts meets the Acquisition Constraint which says that if a given cognitive capacity is psychologically real, then there must be an explanation of how it is possible for an individual in the normal course of human development to acquire that capacity. If we accept that self-consciousness is independent from language competence (by denying 1) then we have to account for nonconceptual as well as conceptual forms of self-representation (Newen/Vogeley 2003).

4. Personal identity: Self-consciousness is closely related to the debates on personal identity. The question

"What are the criteria of individuating a person?" was introduced by John Locke and he claimed that the person, which he identifies with the self, is defined by the continuation of the content of the memory the human being ascribes to itself. This criterion can be called the demand of psychological continuation. It means that if a human being loses his memory then he no longer remains the same person. Modern thought experiments can illustrate another consequence of this criterion (Parfit 1984): If the content of the memory is represented in the brain and the brain of Peter is transplanted into the body of Karl, then the body of Karl including the brain of Peter will be the person Peter. Psychological continuation only demands a partial overlap of the memories to individuate a person. One problematic consequence of this criterion is that it can easily be imagined that there are several human beings fulfilling the criterion of partial overlap of memories with the content of the self-ascribed memories of Peter at the time t0. Presupposing that the memories of Peter at t0 are represented in his brain, we can make the following thought experiment: One half of Peter's brain is transplanted into the body of Jo and the other half of Peter's brain is transplanted into the body of Sam. It is presupposed that in both cases a significant part of Peter's memories was transferred to Jo as well as to Sam. If this scenario seems too unrealistic then think of the brain as a piece of hardware. Then the same result of having a significant overlap with Peter's memories at t0 can be produced by whatever method leads to copying or transferring a large part of Peter's memories to Sam's brain and to Jo's brain. In both varieties of thought transfer the intuitive result is that Sam and Jo both have a significant overlap with Peter's memories at t0. Who then is the person Peter at t1, after the transplantation of his brain partly into Sam and partly into Jo? The criterion says that there cannot be two persons which are both Peter and in the scenario of copying the memories of Peter into another brain, provided it happens without harming Peter, we would even have three persons Peter, the original one being identical with Sam and Jo. This leads us to an unacceptable violation of our intuitions concerning the principle of identity: Because of the normal change of a human being over time we have to accept that human beings differing in their material constitution can be the same person at different times. We cannot however accept that different human beings are the same person at the same time. Modern views of personal identity try to combine a criterion of space-time continuation with the demand of psychological continuation.

The modern debates in philosophy and cognitive science about the self are characterized by a lot of different scientific approaches – partly mentioned above – which aim at naturalizing the self and self-consciousness in all its facets, on the one hand, and some new considerations which try to present principle reasons for the thesis that this aim can never be reached (Baker 1998, Bealer 1997), on the other.

# Self-administration

## Definition

In a behavioral experiment the animal may be awarded. If the animal is allowed to administer the award by itself, we speak of self-adminstration. This way of award is often used to study the addictive potency of a drug.

## Self-antigen

►Anti-DNA Antibodies against Microbial and Non-Nucleic Acid Self-Antigens

## Self-appraisal

### Definition

Self-appraisal refers to the process of self-reflecting on and evaluating own meta-cognitive knowledge and strategies (i.e., declarative) (e.g., what strategies are relevant), procedural (e.g., how to apply them), and conditional (e.g., why they are effective and when they should be applied).

►Metacognition

## Self-consciousness

### Definition

A person has self-consciousness when she has a thought that she can express in the first person singular. In a supermarket, one may be well aware that the person with the torn sugar bag is making a mess without realizing that it is oneself who is making a mess.

Realizing this, one lives through an episode of selfconsciousness expressible by "I am making a mess." Sometimes only an introspective awareness of one's own consciousness is called "self-consciousness."

►Argument
►Logic

## Self-management

### Definition

Self-management refers to the dynamic process of translating metacognitive knowledge adaptively to the task performance, and can be described as metacognition in action. It includes at least the three processes for actions: Planning, on-going evaluation by monitoring, and regulation by modifying plans and changing/adjusting strategies, and these three processes recur repeatedly depending upon situations.

►Metacognition

## Self-motion Cues

### Definition

Self motion cues are derived directly from locomotion and provide feedback information about speed and direction of motion. Self motion cues are egocentric.

Therefore, in order to provide information to update a location on a map, self motion cues must be accompanied by a sighting, which positions and orients the traveler on the map. Self-motion cues include proprioception (sensations from the body), optic flow, and feedback from motor commands – also called an efference copy. A synonym for self motion is idiothetic.

►Navigation

## Self-perception

### Definition

A concept in spatial cognition that involves mentally representing one's own action, other's action, and observation of action. Representations between self and others are shared, but not identical, influencing processes of empathy and social interaction.

►Spatial Cognition

## Self-renewal

### Definition

Ability to go through numerous (virtually-indefinite) cycles of cell division while maintaining the undifferentiated state. To ensure self-renewal, stem cells undergo two types of cell division: symmetric cell division gives rise to two identical daughter cells both endowed with stem cell properties, while asymmetric

cell division produces only one daughter stem cell and one progenitor cell with limited self-renewal potential.

One theory claims that the molecular distinction between symmetric and asymmetric cell division in neural stem cells lies in differential segregation of certain cell membrane proteins (such as receptors) between the daughter cells. An alternative theory – the cell non-autonomic regulation of stemness during adulthood - is that stem cells remain undifferentiated from environmental cues in their particular germinal niche. Stem cells eventually differentiate once they leave that germinal niche or no longer receive those environmental regulators.

►Autoimmune Demyelinating Disorders: Stem Cell Therapy

## Self-sustaining Oscillation

### Definition

One can imagine at least two starkly different mechanisms for keeping track of the passage of time. On the one hand are timekeeping mechanisms like hourglasses, which only encode the passage of time relative to an external triggering event, and can only keep time continuously if that external triggering event repeatedly occurs. On the other hand are self-sustaining oscillators like pendulum clocks, which encode the passage of time relative to an internally determined repeating interval of time, in this case the 12-h half-day, and keep time over multiple intervals without requiring external triggers.

Circadian clocks are all self-sustained oscillators, as demonstrated by the continuation of circadian rhythms of various biological functions when organisms are maintained in environments that are devoid of any external cues to the passage of time.

# Semantics (Two-Dimensional)

Christian Nimtz
Department of Philosophy, University of Bielefeld, Bielefeld, Germany

## Definition

"Two-dimensional semantics" denotes a family of semantic theories rooted in intensional semantics, held together by shared general ideas, yet divided by deep divergences in semantic aims and philosophical aspiration. Two-dimensional theorists agree that our sentence's truth-values vary with what the facts are, as well as with what the sentences mean. To model this twofold dependence of truth on fact and meaning, 2D semantics assigns our expressions intensions of more than one kind. The resulting formal framework, common to all 2D semantics, distinguishes one dimension of actual worlds and primary intensions from a second dimension of counterfactual worlds and secondary intensions (hence, two-dimensionalism). These formal similarities often obscure the deep conceptual rifts between different interpretations of the 2D framework. Kaplan interprets it to capture context-dependence; Stalnaker understands it to model meta-semantic facts, and Chalmers construes it to display the epistemic roots of meaning.

## Description of the Theory

### Fundamental Ideas of Two-Dimensional Semantics

Traditional intensional semantics assigns a sentence a single intension. This intension captures how the truth of the sentence depends on, and varies with, the respective facts. Two-dimensional semanticists draw our attention to another dependence. A sentence's truth-value also depends on, and varies with, what the sentence means. Two-dimensional semanticists agree that our semantics has to account for this twofold dependence of truth-value on meaning and fact, and they agree that we can capture both dependencies relying on the apparatus of possible worlds and intensions familiar from intensional semantics. We just need to add the distinction between counterfactual and actual worlds, and we have to make use of the threefold distinction of kinds of intension this effects.

The twofold dependence noted is most pronounced in sentences containing indexicals. Whether "I am in *Milano*" is true in some possible world depends on the facts in that world, and it depends on who utters this sentence in the first place. If Pavarotti utters it, the sentence is true in a possible world if in that world, Pavarotti is in Milan. If someone else utters it, the sentence has different truth-conditions. Put generally, the truth of an indexical sentence in some counterfactual world depends on what is the case in that world, and it depends on what is the case in the actual world it is uttered in. This inspires a general way to analyze the twofold dependence noted. We can hold that whether a sentence is true in some counterfactual world depends on the facts, depicted by what is the case in that world, and it depends on what the sentence means, determined by what is the case in the actual world. The counterfactual and actual worlds set apart here are not different entities. What gets discriminated are two different roles the very same possible worlds can play (assuming that we specify for worlds considered as actual a center consisting of a speaker, a place, and a time).

The distinction between counterfactual and actual worlds allows 2D semanticists to distinguish three different kinds of intensions. An expression's *primary intension* assigns it an extension in every *actual* world, determining a function $f$: $W_A \rightarrow E$ from actual worlds to extensions. An expression's *secondary intension* assigns it an extension in every *counterfactual* world, determining a function $f$: $W_C \rightarrow E$ from counterfactual worlds to extensions. An expression's *two-dimensional intension* assigns it for any actual world a secondary intension, determining a function $f$: $W_A \rightarrow (W_C \rightarrow E)$ from actual worlds to secondary extensions that portray how the expression's primary and secondary intensions interlock.

Assigning these different intensions to a sentence allows 2D semantics to capture the way its truth-value varies with the actual and counterfactual world and, hence, depends on fact and meaning. A plausible assignment of intensions to "I am in *Milano*" is this: the primary intension of "I am in *Milano*" yields varying extensions across actual worlds depending on who utters the sentence. The secondary intension yields varying extensions across counterfactual worlds, depending on whether or not the one having uttered "I" is in these counterfactual circumstances in Milan. The 2D intension combines these two, capturing for each actual world which secondary intension an utterance of "I am in *Milano*" in this actual world effects.

The resulting formal structure (see Fig. 1), comprising two dimensions of worlds and three kinds of intensions, is common to all 2D semantics. Two-dimensional semanticists agree that we can model all representational properties of our language by assigning primary, secondary, and/or two-dimensional intensions to our terms and sentences. This consensus extends to the dimension of counterfactual worlds and secondary intensions. Two-dimensional semanticists agree that this dimension captures how an expression's extension depends on the facts, and they take these worlds and intensions to be the possible worlds and

| | Dimension 2 counterfactual worlds → | | |
|---|---|---|---|
| Dimension 1 actual worlds → | W1 | W2 | W3 |
| W1* | W | W | f |
| W2* | f | W | W |
| W3* | W | W | f |

**Semantics (Two-Dimensional). Figure 1** A 2D matrix displaying a sentence's intensions for a small sample of worlds. The diagonal displays a single primary intension. Each row displays a secondary intension. The whole matrix displays a single two-dimensional intension.

standard intensions familiar from traditional intensional semantics. There is no consensus on the understanding of actual worlds and primary intensions. Two-dimensional theorists agree that this dimension captures how an expression's extension depends on what it means. This claim is open to interpretation, and the paradigmatic interpretations put forth by Kaplan, Stalnaker, and Chalmers exhibit deep divergences in semantic aim and philosophical aspiration. They even yield different answers to the questions (i) "What are actual worlds?" and (ii) "What precisely do we need actual worlds and primary intensions for?"

## Kaplan: Actual Worlds as Contexts of Use

Kaplan [1,2] propounds a semantic interpretation of the 2D framework. He holds that (i) actual worlds are contexts, or possible occasions expressions can be used in, and he (ii) maintains that we need actual worlds and primary intensions to model the context dependence of language.

Kaplan detects an asymmetry between indexical tokens and indexical types. Indexical tokens have reference but no descriptive meaning. An utterance of "I" in a context refers to an individual. This fact exhausts its meaning. Pavarotti's utterance "I am in *Milano*" thus expresses a proposition about *him*, i.e., Pavarotti. Indexical types, on the other hand, have descriptive meaning but no reference. The type "I" does not refer. It still has a descriptive meaning any competent speaker must know. This meaning consists in a conventionally assigned rule dictating that any utterance of "I" refers to whoever produces the token in the respective context. Thus, the sentence type "I am in *Milano*" does not express a proposition, but any competent speaker will know which proposition a token of this type expresses *if* it is uttered in a context.

Kaplan concludes that we must distinguish two kinds of meaning. Linguistic tokens have *contents*. The content of a term captures what it refers to, and the content of a sentence is the proposition it expresses. Linguistic types have *characters*. The character of an expression is a conventionally determined rule dictating which content a token of that expression expresses if it is uttered in a context. The characters of terms like "grandmother" will assign all tokens the very same content. By contrast, the characters of indexicals and demonstratives will assign their tokens varying contents, depending on the respective contexts.

It is this dependence of token meaning (or content) on type meaning (or character) cum context that Kaplan captures by means of a 2D framework. He models contents as secondary intensions. He models characters as two-dimensional intensions. The character of a sentence type specifies a secondary intension for each actual world, and thus captures how the proposition expressed by a token of that sentence varies with the context the token occurs in.

## Stalnaker: Actual Worlds as Means for Reinterpretation

Stalnaker [3,4] offers a meta-semantic interpretation of the 2D framework. Stalnaker's holds (i) that actual worlds are possible alternative environments we might have introduced our terms in, and he (ii) distinguishes the subject matter of the 2D framework from its application: we need the apparatus of actual worlds and primary intensions to describe meta-semantic facts, but we put it to a pragmatic use.

Endorsing (i)–(iii), Stalnaker finds himself in a quandary: (i) Being necessarily true, the proposition expressed by "Hesperus = Phosphorus" does not exclude any possibility. (ii) A sentence can be used to communicate contingent information about the world only if the proposition it conveys excludes some possibility. (iii) "Hesperus = Phosphorus" can be used to communicate contingent information about the world. To resolve the puzzle, Stalnaker distinguishes the proposition *conveyed* with an informative use of "Hesperus = Phosphorus" from the proposition *expressed* in that use. The latter is determined by the standard semantic rules for the sentence, and it is necessarily true. The former is inferred from the speaker's pragmatic communicative intentions, and it is contingent. Reinterpreting the speaker's utterance to convey this contingent proposition allows the hearer to make sense of his utterance.

Reinterpretation is a familiar pragmatic procedure. If the standard semantic content of an utterance manifestly violates a conversational maxim, we assign it a different content by drawing on the speaker's communicative intentions. This is what the hearer of "Hesperus =

Phosphorus" does, noticing that the standard proposition expressed is ill-fit to convey information. The hearer reasons thus: (i) "Hesperus" has been introduced as a name for the brightest star in the evening, and "Phosphorus" has been introduced as a name for the brightest star in the morning. (ii) Which objects these introductions did yield depended on astronomical facts in our actual world. If the astronomical facts in the actual world had been relevantly different, "Hesperus" and "Phosphorus" would name two different objects. (iii) What the speaker intends to convey is that our world is one where this is not so. He wants to convey that our world conforms to the proposition *that the brightest star in the evening = the brightest star in the morning*.

It is this dependence of semantic meaning on introductory procedure cum actual world that Stalnaker captures by a 2D framework. He models standard semantic meanings as secondary intensions. Stalnaker models the propositions assigned in reinterpretation as primary intensions (which he calls, in line with Fig. 1, *diagnonal propositions*). By displaying how an expression's extension varies with the respective actual world, a primary intension captures how a term's standard semantic meaning varies with the circumstances under which it is introduced.

### Chalmers: Actual Worlds as Epistemic Possibilities

Chalmers [5–8] offers an *epistemic* interpretation of the 2D framework. Chalmers (i) maintains that actual worlds are epistemic possibilities, and he (ii) holds that we need actual worlds and primary intensions to capture the epistemic dependence of meaning.

Chalmers draws on two ideas. His one idea is that reference and truth are *scrutable*. Given a description of our world cast in neutral terms, a speaker can (in principle) *a priori* infer what her expressions refer to, and which of her sentences are true. From a description of the appearance, make-up, and behavior of chemical substances that makes no use of the term "gold," she can *a priori* infer the truth of "Gold is the chemical element with atomic number 79." Chalmers' other idea is that of epistemic modality. Epistemically possible hypotheses depict ways our world might be for all we can (in principle) *a priori* know, and a complete epistemic possibility depicts an epistemically possible world. For all we can know *a priori*, gold could be the chemical element with atomic number 55. A world in which this is true, hence, is an epistemic possibility. Chalmers merges these ideas in his thesis of *generalized scrutability*. Given a description of any epistemically possible world phrased in neutral terms, a competent speaker can (in principle) *a priori* infer what her terms refer to in that world, and which of her sentences are true in that world. This ability reveals that speakers associate epistemic intensions – i.e., functions from epistemically possible worlds to extensions – with their terms and sentences. The epistemic intension associated with an expression is fundamental to the expression's significance. For one thing, it captures cognitive significance. If a term plays a cognitive role for a speaker at all, she associates an epistemic intension with it that reveals what the term means for her. Secondly, the epistemic intension determines an extension in the actual world. For the actual world simply is the actualized epistemic possibility. Thirdly, the epistemic intension will ground the counterfactual intensions of all terms whose counterfactual intension depends on actual world extension.

It is this dependence of truth and reference on our ability to determine *a priori* extensions in epistemically possible worlds that Chalmers captures by means of a 2D framework. He identifies secondary intensions with standard truth-conditional meanings, and he employs two-dimensional intensions to model the dependence of secondary intensions on primary ones. Chalmers identifies primary intensions with epistemic intensions. By displaying how an expression's extension varies with the respective actual world, a primary intension captures how a term's actual extension varies with the respective epistemic possibility that is realized in our world.

# Semaphorin

## Definition

Family of secreted or cell surface-bound guidance molecules with attractive and repulsive actions mediated by receptors comprising plexin proteins and,

in certain cases, neuropilin. Semaphorins mainly act as short-range signals (semaphor is the Greek word for signal) to deflect growing axons from innervating inappropriate regions.

►Growth Inhibitory Molecules in Nervous System Development and Regeneration

## Semaphorin-3A

### Definition

Semaphorins constitute a family of secreted and transmembrane signaling proteins.In the nervous system, members of this family have been shown to play a role in axon pathfinding, branching and targeting. Some members of this family, including semaphoring-3A, function as chemorepellents of specific growth cones.

►Axon Pathfinding
►Growth Cone
►Semaphorin

## Semicircular Canals

### Definition

Parts of the membranous labyrinth in the form of semicircular ducts that stem from a structure of larger diameter (utriculus). There are three for each side, oriented along three different, roughly orthogonal planes and contain labyrinthine (ampullar) receptors located in an enlargement at the base of each canal (ampulla). Angular acceleration in space induces motion of endolymph within the canals, which is maximal when the plane of rotation corresponds to that of the canal and absent when the two planes are perpendicular. The central axons of the primary afferents from the vestibular system (vestibular nerve) run with the VIIIth cranial nerve and terminate in the vestibular nuclei.

## Semicompatibilism

### Definition

The thesis that free action is compatible with the truth of determinism even if the ability to have acted otherwise than one in fact acted is incompatible with the truth of determinism.

►Freedom of Will

## Semi-intact Preparations

### Definition

Typically refers to in-vitro preparations in which some part of the body is kept intact in addition to the nervous system. For example, semi-intact preparations of spinal cord along with attached hindlimbs can be used to record muscular contractions in response to stimulation of the spinal cord tissue. These preparations provide opportunities to better approximate in vivo conditions while retaining the ability to control the external environment.

## Sender

### Definition

In communication theory the partner that emits a signal.

## Sensation Level (SL)

### Definition

The decibel level expressed relative to some other level measured in an experiment.

►Acoustics

## Sense Data (Singular: Sense Datum)

Alexander Staudacher
Institut für Philosophie, Otto-von-Guericke-Universitaet Magdeburg, Magdeburg, Germany

### Synonyms

Sensa (singular: sensum)

### Definition

One of the central debates in the philosophy of perception deals with the question of what we are immediately aware of in perception. According to sense-datum-theories the objects of this immediate awareness are sense data. A typical example for a sense datum is the more or less round, red, bulgy expanse you are immediately aware of when you see a ripe tomato during normal daylight. At first, one might think that sense data are identical to those surfaces of physical objects facing us in a perceptual situation. In this case the claim that, in perception, we are immediately aware of sense data would just spell out our common sense assumption that, in perception, we are immediately aware of the facing surfaces of physical objects. But sense data should to be distinguished from these surfaces for the following four reasons: (i) certain changes in the perceptual situation lead to changes in our sense data, whereas the features of the surfaces of the perceived physical objects are not affected by these changes: if you change your perspective on the tomato in the right way you will become aware of a new sense datum which is not round but elliptical; the surface of the physical object, however, won't undergo any such change. Likewise, with a change of the lighting-conditions you might become aware of a sense datum showing a different color, whereas the surface doesn't change. Finally, drugs, impairments of sense organs or psychological factors like expectations or prejudices concerning the object of perception may influence what kind of sense data we will have without any change in the perceived physical objects. (ii) Sense data are generally taken to be private, that is, they are accessible only to one perceiving subject and not to other subjects. Physical objects, on the other hand, are taken to be publicly accessible to many perceiving subjects. (iii) Most defenders of sense data take them to exist only when we are aware of them. Physical objects are generally supposed to continue to exist when nobody is aware of them. (iv) In cases of hallucination where no physical object is present at all (think of the rats hallucinated by the delirious drinker or the dagger that appears to Macbeth in Shakespeare's play), there is nevertheless a sense datum present which we are aware of. The same holds in cases of illusions where we are aware of a sense datum with properties differing from those of the physical object present in that perceptual situation (when you immerse a straight oar into water you will be aware of a sense datum which is bent).

These four points lead on the one hand to the question of how sense data are related to the physical objects of our environment and on the other hand to the question of how they are related to our perceptual awareness. To the first question the two main sense datum theories, ►phenomenalism and ►indirect or representative realism, give radically different answers explored in the next section. To the second question a certain version of the so called "act-object analysis" of perceptual awareness has been customarily presented as an answer. According to this analysis, perceptual states consist of two parts which have to be distinguished:

an act of awareness (sometimes called the "act of sensing" or just the "sensation") and a sense datum which is the object this act is directed upon [1]. Since sense data form a part of a mental state, they have to be seen as something mental and therefore cannot exist unperceived.

## Description of the Theory

Sense data have been given two roles in the literature: (i) they have been taken as necessary for an adequate account of what we are immediately aware of in perception. (ii) They have been seen as the secure base of our empirical knowledge because it has been held that we cannot err with respect to their character: if a sense datum appears to you red it has to be red. You might mistake a white plate during sunset to be pink but you cannot mistake the pink expanse you experience in this situation for something else. It is important to note that one can give sense data the first role without putting any weight on the second role. The motivating idea behind the second role is the claim that empirical knowledge needs a secure fundament. One might refuse this idea, however, without giving up the claim that sense data play an indispensable role as immediate objects of perceptual awareness, because physical objects, as they are conceived by common sense, cannot play this role. Most of the more recent defenses of sense data theories lay their emphasis only on the first role. Therefore, this essay will concentrate on this point.

Historically, sense data can be seen as the heirs of the "ideas" or "impressions" of the epistemology of the seventeenth and eighteenth century, since the latter also had to play the two mentioned roles. The heyday of sense-datum-theories was the first half of the twentieth century [2–5]. For more recent defenses see [1,6–8].

According to common sense we are in perception immediately aware of the physical objects we perceive and these objects share the characteristics given in the four distinctive features above. Therefore, a defender of sense data has to give up either the claim that we are in perception immediately aware of physical objects or the claim that they share all of these features. Indirect realism follows the first route and phenomenalism the second one.

According to indirect realism, our perception of physical objects is only indirect because it is mediated by the immediate awareness of sense data in the following way: in the case of veridical perception a physical object will initiate a causal chain which leads via an affection of our sense organs and respective processes in the brain to the appearance of a sense datum (or a collection of sense data, for that matter). Such a sense datum serves the perceiver as a representation or sign of the physical object. In cases of illusion and hallucination the causal chain leading to the appearance of the sense datum doesn't start with the same kind of object as in the case of veridical perceptions. In the case of hallucinations it starts in the brain, because no external object is present. In the case of illusions it starts with an object that has properties which are different from those the object of your immediate awareness has. Indirect realism can admit that we perceive physical objects, but it claims that we have to distinguish between the objects of our immediate perceptual awareness (sense data) and the objects of perception (physical objects). Phenomenalism, on the other hand, does not distinguish between sense data and physical objects in that way. According to this theory physical objects are nothing but complex sequences of actual and possible sense data. A tomato is then nothing but the complex sequence of actual sense data I have at the time of seeing and touching it now and the sequence of possible sense data I would have if I changed my perspective relative to it, cut it into pieces and so on. If sense data exist only when we are aware of them, this leads to the consequence that physical objects cannot exist independently of the fact that we are aware of them. The common sense assumption that a rock in the desert also exists when no one perceives it becomes, in the hands of phenomenalism, the claim that one would be aware of the required rock-like sense data if one went to the relevant place in the desert. (For more on phenomenalism and indirect realism see the essay "perception.")

But why adopt any sense-datum-theory at all? Several arguments in favor of the existence of sense data have been put forward. The general idea behind these arguments is always the same: First it is argued that there is a certain class of cases where it is impossible that we are immediately aware of physical objects, so that at least in these cases we have to be aware of something different. Then it is claimed that only by supposing our immediate awareness of certain objects of another kind, namely sense data. Can we do justice to these cases in the next step it is claimed that there is no sensible argument which allows us to restrict the result to these special cases, so we finally have to admit that we are in all cases of perception immediately aware of sense data.

The most famous of these arguments is probably the ►Argument from illusion. The conclusion that we are in perception always immediately aware of sense data is reached here in four steps. The first step consists of the observation that in perception things sometimes appear to possess sensory qualities (colors, forms, felt temperatures etc.) then they don't possess. The second step is the claim that in all cases where something appears to a subject to possess a sensory quality, there is something of which the subject is aware which does possess that quality. The third step, an application of a logical principle known as Leibniz' law, holds that if an object *a* possesses a sensory quality that an object *b* lacks, then *a* is not identical to *b*. According to the fourth step there is such continuity between those cases

in which objects appear other than they actually are and cases of veridical perception that the same analysis of perception must apply to both. An example may be helpful for illustration: A straight oar immersed in water will appear bent. Therefore, what we are immediately aware of can't be the straight oar, but must be a sense datum which is bent. And because of the continuity of the perceptual situation we will also be aware of a sense datum when we remove the oar from the water. But then we may conclude that we are always immediately aware of sense data.

Well known arguments coming to the same conclusion as the Argument from Illusion by more or less similar routes include the following: The ►Argument from perspectival variation: Objects appear different to us from different perspectives although the objects themselves don't change. Therefore, we have to be aware of different sense data in order to explain these changes. The ►Argument from hallucination: In cases of hallucinations where no object is present at all we are nevertheless aware of something which has certain sensory qualities, and therefore we are aware in these cases of certain sense data which are the bearers of these qualities. Since hallucinations and veridical perceptions are indistinguishable for the perceiving subject we can conclude that we are also aware of sense data in the latter case. The ►Argument from science: Science tells us that nothing has the properties it appears to have in perception. For example, nothing is colored in the way it appears colored to our eyes and what appears a grainless solid structure may in reality be a swarm of molecules. Therefore, perception we have to be aware in of something other than physical objects, namely sense data which are literally colored and appear grainless and solid. The ►Time gap argument: Our perceptual awareness is restricted to the present, we can't be immediately aware of things existing at earlier or future times, and all perception requires the transmission of information from the perceived object. These processes need time (as is most obviously the case when light from long ago extinct stars reaches our eyes), therefore, what we are immediately aware of in these cases can't be the physical object but has to be a sense datum. For a detailed critical discussion of these and related arguments compare [8,9].

Criticisms of sense-datum-theories take generally the following forms: (i) the validity or soundness of the aforementioned arguments is questioned. (ii) It is augued that a conception of sense data as special kinds of mental objects leads to difficulties better of avoided. (iii) Phenomenalism and indirect realism being, It being the relevant theories are supposed to have general implications which are utterly implausible or even disastrous. (For a discussion of this point see the essay on ►perception).

Concerning (i) only two prominent criticisms concerning the refusal of the second premise of the Argument from Illusion can be briefly noted here. This premise has been criticized as fallacious in a variety of ways but the most common strategy is just to deny that in cases of illusory perception there has to be something which possesses the sensory qualities the physical object lacks. If we erroneously believe that our neighbor has got a new car, the possibility of this false belief doesn't presuppose that we are aware in this case of someone else, possibly existing only in our mind, who his a new car. Indeed, such a supposition would be a mistake, because then our belief wouldn't be about our neighbor but about this other person. If this is true in the case of belief why should we invoke special objects as bearers of sensory qualities in the case of perception? Defenders of the Argument from Illusion typically retort that perception forms a special case here, because the appearant features of objects we are presented with in perception are present in one specially vivid way lacking in the cases referred to in this criticism. In the case of illusions we not only take the physical object to be different from the way it actually is, the illusory feature (e.g. a color the physical object lacks) is vividly present in perceptual consciousness as a property of the object of awareness [8].

In order to avoid the introduction of sense data at this point the so-called adverbial theory of experience has held that the phenomenal aspect of our sense experiences can be analyzed in the following way: a vivid conscious experience of something red (be it veridical or not) can be understood as a certain way of perceiving; that is, we are not conscious of something instantiating the property which is responsible for the character of our conscious experience (a sense datum), but our perceptual state itself is characterized by that property, in the case of a experience as of something red we "sense in a redly manner" as it has been put [10]. It has been claimed, however, that this account cannot deal adequately with situations where we have an awareness of a manifold of different items with different colors and forms because this seems to require being aware of different items instantiating these properties [1].

Concerning (II) the following problems have been prominent in the debates: if sense data are something mental how can their existence be accommodated within the most widely shared metaphysical position of today, physicalism, which holds that everything is physical? Defenders of sense data can try here to refute physicalism [8], or they can try to reduce the data to physical phenomena along the lines of an identity of theory [7]. A related difficulty concerns the question where sense data have to be located, if they are to be distinguished from physical phenomena. Sense data possess extension (an expanse is at least two-dimensionally extended; there is no unanimity among the defenders of sense data whether they are three-dimensional or not), which seems to require that they are located in space. But can we locate them in physical space? They are private in the sense that

only the person who experiences them has access to them. Objects in physical space are not private in that way, however. One might introduce here private spaces but such a proposal leads to further difficulties, in particular of the question how these private spaces are related to each other and how they are related to public physical space. And this is not the only problem with respect to the claim that sense data are private: The claim also seems to be at odds with the common sense claim that different persons can be, in perception, immediately aware of the same object. This seems to be a presupposition of the idea that it makes sense at all to dispute the way things appear to us in perception. Furthermore, it has been contested whether the conception of a private object makes any sense at all.

Generally, sense data have been taken to be the way they appear to the perceiver. This was why they were introduced them in cases of illusion etc. While the straight oar immersed in water isn't bent there is another object which really is as it appears: the bent sense datum. But this claim leads to the following difficulty: sometimes the features of objects we are aware of will appear indeterminate; e.g. when we see a speckled hen the number of its speckles will appear indeterminate. If we are aware of a sense datum in this situation, and sense data are exactly as they appear, the sense datum in question would have an indeterminate number of speckles. But this is a logical impossibility. At least one defender of sense data has simply contested the applicability of this logical principle to sense data [2]. But defenders of sense data might try to solve the problem by claiming that the number of speckles is only indeterminate in the sense that we are unable to determine it by counting the speckles in the given amount of time. This is compatible with the idea that the sense datum has a determinate number of speckles we are all perceptually aware of.

## Sensitive Period

### Definition

In the life span of an animal, the ability to react to environmental changes is not constant. There is a period during which exposure to abnormal conditions leads to abnormal function. This period is called sensitive period. The sensitive period has to be discriminated from the critical period. The latter describes the time during which an organism acquires normal function if it is exposed to normal conditions (see also Critical Period).

## Sensitivity of Sensory Receptors

### Definition

In regard to the physiological characteristics of a sensory receptor cell, sensitivity is defined in relation to two variables: threshold and steepness (gain) of the relationship between stimulus intensity and receptor response. The detection sensitivity is inversely related to the detection threshold, while the gain sensitivity is related to the steepness in a static or dynamic gain curve. Corresponding Definitions hold for central neurons.

## Sensitization

### Definition

Sensitization is a type of non-associative learning that results in an increase in responses in general (increase in arousal and enhancement of all reflexes) or responses once habituated. Sensitization typically occurs when noxious or fearful stimuli are presented to an animal.

## Sensorimotor

### Definition

Animals register external events by their sensors and they act by their motor system. In general, the sensory information is represented in a different coordinate system than that of the motor system. Thus, the information has to be transformed from one code in the other. The processes underlying this transformation happen in sensorimotor areas and may be called sensorimotor transformations.

# Sensorimotor Integration

## Definition

The process of generating appropriate motor outputs, based on sensory inputs. In order to efficiently move in the world, we must integrate incoming sensory signals with each other and with motor commands. For example, to reach for a visual object, one must integrate visual representations of the object and its location with proprioception from the moving arm and hand, together with motor commands that appropriately project the arm in space. For many behaviors, motor actions and sensory processing are so tightly woven together that the two processes become inseparable.

## Synonyms

Value, actions and reinforcement learning in the basal ganglia

## Definition

Sensorimotor learning in the basal ganglia refers to the learning in which neurons in the striatum learn to encode and update the reward values of external stimuli and actions based on the reward prediction error signals from dopamine neurons.

## Characteristics

### Dopamine-Dependent Plasticity of Cortico-Striatal Synaptic Transmission

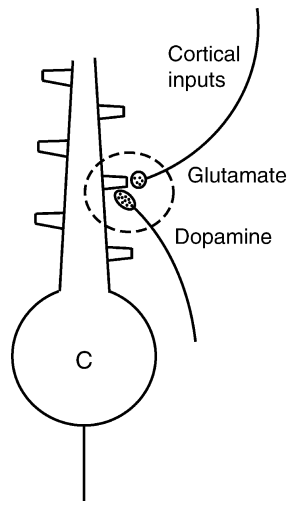
The striatum is a rostro-caudally elongated subcortical structure, and is composed of laterally located putamen and medio-dorsally located caudate nucleus. It is the input stage of the basal ganglia receiving major signals from almost all parts of the cerebral cortical areas and centro-median parafascicular nuclei of the thalamus in a topographically organized manner. These projections use glutamate as a transmitter. In addition, dopamine neurons in the substantia nigra pars compacta, serotonin-containing neurons in the dorsal raphe and noradrenergic neurons in the locus ceruleus project to both the putamen and caudate nucleus. Motor cortical areas in the frontal cortex and post-central somatosensory cortex project to the putamen, while the prefrontal, parietal and temporal cortical areas project to the caudate nucleus.

The axon terminals of cortical pyramidal neurons end and synapse on the spine of dendrite, while those of the thalamus end on the shaft of proximal dendrite of medium-spiny neurons of the striatum. The axons of single cortical neurons make as many as 2,900 (average 879) synapses on the striate neurons [1]. Varicosities of dopamine neurons make synapses on the neck of the dendritic spine (Fig. 1).

For single medium-spiny neurons in the striatum, about 10,000 terminals of pyramidal neurons in the cortex and 1,000 dopamine varicosities are estimated to make synapses on their dendrite [2]. This characteristic arrangement of synapses of cortical and dopaminergic origins makes an ideal framework for modification of cortico-striatal signal transmission by dopamine inputs. Indeed, long-term potentiation of cortico-striatal EPSP occurs in a dopamine D1 receptor-dependent manner [3].

### Striatal Neurons Learn to Encode Action-Specific Reward Value

As mentioned above, the striatum is the locus of converging cortical and subcortical signals on actions, external sensory events, motivation or reward value and others in a variety of combinations. This makes the striatal neuron activity so variable. A subset of neurons is selectively activated during limb movement or eye movement, another subset of neurons are activated by external stimuli and appear when the subjects are performing behavioral tasks. Still another subset of

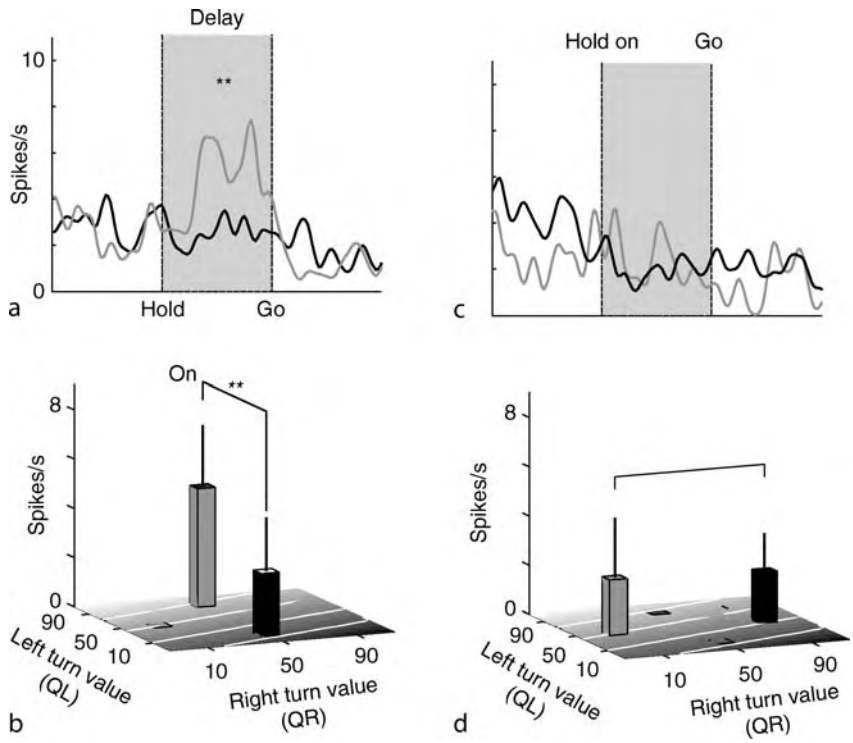


**Sensorimotor Learning and the Basal Ganglia. Figure 1** Schema of synaptic arrangement on the dendrite of striate projection neurons. Cortical terminals synapse on the spine, while dopamine varicosities contact with its neck.

neurons is activated when the outcomes of behavioral responses have occurred. While the ▶basal ganglia receive signals of action, sensory events, motivation or reward value in the striatum, their outputs are directed mainly to the cerebral cortex through the cortico-basal ganglia loops [4] and partly to the superior colliculus and brain stem. A key question about the basal ganglia functions is: How are the variety of neural signals represented in the striatum different from those in the cerebral cortex? Limb or eye movement-related neurons are found in both the striatum and cerebral cortex. Similarly, neurons encoding reward value of external events are found in both structures.

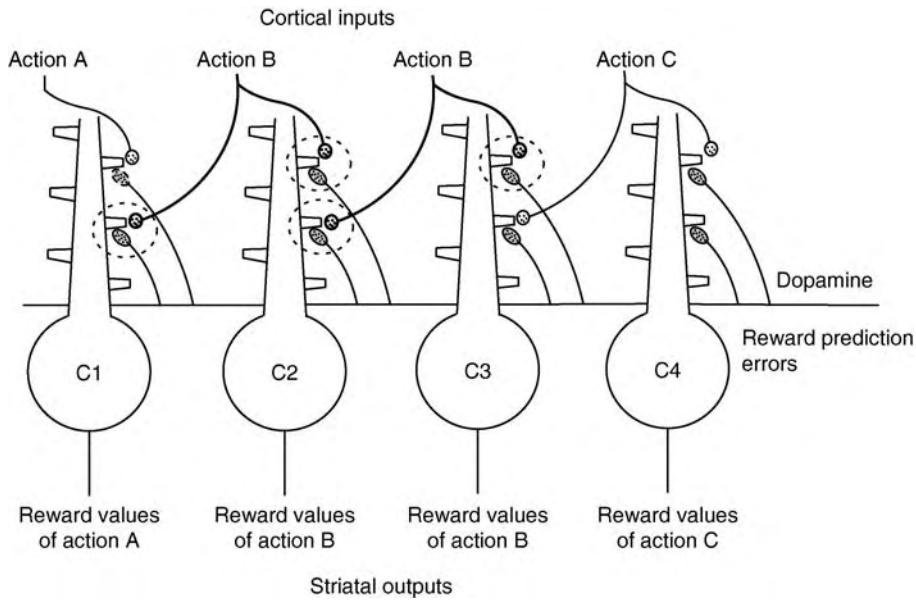
Recent studies revealed an important aspect of representation and processing of sensorimotor signals in the striatum. For instance, through T-maze learning of rats, Graybiel and her group found that striatal neurons learn to encode automatized procedures of behavioral acts [5], suggesting involvement of the basal ganglia in habit learning. Caudate nucleus neurons of monkeys respond to visual cues for the directions of saccadic eye movements after which a reward is delivered. The magnitude of the responses is broadly tuned to the contralateral visual field. But if a reward is given only after the saccade to one of eight directions, neuronal responses are strongly biased towards the reward direction [6].

In another study by Samejima et al., monkeys performed a reward-based free choice task of turning a handle to the left or right [7]. They held a handle in the center position for 1 s, and turned the handle in either the left (L) or right (R) direction. The handle-turn was followed by either a large reward or a small reward. The probabilities of a large reward after left- and right-turns were fixed during a block of 30–150 trials, and varied between five types of trial blocks. In the "90–50" block, for example, the probability of a large-reward for the left-turn was 90%, and for the right-turn, 50%. In this case, by taking the small reward as the baseline (r = 0) and the large reward as one hundred (r = 100), the value for the left-turn $Q_L$ was 90 and the value for the right-turn $Q_R$ was 50. There are four asymmetrically rewarded blocks, "90–50," "50–90," "50–10," and "10–50," and one symmetrically rewarded block, "50–50." The neuronal activity related to reward expectation could be dissociated from that related to action selection. Although the monkeys should prefer the left-turn in both the 90–50 and 50–10 blocks, the reward values are different. Conversely, in the 90–50 and 10–50 blocks, although the monkey's choice behavior should be the opposite, the action value for the right-turn $Q_R$ remains at 50. Figure 2 shows a representative neuron in which the delay period



**Sensorimotor Learning and the Basal Ganglia. Figure 2** A "left-turn value neuron" Firing rates in 90–50 (grey) are higher than 10–50 (dark) block (a,b), but weak in both 50–10 (grey) and 50–90 (dark) blocks (c,d). Adapted from [7].

S



**Sensorimotor Learning and the Basal Ganglia. Figure 3** Hypothetical schema of how the striatal neurons encode reward values of actions. The cortical signal of action B is reinforced and updated by dopamine's reinforcement signals.

discharge rate was significantly higher in the 90–50 block (grey) than in the 10–50 block (dark).

This suggests that the neuron is selective to either left-turn action because monkeys turn the handle to the left in most trials of 90–50 block or left-turn value. But, because the neuron is only weakly activated during both 50–10 and 50–90 blocks (Fig. 2c and d), this neuron is regarded as a "left-turn value neuron." There was a similar number of "right-turn value neurons." The observation revealed that action-specific reward values are represented in the activity of the striate neurons rather than in the preparation for particular actions or relative values between the two alternative actions.

## Reinforcement Learning in the Basal Ganglia

How are the signals of action-specific reward values represented in the striatum processed for action and cognition, specifically for action selection? An important answer to the question was obtained by examining whether the monkey's action choice could be predicted by action values, which are estimated by previously chosen actions and their outcomes, and updated by reward prediction errors using a standard reinforcement learning model [8]. Samejima et al. [7] showed that the action values thus estimated successfully predicted individual action choices of monkeys. Furthermore, the discharge rates of "left-turn value neurons" and "right-turn value neurons" was correlated with the action values on a trial-by-trial basis [7]. Figure 3 illustrates schematically how the striatal neurons encode and update action-specific reward values based on the action signals from the cerebral cortex and reward prediction error signals from the dopamine neurons.

This suggests that the action values are used for selection among alternative actions, and supports the proposed reinforcement learning model of basal ganglia [9]. On the other hand, it is still to be studied where and how the action value-based selection of action occurs. Does it occur in the striatum or its downstream? Intriguingly, while action value coding neurons are dominant in the striatum, neurons in the internal segment of globus pallidus, output nucleus of the basal ganglia, preferentially encode reward values of chosen actions [10]. This suggests the selection mechanisms are downstream of the striatum. Further research is necessary to answer the key question of how the reward values of behavioral cues and actions are encoded, stored and updated by dopamine signals for pursuing a multi-step action plan towards specific distant goals.

### Definition

All animals including human beings obtain information about the external world through sensory organs such as eyes, ears, a nose, a tongue, skin etc., and respond to the stimuli by executing some actions with muscular movements in some cases. The sensory information is processed and integrated in the central nervous system, and the action is coordinated. The cerebellum plays a critical role in the motor control utilizing sensory information. The efficacy or smoothness of action in a particular condition improves with practice. Such improvement is the sensory motor learning. The cerebellum is also implicated in this type of learning, which is classified into the procedural learning (►Procedural memory).

### Characteristics

The cerebellum plays roles in the motor control and in the sensory motor learning. Familiar examples of the latter are improvement of skills in sports or riding bicycles with practice. However, the characteristics and mechanisms of sensory motor learning have been studied utilizing simple model tasks such as ►adaptation of vestibulo-ocular reflex or saccadic eye movement, ►prism adaptation, and classical conditioning.

#### Adaptation of Vestibulo-Ocular Reflex

A head position of animal does not stay still during execution of an action. Thus, the visual scene captured

by an eye would move or drift (retinal slip, image motion on the retina), possibly causing blur of the image. You can experience such blur by watching the replay of video recorded with a camera held by someone's hands that would sometimes make you feel like seasick. However, we can usually get clear vision of the external world even if we are moving, and do not suffer from seasick in daily life. We owe this to two reflex mechanisms that compensate the eye position during the head movement. One is the vestibulo-ocular reflex and the other is the optokinetic response [1]. In the vestibulo-ocular reflex, the inner ears (semicircular canals and otolith organs) sense the head motion and send information to vestibular nuclei, and then to motor neurons controlling extraocular muscles. This reflex pathway enables eyeballs to move in the opposite direction of head motion. In the optokinetic eye movement, the movement of whole visual field is detected and the eyeballs move in the same direction of the visual field movement.

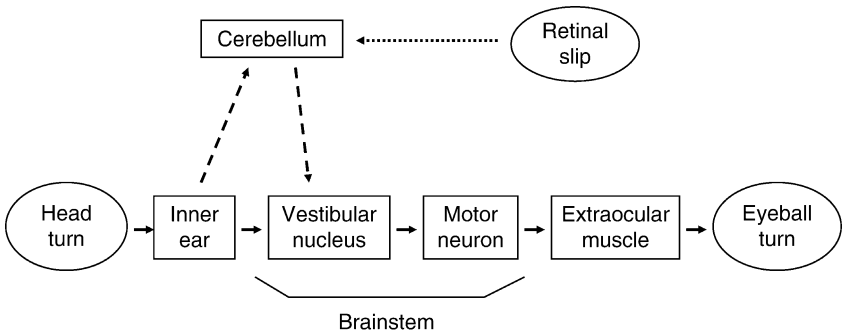
For the best performance of vestibulo-ocular reflex, the eyeball has to turn the same amount as the head turn in the opposite direction without delay. However, this is not an easy job. The sensory input that drives the vestibulo-ocular reflex is not visual signal but the information about the angular acceleration of head turn. Thus, the input sensory system has no way to know how well the retinal slip is suppressed by the reflex. Integration of visual and head rotation information is necessary for the good performance of reflex. The cerebellum adjusts the amplitude and timing of reflex by combining vestibular, visual, and eye movement information. The neuronal circuit controlling the vestibulo-ocular reflex is schematically presented in Fig. 1.

►Purkinje neurons, sole output neurons of the cerebellar cortex, send inhibitory outputs on neurons in the vestibular nuclei. The excitability of vestibular nuclei neurons is controlled by these inputs. Thus, the information transmission through the brainstem reflex pathway is regulated by the cerebellum. A mismatch of the visual and the vestibular inputs alters the vestibulo-ocular reflex so that the retinal slip is reduced. This phenomenon is the adaptation of vestibulo-ocular reflex. The mismatch occurs when a man wear glasses or an extraocular muscle is injured etc. In experiments, the mismatch can be brought about by rotating an animal placed in front of a dotted or striped screen that is moving either in the same or opposite direction to the animal rotation. The activities of Purkinje neurons change gradually when such a mismatch is given to the animal. A cause of the alteration in ►Purkinje neuron activities has been considered the long-term depression, a type of long-lasting modulation of synaptic transmission (synaptic plasticity) occurring in Purkinje neurons. Detailed explanation about the long-term depression is described below. The long-term depression and the resultant alteration of Purkinje neuron activities have been considered to contribute to the adaptive modification of vestibulo-ocular reflex, although implication of additional mechanisms such as alteration in vestibular nuclei neurons has been suggested [2,3].

Optokinetic response also undergoes adaptation in some animal species, in which the amplitude of eye movement is less than that of the external scenery, resulting in a certain retinal slip. Continuous presentation of sinusoidally oscillating scene to an animal gradually increases the amplitude of eye movement so that the retinal slip is reduced. Long-term depression is also implicated in this adaptation.

## Eye Blink Conditioning

►Eye blink conditioning is one type of classical conditioning. Application of air puff to an eye or electrical stimulation around an eye makes the eyelid close. This is a simple defensive reflex to prevent injury of an eyeball, and the air puff or electrical stimulation that always induces the response is called an unconditioned stimulus (US), and the response induced



**Sensory Motor Learning/Memory and Cerebellum. Figure 1** Neuronal pathways controlling the vestibulo-ocular reflex.

by an unconditioned stimulus is called an unconditioned response (UR). When some sound is presented before application of the air puff repeatedly, the animal learns to close the eye just hearing the sound. This phenomenon is the eye blink conditioning [4], and the sound is called a conditioned stimulus (CS) and the response induced by the conditioned stimulus is called a conditioned response (CR). The eye blink conditioning is similar to Pavlov's conditioned reflex.

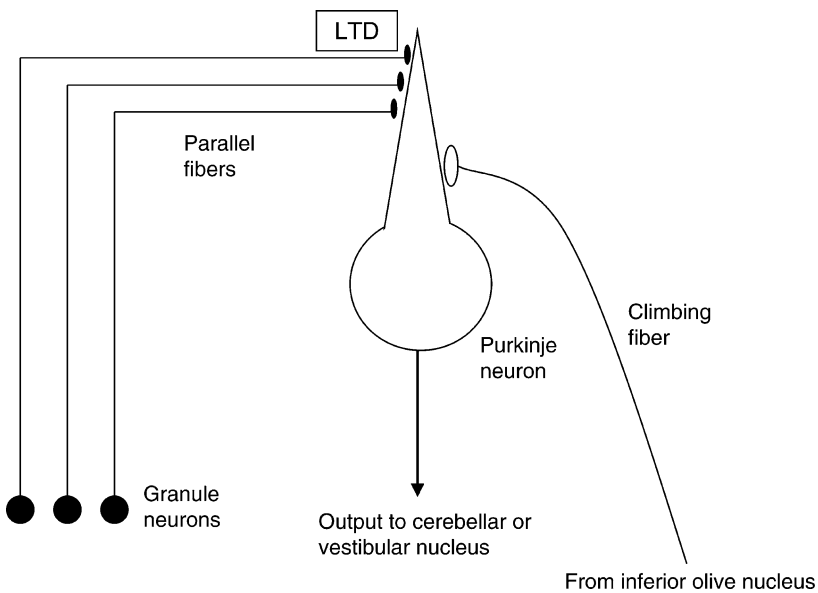
The cerebellum is involved in this eye blink conditioning. The lesion of cerebellum impaired the conditioning. Implication of the long-term depression has been reported. The information about CS is transmitted to a cerebellar nucleus and also to Purkinje neurons through parallel fibers and that about US is transmitted to Purkinje neurons through climbing fibers (Fig. 2).

Mossy fibers and climbing fibers are the major inputs to the cerebellar cortex. A climbing fiber forms large number of excitatory glutamatergic synapses on a Purkinje neuron. On the other hand a mossy fiber forms glutamatergic synapses on granule neurons. More than 100,000 granule neurons form glutamatergic synapses on a Purkinje neuron through parallel fibers (axons of granule neurons). Coupling of CS and US induces the long-term depression at parallel fiber-Purkinje neuron synapses, decreasing Purkinje neuron activities and hence inhibition on neurons in the cerebellar nucleus. Thus, neuronal activities in the cerebellar nucleus are upregulated, facilitating the information flow through the CS pathway including the cerebellar nucleus. Involvement of the central nervous system other than the cerebellum such as the hippocampus in the eye blink conditioning has also been known.

## Long-Term Depression

Long-term depression is a type of synaptic plasticity accompanied with the long-lasting decrease in the efficacy of synaptic transmission [5]. In a cerebellar Purkinje neuron, the repetitive coupled activation of parallel fibers and a climbing fiber induces the long-lasting depression at the parallel fiber synapses. It has been proposed that the climbing fiber conveys the information regarding the motor error, and that the long-term depression works to reduce the information flow through the parallel fibers that have been involved in the error production (Fig. 2).

The cellular and molecular mechanism of long-term depression has been studied in vitro preparations such as brain slices and neuronal culture. A climbing fiber forms large numbers of glutamatergic synapses on dendrites of a Purkinje neuron providing exceptionally strong excitatory synaptic drive. Thus, when a climbing fiber is activated, a large increase in the intracellular $Ca^{2+}$ concentration is induced in the postsynaptic Purkinje neuron. In contrast, each parallel fiber forms only one or two glutamatergic synapses on dendritic spines of a Purkinje neuron. The excitatory postsynaptic potential induced by a parallel fiber activation is far smaller than that by a climbing fiber. On the postsynaptic membrane of a Purkinje neuron at parallel fiber synapses, both ionotropic AMPA (α-amino-3-hydroxy-5-methyl-4-isozaxole propionic acid) type glutamate receptor and metabotropic glutamate receptor (mGluR1) are located.



**Sensory Motor Learning/Memory and Cerebellum. Figure 2** Synaptic inputs to a cerebellar Purkinje neuron and the long-term depression (LTD).

Glutamate released from a parallel fiber activates both receptors. Activation of AMPA receptors causes the excitatory postsynaptic potential, and that of mGluR1 activates an enzyme called phospholipase C, which produces diacylglycerol and inositoltrisphosphate. The latter contributes to the increase in the cytoplasmic $Ca^{2+}$ concentration through $Ca^{2+}$ release from the intracellular stores, and the former contributes to activation of an enzyme called protein kinase C together with the intracellular $Ca^{2+}$. Activated protein kinase C phosphorylates the AMPA type glutamate receptor on the postsynaptic membrane. The phosphorylated AMPA receptor is then internalized to the cytoplasm and becomes nonresponsive to extracellular glutamate. This is the current simplified model of induction of long-term depression [5]. Implication of numbers of additional molecules including glutamate receptor δ2 receptor, specifically expressed at parallel fiber-Purkinje neuron synapses, has been reported [6].

Roles of long-term depression in the sensory motor learning have been studied using mutant mice with the impaired long-term depression. These studies have shown the correlation between the long-term depression and the sensory motor learning. However, some sensory motor learning occurs in animals with impaired long-term depression. Thus, the ►cerebellar long-term depression seems not to be the sole mechanism for the sensory motor learning.

### Synaptic Plasticity Other than Long-Term Depression

Long-term potentiation, long-lasting increase in the efficacy of synaptic transmission, is also reported to occur at parallel fiber and Purkinje neuron synapses by repeated activation of parallel fibers alone. There are two types in the long-term potentiation. One is accompanied with the increased postsynaptic sensitivity to glutamate, and the other is caused by the enhanced release of glutamate from the presynaptic terminals of parallel fibers. The former long-term potentiation is the counterpart of the long-term depression. Implication of the long-term potentiation in the sensory motor learning has been suggested. The long-term potentiation and the long-term depression seem to play distinct roles in the sensory motor learning [7].

Synaptic plasticity has been reported at other synapses in the cerebellar cortex [8]. The long-term depression occurs also at climbing fiber-Purkinje neuron synapses. The efficacy of inhibitory synaptic transmission on a Purkinje neuron is potentiated for long-term by postsynaptic depolarization. The glutamatergic synapses between mossy fiber and a granule neuron also show long-term potentiation. Further, the synapses between parallel fibers and inhibitory interneurons (stellate or basket cells) also show synaptic plasticity. The respective role of each type of synaptic plasticity is unclear at present. They might contribute to the sensory motor learning in concert with the long-term depression at parallel fiber-Purkinje neuron synapses.

## Definition

Perceptual learning, a type of sensory plasticity, enhances perceptual performance based on changes in brain physiology and adjusts the cortical representation of the world. *Sensory Plasticity* in general includes both behavioral and physiological changes in perceptual learning, sensori-motor enhancement and long-term adaptation resulting from ►experience.

## Characteristics

### Improved Perceptual Performance as a Result of Training

Lasting improvement in detecting, discriminating or categorizing sensory stimuli based on preceding experience is usually based on perceptual learning [1–3]. *Perceptual Learning* (PL) improves the representation and analysis of sensory information and reduces ►noise in sensory signals. Perceptual learning and plasticity of behavior are essential for humans to cope with changing environments. Better representation of a stimulus in the brain through learning improves its ►*detection*. Sharper ►*discrimination* from other stimuli – a more elaborate feat – is often task-specific and depends on attention being focused on specific feature(s) of the stimulus, thus restricting the learning to features important for the assigned task. A further aspect of plasticity and learning is the adjustment to the *situation* in general, especially under the usually somewhat artificial conditions of an experiment.

The improvement achieved through PL persists over extended time-spans, thus distinguishing PL from other changes in sensory processing such as short-term adaptation, ►sensitization, ►habituation, attention, and priming. These other processes all produce more transient changes of performance. PL clearly is of the procedural type, produces ►implicit memory traces and cannot be communicated to others, unlike declarative forms of memory such as ►declarative (explicit) memory. Another important characteristic of PL is that it appears to directly modify the neuronal mechanisms processing the task required [4]. Declarative forms of learning, on the other hand, lead to memory traces that are stored at least partly in specialized brain regions such as the ►hippocampus. To detect, discriminate, and extract the most relevant features from the multitude of signals supplied by the sense organs requires extensive PL during especially infancy and childhood. This plasticity of sensory processing continues throughout life even if with decreasing velocity and ease.

### Interaction of Different Cortical Levels in Perceptual Learning and the Role of Attention

Sensory plasticity and PL take place on a number of ►cortical levels, including even highly specialized ►early sensory cortices, while, of course, also on higher, more cognitive ones [5]. Hence, an important distinction between different types of PL is whether the improvement achieved through ►training generalizes to other stimuli or tasks, indicating involvement of higher cortical areas, or else is highly stimulus-specific, indicating involvement of early levels.

Psychophysical, imaging and electrophysiological studies all indicate that early sensory cortices are involved in at least some forms of Perceptual Learning while these sensory cortices used to be considered as "hardwired" in adults.

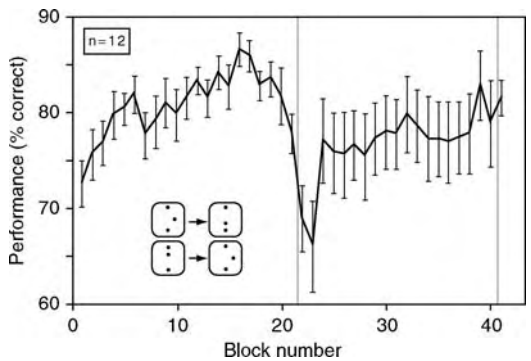
The task required of the subject may be quite different for identical stimuli – the more complex a stimulus is, the higher is the number of different discrimination tasks that can be defined for this stimulus, such as searching for a specific geometrical configuration or color. Therefore, feedback from "higher" to "lower" levels of processing is required for the "early" cortices to be tuned to the task at hand – purely bottom-up information extracted from the stimulus does not suffice to define the task.

The effects of PL are similar to those of attention both behaviorally and regarding enhanced activity of cortical neurons. In both cases, processing of sensory stimuli improves even in "early" cortical areas as demonstrated by ►single-cell recordings in animals. However, while the effects of attention are similar to those of adaptation in that they do not leave any permanent traces, PL *does* leave long lasting traces. The extreme stimulus specificity of some forms of PL sets it further apart from the more general and transitory effects of attention.

## Stimulus Specificity in "Early" Perceptual Learning: "Early Selection" in Visual Perception

Training in many ►perceptual tasks enhances performance within about 10–20 min of training to slow down thereafter. But often, the improvement achieved with one stimulus is quite specific for this stimulus and does not transfer to a stimulus rotated by even a few degrees. Improvement is similarly specific for the eye trained (under monocular conditions), for position in the visual field, as well as for motion speed, motion direction, and the exact task trained (Fig. 1).

The enhancement is specific for stimulus orientation for some tasks, for example for vernier discriminations, as outlined above, while not for other perceptual tasks. Learning usually generalizes more on later (cortical) levels than on lower ones since there ►receptive field characteristics are less position specific. Hence, high position specificity indicates changes on early processing levels that select important information as soon as possible [6].



**Sensory Plasticity and Perceptual Learning.**
**Figure 1** Specificity of improvement in Perceptual Learning. One group of observers started with a three dot bisection task, indicating whether the middle one of the dots was closer to the upper or else to the lower end point. The second group started with training a three dot vernier task, indicating whether the middle point was offset to the left or to the right relative to an imaginary line through the end points. Mean performance of both groups improved markedly within an 1-h training session (blocks 1–21). But when the tasks were switched between groups of observers (*left vertical line*), performance dropped even below baseline levels. Hence, improvement through training was highly specific for the task trained, even though the stimulus in both tasks differed by less than a photoreceptor diameter. Retesting the first task at the very end of the second session (*right of right red line*) revealed good performance (from Fahle, M. & Morgan, M.; No transfer of perceptual learning between similar stimuli in the same retinal position. *Current Biology* 6:292–297, 1996).

## Generalization of Improvement in Late Visual Perceptual Learning, "Late Selection," and Further Sense Modalities

PL can enhance discrimination between complex classes of stimuli such as different wines, in addition to the improvement in discrimination between simple stimuli. More complex tasks and more noisy stimuli tend to generalize more than simpler ones do, hence enhancement seems to be achieved at a relatively late stage for these forms of PL.

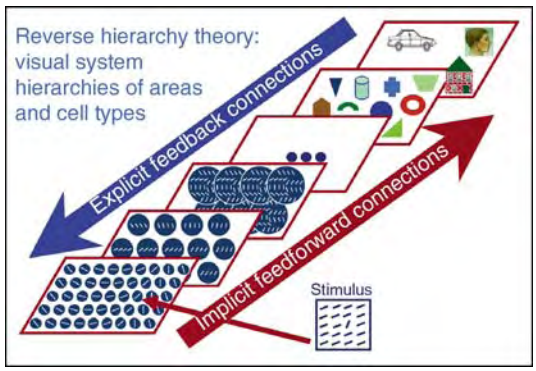
Training *auditory* tasks such as discriminating tone frequencies embetters [►improves] performance and is accompanied by ►reorganization of primary auditory cortex and other brain regions after some forms of PL while not after others. Similarly, training can improve discrimination in the realms of both taste and olfaction, and the representations in motor and somato-sensory cortex often increase in size for those body parts used during motor training, accompanied, for example, by improved two-point tactile resolution [7].

## Models of Perceptual Learning

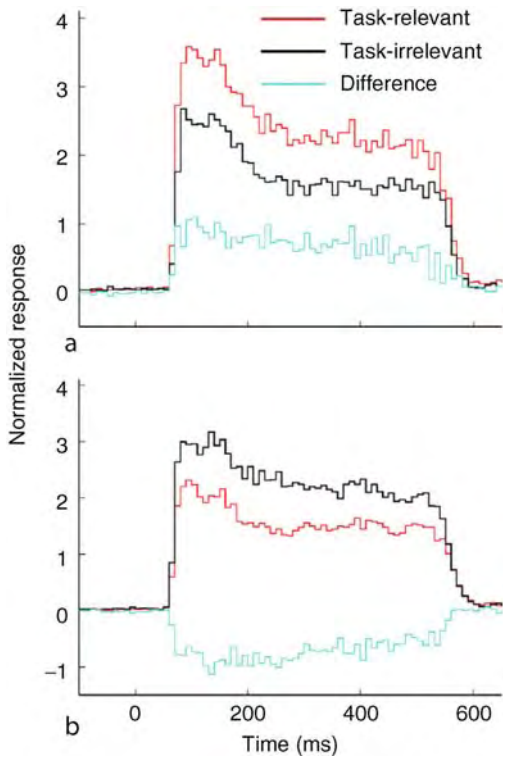
Recent models of PL incorporate both aspects of PL, specificity and ►generalization of learning. These models take into account both internal and external noise, implement recurrent (feedback) connections, and assess the change of internal templates. It turns out that sharper orientation tuning curves may account for the psychophysical results and that training seems to better eliminate external noise, possibly by retuning internal templates.

PL is based on at least two different mechanisms, one fast, the other slower. The first mechanism, as outlined in the Reverse Hierarchy model, starts fast and generalizes improvement at high cortical areas, adding the second mechanism if necessary. This second mechanism involves lower cortical levels leading to slower and more specific enhancement (Fig. 2).

These two mechanisms lead to either an early or a ►late selection of relevant signals in analogy to theories on attention [6]. The slower and more specific mechanism of PL is highly specific for stimulus features – indicating an involvement of "early" stages of cortical information processing. On these early cortical stages, such as the primary visual cortex V1, neurons are specific for the eye and the visual field position stimulated. Therefore, this mechanism apparently involves changes in functional connectivity between neurons already on the level of V1. Such tuning of signal processing on an early level removes irrelevant noise early on. However, the adaptation of processing at peripheral levels modifies the neuronal front end for all possible stimuli and may therefore deteriorate detection for stimuli differing from the recently learned ones by interfering with processing optimized for other tasks. For example,



**Sensory Plasticity and Perceptual Learning.**
**Figure 2** The Reverse Hierarchy Model of Ahissar and Hochstein conjectures that Perceptual Learning for easy tasks takes place on a "high" level of cortical information processing, improves performance fast, and generalizes to similar stimuli. If necessary, PL also involves lower levels where it is slower and highly stimulus specific (from Ahissar, M. & Hochstein, S.; The reverse hierarchy theory of visual perceptual learning. *Trends in Cognitive Sciences*, 8:457–464, 2004).



**Sensory Plasticity and Perceptual Learning.**
**Figure 3** The characteristics of receptive fields in the visual cortex of an adult macaque monkey changed significantly as a result of training, though the exact mechanisms are still under debate. In any case, the changes depended on whether or not the stimulus was task relevant with both increase (a) and decrease (b) of responses after training (from Li, W., Piëch, V. & Gilbert, C.D.; Perceptual learning and top-down influences in primary visual cortex. *Nature Neuroscience*, 7:651–657, 2004).

shallow luminance gradients are best detected by large receptive fields, which in turn are unable to detect fine gratings. Training to detect fine gratings would therefore improve their detection by decreasing receptive field size, but deteriorate detection of shallow gradients. Task-dependent switching between different "modes" of early cortical signal processing governed by top-down influence could solve this dilemma. Top-down control would select the most appropriate type of processing for the task at hand from a repertoire of (previously learned) alternatives, for example, by adjusting the neuronal gain of a defined population of neurons, or by modifying the amount of lateral inhibition on an early cortical stage.

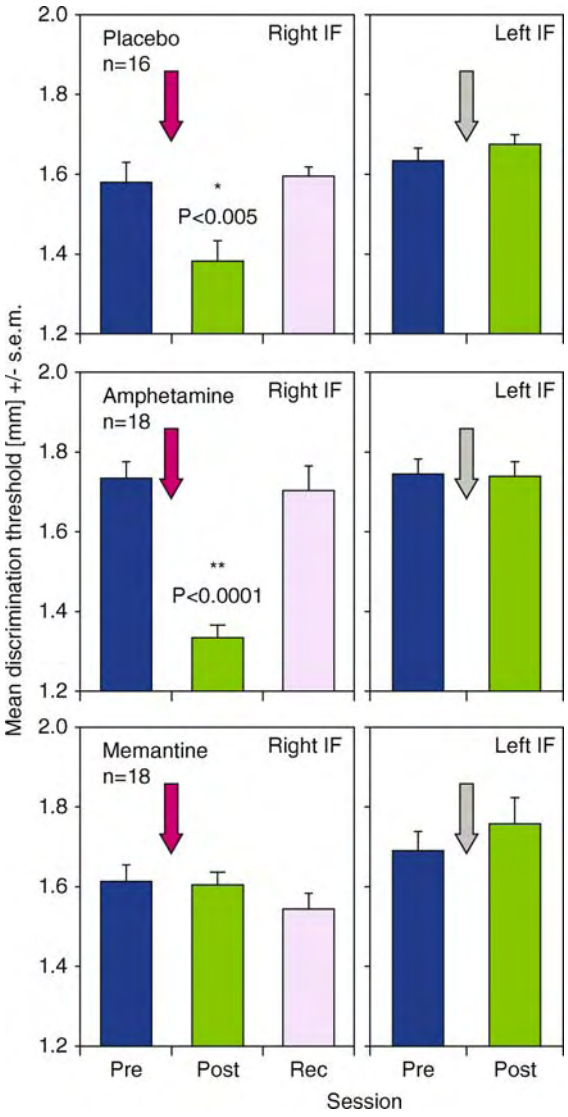
The fast mechanism of PL resembles and may be identical with "conventional" forms of learning. It generalizes and is probably implemented in more central sensory cortices, located in the temporal and parietal lobes. Some forms of Perceptual Learning, especially the one generalizing over different stimulus types may take place exclusively on these higher processing levels.

## Possible Mechanisms and Electrophysiological Correlates of Sensory Plasticity

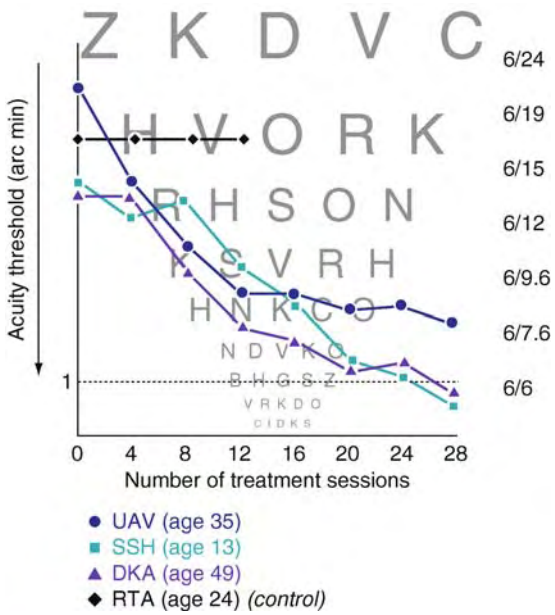
To indicate the level of neuronal plasticity is almost impossible on the basis of psychophysical results. But both sum-potential recording and single-cell recording detect plasticity on early stages of sensory cortices in visual, auditory and somato-sensory cortices, indicating some plasticity even in the lateral geniculate nucleus and primary visual cortex of adult animals including man (Fig. 3; [8,9]). Plasticity in the somato-sensory system may be especially pronounced [7]. Some of the transmitter substances involved are known (Fig. 4).

Sum potentials in humans change as a result of PL, even at latencies below 100 ms, and most pronounced over the occipital pole. The number of neurons in primary visual cortex representing a given orientation surprisingly decreased in monkeys who trained orientation discrimination for this orientation. This decrease was not associated with any evident changes in permanent receptive field properties, neither in V1 nor in inferior temporal cortex [10].

To sum up, PL changes perception as well as sum potentials and single cell responses and increases activity in the stimulus representation of V1 as demonstrated by fMRI. All these findings point to an involvement of early sensory cortices in Perceptual Learning.



**Sensory Plasticity and Perceptual Learning. Figure 4** Pharmacological influences on Perceptual Learning. The amount and speed of Perceptual Learning can be influenced by different pharmacological agents. (a) Memantine, an antagonist of NMDA receptors, abolishes PL (as does GABA receptor blockade), (b) Amphetamine, on the other hand, speeds up the improvement through PL; (c) Under the influence of an placebo, PL is far more pronounced than in (a), but less pronounced than in (b) (from Dinse, H.R., Ragert, P., Pleger, B., Schwenkreis, P. & Tegenthoff, M.; Pharmacological suppression of perceptual learning and associated cortical reorganization. *Science*, 301:91–94, 2003).



**Sensory Plasticity and Perceptual Learning. Figure 5** Improvement of amblyopic patients. The classic view is that amblyopia, a functional decrease of visual acuity, due to strabism or optical factors, cannot be cured in adults. However, using a specific type of training, Polat and co-workers (Polat, U., Ma-Naim, T. Belkin, M. & Sagi, D.; Improving vision in adult amblyopes by perceptual learning. *Proc. Nat. Acad. Sci. USA*, 101, 6692–6697, 2004) were able to improve visual acuity in about half of their patients, sometimes dramatically, while those in the control group did not improve.

## Conditions for Consolidation of Learning and Visual Rehabilitation of Patients

Consolidation of perceptual improvement achieved through training requires *sleep* or at least restful waking in both visual and auditory learning. In the realm of sensory rehabilitation, patients wearing a ►*cochlear implant* learn to make better use of the signals stemming from the implant, often up to the point of eventually being able to understand speech. Similar approaches are under way for the visual input. Especially amblyopic patients can benefit from PL, since visual training may double contrast sensitivity and significantly increase visual acuity (Fig. 5).

## Conclusions and Outlook

Perceptual learning can significantly improve both the detection and discrimination of stimuli after a short training. PL relies on at least two mechanisms, probably represented on different levels of cortical processing. Modifications on early cortical levels require long training and produce stronger improvements, that do not transfer to similar tasks or similar stimuli, such as a slightly rotated stimulus, while the faster mechanism generalizes. No perceptual learning seems to take place without some form of attention. Irrelevant signals including noise must be eliminated as early as possible during processing to achieve optimal performance. Top-down signals may be able to activate modifications

in neuronal processing achieved on early levels in a task-dependent way to prevent interference of learning one task with performance in other tasks. Learning easy perceptual tasks may not modify early sensory cortices, but only higher ones, allowing generalization of improvement to similar tasks. In summary, Perceptual Learning enables humans to sharpen up the detection, discrimination and classification (►Categorization or Classification) of stimuli, to cope with varying sensorimotor requirements and to adjust rather fast to changing environments.

## Sensory Receptor

### Definition

Sensory receptors (in physiology) is any structure which, on receiving environmental stimuli, produces an informative nerve impulse. The receptor recognizes a stimulus in the external or internal environment, initiates a transduction process by producing graded potentials (receptor potentials), from which all-or-none action potentials are elicited, that are conducted along afferent fibers originating in the same or adjacent cells.

## Sensory Substitution

### Definition

A mechanism whereby information from one sensory modality is replaced by or substituted for information from another sensory modality. This term often refers to prosthetic devices that are meant to convey one form of sensory information through a sensory system that is typically not used for that form of information. An example would be an array of tactile vibrators that represent a visual scene.

## Sensory Systems

Uwe Windhorst
Göttingen, Germany

### Introduction

In order for organisms to survive and reproduce, they need an appropriate habitat. A habitat may be appropriate in terms of chemical constitution, ambient temperature, light conditions, food supply, availability of potential mates, and/or optimal conditions for their offspring. To continuously check for this appropriateness, organisms need information about the environment and the internal state of their body. An essential primary requirement is therefore the capacity to select, acquire and handle suitable information.

### Functions of Sensory Systems

Environmental and internal-state signals of importance to the animal (or plant) must be received. This in turn requires specialized ►sensory receptors. The information delivered by receptors must then be processed for particular purposes. Sensory systems usually have multiple functions. On the one hand, they provide signals for regulatory systems. At higher levels, they serve to generate sensations and ►perceptions. Perception requires ►consciousness. In multi-cellular organisms (metazoa), information acquisition, transmission and processing are performed by a more or less complex nervous system. From the viewpoint of the central nervous system (CNS), there are two environments: its own body as an internal environment and the body's external environment.

The general functions of sensory systems can be briefly summarized as follows:

1. Selected representation of aspects of the body's external world in space and time. This in turn requires:
   (a) Selectivity in focusing on world aspects of survival value for the organism.
   (b) Detection, localization, and identification of stimuli from the external and internal environments.
   (c) ►Figure-ground perception discrimination, i.e. isolation, identification and recognition (for perception) of important objects and events (figure) against the background of all existing objects and events (ground).
   (d) Discrimination of invariant and changeable properties of world aspects.
   (e) Memory. Recognition requires current sensory data to be compared with records of past experiences.
2. Selected representation of aspects of the body's internal world in space and time, including:
   (a) Body schema.
3. Provision of inputs for evaluation and decision systems that steer ►behavior.
4. Provision of inputs for fast motor responses, such as escape ►reflexes.

### Classification of Senses

Senses can be classified according to several criteria.

#### Nature of Stimuli

One classification is according to the physico-chemical nature of the stimuli activating peripheral sensory receptors (Table 1). Except in a few cases (e.g. ►vision), the ensuing classes may encompass diverse senses and therefore not be very useful. For example, the "mechanical" category includes hearing (►Auditory neuroscience - Introduction), the ►vestibular system, cutaneous mechano-reception (►Tactile senses-touch) and deep mechano-reception (►Proprioception), sensations arising from visceral receptors etc.

#### Origin of Specific Stimuli

Senses can be grouped according to the site of origin of the specific stimuli:

1. ►Exteroceptive senses receive stimuli from the world external to the body and comprise ►vision, ►magnetic and electric senses, hearing (audition), ►taste and ►olfaction (►Sensing chemical stimuli).
2. ►Enteroceptive senses receive stimuli arising within the body and comprise proprioception, and various other senses, such as deep thermosensibility and nociception (►Pain).

This division is not unequivocal because some senses bridge the border. For instance, cutaneous mechanoreceptors can be excited by stimuli from both

S

**Sensory Systems. Table 1** Sensory modalities, qualities, receptors and adequate stimuli

| Modality | Quality | Receptors | Adequate Stimuli |
|---|---|---|---|
| *Vision* | Brightness | Rods | Electromagnetic radiation |
| | Green | Cones | |
| | Red | | |
| | Blue | | |
| *Hearing* (*audition*) | Tone frequencies | Hair cells | Air pressure fluctuations |
| *Tactile sense* | Touch | Meissner | Mechanical deformation |
| | Pressure | Merkel | |
| | Vibration | Pacini etc. | |
| *Statokinetic sense* | Equilibrium | Hair cells | Absolute head position and acceleration |
| *Proprioception* | Body position and motion | Joint and ligamentous receptors | Joint position and motion |
| | | Muscle spindles | Muscle length |
| | | Golgi tendon organs | Muscle force |
| | | Skin mechano-receptors | Joint position/motion |
| *Temperature* | Cold | Cold receptors | Electromagnetic radiation 700–900 nm |
| | Hot (warm) | Warm receptors | |
| *Pain* | Fast (first) pain | Nociceptors | Injuries, inflammation etc. |
| | Slow (second) pain | | |
| *Taste* (*gustation*) | Sweet | Chemo-receptors | Chemical substances and ions |
| | Salty | | |
| | Sour | | |
| | Bitter | | |
| | Umami | | |
| *Smell* (*olfaction*) | Odors | Chemo-receptors | Odorants (pheromones) |
| Internal mechano-reception | Stomach extension | Extension receptors, pressoreceptors | Extension and pull |
| | Lung extension | | |
| | Blood pressure | | |
| Internal chemoreception | Osmotic pressure | Chemoreceptors | Osmolarity of body fluids |
| | $CO_2$ pressure | | pH and $pCO_2$ |
| | $O_2$ pressure | | $pO_2$ |

In some animals: *electric or magnetic senses.*

the exterior and interior world, thus being exteroceptors and proprioceptors. The vestibular system monitors the spatial relation and its changes between the head and external space and thus belongs to both proprioception (with active head movement) and exteroception (with passive head movement). Finally, nociception and temperature senses go under both rubrics of entero- and exteroceptive senses.

## Modalities and Qualities (Sub-Modalities)

Using a number of different mechanisms, receptors are specialized to sense specific aspects of external and internal stimuli. These aspects define their ►adequate stimuli, which are those that excite the receptors most easily and at lowest energy levels. Specialization of this sort is the basis of the "law of specific sense energies" propounded by Johannes Müller in 1826 [1]. It states that the quality of a sensation is not due to the stimulus but to the special sensory organ stimulated. Subjective sensory physiology further splits senses into modalities and qualities (or sub-modalities), which in turn are based on specific receptor systems, with some qualification [2]. Modalities refer to large classes of senses and the related receptors, e.g. visual, auditory, olfactory, gustatory and tactile (the five classic senses). Qualities refer to subclasses such as, in the ►visual system, perception of shades of grey from black to white and of different colors, or in the tactile domain, differentiation of pressure, touch and vibration sensations. An overview is given in Table 1.

### Proprioception

Proprioception is classically defined as being activated by mechanical stimuli arising from the body's self-generated motor actions [3]. Proprioceptors thus monitor the positions and movements of the body and its parts and include all receptors that carry signals related to these variables, irrespective of whether the signals reach consciousness or contribute to unconscious movement control [4]. Proprioceptors therefore comprise a fairly wide group of different mechano-receptors, from muscle receptors (►muscle spindles, ►Golgi tendon organs, arguably free nerve endings), joint receptors, ligament receptors, to cutaneous mechano-receptors.

## Psychophysics

Before the development of objective recording techniques, the study of sensory processes had to rely on observations of subjective phenomena and their relations to the underlying external events (stimuli). A basic question in ►Psychophysics is to what extent attributes of subjective perceptions are linked to properties of stimuli. This approach may diversify into detection, identification, discrimination (from background) and scaling of stimuli.

### Sensitivities

An organism should be interested in a great sensitivity to any stimulus that has an important survival value. Sensitivity means a number of things. The detection sensitivity is inversely related to the detection threshold, while the gain sensitivity is related to the steepness of a plot of response vs. stimulus intensity.

### Thresholds

Thresholds may be distinguished into absolute threshold and difference threshold, and so are the respective sensitivities.

The *absolute threshold* ($S_o$) is defined as the minimum stimulus intensity evoking a recognizable response in the receptor cell or perception. However, the peripheral (receptor) threshold and the central (sensation) threshold need not coincide because the latter is influenced by processes such as context, attention etc. (see below). Many receptor systems are exquisitely sensitive to their adequate stimulus. For example, a ►photoreceptor of the visual system can be excited by a single photon; the inner ear of some vertebrates reacts to very weak sounds barely above the mechanical noise level; and the bacterium Escherichia coli reacts to a few molecules of a chemical agent of interest, such as the amino acid aspartate [5]. Mechanical systems are often much less sensitive.

The *relative threshold* is defined as the minimum *just-noticeable difference* ($\Delta S$) in a stimulus variable. For intensity, this difference, $\Delta S$, is taken relative to the starting intensity, S. For example, $\Delta S/S$ is about 1–2% for vision, 3% for pressure and between 10 and 20% for other senses. Relative thresholds can also be defined and measured for other stimulus dimensions like quality, time and space. For instance, in vision, relative thresholds exist for brightness (intensity) and color (frequency resolution). In hearing, relative thresholds determine the frequency resolution of different sounds; and differences in the times of arrival in both ears are important for the location of a sound source (►Interaural time difference (ITD)). Finally, the spatial resolution is important for stimulus localization and distinction (below).

### Psychophysical Functions

Of prominent interest in supra-threshold psychophysics is the relationship between the stimulus intensity, which can be measured objectively, and the subjective intensity of sensation, which needs to be measured in some indirect way using scales. This relationship has been studied using various methods, leading to different quantitative descriptions (►Psychophysics).

### Spatial Discrimination

Of major importance for organisms is the localization of stimuli (topognosis). The spatial localization and discrimination capacities vary widely between different senses, being very good in vision and audition, modest to good in cutaneous mechano-sensation, (►Tactile senses-touch) and almost nil in taste and ►smell. In vision, the relative threshold in the fovea centralis is ca. 1′ under favorable conditions, but in touch, the relative threshold (as determined by ►two-point discrimination) is much worse and varies considerably across the body surface, being greatest at the fingertips and on the lips (1–4 mm).

## Information, Signals and Carriers

Information is an abstract entity that needs to be encoded in a signal to be transmitted. Signals in turn are generated by some material substrate or carrier, which uses some mechanism to produce the signal. In the nervous system, there are essentially only two broad classes of signals: membrane potential changes (►Membrane potential-basics) and concentrations of chemical substances (although at many chemical ►synapses, the concentrations of released ►neurotransmitters may be immaterial because they are so high as to saturate the available postsynaptic receptors). Membrane potential changes occur in two forms: continuous, ►graded potentials (depolarizations or hyperpolarizations), and ►action potentials (►spikes). These signals are essentially produced by and at membranes as carriers, and the mechanisms used are manifold. The existence of two forms of signal suggests that they need to be transformed into each other (see below).

## Principles of Receptor Systems

The limited set of signal types used by the nervous system contrasts with the abundance of physiologically important world aspects. This requires that the receptor cells convert these diverse forms into one common primary nervous language. For this purpose, sensory receptors have evolved specialized ►sensory transduction and accessory structures.

### Receptor Cells

Sensory receptor cells may be of neural or epithelial origin. Due to their limited expansion, each receptor can sample stimuli from only a limited body region called ►receptive field (RF). Sensory receptors may produce the first-order sensory axon as part of the cell or make synaptic contact with another neuron. Primary sensory axons may travel considerable distances (more than a meter) to reach their first postsynaptic neurons at the next processing stage (e.g. in the spinal cord).

### Stimulus Transformation

Conversion of a stimulus into a form suitable for excitation of the receptor membrane is called sensory transformation. Important factors in this process are:

1. Location of receptors. For example, different types of ►cutaneous mechano-receptors, (►Cutaneous mechanoreceptors, anatomical characteristics) giving rise to tactile sensation lie in different regions and strata of the skin; and it is the different spatial relation and mechanical coupling to skeletal muscle fibers that makes sensory endings of ►muscle spindles and ►Golgi tendon organs respond to different mechanical variables of muscle performance (►Proprioception: Role of muscle receptors).
2. "Auxiliary" or "accessory" structures. For instance, cutaneous mechano-receptors display specific sensitivity to particular temporal aspects of mechanical stimuli because of the filtering properties of the special anatomical structures associated with their sensory endings; in the auditory system, the complete mechanical apparatus from the tympanic membrane to the ►basilar membrane transforms and filters the frequency content of the mechanical stimulus before reaching the ►hair cells in the inner ear; and in the ►visual system, light refraction and focus are performed by accessory structures (cornea, lens, etc.).

### Sensory Transduction

The transformed stimulus then strikes the receptor cell. By the process of transduction, the transformed stimulus causes the opening or closing of ►ion channels in a local membrane region and produces a ►receptor current, which in turn gives rise to a ►receptor potential. In most receptors, the receptor potential is in depolarizing direction, while in photoreceptors it is hyperpolarizing. The ions involved in the production of receptor potentials depend on the specific receptors. The receptor potential encodes various stimulus properties in a continuous amplitude-modulated way.

### Encoder

Since receptor potentials usually are graded local events in neurons (graded potentials) and thus undergo the typical electrotonic decrement in amplitude and slowing of their temporal transients when spreading electrotonically (►Electrotonic spread), action potentials are needed to carry information over long distances. Thus, there must be a neuronal site, where the receptor potential is translated (encoded) into a train of action potentials. This site may be in the receptor cell itself or in a following nerve cell, depending on the organization of a particular sensory system.

In so-called primary receptor systems, the receptor cell itself has an axon to propagate action potentials to central nervous structures. The receptor cell proper thus contains the ►encoder. In this case, ►receptor current and potential are also called ►generator current and ►generator potential because they generate action potentials.

In so-called secondary sensory systems or tertiary sensory systems, such as the ►inner ear or ►retina, the receptor potential of the primary receptor cell is, via intermediate steps involving synapses, converted into membrane potential changes in secondary or tertiary cells, which then encode these changes into action potential sequences.

### Coding of Modality and Quality

Many sensory receptors are most sensitive to selected stimulus energies (receptor specificity). Their excitation thus defines the stimulus modality or quality in a ►labeled-line code [6]. However, there are many ►polymodal receptors, many of which are associated with small-diameter axons. In particular, ►chemoreceptors for ►taste and ►smell often respond to several chemical agents, any one of which cannot, therefore, be coded in the discharge of individual receptor types, but only in the activity patterns of populations of receptor afferents (►across-neuron pattern code [6]). This may also apply to other modalities. For example, in ►vision, any particular wavelength is sensed by more than one retinal cone ►receptor type (►Photoreceptors; ►Retinal color vision in primates; ►Color processing) and in cutaneous mechano-sensation, natural stimuli usually excite more than one type of mechano-receptor (although the excitation of individual mechano-receptors may lead to defined sensations) (►Processing of tactile stimuli).

### Coding of Stimulus Intensity

The quantitative relationships between the intensity of a stimulus and the discharge rate of an afferent sensory nerve fiber may take different forms in different sensory systems. In many mechano-sensory systems, it is close to linear, while in the visual and auditory systems it can be approximated by logarithmic or power-law functions with exponents <1. This diversity is related to the range of stimulus intensities encountered in these systems. As a gross rule, linear relationships prevail where stimulus range is relatively limited, and nonlinear mappings occur in systems where stimulus intensity can vary over many orders of magnitude, such as in the visual and auditory systems.

Another factor important for intensity coding is a spatial characteristic, especially in higher metazoa: recruitment. As the intensity of a stimulus increases, increasingly more sensory receptors and axons are excited and contribute to the flow of information in parallel channels. This is a ►population code.

### Coding of Stimulus Time Course

The filtering characteristics of sensory receptors vary. Based on their temporal response profile to stimuli, receptors are traditionally classified grossly into rapidly adapting or slowly adapting. Rapidly adapting receptors, such as cutaneous hair-follicle endings (►Cutaneous mechanoreceptors, functional behavior), which produce only one or little more action potentials to sudden and then maintained deflection of a skin hair, are also called phasic types. Slowly adapting receptors, such as the ►muscle spindle, are also referred to as tonic types. Usually, however, most of them show an initial firing-rate overshoot in response to a step increase in stimulus intensity. They only differ in the relative amplitude of overshoot and the rate of firing decay (adaptation) from the overshoot. Thus, even tonic receptors often display a marked initial overshoot, which is an expression of sensitivity to change in the adequate stimulus. Adaptation may occur in all the processes important for sensory reception: transformation, transduction and encoding. An example for the filtering effects of the accessory apparatus is the ►Pacinian corpuscle, (►Vibration sense) in which the onion-like sheath surrounding the sensory nerve ending filters out maintained stimulus components and makes the receptor a ►high-pass filter. The next site of adaptation is the transducer. That is, even though a stimulus may be maintained, the receptor potential adapts. Finally, the encoder translating the receptor or generator potential into a train of action potentials may also adapt. Spike-frequency adaptation also occurs in central neurons, such as ►motoneurons, in response to supra-threshold, step-like, maintained depolarization and is the result of several underlying processes. One is the inactivation of transient voltage-gated $Na^+$ channels (►Action potential), this process being specifically referred to as accommodation [7].

## Principles of Central Processing

In general, processing of sensory signals occurs through a succession of hierarchically organized stages from the periphery to the cerebral cortex, with many descending feedback and cross-connections. A few general principles are as follows.

### Modularity

One of the leading concepts in sensory physiology is the existence of parallel processing in various subsystems, here of signal flow from the periphery to the cerebral cortex [2]. Parallel processing is evident in various forms. First, individual receptor cells and their receptive fields need to be small for adequate spatial resolution and cannot therefore cover the whole area to be monitored, which instead requires a multitude of receptors. In several sensory systems (e.g. cutaneous senses, retina), receptor cells are arranged in two-dimensional sensory surfaces, which are tesselated by the receptor cells. The spatial order of this tessellation is maintained up to the cerebral cortex (topography), albeit in distorted form. Second, in some cases, the different modalities and submodalities are processed in functionally specialized systems, as, for example, in vision (►Visual Processing Stream in Primates; ►Extrastriate visual Cortex). However, at some stage, the pieces of information transmitted through, and processed within, spatial and functional channels must be integrated into unified representations (see below).

### Topography

In several sensory systems, the pattern of neighborhood relationships among receptor cells is preserved throughout their central projections to higher stages, thus giving rise to topographic projections and topographic maps. Thus, the retina is mapped retinotopically onto several visual cortex areas (►Vision); the cochlea is mapped cochleotopically or tonotopically onto the auditory cortex; and the skin surface is mapped somatotopically onto somatosensory cortex areas (►Somatotopic organization; ►Primary somatosensory Cortex (s1); ►Somato-sensory Cortex, plasticity). Similar maps exist in subcortical structures such as ►thalamus, ►colliculus superior and cerebellum.

#### *Functions of Maps*

In considering the functional role of orderly maps, one has to take into account that there are different kinds of maps, which most likely have different functions [8]. Topographic maps allow for spatially close stimuli impinging on the receptor surface to be processed by

computations in local networks of neurons or modules that need not be connected via metabolically costly and space-consuming long-range connections. Also, local continuity on the map might serve as a metric for similarity in the space of the represented variables. For example, in the cochleotopic map of the auditory system, neighboring frequencies are represented such that they can interact over fixed distances [8]. Furthermore, cross-correlated activity in adjacent cell groups may serve to detect combinations and associations of the variables represented by any single group. Since most cortical connections are of short range, this mechanism would most readily work between adjacent cell groups. It may be assisted by the fact that gross topographic maps are often split into interdigitated reiterated slices representing different variables (features) and leading to multiple mappings within each small representational area. This pattern appears to make good sense in that a multi-dimensional variable or feature space (as in vision) is represented on a virtually two-dimensional surface. These additional variables (e.g. modalities or sub-modalities) can thus be labeled with a common spatial sign before being assembled into more complex higher-level entities.

## Integration of Senses

Events or objects in external space manifest themselves by emanating different kinds of energy, which are picked up by different senses, e.g. vision, audition, somato-sensation, smell. Despite this analysis in parallel sensory systems and sub-systems, the nervous system must ultimately come up with a unified ►percept of the event or object, which requires that the different aspects and features supplied by the sensory systems be integrated (►Multimodal integration). This integration must even be accomplished within individual sensory systems that often analyze objects according to different sub-modalities in different brain areas (e.g. in vision: form, color, depth and motion in space etc.). But integration must also be achieved intermodally. How and at what neural stage this integration is performed is referred to as the ►binding problem (e.g. [9]).

Psychophysical, neurophysiological and brain-imaging studies have provided increasing evidence of vigorous interactions between sensory modalities. For example, vision and audition heavily interact, as already evidenced by the "►ventriloquist effect," but there are many other examples of cross-modal influences. Many of these interactions appear to take place at cerebro-cortical level, but at stages before the elaboration of conscious percepts [10].

### *Multimodal Integration*

There have been several hypotheses as to how the nervous system might handle the binding problem. One hypothesis is based on the convergence of pathways from different receptor systems onto multimodal neurons [11–13]. Such multimodal convergence occurs throughout the neuraxis. Already in the spinal cord, different afferent nerve fibers carrying sensory information from different types of sensory receptors converge on central neurons [14,15]). The best investigated structure for multimodal convergence is the ►superior colliculus of the midbrain, which integrates sensory signals from vision, hearing, somato-sensation and pain for attentive and orientation behaviors [11–13]. Multisensory convergence also takes place at cerebro-cortical levels. For example, areas in the posterior parietal cortex contribute to the multisensory construction of spatial frames of reference (see Sect. 8.1) for planning eye, arm and hand movements [16,17]. And the human lateral occipital complex contains a subregion, which is activated by objects when either seen or touched. This convergence of visual and somatosensory signals appears to enable the precise recovery of object shape [18].

Another hypothesis posits that separate cell groups representing different object features are temporarily linked by dynamic connections that entail, and are maintained by, synchronization between their discharges. If synchronization is understood in a loose way, it is easily seen that an object will elicit nearly simultaneous activity in different regions of the brain, all of which may be concerned with one or the other aspect of it. But it has been hypothesized that synchronization on a millisecond time base may couple many neurons into assemblies representing objects [9]. On a gross scale, these synchronizations often appear in the form of oscillations in the high-frequency γ-range (20–80 Hz), which may be widespread over the cerebro-cortical surface. In the locust olfactory system, higher-order cells appear to be able to read out input synchronization and use it to fine-tune their sensory properties [19].

An exaggerated form of multimodal integration may be ►synesthesia, which is a condition in which otherwise normal persons experience sensations in a non-stimulated sensory modality by a stimulus applied to another sensory modality or ►sub-modality (also quality).

## Memory

In order for organisms to properly appreciate objects and events, they should compare them with previous experiences, that is, stored information about themselves and the environments. This "knowledge" (not necessarily conscious, of course) is diverse, ranging from genetic information via internalized standards (e.g. sustainable substance concentrations) to fairly intricate internal representations or ►internal models (►hearing and memory).

## Representation of Space

A basic requirement for perception, orientation, movement and object manipulation is the representation of space and spatial relationships between objects, including the own body. Although theoretically this representation need not be based on frames of reference and coordinate systems as used in physics and engineering, there is much experimental evidence for the existence of such frames [20].

### Frames of Reference

Perceptual determination of an object's location, orientation and three-dimensional shape could make use of clues from several senses, e.g. vision, audition, proprioception and touch, not all of which may be available all the time. The sense receptors involved have different orientations to internal (body) and external space. For example, when an invisible object is localized by the position of the fingers touching it, finger position relative to the body can be determined making use of proprioception, which heavily involves muscle spindles. Since muscle spindles measure muscle lengths, their signals vary along dimensions of an *intrinsic frame of reference*. By contrast, when vision is primarily used for object localization, the object is projected onto the eye-fixed retinas, in an *extrinsic eye-centered* coordinate system. Already at this stage, three points are clear. (i) There is a difference between proprioception and vision in that the former can be used only in *peripersonal space*, whereas the latter covers far space as well, which imposes functionally differentiated roles on different senses. (ii) The spatial representations based on data from different senses operating with different reference frames must be brought in register with each other, involving *coordinate transformations* and *calibrations*. (iii) As a corollary, this process requires multimodal integration (see above).

The concepts of reference frames and coordinate transformations are extended when skilled movements guided by sensory feedback and thus involving sensorimotor transformations are considered. For example, consider a goal-directed movement such as pointing to a visible target. This task involves localization of the target and of initial hand position and collapsing hand with target position. As outlined above, the target is first projected onto the eye-fixed retinas, in an *extrinsic eye-centered* coordinate system. Since the eyes can move within the head, the eye-centered representation must be transformed into a head-centered representation, and, if the head is movable on the trunk, the head-centered representation must be transformed into a body-centered representation. When hearing is used for object localization, a head-centered auditory representation is the first step. Finally, the position of the arm/hand must be represented. The hand position can be given in terms of an intrinsic, rectangular Cartesian coordinate system, where the $x$-axis is in a parafrontal and the $y$-axis in a parasagittal plane through the shoulder. Alternatively, the hand position can be described in terms of joint angles, thus establishing an intrinsic system based on body geometry. Both systems are used by the nervous system, with their relative weight often depending on conditions. Note that motor actions are ultimately expressed in the latter system, that is, as changes in joint angles. The organization of goal-directed movements must therefore include transformations of all needed sensory signals in different reference frames into the intrinsic frame of joint angles, which involves a cascade of processes. All these systems are egocentric coordinate systems related to the organism. There is evidence that monkeys and humans are able to build ►allocentric (world-based, e.g. object-centered) ►reference frame, for example in the ►supplementary eye field. As mentioned and emphasized again, object locations are often determined from contributions of several senses (vision, hearing, vestibular, tactile, proprioceptive systems), whose different representations must be unified into one multimodal representation, requiring that the different coordinate systems be aligned [16,20–22].

### Body Schema

In order to perceive and act, the nervous system must be able to relate the positions of the body and its parts to each other and to a representation of the external world. This complex representation is called the ►body schema. Humans normally are consciously aware of their body configuration, but often do not pay much attention to it. There are many pathological conditions, however, in which the existence of a body schema becomes strikingly apparent:

1. Phantom limb. When a limb is amputated or otherwise lost, the patient often feels the missing limb as if still existing. The configuration can change over time, however.
2. Hemispatial neglect arises in some forms of brain damage and may entail that the patients neglect entire parts of the external world or do not accept parts of their own body and associated extracorporeal objects (such as rings etc.) as belonging to them.
3. Paranoid ►schizophrenia may lead the patients to over- or underestimate the size or their limbs.

The body schema incorporates a representation of verticality based on signals from visual, vestibular, proprioceptive and several gravity receptors in the trunk [23], as well as a representation of the shape of the body and its dynamic changes. The sensation of shape depends on sensory signals carried by group Ia afferent fibers from muscle spindles [24] and conveying the positions of body parts relative to each other [25]. The sensory origin of the dynamic

movement information is not quite clear yet. How the body schema is generated centrally is largely unknown.

## Modulation of Sensory Processing

Potentially, the many sensory systems could deliver immense amounts of information, which, if processed unsifted, would swamp the processing capacities of the nervous system. Moreover, much of the sensory information impinging on the nervous system is not immediately relevant behaviorally. Thus, extensive processing of sensory signals can, and needs, only be done on selected aspects.

The consequence is that, as best investigated in ►vision, the many objects in a visual scene compete for neural representation ([26] ►Visual attention). Resolution of this competition requires mechanisms ensuring

1. Selection of relevant pieces of information, involving
   (a) Suppression of unneeded information
   (b) Facilitation of needed information
2. Localization of the relevant information and directional processes toward this locus
3. Eye movements toward selected objects (if needed) to focus and observe them at high spatial resolution

The competition can be resolved by means of various processes steering ►attention [26]:

1. Bottom-up modulation by stimulus-driven processes
2. Top-down modulation, involving directed selective attention

Descending modulation of sensory processing can occur all the way from the cerebral cortex to the peripheral receptors, in the latter case by efferent control of receptor sensitivity (e.g. of auditory and vestibular ►hair cells, ►muscle spindles).

### Bottom-Up Mechanisms: Salience

Stimulus-driven processes are based on the salience and "pop-out" of stimuli. Bottom-up means that attention is captured more easily by stimuli that are stronger, more extensive and/or move faster than others. Salient stimuli are easily detected among a number of distractors.

### Top-Down Mechanisms

Top-down refers to attention-shifting processes controlled by the brain.

#### *Selective Attention*

Generally speaking, attention is the mental capability to select stimuli, responses, memories or thoughts, which are behaviorally relevant, from among those that are not [27]. Selection is achieved, at any time, by funneling the information flow through a small window of attention that may be shifted appropriately to interesting things currently relevant to behavior. If relevant information is to be selected from non-important one, neuronal activities must be facilitated and/or suppressed appropriately. This implies that neuronal activities must be susceptible to attention. Directing attention like a searchlight again requires the multimodal integration of senses to construct a common spatial frame [17].

#### *Enhancement of Neuronal Response and Sensitivity*

Neuronal responses and sensitivities to a stimulus are enhanced when attention is directed to the receptive field as compared to attention directed outside the receptive field. In vision, such attentional effects have been demonstrated in various visual areas (►Visual attention). Compatible results have been obtained in humans using functional brain imaging and event-related potentials. Response enhancement also occurs when attention is directed to a specific stimulus attribute, such as luminance, orientation, shape, color, and direction or speed of motion [26].

#### *Sources of Attentional Top-Down Influences*

The top-down attentional modulations probably originate in a distributed network of higher-order areas in parietal and frontal cortex. For spatially directed attention, these areas include the superior parietal lobule (SPL), frontal eye field (FEF), supplementary (frontal) eye field (SEF) and perhaps inferior parietal lobule (IPL), middle frontal gyrus (MPF) and anterior cingulate cortex [26].

## Plasticity of Sensory Systems

The nervous system must be able to adapt to changing circumstances, at time scales from seconds to years. In ontogeny, this involves the dynamic establishment and maintenance of appropriate connections, including topographic representations of sensory surfaces and the peripheral motor apparatus [28]. However, such representations in sensory and motor cortices (and related subcortical structures) are alterable throughout life, in response to environmental and internal changes, e.g. frequent types of stimulation and lesions [29–35]. For example, consequent to loss of a digit, the somatotopic maps along the mechano-sensitive route to the cortex can be reorganized at all the intermediate processing levels, e.g. spinal cord, ►dorsal column nuclei, thalamus and cerebral cortex [35] (►Somatosensory Cortex, plasticity).

### Mechanisms of Map Plasticity

A number of different processes and mechanisms contribute to the plasticity of topographic maps, from the influence of inhibitory interneurons to structural changes of axons and dendrites to synaptic plasticity. Structural changes, such as axon sprouting, synapse creation, retraction or elimination, occur in the initial

build-up of appropriate connections and have also been implicated in long-range reorganizations. Changes in dendritic arborization following prolonged exposure to complex environments or to specific motor tasks may be involved as well. Some mechanisms commonly shared with long-term synaptic plasticity may be at play here as well.

## Information Transfer and Neural Codes

Each stage of neural processing converts the input into an output, and each of these conversion processes distorts the signals to some extent. There are several reasons, among which three pop out:

1. Dynamic range. A neuron's response range is limited.
2. ►Bandwidth. Each neural channel is bandwidth-limited, limiting its speed of response and temporal resolution.
3. ►Noise. Each channel is corrupted by noise.

### Statistical Nature of Information Transfer

Noise implies that the coding and transfer of information are not completely reliable. Neuronal input-output relations are therefore of probabilistic nature. For instance, peripheral sensory systems encode stimuli into sequences of action potentials. Noise or uncontrolled variables in the encoding process entail that any particular stimulus may evoke several different sequences of action potentials and, conversely, any particular action potential sequence may be related to different stimuli. The same applies to synaptic inputs to neurons. Synapses may be fairly unreliable because transmitter release is a stochastic process with occasional failures.

### Neural Encoding

Noise, and dynamic–range and bandwidth limitations, co-determine the efficiency of any code used to encode and transmit information. Inefficiency would be expensive because it would imply more storage space, more expenditure of transmission energy, longer transmission times or larger bandwidths or dynamic ranges to store or transmit the same information [36]. The ►efficient coding hypothesis posits that sensory receptors and neurons have adapted so as to minimize the costs and get the job "done just right-enough" [37].

How efficiently do sensory systems code sensory signals into action potential trains?

#### *Sources of Inefficiency*

One problem to be dealt with by sensory systems is natural stimulus statistics, i.e. the non-random statistical properties of environmental stimuli impinging onto sensory surfaces [38]. There are two main sources of redundancy:

1. Unequal probabilities of stimulus elements
2. Correlations between stimulus elements:
   (a) Spatial correlations between parallel stimulus elements
   (b) Temporal correlations between sequential stimulus elements

#### *Unequal Probabilities of Stimulus Elements*

Consider primate vision. The image is cast on the retina and sampled by photoreceptors (and can thus be regarded as a two-dimensional array of picture elements: pixels). Natural images contain an abundance of statistical regularities that may in fact be important for survival [39]. For example, in indoor, outdoor and natural environments, the orientations of contour segments defining objects occur at different frequencies, with vertical and horizontal orientations occurring more frequently than oblique ones [40,41].

#### *Spatial Correlations between Parallel Stimulus Elements*

Stimulus attributes at different pixels are correlated with each other [42] (see also [41]. This implies that "knowledge" of some section of an image can be used to predict other sections. In line with the above results, different contour segments of natural objects show orderly patterns, explaining the existence of long-range correlations in the distribution of oriented line segments over the visual field [43].

#### *Temporal Correlations between Sequential Signal Elements*

The time courses of natural signals differ from white noise, in which successive values vary randomly. Stimuli vary smoothly and continuously in time, making any value at any time instant dependent on the previous history. This also applies for neural signals and is readily apparent in receptor and synaptic potentials, but often holds true also for spike trains, where the probability of a spike depends on the occurrence of previous spikes.

#### *Code Optimization*

Because of its limited resources, the nervous system should try and reduce any coding inefficiency. Whether it does so, and if so what mechanisms it uses, is only partially known and may depend on the specifics of particular channels (see, e.g. [39]). There may be channels with limited capacities, in which coding efficiency may be pressing (for example, the optic nerve in mammals). By contrast, at other places (e.g. the cortical visual areas), redundancy might be of advantage; after all, the regularities in the environment allow the nervous system to make predictions [39].

An example for how to construct an optimal code is presented by the fly compound eye with possible extensions to the mammalian visual system [44]. Pictorial information is derived from the two-dimensional

spatial array of light intensities and their changes in time. The intensities in ambient daylight may vary over several orders of magnitude. If this range were transduced linearly into photoreceptor potentials, the gain would be uniformly low. Moreover, of prime importance in an image are changes, spatial contrasts and temporal variations, which delineate objects from others. Thus, some other form of coding is required. ►Contrast is a measure of relative intensity at some point in relation to the average (background) intensity level, $I$, in its surroundings, usually expressed as $\Delta I/I$.

The background intensity $I$ can be estimated as a weighted average of the signals from surrounding photoreceptors. Such weighting functions have been computed for pictures of different statistical properties and intensities and different ►signal-to-noise ratios, and compared with measured data. To remove temporal correlations requires a biphasic response to an instantaneous flash (►impulse response). Thus, the weighting functions necessary for this computation are functions of space and time, over which the local means should be determined. This coding scheme has some essential features:

1. ►Center-surround antagonism in the receptive field (RF). Here the center is excitatory and the surround inhibitory. This receptive field organization is often found in sensory systems.
2. Reduction of redundancy resulting from spatio-temporal correlations. These correlations can be captured by properly designed weighting functions, and subtraction of the predictive signal thus removes or at least reduces the correlation-based redundancy from the center signal.

In summary, center-surround antagonism in receptive fields is capable of enhancing spatial contrasts, and this in turn reduces spatial redundancy that would otherwise be present in the signals of parallel neuronal elements due to spatial correlations in the sensory signals. Similar principles apply in the temporal domain, where properly chosen impulse functions may reduce temporal redundancy.

## Acknowledgment

*Dedicated to the outstanding scientist, academic teacher and friend Rainer F. Greger (3.1.1946-16.12.2007)*

I am grateful for encouragement and suggestions for improvement to Marc D. Binder and Douglas G. Stuart."

## Sensory Transduction

### Definition

Sensory transduction denotes the process by which, in a sensory receptor cell, a physico-chemical stimulus is converted, by the opening or closing of ion channels in a local membrane region, into a receptor current, which in turn gives rise to a receptor potential.

►Receptor Potential
►Sensory Systems

## Septal Complex

►Evolution of Septal Nuclei

## Septal Nuclei

### Synonyms

►Nuclei septales

### Definition

The nuclei located in the septum verum (lateral septal nuclei, medial septal nuclei, nucleus of diagonal band) are involved in complex function circuits between hypothalamus and hippocampus. Lesions and stimulation show that the nuclei are involved in autonomic behavioral processes such as eating, drinking, micturition, defecation, sexual, reproduction and aggression behavior.

►Telencephalon

## Septal Organ

### Definition

"Organ of Masera," bilaterally, isolated small patch of olfactory epithelium in several mammalian species at the nasal septal wall with axonal projections of specific

glomeruli in the olfactory bulb. Discovered 1921 by Broman, function yet unknown.

►Chemical Senses
►Olfactory Perception

## Septal Region

### Definition

The septal region (area septalis) lies medial and dorsal to the nucleus accumbens, and terminates dorsally in the septum pellucidum. The septal regions contains the septal nuclei and the diagonal band of Broca.

►Evolution of Septal Nuclei

## Septum, Lateral

### Definition

Part of the septal complex, comprising mostly GABAergic medium sized, spiny neurons, that receives massive inputs from the hippocampus and projects strongly to the preoptic region and medial septumdiagonal band complex, which is rich in cortically projecting cholinergic and GABAergic neurons.

## Septum Medullae

►Floor Plate

## Septum Pellucidum

### Definition

The septum pellucidum is part of the medial border of the cerebral hemisphere and third ventricle. It consists of a thin layer of glial tissue almost void of neurons. The septum pellucidum spans between corpus callosum, fornix, and septal region. The septa pellucida of both hemispheres are partially adherent but may contain the cavum septi pellucidi, a cavity filled with fluid.

## Sequence Learning

### Definition

Sequence learning is of behavioral procedures or "how to," which is similar to skill learning. But it is learning of a series of multiple discrete movements towards a goal, like learning to play a musical instrument or learning to play tennis. It can reflect acquisition of processes of simple stimulus-response association or more extensive, sequential patterns of discrete movements.

In this learning, cortical motor areas, prefrontal cortex and subcortical areas especially the basal ganglia play major roles. Basal ganglia with dopamine system and prefrontal cortex are responsible for acquisition of a series of movements or actions towards a goal, favorable condition.

►Sensorimotor Learning and the Basal Ganglia

## Sequence of Pulse Intervals (SPI)

### Definition

A measure of the temporal patterning of electric organ discharge (EOD) production. Refers to the intervals between adjacent EODs over time.

►Reafferent Control in Electric Communication

## Serial Analysis of Gene Expression

Anthony Berndt, Cairine Logan
Institute of Maternal and Child Health, Genes and Development Research Group, Department of Cell Biology and Anatomy, Faculty of Medicine, University of Calgary, Calgary, AB, Canada

### Synonyms

SAGE; LongSAGE; SuperSAGE

### Definition

Serial Analysis of Gene Expression (SAGE) is a sequence-based approach that allows for global analysis of ►mRNA transcripts, without the requirement of

*a priori* knowledge of an organism's ►transcriptome. SAGE produces a large library of short sequence tags that originate from mRNA extracted from a tissue or purified cell sample [1]. The frequency of each tag directly reflects transcript abundance while the sequence is sufficient to identify known transcripts in database searches. SAGE can be utilized to discover previously uncharacterized transcripts, unlike some types of ►microarray analysis, but currently costs several fold more than microarrays to implement.

## Characteristics

### Overview

Diverse interactions of many neuronal and glial cell types allows for intricate wiring and organization of the nervous system, making it one of the most complex tissues in animals. Although each cell in the nervous system contains an identical copy of the organism's genome, distinct gene expression profiles allows for variegated cellular and functional diversity. In the past, global differences in gene expression profiles have been examined by Northern Blotting, subtractive hybridization, comparative ►expressed sequence tag (EST) analysis and differential gene display [2]. However, these methods are capable of analyzing only a limited number of highly expressed transcript species and do not provide quantitative data on expression levels. Therefore, an approach to quantitatively and qualitatively examine the expression of large numbers of genes expressed at both low and high levels was needed to yield more detailed information on transcript expression profiles. SAGE, originally developed by Velculescu et al. (1995) [1], fulfilled this requirement and was readily adopted by investigators in many fields of biology in subsequent years. While genomics has been extremely successful in cataloguing protein coding gene sequences, it has provided less information on how these genes work in concert to maintain homeostasis by responding to environmental and internal cues, SAGE, therefore, offers an opportunity to increase our understanding of how large numbers of genes operate in a global manner.

### Purpose

SAGE data is utilized to determine the qualitative and quantitative expression distribution of thousands of transcripts simultaneously from a single RNA sample through the generation and sequencing of oligonucleotide tags derived from RNA transcripts [1]. These data can be used to describe the gene expression profile of a single cell or tissue type, or be used to compare different gene expression profiles of two or more samples [3–6]. SAGE tags without a match to known transcripts can also act as a starting point for the investigation of previously unknown genes. Further, SAGE libraries are digital and are thus easily stored in publicly accessible databases for future comparison and analysis.

### Principles

Firstly, sufficient information is contained in a short nucleotide sequence, termed a "tag," to accurately identify the transcript [1]. Standard SAGE tags are 10 nucleotides long, while the currently more favored LongSAGE tags are 17 nucleotides long [7]. (Note: these SAGE tags are actually 14 or 21 nucleotides long, respectively, but all tags contain a common nucleotide restriction enzyme recognition site at the 5′ end meaning that only 10 or 17 nucleotides are unique to each tag.) Thus, $4^{10}$ or $4^{17}$ ($1.04 \times 10^6$ or $1.72 \times 10^{10}$) unique permutations can be represented using this short sequence. For comparison, the human genome contains a total of $\sim 3 \times 10^9$ nucleotides, not all of which are transcribed. Secondly, from 25 to 50 concatermerized tags can be cloned into a single vector, allowing for serial analysis of multiple tags in a single sequencing run. Thirdly, each unique SAGE tag provides information on the genes contributing transcripts to the RNA population, as well as the frequency of occurrence when compared to the total populations of transcripts in the SAGE library.

## Method

### *Biochemistry*

A standardized protocol for SAGE based on the original method developed by Velculescu et al. (1995) [1] is available to researchers and can be accessed at http://www.sagenet.org. LongSAGE [7] and SuperSAGE [8] are performed in a similar manner but utilize different tagging enzymes to generate longer tag lengths. Briefly, RNA is separated from proteins and cellular debris. One strand of cDNA is produced from mRNA by using reverse transcriptase and 5′-biotinylated oligo(dT) primers. Double stranded ►cDNA is then produced by digesting the original mRNA template with ►RNAse H followed by DNA synthesis with DNA polymerase and DNA ligase. A type II ►restriction endonuclease, *Nla*III, called the anchoring enzyme (AE) in this context, cleaves the resulting double stranded cDNA. The product of the anchoring enzyme step is washed over ►streptavidin coated magnetic beads, capturing the biotinylated double-stranded cDNA fragments while the remaining cDNA is washed away. The anchored tags are then divided into two pools. Different linker sequences are ligated to each pool of anchored tags. The linkers contain a recognition motif for a type IIs restriction endonuclease, such as BsmFI, which cleaves DNA at a set distance from the recognition site. Blunt ends are generated by use of ►Klenow fragment. Mixing of the two populations of tags is followed by the ligation of these tags with DNA ligase to form ditags. PCR

amplification of the ditags is performed followed by purification of the PCR products by gel electrophoresis and extraction. The linker portions of the ditags are released with digestion by the anchoring enzyme (*Nla*III). The ditags are concatenated with DNA ligase and inserted into a ►plasmid vector for sequencing.

### Sequence Analysis and Tag Identification

High throughput sequencing methods produce digital datafiles of the concatamers. The beginning and end of each tag in the concatamer are identified by searching for the restriction site of the anchoring enzyme contained in each tag (CATG in the case of *Nla*III.) The sequence of each tag is then logged in a data file for further analysis. A conventional SAGE library will contain 50,000 to 100,000 total tags [3,4,6].

Virtual tag libraries have been generated *in silico* from cDNA sequences archived in the GenBank databases. These cDNA sequences are both cDNAs of described genes and ESTs. Software programs are used to compare the experimentally generated SAGE library with the *in silico* library. When an experimentally generated SAGE tag matches a virtual tag, the identity of the transcript or the gene from which the virtual tag was extracted is assigned to the experimentally generated SAGE tag.

### Data Analysis and Presentation

A common pattern of SAGE data presentation has evolved. The fraction of total tags is often plotted against the frequency with which the tags appear in the population. This relationship often assumes a power law distribution in which a small number of the tags found in the library is present at a very high frequency, while many different types of low copy number tags make up the bulk of the tag population. Tag frequency, sequence, and identity are presented in tables. Tags are often grouped into functional classes based upon Unigene Gene Ontology nomenclature. When two or more samples are compared, tags are presented in tables with the greatest differences between samples listed in descending order. Difference in gene expression level is evaluated based on the result from a statistical test rather than simple fold-difference in tag count between the groups being compared. These methods include a Poisson approximation developed by Audic and Claverie [4], Bayesian method, Monte Carlo Simulation or Fisher's Exact test [6]. Each technique has its own strengths and weaknesses; however, in each case a probability value ($p$-value) is generated that represents the probability of obtaining a result as extreme as the given case, assuming the case was generated by probability alone. When the p-value is less than an a *priori* chosen significance level ($\alpha$), usually $\alpha = 0.05$ or 0.01, the null-hypothesis of no difference between gene expression levels is rejected.

## Advantages and Disadvantages

### Advantages

Techniques such as reverse real-time quantitative PCR (►RT-qPCR) and northern blotting are useful for studying the expression levels of one or a limited number of known genes [6]. Larger scale screening methods such as cDNA subtraction utilize hybridization to uncover differential expression of unknown genes on a small to medium scale, but provide little information on transcript abundance [2]. Conventional microarray analysis is usually used to study known transcript expression. However, recently developed tiling microarrays employ probes representing large stretches of a genome and can detect previously uncharacterized transcripts [9]. In contrast, SAGE provides exact counts of transcript frequency and identity within a library. SAGE can be considered an open experimental format where prior knowledge of the subject's genome is not required, and previously uncharacterized transcripts can be identified. Nevertheless, the true power and utility of SAGE is only fully actualized when a well annotated genome is available to match tags to known genes. Further, the number of SAGE tags collected in an experiment can easily be increased so that even very rare transcripts can be identified with a high probability that these rare transcripts will be previously uncharacterized.

### Disadvantages

Tag sequence specificity has been cited as a weakness in SAGE. Transcripts from two or more different genes can share the same tag sequence [7,8]. This weakness has been addressed by the development of LongSAGE [7] and SuperSAGE [8] approaches that expand SAGE tags from 10 to 17 or 26 nucleotide long tags, respectively, greatly increasing tag specificity.

In many studies, from 30 to 50% of SAGE tags do not map to known transcripts or genes [4,6]. Many of these unmapped tags appear as ►singletons. These unmapped transcripts could originate from introduction of base changes or sequencing errors since multiple steps are involved in SAGE tag collection and single pass sequencing can contain base errors. However, recent work utilizing tiling microarrays has shown that much of the genome may actually be transcribed at low levels suggesting that these unmapped tags may indeed represent unknown low abundance transcripts [9]. In many studies, singleton transcripts are excluded from further data analysis. Obviously, this approach, while simplifying interpretation of the data, detracts from the experimental power of SAGE to discover uncharacterized low copy number transcripts.

## Uses of SAGE in Neuroscience

The use of SAGE in neuroscience spans the genetic and neural complexity of organisms from the nematode *C. elegans* to mouse and human. The following

summaries of studies utilizing SAGE libraries have been chosen to highlight the diverse applicability of SAGE in neuroscience, but in no way acts as a comprehensive catalogue of the research done to date.

A. *Effects of signaling molecules on the central nervous system*

Datson et al. (2001) [3] utilized SAGE to identify corticosterone responsive genes in the ►hippocampus of the rat. Stress causes an increase in the release of corticosterone in rats by increasing the activity of the hypothalamic-pituitary-adrenal axis. Response to glucocorticoids occurs via binding of corticosterone to intracellular mineralocorticoid (MR) and glucocorticoid receptors (GR) which in turn activate or repress target genes. MRs are approximately 10 times more responsive to corticosterone than GRs. Exposing adrenalectomized animals to low or high corticosterone levels resulted in differential gene expression. Furthermore, comparison of MR- and GR-dependent expression profiles revealed that the majority of the corticosterone-responsive genes were regulated either by activated MR or by activated GR, while only a few genes were responsive to both. These differentially expressed genes were grouped into classes such as: energy expenditure and cellular metabolism; protein synthesis and turnover; signal transduction and neuronal connectivity; and neurotransmission. Although some genes were already known to be corticosterone responsive, such as GAP-43 and metallothionein-I, many were novel. Differential expression of six randomly chosen, previously identified genes was examined by *in situ* hybridization and found to correlate strongly with the SAGE data.

B. *Development and differentiation of neuronal types*

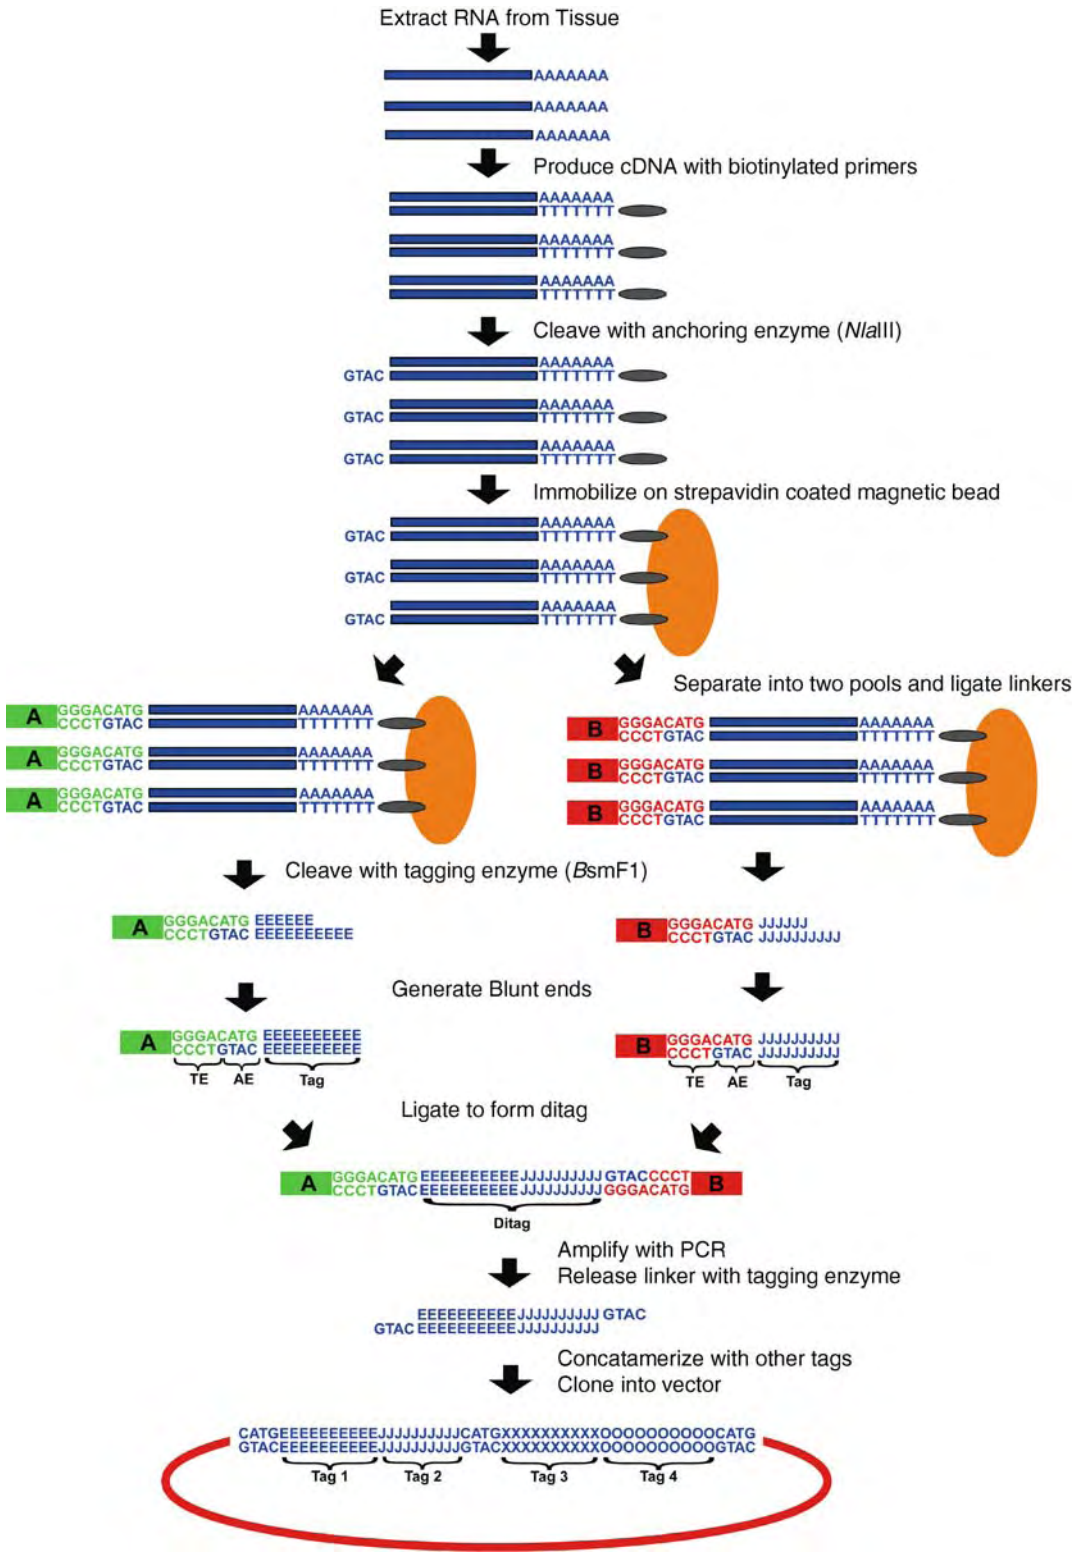
Etchberger et al. (2007) [4] utilized SAGE to compare the expression profile of gustatory neurons (ASE neurons) with thermosensory neurons (AFD neurons) of *C. elegans* and were able to identify >1,302 differentially expressed genes. These genes included transcription factors, ion channels, neurotransmitters, and receptors, as well as seven-transmembrane receptor-type putative gustatory receptor genes. Examination of the *cis*-regulatory sequences, through consecutive deletions of the promoter region of multiple differentially expressed genes, followed by sequence alignment and site-directed mutagenesis revealed a previously uncharacterized "ASE motif" required for the expression of many ASE-expressed genes. The ASE motif was identified as a binding site for the C2H2 zinc finger transcription factor CHE-1, which is essential for proper differentiation of the ASE cell type. This study highlights the usefulness of SAGE when combined with other more conventional approaches to interrogating the genome.

C. *Molecular profile of pathophysiological processes*

Focal Brain Ischemia Reperfusion injury (stroke) has been characterized as having acute and delayed phases. During the acute phase, hypoxia and energy failure cause cell necrosis, while delayed events, involving altered gene expression after blood flow has been re-established, are involved in subsequent inflammation and apoptosis. Trendelenburg et al. (2002) [6] utilized SAGE to identify candidate up-regulated and down-regulated genes involved in the delayed response. Metallothionein-II (MT-II) was the transcript most significantly increased 14 h after ischemia as compared to controls. However, the expression of the closely related gene Metallothionein-I (MT-I) could not be analysed using SAGE as it did not contain a NlaIII anchoring restriction site. Northern Blotting and semi-quantitative Western Blotting was utilized to confirm MT-II up-regulation. Immunohistochemistry revealed that both MT-I and MT-II were expressed in reactive astrocytes around the infarct core. MT-I and MT-II deficient knock-out mice were shown to have an infarct volume three times that of wild-type animals. This study demonstrates how SAGE data can be linked to functional relevance. Taken together, these findings suggest a protective role of metallothioneins in a model of stroke.

D. *Comparative Gene Profiles of Developing Brain Regions*

The two cerebral hemispheres of the human brain are specialized for distinct cognitive and behavioral functions. For example, language function is predominantly localized to a distributed network in the left cortex surrounding the lateral sulcus, called the perisylvian cortex, in ~97% of right-handers and ~60% of left-handers. Sun et al. (2005) generated SAGE libraries from the left and right perisylvian regions of human fetal brains at 12, 14 and 19 weeks of development. In all, 49 differentially expressed genes were found between the left and right regions in the 12 week old brain and 68 in the 14 week old brain. Factors known to play a role in cortical development, such as ID2, NEUROD6 and Lim Domain Only 4 (LMO4) were found to be asymmetrically expressed. LMO4 was further investigated with RT-qPCR and shown to be expressed at a higher level in the right cortex compared to the left at 12 weeks and 14 weeks, but not 19 weeks. *In situ* hybridization performed on brains at several different stages from 12 to 19 weeks of development also demonstrated that LMO4 expression is found to a greater extent over the right perisylvian cortex than the left, with diminishing asymmetry over the same period of development. LMO4 expression was also profiled in embryonic mice and exhibited a similar temporal pattern of lateral asymmetry but was not consistently lateralized to the right or left side. This may



**Serial Analysis of Gene Expression. Figure 1** Schematic of SAGE Library Construction. Double stranded cDNA is produced from polyadenylated RNA transcripts. The anchoring enzyme defines the 5′ end of the tag. After ligation to linkers, the tagging enzyme defines the 3′ end of the tag. The anchoring enzyme is used to free the tags of the linkers before they are blunt-ended and ligated together to form ditags. The ditags are then concatenated and inserted into a plasmid for sequencing.

relate to motor asymmetries which are observed in individual mice, like paw preference, but are not biased on a population level as they are in humans where 90% of the human population has naturally greater dexterity with their right hand. The left-right differences in LMO4 expression in humans could potentially represent either a differing topographic mapping in the two hemispheres or alternatively a difference in the rate of cortical development, with the right hemisphere's development occurring more rapidly than the left.

### Future of SAGE

Currently, the sensitivity of SAGE to detect low copy number tags, many of which may represent real transcripts, is limited by cost-efficiency due to the current expense of DNA sequencing on conventional systems. New sequencing technologies are becoming available that should allow sequencing of millions of base pairs for a few hundred to a few thousand dollars with much higher throughput [10]. Furthermore, massively parallel sequencing-by-synthesis approaches like the Solexa 1G system or the 454 system that allow simultaneous sequencing of thousands of short nucleotide sequences at once should theoretically negate the need for cloning or concatamerization; instead, allowing a modified form of ditags to be directly sequenced [10]. Therefore, SAGE, or variations thereof, has the potential to play an increasing role in transcriptome and genome studies for the foreseeable future.

## Serial Learning

### Definition

Serial learning is learning to make a series of responses in exact order. In other words, it is a procedure of learning where the learner is exposed to stimuli to be remembered and later recalls those stimuli in the same order in which they initially appeared. Memory for words is a representative type of serial learning.

## Series Arrangement

### Definition

A combination of two rheological elements, such that the force is common to both and the elongations are to be added to obtain the elongation of the combined element.

►Mechanics

## Series Elasticity

►Tendon

## Serotonin Actions on Suprachiasmatic Nucleus

### Definition

One of the major transmitters in the nervous system. Serotonergic neurons from the raphe region densely innervate the suprachiasmatic nucleus (SCN). Raphe

neurons typically generate action potentials and release 5HT during the phases of the daily cycle in which the animals are awake. A diverse array of 5HT receptors have been reported in the SCN including the 5HT1A, 5HT1B, 5HT2A, 5HT2C, 5HT5A and 5HT7 receptor types. These G-protein linked receptors are coupled to adenylyl cyclase or phospholipase C. Activation of these signaling pathways could produce a variety of cellular effects in SCN neurons. The modulations of potassium and calcium channels most commonly mediate the ionic actions of 5HT in other brain regions although the specific ionic mechanisms that underlie 5HT's actions in the SCN are unknown.

Functionally, 5HT receptor agonists cause phase shifts of the SCN circadian oscillator when administered at times in the circadian cycle during which light does not cause phase shifts both in vitro and in vivo.

Evidence suggests that this pathway may mediate nonphotic activity induced phase shifts of the circadian system. In addition, a variety of evidence suggests that 5HT can also modulate photic input to the SCN. Neurotoxic destruction of the serotonergic input to the SCN alters the relationship between the light-dark cycle and locomotor activity and increases in 5HT levels alter the effects of light on the circadian system. Administration of 5HT can inhibit optic nerve induced field potentials in the SCN brain slice preparation, light-induced Fos expression and phase shifts of the circadian rhythm of wheel-running activity. Interestingly, 5HT receptor antagonists have been reported to enhance light-induced increases in the firing rates of SCN neurons and light-induced phase shifts. These results raise the possibility that 5HT may be involved in a tonic inhibition of the light-input pathway to the SCN. These studies are all consistent with the hypothesis that the serotonergic innervation of the SCN serves to modulate light input as well as mediate non-photic activityinduced phase shifts of the circadian system.

## Serotonin (5-hydroxytryptamine; 5-HT)

### Definition

Serotonin (5-hydroxytryptamine; 5-HT) is synthesized from L-tryptophan and can be converted to melatonin. It is a monoaminergic neurochemical that is common to the nervous and immune systems. Neurons containing serotonin are located near the midline or raphé regions of the brainstem. Serotonergic fibers project widely throughout the central nervous system (CNS) and exert complex neuromodulatory effects mediated through 15 receptor subtypes. 5-HT contributes to functions such as endocrine and circadian rhythms, sleep, body temperature regulation, appetite, food intake, sexual and reproductive activity, aggression, motor functions, cognition, mood, anxiety, learning and memory. Outside the central nervous system, 5-HT is present in immune cells such as platelets, lymphocytes, monocytes and macrophages.

## Servo Control

### Definition

The operation of a proportional feedback controller whereby the feedback loop serves to minimize the error between the desired and actual values of the controlled variable.

►Feedback Control of Movement

## Servomotor

### Definition

A motor that automatically controls the action of a mechanical device in a feedback system consisting of a sensing element and an amplifier.

## Set-point

### Definition

In the body, certain variables must be kept within a narrow limit for survival. This desired or reference point is called set point.

►Homeostasis

## Set-point in Temperature Regulation

### Definition

The value of a regulated variable that is stabilized by the processes of regulation. In temperature regulation, this variable is the core temperature ($T_c$). In fever, its value shifts due to pyrogen-induced changes in the characteristics of the thermal controller such that the properties of the various feedback, feedforward and open-loop components that together contribute to thermal balance cause this balance to occur at a higher than "normal" $T_c$.

## Seven Transmembrane Receptors

►G-protein Coupled Receptors (GPCRs): Key Players in the Detection of Sensory and Cell-Cell Communication Messages

## Severe Myoclonic Epilepsy of Infancy (SMEI)

### Definition

SMEI is a rare form of childhood epilepsy. The symptoms of this disorder begin with tonic/clonic seizure during the first 6 months of life and accompanied by elevated body temperatures. As time progresses, increasingly worse symptoms develop, such as myoclonic seizures, ataxia and photosensitive seizures. In 70% of children with SMEI bear a missense, frameshift and nonsense mutations in the SCN1A sodium channel gene that results in nonfunctional and truncated proteins.

►Epilepsy

## Sex

### Definition

Biological construct used to divide members of a species into reproductively distinct and often complementary groups. A term used to classify organisms as male or female according to genetic composition and consequent anatomic structures and functions. The term sex can be used in reference to human or non-human animals.

►Gender/Sex Differences in Pain

## Sex Differences in Pain

►Gender/Sex Differences in Pain

## Sexual Behavior

### Definition

Behavior that is directed towards a sexual partner, includes courtship and copulation.

## Sex Lethal

### Definition

A name of a gene in Drosophila that undergoes sexspecific splicing to form an active Sex lethal protein in females, and non-active Sex lethal protein in males. The active form of Sex lethal initiates the female-specific development.

## Sexual Neurophysiology

►Neurophysiology of Sexual Spinal Reflexes

# Sexual Reflexes

Lesley Marson
Division of Urology, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

## Definition

Sexual reflexes in males and females comprise of complex integrated systems that are influenced by hormonal levels and sensory signals that are regulated by the central and peripheral nervous systems. Genital reflexes in males and females, such as genital arousal, erection and climax arise from spinal cord reflex mechanisms that are modulated by brain inputs. Other pathways, such as sexual desire and arousal may be regulated by higher central nervous system mechanisms, yet to be determined.

The structural components and mechanisms that lead to Sexual Reflexes, in particular genital reflexes, are outlined in this essay.

## Characteristics

### Higher Level Structures

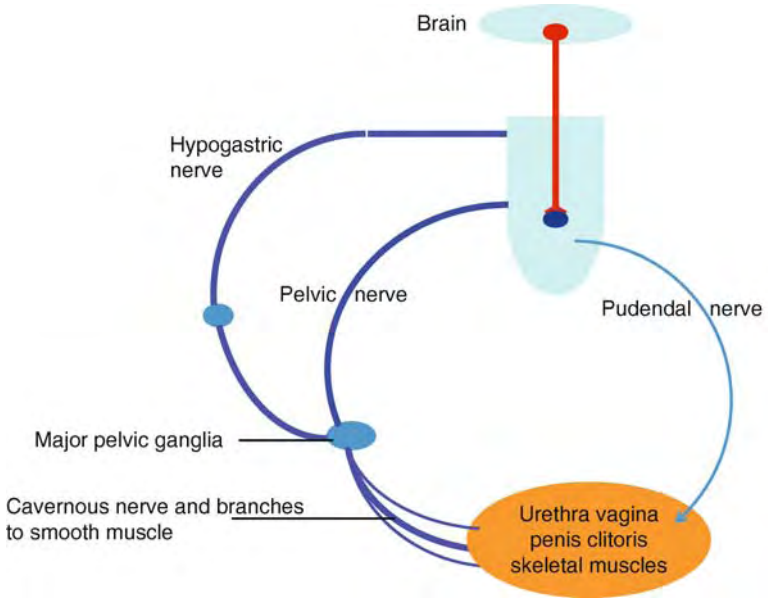
#### *Major Components: Peripheral Nerves, Spinal Cord and Brain (see Fig. 1)*

Sexual reflexes such as clitoral and vaginal ►vasocongestion, erection, ejaculation and sexual climax are organized at the spinal level. This conclusion is based on experimental studies in animals with transected spinal cords and in human patients with spinal cord injury. Sensory stimulation from peripheral nerves increases activity in the spinal cord, which results in increased sexual motor output. For the most part the organization of the neural structures mediating sexual reflexes are similar in males and females.

Sexual responses require the complex coordination of sympathetic, parasympathetic and somatic efferents that are distributed over several spinal segments. These efferents must be coordinated by an interneuronal system that traverses multiple spinal segments. These spinal circuits are regulated by peripheral sensory inputs and descending inputs from the brain. The major supraspinal input is inhibitory and neurons in the caudal ventral hindbrain, in a region known as the nucleus paragigantocellularis, mediate the inhibition in both males and females. Forebrain sites can also facilitate activity of the spinal circuits.

The medial preoptic area is essential for male copulatory behavior (erections and ejaculation) in every species tested [1], and stimulation of this site evokes sexual reflexes in male rats [2]. In females, the brain sites facilitating sexual reflexes are less clear. The medial preoptic region in rats inhibits the display of ►lordosis, but may facilitate genital reflexes. The ventromedial nucleus of the hypothalamus is critical for the expression of lordosis [3], but lordosis is not seen in all species.

Other forebrain regions involved in sexual function have largely been identified on the basis of visualization



**Sexual Reflexes. Figure 1** Diagrammatic representation of the major components involved in sexual reflexes. Peripheral sympathetic (hypogastric), parasympathetic (pelvic) and somatic (pudendal) nerves regulate sexual reflexes. The spinal cord inputs (afferents) and outputs (efferents) are located on the lumbar and sacral cord. The brain modulates the activity of the spinal circuits, mainly be descending inhibition.

of activated neurons in association with particular events, for example, ejaculation or vaginocervical stimulation. The medial amygdala, bed nucleus of the stria terminalis, medial preoptic area, paraventricular nucleus, ventromedial hypothalamus, lateral hypothalamus and central gray are most consistently activated in response to sexual reflexes [4]. These areas may be part of the sensory, motivational or reward circuits that are associated with sexual satisfaction, in addition to regions processing sexual reflexes. Imaging studies in humans have identified areas in the cortex (inferior frontal cortex and insular cortex), midbrain and cerebellum that are activated with visually-evoked sexual stimulation or climax [5].

## Lower Level Components

### *Peripheral Nerves and Spinal Circuits*

The peripheral innervation of the pelvic organs involved in sexual reflexes comprise of the autonomic (pelvic and hypogastric) and somatic (pudendal) nerves. Spinal afferents and efferents that regulate sexual function are located in the lower thoracic lumbar region (T11-L2 in humans, sympathetic) and sacral cord (parasympathetic and somatic). Sensory information from the genital areas travel in the afferent fibers of the pudendal nerve, which enter the spinal cord through the superficial dorsal horn and project to the dorsal gray commissure, which is located in the medial cord, where they terminate. The afferent neurons then synapse on spinal interneurons, which eventually send signals to the efferent spinal neurons that control the pelvic organs. The sensory information is also sent to other spinal segments and to the brain. The sensory afferents of the pelvic (parasympathetic) and hypogastric (sympathetic) nerves may also contribute to sexual reflexes; these fibers enter the dorsal horn and terminate in the lateral and medial gray matter. The efferent fibers of the pudendal nerve provide innervation of the pelvic floor, anal and urethral sphincters. The pudendal motor neurons are located in the ventral horn of the spinal cord (Onuf's nucleus). The efferent sympathetic and parasympathetic fibers relay through the major pelvic ganglion and the hypogastric plexus to form the ►postganglionic nerves (cavernous nerve, dorsal nerve of the penis and clitoris).

## Ascending and Descending Spinal Pathways

The ►spinothalamic and ►spinoreticular pathways relay sensory information to the brain. These pathways travel in the dorsal region of the spinal cord and terminate in the thalamus. Most of the spinoreticular fibers travel in the lateral columns that terminate in the brainstem reticular formation. Descending information from the brain also passes through the dorsal spinal cord. The majority of these pathways cross over to the opposite side.

### *Brain Sites*

The nucleus paragigantocellularis projects directly to efferent neurons of the hypogastric, pelvic and pudendal nerves as well as interneurons in the spinal cord [2]. Lesions of this nucleus allow climactic-like responses to be evoked by peripheral stimulation [2]. Higher brain regions involved in sexual function, for example the medial preoptic area, paraventricular nucleus of the hypothalamus, ventromedial nucleus of the hypothalamus and amygdala, either project directly or indirectly to the nucleus paragigantocellularis and/or to the spinal cord. However, research from a number of laboratories has shown that the central gray is an important relay center for ascending and descending sexually relevant stimuli. Reciprocal connections between most of the brain regions involved in sexual reflexes have been identified.

## Structural Regulation

Spinal sexual reflexes are regulated by the amount of peripheral sensory stimulation received and by inhibition from brainstem regions. These spinal reflexes can function independently from inputs from the brain (as in the case of complete spinal cord injury). However, higher brain regions can evoke sexual reflexes, for example during nocturnal erections and ►psychogenic elicitation of climax.

The spinal and brainstem sites are relatively insensitive to the effects of gonadal steroid hormones (estrogen, progesterone, and testosterone). However, these hormones can modulate sexual reflexes in part by affecting the higher brain control of reflexive mechanisms, as well as altering the sensory threshold of the peripheral nerves.

## Higher Level Processes

Figure 2 summarizes the major processes.

The pelvic and hypogastric nerves mediate sensory information from the internal pelvic organs. Sensations to light touch, chemical stimuli and noxious stimuli of the vagina, cervix, penis and uterus are mediated via the pelvic nerve. Therefore, the pelvic nerve relays sensory information from genital manipulations during sexual behavior. The pelvic nerve is also crucial for the induction of pregnancy or pseudocyesis induced by mating or cervical stimulation. The hypogastric afferents that innervate the uterus, cervix and ovaries may be important in the transmission of noxious stimuli from the uterus. Both the pelvic and the hypogastric nerves are sensitive to circulating gonadal steroid hormones. These preganglionic nerves and their postganglionic nerves also control the contractile and blood flow changes that occur in the genital organs during sexual responses and regulate the secretion of seminal fluids into the urethra. The pudendal nerve mediates sensory

stimuli from the external genitals, the pelvic floor musculature, and surrounding areas including the perineum, clitoris, penis and urethra. The sensory signals that relay through the pudendal nerve are essential for lordosis and ▶urethrogenital reflexes.

Many brain sites receive genital sensory information, indicating that the descending control of spinal sexual function is itself strongly influenced by peripheral stimuli. For example, the nucleus paragigantocellularis, the paraventricular nucleus, the central gray and medial amygdala have all been shown to contain neurons whose activity is modulated by pelvic sensory input. These nuclei are involved in the modulation of spinal sexual reflexes and their activity is, in turn, modulated by genital sensory input.

Higher brain sites (midbrain, hypothalamus and amygdala) also receive cognitive sensory information and have estrogen and androgen receptors on the neurons. These structures are likely sites by which hormones regulate sexual behavior and motivation. However, lack of reward or increased inhibition of the CNS circuits may lead to disruption of the sex cycle and can terminate the occurrence of sexual reflexes.

## Lower Level Processes

### *Peripheral Mechanisms*

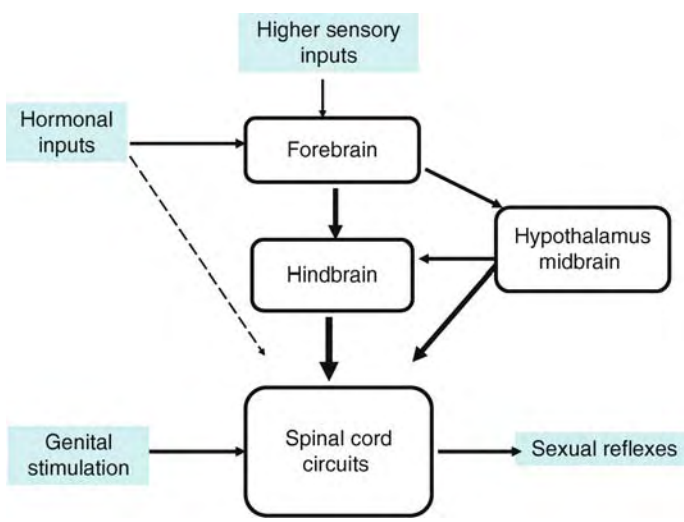
Noradrenaline and neuropeptide Y released by sympathetic nerves results in smooth muscle contractions of the penis and clitoris. Acetylcholine, vasoactive intestinal polypeptide and nitric oxide are released by the parasympathetic nerves. Acetylcholine release results in contraction of the smooth muscle and stimulates release of endothelial nitric oxide. Vasoactive intestinal polypeptide and nitric oxide act to relax smooth muscles, which results in increased blood flow causing erection and vaginal and clitoral engorgement. Acetylcholine released from somatic nerves causes contractions of skeletal muscles.

### *Spinal Mechanisms*

Multiple neurotransmitters and their receptors are present in the spinal cord and may mediate the inhibition and/or facilitation of sexual reflexes. These include, but are not restricted to, adrenaline, dopamine, serotonin, oxytocin, substance P, melanocortin, nitric oxide, enkephalin, galanin, glutamate, and GABA.

A number of studies have shown that the descending inhibition of spinal sexual reflexes is mediated in part by serotonin [2]. Multiple serotonin receptors are present in the spinal cord, and serotonin receptor 1A and 1B are presently prime candidates for mediation of this inhibition. Peripherally evoked sexual reflexes are also altered by these classes of drugs; dopaminergic, adrenergic, peptides, steroids, hormones and cholinergic compounds. More information is needed as to the mechanisms of these drug effects.

Recent evidence from studies in male rats has demonstrated a group of galanin containing cells in the lumbar cord is essential for ejaculation, and may be part of a spinal ejaculatory generator in males [6]. These cells are also present in female rats but their function has not yet been determined.



**Sexual Reflexes. Figure 2** Diagrammatic representation of the higher level processes regulating sexual reflexes. Genital sensory information enters the spinal cord; interneurons then relay messages through the spinal cord through multiple segments. These signals may also be sent to the brain. The efferent output then coordinates the appropriate sexual motor output, for example orgasm. Sensory and hormonal inputs also regulate the forebrain to activate sexual responses. Pathways relay through multiple sites including the hypothalamus and the nucleus paragigantocellularis in the hindbrain. The brain messages may also act on spinal cord circuits, either to inhibit or evoke sexual responses.

### Brain Mechanisms

Due to the complexity of neuronal connections in the brain and the multiple brain regions involved in sexual reflexes the brain mechanisms mediating sexual reflexes is still under study. However, a number of regulating mechanisms are known. Serotonin neurons in the nucleus paragigantocellularis are involved in the tonic inhibition of sexual reflexes [2]. Dopamine mechanisms in the forebrain appear to mediate the facilitation of sexual reflexes [7]. In addition, serotonin also acts in the forebrain and may alter dopamine release to decrease or increase sexual reflexes. During sexual arousal and orgasm, oxytocin from the paraventricular nucleus is secreted from the posterior pituitary into the blood stream in males and females [8–9].

## Process Regulation

Cognitive emotional desire may lead to arousal, which in turn may cause erection or genital vasocongestion (arousal), which may in turn lead to orgasm which terminates the sex cycle for some refractory period. Alternatively, genital stimulation may activate spinal pathways that lead to arousal and orgasm.

The spinal systems generating sexual responses can be excited or inhibited by peripheral sensory stimuli. A major afferent pathway travels in the pudendal nerve and is responsible for transmitting sexual stimuli from the external genitals and perineum. Visceral afferents in the pelvic and hypogastric nerve have been shown to transmit pain signals from the internal genitals and are probably inhibitory to sexual responses.

The spinal sexual reflex mechanisms are under descending excitatory and inhibitory control from the brainstem and hypothalamus. A major inhibitory site in the medulla has been shown to suppress sexual reflexes through serotonergic mechanisms. Hypothalamic stimulation can elicit sexual responses.

Many of the supraspinal sites influencing spinal sexual reflexes are interconnected and also receive genital sensory information.

Sensory and efferent information related to genital responses may also be relayed through the vagal nerve in addition to the spinal cord. The vagal pathway remains functional after spinal cord transection and may account for the menstrual cramping, analgesia, and orgasm reported in women with complete spinal cord transections [10]. However, further animal studies and verification of this hypothesis in clinical studies is required.

## Function

Sexual reflexes facilitate reproductive processes, male sperm transportation and induction of pregnancy. In addition sexual behavior is often rewarding.

A number of autonomic responses accompany sexual reflexes. Heart rate, blood pressure and respiration increase. In addition, swelling or vasodilatation of the nipples, flushing, and sweating may occur. Reduced pelvic pain may also occur during sexual responses. Contractions of the anal sphincter, vagina, pelvic floor muscles and perineal muscles accompany climax. Prolactin, catecholamine and oxytocin are also released into the circulation with orgasm.

## Pathology

Erectile dysfunction in males may arise from inadequate vasodilatation, nerve degeneration, structural abnormalities such as Peyronie's disease, psychological disorders or as side effects of treatment for other disorders such as hypertension and depression. Premature ejaculation may arise due to hormonal imbalance in the CNS or hypersensitivity of the peripheral nerves. ►Anorgasm in males and females may occur if there has been peripheral nerve damage, lower spinal cord injury, or may be a result of psychological disorders including stress or as a result of treatment therapies for depression. Neurological disease that can cause sexual dysfunction include stroke, tumors, Parkinson's disease, dementia, epilepsy and diabetes, in addition to peripheral or central hormonal changes, like those present after giving birth and during and after menopause, or low testosterone levels. Dysparunia and vaginismus are common painful disorders in females that may be due to structural changes or psychological problems. Surgeries such as hysterectomy or removal of the prostate may result in nerve injury that leads to decreased sexual function.

## Therapy

The most common treatment for erectile dysfunction is PDE5 inhibitors e.g., sildenafil, vardenafil and tadalafil, which act on penile corpus cavernosal smooth muscle to aid relaxation by inhibiting the action of PDE5, which is an enzyme that degrades cGMP. The increased levels of cGMP lead to alterations in calcium concentrations that aid relaxation of the tissue; without penile stimulation the PDE5 inhibitors are not effective. Similar mechanisms are found in the clitoris. In addition, topical vasodilator substances, for example alprostadil or papavarine, may be used to increase blood flow to the genital organs and thus facilitate arousal-like responses. Vibratory and vacuum stimulatory devises can be used to facilitate genital arousal by increasing sensory inputs.

Structural abnormalities may be normalized with surgery or implants, but care is needed to avoid nerve damage.

A few drugs have gained some success in treating CNS disorders (yohimbine, apomorphine, bromocryptine, androgens). However, side effects do occur and the completeness of treatment is still unclear. Usually, psychotherapy and sex therapy is recommended prior to, or concomitant with, any drug therapy [11].

# Shaker-Channels

## Definition

Shaker-channels, eag (ether-á-go-go)-channels, slo (slow-poke)-channels were cloned from behavioral Drosophila melanogaster mutants. The channels were named according to the Drosophila mutant phenotype, Shaker, ether-go-go, slow-poke. Subsequently, eagcDNA was used to clone related voltage-gated potassium channel subunits erg (eag-related) and elk (eaglike). The human erg ortholog (HERG) mediates cardiac IKS.

►Information Theory

# Shape Processing

## Definition

Shape refers to a distinctive combination of boundary and surface properties of a visual form. Shape processing refers to the brain's ability to combine many types of locally ambiguous visual signals, such as edges, texture, shading, depth, and color, to generate an emergent representation of an object's shape.

►Form Perception
►Visual Object Representation

# Sharpening

►Contrast Enhancement

# Shear Strain

## Definition

The components of strain associated with shear – e.g. one layer of tissue attempting to "slide" over another.

# Shear Stress

## Definition

The components of stress generated by the material shear strain.

►Shear Strain

## Shearing

### Definition

In any layer of tissue, a number of theoretical parallel planes can be distinguished. Shear is deformation of such a tissue layer in such a way that the parallel planes remain parallel but are shifted relative to each other along their original direction. If, for example, a square shape is sheared it turns into a parallelogram. Note that the legs of the parallelogram have changed length due to shearing.

►Intramuscular Myofascial Force Transmission

## Sherrington's Law of Reciprocal Innervation

### Definition

The contraction of a muscle is accompanied by simultaneous and proportional relaxation of its antagonist; also attributed to Descartes.

►Omnipause Neurons

## Shift Work

### Definition

Working outside the traditional 08:00 (8 A.M.) to 17:00 (5 P.M.) day shift. It is common to distinguish early morning shifts starting before 08:00 (8 A.M.), afternoon and evening shifts starting after 12:00 (noon), and night shifts typically starting at 23:00 h (11 P.M.). Working night shifts or morning shifts usually leads to sleep restriction, as one is forced to sleep during the day or early evening despite a high Alertness Level due to elevated wake drive in the circadian cycle. Working afternoon or evening shifts typically yields the most sleep of any of the possible shift work regimens including the normal day shift.

►Alertness Level
►Internal Desynchrony

## Short-Term Memory

Yoshio Sakurai
Department of Psychology, Graduate School of Letters, Kyoto University, Sakyo, Kyoto, Japan

### Definition

This is one of the three storage systems of memory, i.e., sensory store, short-term memory and long-term memory. Short-term memory (►short term memory syndrome) is a system for temporarily storing and managing information necessary to conduct learning and cognitive tasks. It acts as a scratch-pad for temporary recall of information under process and is involved in the selection, initiation, and termination of the information processing functions such as encoding, storing, and retrieval. Short-term memory is sometimes referred to as primary memory or active memory (►active learning/memory) and relationship to ►working memory is often discussed in psychology and neuroscience.

### Characteristics

#### Rapid Decay

Short-term memory decays rapidly. It retains information for a limited length of time only, no more than about 30 s, if no rehearsal of the information is carried out. Memory that exceeds short-term memory duration limits is known as long-term memory. In order to overcome the limitation of short-term memory, and retain information for longer periods, the information must be periodically rehearsed. During the rehearsal, the information re-enters the short-term store and be retained for a further period. The process of consolidation, i.e., transferring short-term memory to long term memory, is enhanced by the relationship of an item of short-term memory to an item in long-term memory.

#### Limited Capacity

Short-term memory has a limited amount of capacity. Human short-term memory has a forward memory span of approximately seven items plus or minus two [1], called "magical number seven". Recent psychological researches have shown that this magical number seven is roughly accurate for college students recalling lists of

digits. Such length of recalled digits is sometime called "►digit span." Digit span is based on capacity of short-term memory, but the order of digits is required to be recalled. To test the auditory digit span, for instance, numbers are said slowly, then a person repeat it back. The average correctly recalled numbers are seven, the magical number seven.

However short-term memory span varies widely with populations tested and with material. For example, the ability to recall words in order depends on a number of characteristics of these words: Fewer words can be recalled when the words have longer spoken duration; this is known as the "word-length effect" [2]. Fewer words can be recalled when their speech sounds are similar to each other, this is called the "phonological similarity effect" [3]. More words can be recalled when the words are highly familiar and/or occur frequently in the language; recall performance is also better when all of the words in a list are taken from a single semantic category (such as sports) than when the words are taken from different categories.

## Chunking

Though the magical number seven, retaining about $7 \pm 2$ different items in short-term memory is generally supported by experimental evidence, chunking of information can lead to an increase in the short term memory capacity and greatly increase amount of recalled items. Through putting each unit into a meaningful word or phrase, a person's recall ability can improve through practice [4]. For example, in recalling a phone number, the person usually chunks the digits into three groups: first, the area code, then a three digit chunk and lastly a four digit chunk. This method of remembering phone numbers is far more effective than attempting to remember a string of ten digits.

## Separation From Long-Term Memory (Psychology)

An example of experimental psychology studies showed that some manipulations (e.g., a distracter task, such as repeatedly subtracting a single-digit number from a larger number following learning) impair memory for the 3–5 most recently learned words of a list (presumably still held in short-term memory), while leaving recall for words from earlier in the list (presumably stored in long-term memory) unaffected; other manipulations (e.g., semantic similarity of the words) affect only memory for earlier list words, but do not affect memory for the last few words in a list [5]. These results suggest that different factors affect short term recall (disruption of rehearsal) and long-term recall (semantic similarity). Together, these findings indicate that long-term memory and short-term memory can vary independently of each other. This is regarded as "double dissociation" and constitutes evidence for separate systems underlying short-term and long-term memory.

## Separation From Long-Term Memory (Neuropsychology)

One form of evidence in favor of the separate existence of short-term memory from long-term memory comes from anterograde amnesia, the inability to learn new facts and episodes. Patients with this form of amnesia, typically caused by damage to the medial part of temporal lobe, especially to the hippocampus have intact ability to retain small amounts of information over short time scales (up to 30 s) but are dramatically impaired in their ability to form long-term memories (a famous example is patient H.M.) [6]. This is interpreted as showing that the short-term memory is spared from amnesia.

## Related Brain Structures

Short-term memory is, as like the most types of memory, appear to be stored in the cerebral cortex. Different sensory areas of the cerebral cortex receive sensory information from eyes, ears, and other body parts and hold the information for a fraction of a few seconds in the sensory stores. Then only the attended information are encoded into short-term memory and not attended information will be lost. The short-term memory then is stored in the sensory areas of cortex and some of them are further transferred to the hippocampus and encoded into the long-term memory [6]. However, some neuroscience researchers suggest that short-term memory is further converged to the prefrontal cortex and then serve the information to working memory, speculated to be involved in the prefrontal cortex [7].

## Synaptic Mechanisms

Short-term memory is plastic and dynamic in nature and is still a matter of subject of various arguments not only about the related brain structures but also about underlying neural and synaptic mechanisms. It often describes synaptic events and refers particularly to the temporal sequence of events leading to stable and structural changes in synaptic efficacy [6]. Short-term memory may be formed by brief changes in synaptic transmissions. In the dynamic theory, it may arise out of a reverberating feedback circuit of neurons, where a memory is held electrically within a loop [8]. Thus, no physical changes are made, and synaptic connections are not modified. On the other hand, long-term memory, may be encoded by plastic changes of structures in existing synapses.

## Relationship to Working Memory

The relationship between short-term memory and working memory differently described by many theorists, but it is generally acknowledged that the two concepts are distinct. Working memory is a workspace or memory buffer in which information is maintained and

manipulated while it is being processed. It is a theoretical framework that refers to structures and processes used for temporarily storing and manipulating information. As such, working memory might also just as well be referred to as attention and processing. Short-term memory generally refers to just short-term storage of information. In other words, short-term memory may be passive memory and ►working memory is active memory. Thus while there are short-term memory components to working memory models, the concept of short-term memory is distinct from these more hypothetical concepts. Within one influential model of working memory [9] there are two short-term storage mechanisms: the phonological loop and the visuo-spatial sketchpad.

### Definition

Signal peptide is a short peptide attached to the amino terminus of secreted or transmembrane proteins, which is bound by a signal recognition particle as soon as the protein leaves the ribosome, and results in targeting of the protein to the endoplasmic reticulum.

## Signal-to-Noise Ratio (SNR)

### Definition

Physiological measurements record changes of light or electricity or other physical parameters. However, measurements always have a component of noise, be it from the technical apparatus, from the physical properties of the processes involved (e.g. the statistical nature of light), or from biological sources (e.g. the statistical nature of neuronal signaling). The signal-to-noise is the ratio between the power of the signal of interest and the noise accompanying it. The SNR is usually expressed in logarithms of this ratio, a unit known as Bell, or in units of one-tenth of a Bell, the decibel or dB.

## Description of the Theory

### Introduction

Biological systems are frequently analyzed using engineering tools. This can be done in several ways, two of which are through the investigation of the signals produced by the system and by modeling the system and its environment to predict their behavior under different conditions. These are closely related approaches, and many of the tools developed for one are applicable to the other. This essay gives a broad overview of these tools, known collectively as the field of signals and systems.

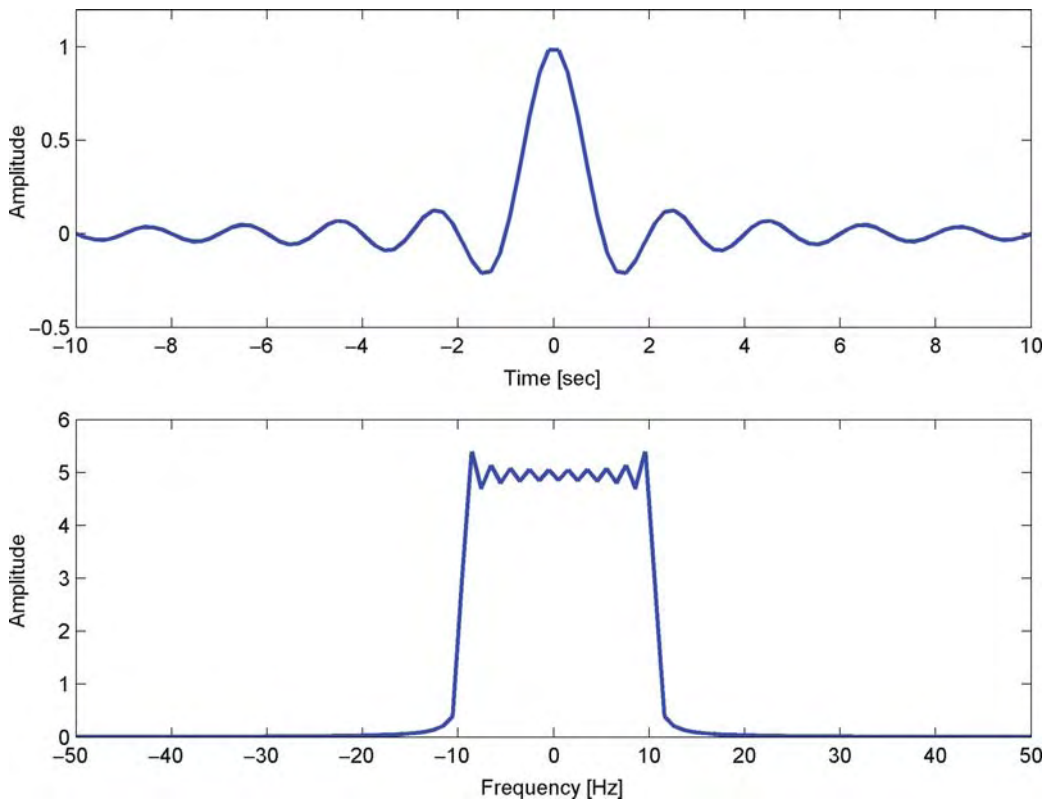
### Signals

The human body generates a multitude of signals, many of which can be used to track its activity. However, meaningful information can usually be gained only after these signals are recorded and processed. In this section, various methods of processing are described.

An important aspect of signal processing is the notion of the ▶time domain and the ▶frequency domain of signals. The time domain of the signals is a description of their progression through time. The frequency domain is a description of the signal as a sum of (a possibly infinite number of) sine waves at different frequencies and phases (the actual description is simply the phase and amplitude of each sine). This description, also known as the spectrum, is extremely useful in many applications, for example, ▶filtering. One should note that processing in one of these dimensions directly affects the other.

The frequency content of a continuous signal can be computed using the ▶Fourier Transform [1]. The output of this transform is the amplitude and phase of the sines at each frequency in the spectrum, which, if summed, will exactly match the signal in the time domain. Fig. 1 shows an example of a signal (the function sin(x)/x in the time domain and its amplitude in the frequency domain).

The frequency-domain representation can be transformed back to the time domain using the Inverse Fourier Transform. Essentially, the Fourier transform is computed



**Signals and Systems. Figure 1** A signal in the time domain and in the frequency domain. The top figure shows the progression of the signal sin(x)/x through time. The bottom figure shows the amplitude of the frequency-domain representation of the same signal.

S

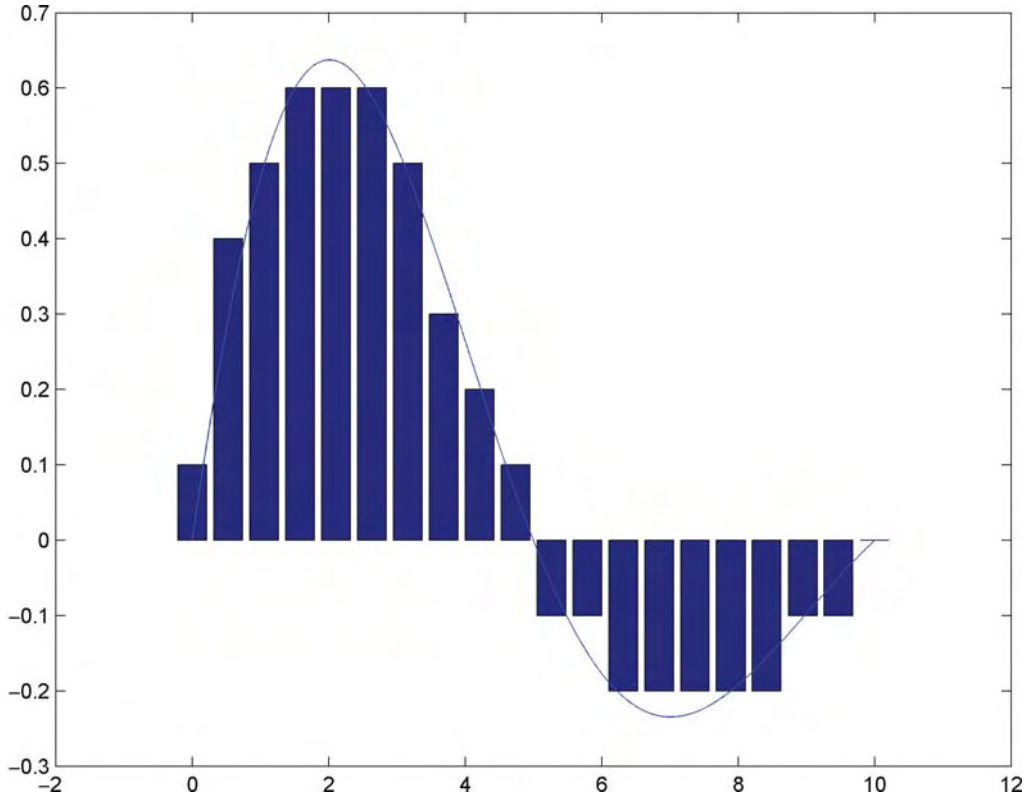
by finding the projection of the signal on sine functions (the kernel functions for this transform) at each frequency. There are special variants of this transform to deal with periodic signals and with discrete signals. If the signal is discrete, the relevant transform is the ►Discrete Fourier Transform (DFT). The efficient algorithm for computing the Discrete Fourier Transform is known as the ►Fast Fourier Transform (FFT).

Nowadays, most processing of signals is done digitally. Many of the methods we describe in this section can be performed on analog signals, but for the sake of clarity, they will be described in the digital domain.

The first stage in digital processing of a signal (after the appropriate sensor has acquired the signal) is to sample it. ►Sampling is the process of taking a continuous signal (i.e. one that has a value for each point in time) and recording its value in discrete points. The sampling rate needed in order to be able to reconstruct the signal back to its original (analog) form, without loss of information, should be at least twice as fast as the highest frequency component in the signal, as stated in ►Nyquist's sampling theorem [2]. Since most analog signals are not strictly band-limited, that is, they cannot be said to have frequency components with a certain highest limit, most signals need to be filtered before sampling to comply with Nyquist's theorem. This is done using analog filters known as ►anti-aliasing filters, which allow only those components that have a frequency lower than a certain threshold to pass into the sampler.

After sampling, the signal is quantized and each sample given a discrete value. This discrete value depends on the range of the sampling device (e.g. in a 12 bit sampling device, the signal is given the closest of $2^{12} = 4096$ values). A sampled, quantized, signal can then be stored on a computer or processed as needed. Fig. 2 shows a continuous signal and its sampled, quantized, representation.

There are a number of categories, by which signal processing systems are classified, among which the most important are linearity, time invariance, finite or infinite response, and causality. ►Linear systems are those that if two signals are passed through them, each multiplied by a constant, and summed, would give the same output if the signals were summed and only then passed through the system. An example of a linear system is an amplifier, which changes the gain of a



**Signals and Systems. Figure 2** A continuous and a sampled signal. This figure demonstrates the process of sampling and of quantization. The line is a continuous signal (i.e. one that has a value at each point in time). The bars show the same signal after it has been sampled and quantized. Sampling causes each time span to be represented by a single (usually average) value, while quantization rounds this value to the nearest value acceptable by the digital system.

signal by a constant factor. A time invariant system is one whose output behaves in a similar matter (albeit delayed) when the same signal is entered twice, with a delay between inputs.

Any digital computer can represent numbers up to a finite value. In finite response systems, it is guaranteed that any finite input will result in a finite output. An example of an infinite system is one that returns the reciprocal value of the inputs. Such a system, when presented with a zero input, will return an infinite value, which in practice means that the output will be distorted. Finally, it is usually desirable for a system to use data from the past and present, not from the future. Such systems are known as causal systems. Note that non-causal systems can still be implemented if a delay in the output is possible.

One of the basic operations, which can be performed on either an analog or a digital signal, is filtering. Filtering reshapes the signal, usually to give required frequency content. A (causal) digital filter operates on a signal by multiplying the filter coefficients by the inputs (current and previous), and possibly some of the previous outputs, and summing them. The most common filter types are the low-pass filter (►low-pass filtering), which passes only those frequency components at the low range of the spectrum; the high-pass filter (►High-pass filtering), which does the same for the high end of the spectrum; the ►band-pass filter; and the notch filter, which removes a slim band of the spectrum, for example, the range occupied by the mains current. Fig. 3 shows an example of how filtering reshapes a signal. The left part of the Fig. 3 shows a signal comprised of the sum of two sines at different frequencies (as is evident from its spectrum in the lower left Fig. 3). This signal is passed through a low-pass filter, which removes the sine at the higher frequency so that the remaining signal is an almost pure sine.

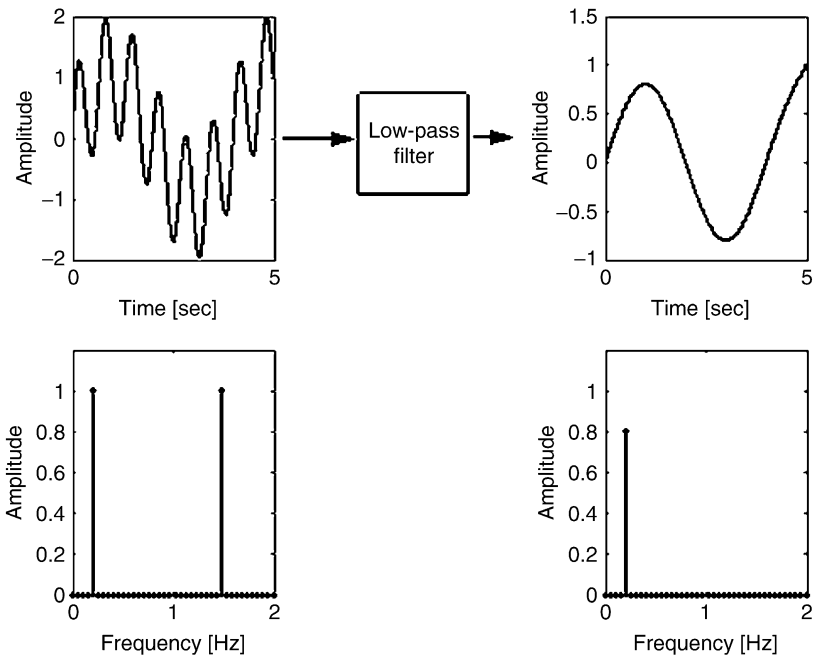
Filters are categorized by the following parameters:

Their ►frequency response determines how the amplitude and phase at each frequency is modified by the filter. The ►bandwidth of a filter is the width of the effective frequency range passed by the filter.

The filter length describes the number of coefficients of the filter. A longer filter makes it possible to design filters with a sharper frequency response, at the cost of higher delays and poorer localization in the time domain due to the filter length.

The ►impulse response of the filter, explained below.

The impulse, known in the continuous domain as the ►Dirac delta, is a signal whose integral is unity, and its width approaches zero (which implies that its height approaches infinity). In the digital domain, it is a signal that is zero everywhere except for a single sample with a value of unity. The impulse is useful for typifying the



**Signals and Systems. Figure 3** Filtering a signal. This figure shows the effect of filtering on a signal. The leftmost figures show a signal comprised of the sum of two sines at different frequencies. The top left figure shows the signal in the time domain, while the bottom left figure shows the same signal in the frequency domain. The rightmost figures show the signal after it has passed through a low-pass filter, which removes one of the sine functions (the one of higher frequency). A by-product of this filter is a reduction in the amplitude of the remaining sine function.

S

time-domain behavior of a filter. Furthermore, filters are commonly classified as either having a finite or infinite impulse response. The former, when presented with an impulse as an input, will generate non-zero output for a finite time period, while the latter may continue to have a non-zero value indefinitely.

Although they are sometimes approximated as such, biological systems are never completely deterministic. The current state of the system, its environment, etc. affects processes. Thus, it is frequently useful to model the system and its signals as stochastic, or at least one to which random noise is added. Such signals require statistical tools for processing.

Arguably, the simplest parameters to estimate are the average and standard deviation of a signal, or its variance. In the case of several signals, we can instead measure the ►cross-covariance between these signals, and its normalized version, the cross-correlation (or simply the ►correlation). These latter parameters are used for measuring the linear dependency between signals. Higher-order correlations (or moments) can be useful in typifying systems, but these are rarely used in the processing of biological signals, except for cases where the object of the analysis is to discover ►oscillator coupling between signals (For example, [3]).

The correlation [1] can be computed at various time differences between signals (or between a signal and itself), yielding the cross-correlation function (or, similarly, the auto-correlation function). This yields information about the linear dependency between signals, assuming some delay between them.

The spectrum of a stochastic signal is computed by transforming the cross-correlation function instead of performing the Fourier transform on the signal itself. Such ►cross-spectrum (or, in the case of auto-correlation, the ►autospectrum) is useful, for example, in detecting frequencies where signals correlate. Similar functions are achieved by the ►coherence function, which is the cross-spectrum normalized by the square root of both auto-spectra.

Note that when the spectrum of a signal is estimated from a finite sample of data, the resulting auto-spectrum is only one of an infinite number of possible estimations of the spectrum, since the data itself is stochastic. There are two parameters of interest when assessing how close this estimation (like all other estimations based on stochastic data) is to the real spectrum. These are the ►bias and the ►variance of the estimate. The bias refers to how far the estimation would be from the real value, if an infinite number of signals were used to generate spectra estimations, and these would in turn be averaged. The variance is the variance of a finite number of spectra. In practice, one can usually minimize either the variance or the bias, but not both.

►Noise is a signal that accompanies the signal of interest, but does not convey useful information. If, for example, we were interested in a specific component of the ►electroencephalogram (EEG), any other parts of the recorded signal, including other components of the EEG, would be considered noise. In most cases, it is assumed that the noise is added to the signal. The relation between the power of the signal of interest and that of the noise is measured by the ►Signal-to-Noise ratio (►SNR), expressed in decibels, that is: SNR = 10 log (Signal power/Noise power).

The spectrum of the noise is also of interest. If the noise has a flat spectrum, which implies that it is completely uncorrelated in time, it is known as ►white noise. Similarly, a noise that has a non-flat spectrum is known as ►colored noise. If the noise is distinctly different from the signal in some way, it might be easily separated from the signal (for example, if its frequency range is different from that of the signal, it can be removed using an appropriate filter). Unfortunately, there are many cases where such separation does not exist. In such cases, more sophisticated processing methods are needed, for example, [4–7].

Fourier transform is limited by the fact that it implicitly assumes that the signal is infinite in time. Thus, when a limited number of samples are available, the estimation of the frequency components at low frequencies is problematic. Furthermore, the Fourier transform is limited in that one can either observe the time domain or the frequency domain, but not both. This limitation is slightly reduced by the Short Time Fourier Transform, essentially a division of the signal into short time sequences. In recent years, however, several methods, which enable simultaneous investigation of both the time and the frequency domain, have emerged. Essentially, instead of using a sine for a kernel function, as in the Fourier transform, a different function with a limited time span is used. Many families of such functions (known as wavelets) are known. Probably the most widely used are the Gabor, Daubechies, Mexican Hat, and Haar wavelets. The output of the wavelet transform for a one-dimensional signal is a two-dimensional representation of the time-frequency plane. Thus, local changes in both time and frequency can be observed.

## Systems

Modeling a complicated system is an extremely useful method for gaining understanding into its behavior, and for predicting its performance under various conditions. Modeling a system through the tools of system analysis is performed by identifying the inputs and outputs of the system, and representing its internal workings as a set of equations. A system can have single or multiple inputs, as well as single or several outputs.

Modeling biological systems has proved advantageous for diverse applications. Among them (to name only a few) are pacemaker design, ►seizure prediction based on EEG [8], as well as theoretic studies on ►movement planning [9].

Categories, similar to those used for typifying signal processing systems (outlined in the previous section), are used for classifying modeled systems. These include their linearity, stability, sensitivity to initial conditions, and time-invariance.

The set of equations used for modeling a system is frequently approximated as a linear set, so that the sum of outputs of two signals is equal to the output of the sums. This approximation is useful because there are many more tools for analysis of linear systems than for analysis of non-linear systems. Even when a system is known to be nonlinear, methods exist for ►linearization around a given area of its operational envelope. For example, time delay, which is a non-linear operator, can be approximated in the frequency plane using the Pade approximation.

An important parameter for systems is their stability. A stable system will have a finite output for every finite input value. Determining if a system is stable or not, based on its equations, has been an object of much research. Popular tools for ascertaining system stability examine the system equations in the frequency plane (importantly, both phase and amplitude), using diagrams known as Bode diagrams and Nichols charts. The result of this analysis is both the knowledge whether system is stable or not, as well as how far the system is from instability, as measured by the Phase Margin (PM) and Gain Margin (GM).

The full description from input to output of a system is known as the ►transfer function. Usually, the transfer function of linear systems is defined in the frequency plane or as a system of ►differential equations. When the frequency-plane description is used, instead of using the Fourier Transform for converting the system equations into the frequency plane, system engineers traditionally use the Laplace Transform for continuous systems and the Z-Transform for sampled systems. Both these transforms are identical to the Fourier Transform and the Discrete Fourier Transform, except for a change of variables. The roots of the transfer function polynomial (of linear systems) are useful for determining system stability. The roots of the nominator are known as ►zeros, while those of the denominator as ►poles. The Root-Locus method can be used for determining if the system is stable, and if so, under which conditions.

As noted above, a system can be modeled as a list of differential equations, where some of the equations describe the dependency between the internal variables of the system and previous inputs, while other equations describe the relation between internal and output variables. This description is known as the ►statespace description of a system. The states, in this description, are a particular combination of the internal variables.

An underlining assumption when analyzing a system in the frequency plane is that they are working in their steady-state mode, that is, any changes in behavior resulting from initial conditions have disappeared for all practical purposes. However, the sensitivity of a system to its initial conditions can be highly important. Some systems exhibit chaotic behavior, defined as an extreme sensitivity to initial conditions. A chaotic system will reach vastly different steady states for slightly different initial conditions. In such systems, the behavior in state-space is one where, for some initial conditions, the system does not reach a final single state, but rather it hovers around a point (or several points) known as attractors.

It is possible to distinguish between random systems and systems that are chaotic (and thus contain a structure) by measuring their ►correlation dimension. This is a measure of the size of the attractors in the system. Note that this size can be a ►fractal, a term coined by Benoit Mandelbrot in 1975 [10] to describe objects built using recursion. Thus, while the dimension of a line is one, and of a rectangle two, fractal shapes have a non-integer dimension.

It is sometimes useful to model a system or a subsystem using only its statistical properties. This is useful, for example, in order to generate some stochastic behavior with parameters that are similar to those of a chosen system. Systems that can be modeled in this way, by generating white noise (the driving noise) and passing this noise through a differential equation that depends on previous outputs and the current value of the noise, are known as Auto-regressive (►Auto-regressive model) (AR) systems. Systems that can be modeled through a differential equation that operates on previous values of the noise are known as Moving-Average (►Moving-Average Model) (MA) systems, while those where the differential equation operates on both previous values of the noise and those of previous outputs are known as Auto-regressive Moving Average (►Auto-regressive Moving Average Model) (ARMA) systems. There are several methods for finding the coefficients of the differential equations given data recorded at the output of the system to be modeled. However, finding the coefficients of AR systems involves solving linear equations, while the coefficients of MA and ARMA systems are solved using non-linear equations. There is a useful extension to AR systems whereby, in addition to the driving noise, there is a deterministic input; these systems are known as Autoregressive with Extrageneous input (ARX) systems. One of the most popular applications of AR models is for compression of ►speech. The speech is cut into segments, each a few hundred milliseconds long. Each segment is modeled using its AR coefficients. Instead of transmitting the samples of the speech, only the AR coefficients are transmitted, and at the receiving end, the speech is regenerated using these coefficients and white noise.

# Silent Nociceptor

## Definition

A group of nociceptive C fibers in human cutaneous nerves which are unresponsive to mechanical stimulation in intact skin. The term is misleading, since these nociceptive afferents respond to noxious heating and to chemical agents, e.g., capsaicin. A synonym "sleeping nociceptor" is derived from the observation that these units become sensitized ("awakened") to mechanical stimulation in the course of inflammatory processes.

## Definition

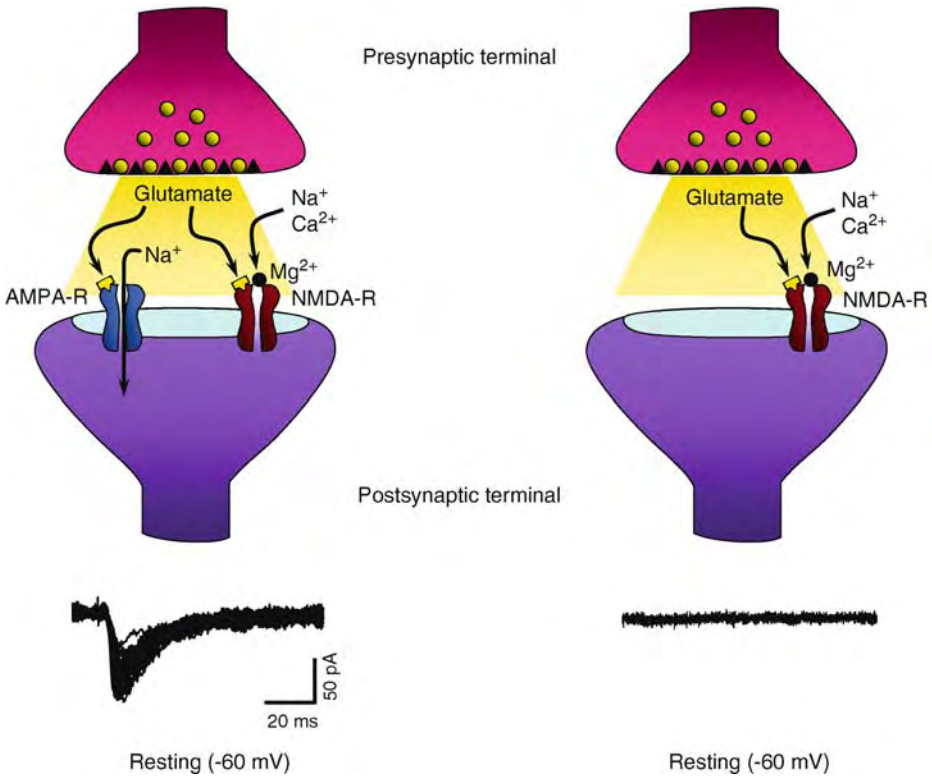
The vast majority of excitatory neurotransmission in the brain is mediated by ►glutamate and its ►ionotropic receptors, AMPA- and ►NMDA-type glutamate receptors. In neuroscience, a silent synapse is an excitatory glutamatergic synapse whose postsynaptic membrane contains only NMDA-type glutamate receptors (►NMDA-Rs) and no AMPA-type glutamate receptors (►AMPA-Rs) (Fig. 1).

An action potential that invades the presynaptic terminal causes calcium entry into the terminal and fusion of neurotransmitter-filled synaptic vesicles releasing glutamate into the synaptic cleft. Presynaptically released glutamate binds to glutamate receptors present at the postsynaptic membrane briefly activating the conductance associated with them. Activation of AMPA-Rs leads to a fast inward current that depolarize the postsynaptic membrane. Activation of NMDA-Rs, however, does not cause an inward current because at the normal neuronal resting potential – around −60 mV – the receptor's channel is blocked by physiological concentration of extracellular magnesium [1]. Thus, in normal synapses containing both, AMPA-Rs and NMDA-Rs, the inward current observed in response to glutamate release is mediated by the AMPA-R (Fig. 1, left). Some synapses, however, contain only NMDA-type receptors. The blockade of the NMDA-R channel by magnesium renders these synapses inactive or "silent" to the release of presynaptic glutamate (Fig. 1, right). It is important to note that if activation of a silent synapse occurs when the postsynaptic membrane is depolarized, the magnesium blockade is relieved and the NMDA-R will conduct current.

## Characteristics

### Description of the Structure

Excitatory glutamatergic synapses in the central nervous system (CNS) consist of a presynaptic button with glutamate-filled vesicles and a postsynaptic



**Silent Synapse. Figure 1** The Glutamatergic Synapse. Left, synapse containing postsynaptic AMPA-Rs and NMDA-Rs at resting potential. Glutamate released from the presynaptic terminal binds to both receptors; however, the recorded excitatory post-synaptic current (EPSC) is due only to the activation of AMPA-Rs (lower traces). NMDA-Rs are blocked by physiological concentration of extracellular $Mg^{2+}$. Right, silent synapse containing only NMDA-Rs at resting potential. Presynaptically released glutamate fails to activate NMDA-R responses due to the blockade by $Mg^{2+}$; therefore no EPSC is recorded postsynaptically (lower traces).

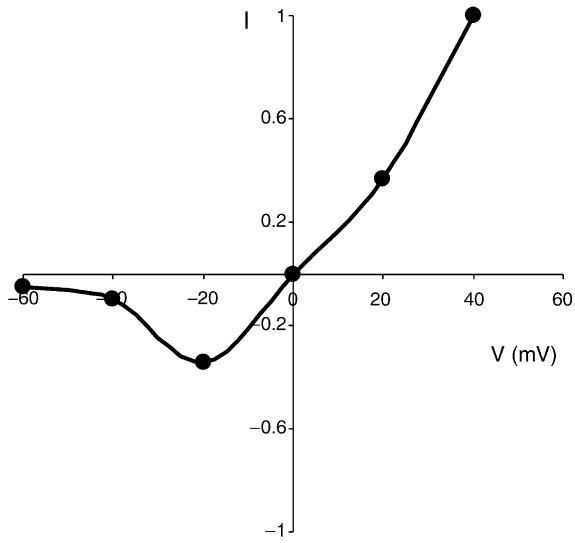
structure containing glutamate receptors. Two types of glutamate receptors can be present at the postsynaptic membrane: (i) metabotropic receptors, associated to signal transduction mechanisms and second messenger cascades, and (ii) ionotropic receptors, directly coupled to ionic conductances. Glutamatergic ionotropic receptors can be further divided into non-NMDA receptors and NMDA receptors (NMDA-Rs) based on their affinity for the agonist NMDA. The most abundant and better understood non-NMDA receptors are the AMPA receptors (AMPA-Rs) [2].

At excitatory chemical synapses, synaptic transmission is mediated by activation of AMPA-Rs and NMDA-Rs. Activation of AMPA- or NMDA-receptors by presynaptically released glutamate results in the opening of an ionic channel which is non-selective to cations. This allows the flow of $Na^+$ and $K^+$ ions depending on the electrochemical gradient across the postsynaptic membrane. A significant fraction of the current flowing through NMDA-Rs is also carried by $Ca^{2+}$. Calcium entry through postsynaptic NMDA-Rs is thought to play a critical role in synaptic plasticity, a cellular mechanism for learning and memory, as well as in some neuropathologies. Certain AMPA-Rs are also permeable to $Ca^{2+}$.

The conductance associated with the NMDA-R has slow rising and decay kinetics and – as mentioned – can be blocked by physiological concentrations of extracellular $Mg^{2+}$. This blockade is strongly voltage-dependent and can be removed when the postsynaptic membrane is depolarized to around −40 mV (Fig. 2).

Thus, partial depolarization of the postsynaptic membrane relieves the magnesium block and allows the flow of ions through the channel when activated by glutamate. It is this property that allows the NMDA-receptor to be a coincidence detector of pre- and post-synaptic activity required in Hebbian models of plasticity [3].

In the hippocampus and other brain regions, the ratio of AMPA-R to NMDA-R mediated transmission is initially low and increases over development. Furthermore, many synaptic events, particularly early in development, are mediated by the activation of only NMDA-receptors. Such responses are proposed to



**Silent Synapse. Figure 2** Voltage dependency of $Mg^{2+}$ blockade of the NMDA-R. Relationship of membrane voltage (V) and normalized current (I) flowing through the NMDA-R when activated by glutamate. The receptor is expressed in heterologous cells and glutamate is puffed onto the surface of a voltage-clamped cell in the presence of physiological concentration of $Mg^{2+}$. Notice that at –60 mV there is practically no current.

occur at structures termed postsynaptically silent synapses, because transmission can only be detected if the postsynaptic membrane potential is raised above the resting level [4]. The prevalence of pure NMDA-R responses measured electrophysiologically decreases during development.

The presence of functionally silent synapses, that lack responses when presynaptic fibers are stimulated at resting potentials, can be explained by other mechanisms. Some scenarios consider the presence of both AMPA-Rs and NMDA-Rs at synapses, and they propose that early in development only low concentrations of glutamate reach synapses. NMDA-Rs exhibit higher affinity for glutamate than AMPA-Rs; therefore, low concentrations could activate primarily NMDA-Rs and not AMPA-Rs. Low concentration of glutamate could be achieved by a presynaptic vesicle that does not release all its content at once [5]. This could cause that glutamate concentration in the synaptic cleft increases slowly, activating only high affinity NMDA-Rs but not low affinity AMPA-Rs. A similar situation will occur if low concentrations of glutamate "spill over" from neighboring synapses [6]. Also, a synapse with a very low presynaptic probability of release will be rarely activated when its input is stimulated appearing to be silent [7]. These hypotheses are controversial and matter of discussion [8].

The existence of synapses lacking AMPA-Rs has been tested directly by immunogold labeling studies, which have shown that the fraction of synapses containing NMDA-R but not AMPA-R immunoreactivity decreased from 84% at postnatal day 2 to 50% at 5 weeks with little changes in NMDA-R immunoreactivity [9].

Thus, silent synapses containing only NMDA-Rs are especially prevalent in development and have been found in many brain regions, including the hippocampus, cerebral cortex, and spinal cord. The molecular properties of NMDA-Rs explain why at resting potential there are no responses when presynaptic fibers are activated. The existence of such synapses has been corroborated with functional and anatomical studies.

## Regulation

Silent synapses stop being silent once they acquire AMPA-Rs and an inward current is produced postsynaptically in response to glutamate released from the presynaptic terminal. Conversion of silent synapses to functional synapses is a developmentally regulated process that requires synaptic activity or sensory experience. Also, silent synapses can acquire AMPA-Rs when cells are stimulated by protocols inducing long-term potentiation (LTP), a synaptic plasticity phenomenon thought to be the cellular correlate of learning and memory. In both cases, incorporation of AMPA-Rs into synapses is a tightly regulated process and requires synaptic activity and $Ca^{2+}$ influx into the postsynaptic cell. AMPA-Rs with different subunit composition have different activity requirement to be incorporated into synapses. Trafficking of AMPA-Rs in and out of synapses involves the coordination of several kinases and phosphatases, as well as the interaction with several scaffolding proteins. Since the discovery of silent synapses, regulation of AMPA-R trafficking has been intensively studied and is currently a very dynamic field in neuroscience [10].

Over the past few years, a number of studies have tested the notion that silent synapses lack AMPA-Rs and that AMPA-Rs can be rapidly delivered to synapses during the induction of LTP. This model suggests that there must be a pool of non-synaptic AMPA-Rs near synapses available for delivery. Several studies have found ample amounts of non-synaptic AMPA-Rs on both surfaces and intracellular regions of dendrites that are delivered to synapses in response to LTP inducing protocols [10].

It is thought that rapid delivery of AMPA-Rs from non-synaptic sites to the synapse occurs via a mechanism analogous to the exocytosis of presynaptic vesicles during transmitter release. This rapid delivery of AMPA-Rs is thought to underlie the increase in synaptic transmission after LTP induction. Early studies in hippocampal slices showed that loading postsynaptic cells with toxins that specifically perturb membrane fusion could block LTP. Also, in dissociated

cultured neurons a form of dendritic exocytosis that was mediated by activation of CaMKII, a key enzyme in LTP induction, has been identified.

### Function

Several lines of evidence indicate that NMDA-receptors are present in synapses before AMPA-receptors and that during development AMPA-receptors are progressively added. Silent synapses are not a separate class of excitatory synapses that lack AMPA receptors, but rather an early stage in the ongoing maturation of the glutamatergic synapse. The fact that silent synapses generate no postsynaptic electrical signal when the postsynaptic cell is at its normal resting membrane potential, but can transmit robust postsynaptic electrical responses once the postsynaptic cell is depolarized, suggest an interesting and simple mechanism to modify neural circuitry. Activation of NMDA-Rs when the postsynaptic cell is depolarized will allow $Ca^{2+}$ entry and the triggering of several calcium-dependent processes including the addition of AMPA-Rs to that specific synapse and activation of signaling pathways necessary for synapse stabilization, dendrite growth, and cell survival.

## Silver Impregnation

### Definition

Nerve tissue has an affinity for silver (argyrophilia) and is easily impregnated by dilute silver solutions. Reducing the silver enables it to be deposited within the neuron's processes thus outlining the neuron (see below).

## Silver Staining

### Definition

Silver staining of nerve tissue is made possible by a variety of so-called reduced silver methods. The neurons appear as golden or dark brown against a yellow background.

## Simple Cell

### Definition

Simple cells are one of two main physiological types of cells in the primary visual cortex. They have receptive fields built of elongated, adjacent On and Off subregions that have a mutually suppressive influence.

The basis of this antagonism is a push-pull relationship between stimuli of opposite contrast in each subregion; e.g. where bright stimuli excite, dark stimuli inhibit. As a result of the geometry of the receptive field and the antagonism between neighboring subregions, simple cells are sensitive to stimulus orientation – they are good edge detectors. Cells with simple receptive fields were first discovered in the cat, where they are found only at the first, or thalamocortical, stage of processing.

## Simple Lobule

### Synonyms
►Lobulus simplex

### Definition
The simple lobule belongs to the posterior lobe and is part of the cerebellar hemispheres. Apart from the areas in proximity to the vermis (intermediate part), the hemispheres belong to the phylogenetically young neocerebellum and receive their afferents via the mossy fibers of the pontocerebellar tract from the pontine nuclei. All hemisphere segments are hence also assigned to the pontocerebellum.

## Simple Receptive Fields

►Visual Cortical and Subcortical Receptive Fields

## Simple Sound

### Definition
A sound with one frequency component, or a sinusoidal sound, or a pure-tone sound.

►Acoustics

## Simulated Annealing

### Definition
A type of supervised learning algorithm based on ideas from statistical physics. It can be used in networks with arbitrary architectures.

►Neural Networks

## Simulated Microgravity

### Definition
Simulated microgravity encompasses ground-based conditions simulating changes in the internal environment of the living body such as changes in fluid distribution in space. For example, methods to induce headward fluid shift as seen in microgravity in space using head-out water immersion, lower body positive pressure, head-down bed rest, etc.

►Autonomic Function in Space

## Single-cell Recording

### Definition
Recording of the electrical activity of single neurons in the nervous system by means of electrodes introduced into the nervous tissue.

►Extracellular Recording

## Single-channel Activity

### Definition
Activity of a single ion channel viewed through the ion current passing through an open channel. Single-channel activity is measured in voltage-clamp conditions using the patch-clamp technique in cell-attached, outside-out and inside-out configuration. Single $Ca^{2+}$ channels give rise to membrane currents in the order of picoamperes (pA) in high $Ba^{2+}$ solutions.

►Calcium Channels – an Overview
►Inracellular Recording

## Single-fiber Action Potential

### Definition
Extracellular potential detected due to the propagation of the transmembrane action potential along a muscle fiber when stimulated.

►Electromyography

## Single-joint Movement

### Definition
Movement that involves rotations in a single joint.

►Motor Control Models

## Single-Photon Emission Computed Tomography (SPECT)

### Definition
Is a tomographic imaging technique based on the emission of gamma rays by a tracer that is absorbed by tissue (e.g., brain tissue) proportional to blood flow. The technique permits measurements of perfusion, which is coupled to metabolism.

## Singleton

### Definition
A set with exactly one element. A term used in SAGE studies to describe unique sequence tags appearing only once in a library.

►Serial Analysis of Gene Expression

## Single-unit Recording

### Definition
Recording from an individual nerve, glia or muscle cell (unit).

►Extracellular Recording

## Sinus Hair

### Definition
The sinus hair is a highly specialized hair follicle characterized by a well-developed venous sinus associated with the hair follicle, and is usually located in the facial skin of mammals except humans. Vibrissae are examples of sinus hairs arranged in rows on the upper lips of cats, dogs, and rats. The sinus hair contains different kinds of sensory receptors including Merkel cell-neurite complexes, various kinds of palisade endings, and lamellated corpuscles.

►Merkel Cell-Neurite Complex Regeneration

## siRNA

### Definition
A small (or short) interfering RNA is a 20–25 nucleotide long double stranded RNA that shows complete complementary to the sequence of a mRNA and interferes with its expression by targeting it to the RNA interference pathway.

## Sister Groups/Sister Taxa

### Definition
In cladistic classification, any two taxa are sister groups if they are descended from the same node in a dichotomous branching tree

►The Phylogeny and Evolution of Amniotes

## Situational Factors in Pain

### Definition
Situational factors are contextual and psychological factors that can vary with the circumstances in which an individual experiences pain. These include: cognitive factors such as understanding of the pain problem, knowledge of effective therapies, and expectations for recovery; behavioral factors such as the specific distress behaviors during pain and the wider behaviors in response to a recurrent or chronic pain; and emotional factors such as fear, frustration, anxiety or depression.

►Pain in Children

# Sjögren's Syndrome

## Definition

Sjögren's syndrome is named after the Swedish ophthalmologist Henrik Sjögren who first described it in 1933. It is a chronic autoimmune disorder in which immune cells cause damage to salivary and lacrimal glands giving dry mouth and dry eyes. Sjogren's syndrome occurs in a primary and a secondary form. The secondary form is associated with rheumatic diseases such as rheumatoid arthritis, systemic lupus erythematosus ("lupus"), and polymyositis.

►Central Nervous System Disease in Primary Sjögren's Syndrome
►Rheumatoid Arthritis (RA)
►Salivary Secretion Control
►Systemic Lupus Erythematosus (SLE)

# SK Channels

## Definition

Small-conductance $Ca^{2+}$-activated $K^+$ channels present in autonomic neurons and sometimes involved in after-hyperpolarization.

►Neuronal Potassium Channels
►Action Potential

# Skeletal Muscle Architecture

Roland R. Roy, Victor Reggie Edgerton
Brain Research Institute and Department of Physiological Science, University of California, Los Angeles, CA, USA

## Definition

Muscle architecture is the structural design of a skeletal muscle in terms of the arrangement of the muscle fibers, muscle units, and connective tissue elements within and around which they are embedded. These design features define the axis of force and displacement generation of a muscle-tendon complex.

## Characteristics

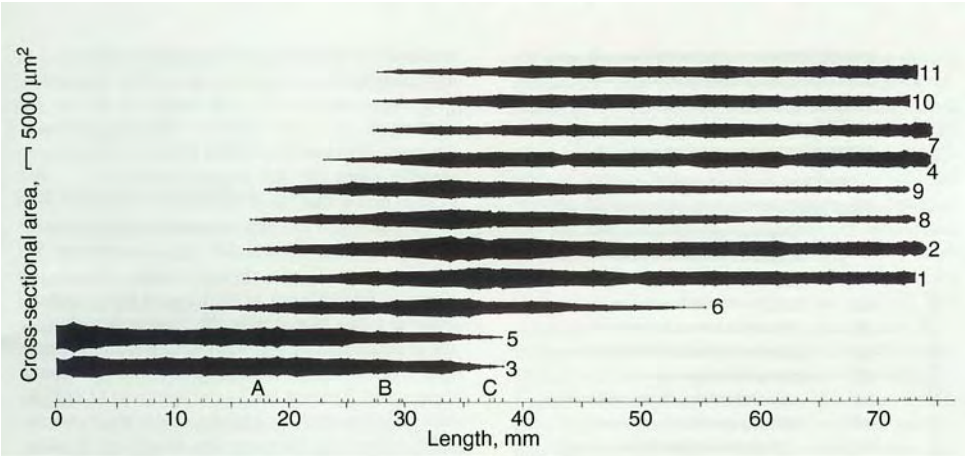
### Muscle Fiber Architecture

Single skeletal muscle fibers are elongated, multinucleated cells that have variable lengths and shapes. A fiber is comprised of a number of myofibrils arranged in parallel and comprised of sarcomeres arranged in-series. A ►sarcomere, in turn, is comprised of myofilaments, i.e. namely myosin and actin, and is the functional unit of muscle contraction. The basal lamina defines the anatomical boundary of a single fiber. A majority of muscle fibers have a single point of innervation identified as the ►neuromuscular junction or motor endplate. Myonuclei are distributed along the length of the fiber, with a higher density usually observed at specialized regions, i.e. the neuromuscular junction and the ►myotendinous junction. The anatomical length of an individual muscle fiber is highly variable, e.g. the range in humans is from a few mm to several cm. In many cases, short muscle fibers are arranged in-series and activated simultaneously such that the functional length of the muscle fiber is enhanced significantly. The shape of an individual fiber is also highly variable (Fig. 1).

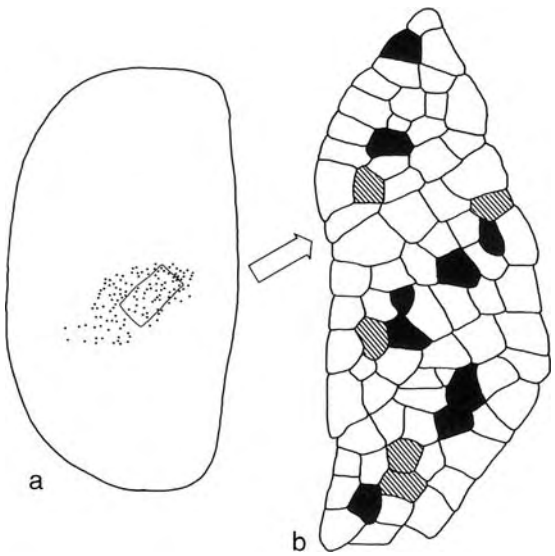
The cross-sectional area of a fiber can be relatively homogeneous throughout its length, or the fiber can taper (show a decrease in fiber area) at one or both ends. The amount of tapering can vary from a partial tapering to a full taper where the cross-sectional area becomes a filamentous strand. The termination of a muscle fiber usually involves some connective tissue interface, i.e. at a tendon, aponeurosis, the end of another muscle fiber, or intrafascicularly. The muscle fiber: connective tissue interface of a non-tapering fiber is usually a blunt ending, i.e. an abrupt termination with complex infoldings between the ►sarcolemma and connective tissue elements. The termination of tapering fibers is much more complex and variable, ranging from blunt-like endings between the sarcolemmal membranes of two fibers arranged in-series to interdigitating myomyonal junctions between the tapering ends of two adjacent fibers.

### Motor Unit and Muscle Unit Architecture

A single ►motor unit is defined as an α-motoneuron and all of the muscle fibers that it innervates. Using repetitive stimulation of a single motor axon or an individual motoneuron, the fibers belonging to a motor unit can be depleted of their glycogen and then identified on histological sections stained for glycogen content. All muscle fibers within a motor unit are, in general, of the same phenotype, i.e. have similar, although not identical, mechanical and metabolic properties. The architectural properties of the constituent fibers vary within a motor unit, although it appears that slow motor units have a higher percentage of non-tapering fibers than fast motor units. The spatial distribution of the fibers in any cross section of a muscle is nonrandom and



**Skeletal Muscle Architecture. Figure 1** Cross-sectional area of eleven fibers reconstructed from serial sections of a glycogen-depleted fast motor unit in the cat tibialis anterior muscle. All fibers are from one well-defined ►fascicle. The proximal end of the muscle is at 0 mm. Note the various shapes of the fibers to include full and partial tapering, and blunt and tapered fiber terminations. (Taken from [1], Fig. 5).



**Skeletal Muscle Architecture. Figure 2** (a) Distribution of glycogen-depleted muscle fibers (*black dots*) belonging to a single motor unit within a single cross section of a cat tibialis anterior muscle. The outlined region in the motor unit area was selected for analysis. (b) Schematic representation of a single fascicle from the area outlined in (a). All fibers in the fascicle were classified as being depleted of glycogen (motor unit fibers) or not depleted of glycogen (non-motor unit fibers) and as slow or fast based on myofibrillar ATPase staining. Muscle fibers are identified as fast, depleted motor unit fibers (*striped*), slow non-depleted fibers (*black*), or fast non-depleted fibers (*white*). (Taken from [2], Fig. 1).

**Skeletal Muscle Architecture. Figure 3** The territory of a fast fatigable motor unit (*white area*) along the proximodistal (*right to left*) axis of a cat tibialis anterior muscle is shown. Segments of the outline of the muscle are deleted to allow visualization of the motor unit territory. Note that the territory tapers and shifts from one surface to the other along the length of the muscle. (Taken from [3], Fig. 1).

is thought to reflect the axonal growth processes occurring during innervation at a developmental stage **(**Fig. 2**)**. In most muscles, the muscle fibers of a single motor unit occupy only a portion of the cross section along the length of the muscle and the extent of this motor unit territory varies considerable. The 3-D shape of the motor unit territory reflects the distribution and length of the fibers comprising the motor unit **(**Fig. 3**)**.

S

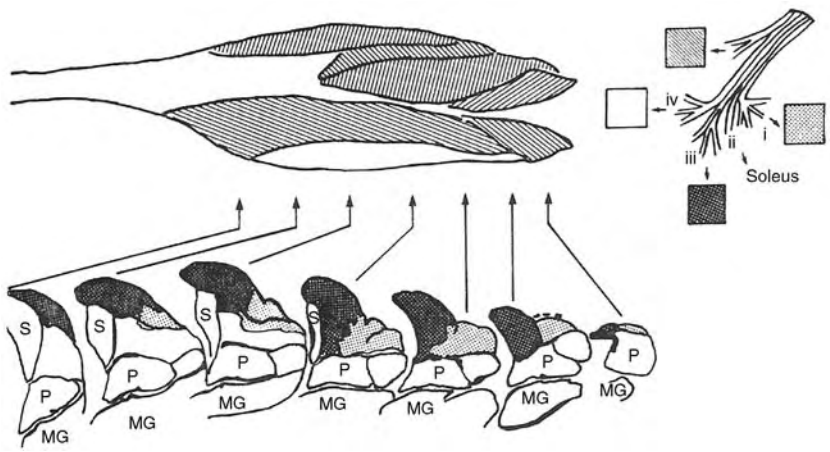
## Connective Tissue Framework

There is a highly specialized connective tissue framework that is distributed throughout a skeletal muscle [7]. As stated above, individual muscle fibers are enveloped by a basal lamina containing primarily type IV collagen, fibronectin, enactin, and laminin. The remainder of the extracellular matrix has been divided into three levels of organization based on its relation to the muscle fibers. The ►endomysium is a collagenous sheath that is contiguous with the basal lamina of the muscle cells. The ►perimysium is the thickened endomysium that circumscribes fascicles of muscle fibers. The ►epimysium surrounds the outer surface of the muscle. These levels of organization are distinguishable primarily by their morphology rather than differences in their composition. All three are composed primarily of types I and III collagen. The endomysium and perimysium are usually referred to collectively as the intramuscular connective tissue. A dramatic illustration of the 3-D structure of the intramuscular connective tissue can be found in ►Figure xx in Huijing et al. (Chapter xx in this book). If the reader imagines this honeycomb of connective tissue extending to each end of the muscle, it is possible to conceive the muscle as a continuous tendon with muscle fibers embedded within.

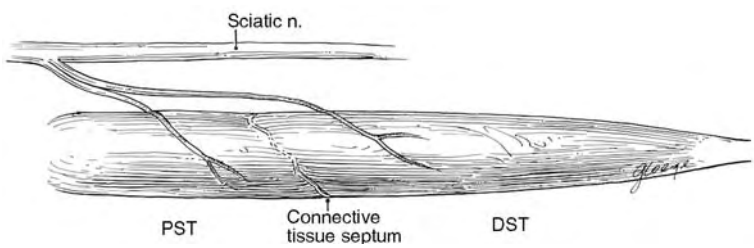
## Muscle Compartmentalization

A large number of mammalian skeletal muscles are compartmentalized, i.e. subdivided into anatomical sub-compartments each having a separate primary nerve branch and showing some sensory partitioning (Figs. 4 and 5).

The arrangement of the compartments within a muscle can be in series, in tandem, in parallel, etc. Many muscles and muscle compartments can also be subdivided by their fiber type composition. For example, many



**Skeletal Muscle Architecture. Figure 4** Compartmentalization of the cat lateral gastrocnemius muscle is illustrated. Muscular subvolumes (compartments) supplied by primary nerve branches are identified. Shown are a compilation of serial sections from several glycogen-depletion experiments that describe the regions innervated by primary muscle nerve branches. Proximal end of the muscle is on the right side. (Taken from [5], Fig. 6).



**Skeletal Muscle Architecture. Figure 5** Schematic drawing of the cat semitendinosus (ST) muscle. A dense connective tissue band divides the ST into a proximal (PST) and distal (DST) end. The muscle fibers of each end are arranged in parallel (angle of pinnation = ~0°) and are connected in series at the connective tissue band, with distal fibers being approximately twice as long as the proximal fibers. Each muscle compartment is innervated by a separate branch from the sciatic nerve. (Taken from [6], Fig. 1).

muscles and muscle compartments show a much higher percentage of slow fibers in the regions that are closer to the center of the limb or trunk, i.e. close to the bony elements, than regions that are more superficial, i.e. away from the bony elements. This type of compartmentalization is much less evident in the muscles of humans compared to most other animals. Compartmentalization has some functional implications [7]. For example, in many instances, the individual compartments can be recruited independently of each other during specific motor tasks. Similarly, a region of a muscle comprised of a relatively high proportion of slow fibers is normally recruited at lower force levels than a region having a lower proportion of slow fibers.

## Structure-Function Relationships

The arrangement of the fibers/fascicles within a muscle influences its mechanical properties. A muscle that has relatively long fibers or fascicles, i.e. a large number of sarcomeres in series, is optimally designed for producing long excursions and thus for speed of contraction. In contrast, a muscle with relatively short fibers or fascicles, i.e. a large number of fibers or fascicles in parallel, is optimally designed for force production. The muscle fibers/fascicles within a muscle can be arranged in parallel to or displaced from (pinnated) the axis of force- or displacement-generation. In pinnated muscles, the muscle fibers can be arranged in a unipinnate or multipinnate arrangement depending on the intramuscular connective tissue framework. The significance of the pinnation angle of the muscle fibers is that the transfer of force or displacement is theoretically compromised along the axis of the force- or displacement-generating axis, i.e. decreased by the cosine of the angle of pinnation. An advantage of fiber pinnation is the increase in the number of fibers that can be arranged in parallel, and thus an increase in force potential. The angle of pinnation in a rested state has been reported to be relatively small across most muscles. Although there are minimal data on sarcomere function in vivo, the fiber angle in some muscles appear to increase dramatically during dynamic contractions, i.e. the fibers are free to rotate during a contraction. This has been elegantly demonstrated in humans using ultrasound techniques. The ability of force to be transmitted laterally via interconnections among the individual fibers arranged in parallel and eventually to the site of insertion ensures the effectiveness of force transmission, even when there is a large angle of pinnation (▶see Chapter xxx by Huijing in this book). A final point here is that, many of the relatively large muscles in humans have multiple compartments and complex tendons of insertion and origin, and we do not understand at all how these compartments interact to generate a given force and displacement.

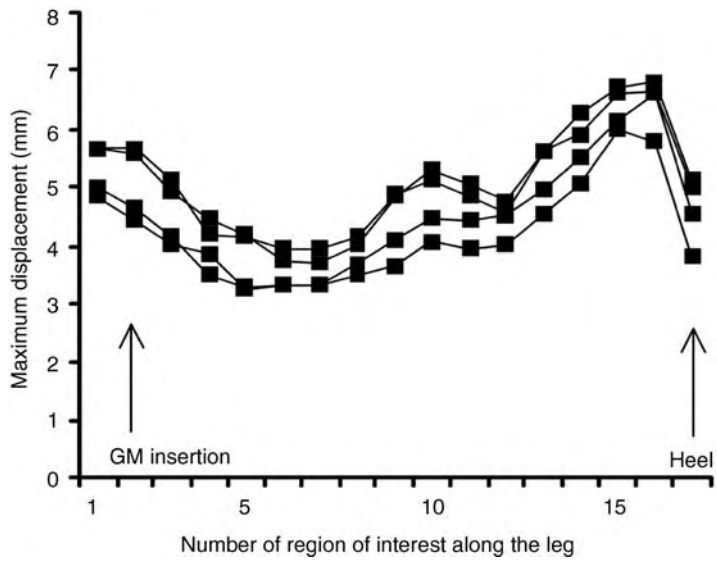
## Plasticity of Muscle Architecture

The architectural properties of a muscle are highly plastic. Muscle and fiber size will increase (hypertrophy, e.g. with resistance training) or decrease (atrophy, e.g. with aging) with changes in the activation/loading conditions. Chronic stretching of a muscle fiber results in the addition of sarcomeres and thus a lengthening of the muscle fiber, whereas chronic shortening has the opposite effect. Hypertrophy of a muscle increases, whereas atrophy decreases, the angle of pinnation of the muscle fibers/fascicles. These considerations may become highly relevant under certain circumstances.

## Functional Implications

It is interesting to note that almost all of the variables measured to characterize muscle architecture are based on the muscle fibers themselves, i.e. the number of sarcomeres arranged in series and in parallel and the angular arrangement of these fibers with respect to the direction of pull of the muscle. There is no inclusion of any of the passive tissues of the musculo-tendinous complex in these measurements. In most experiments any potential contribution of the interfiber matrix, the connective tissue that forms fascicles, aponeuroses and tendons are omitted from the formula to calculate the force and velocity of shortening potential of a muscle. Furthermore, most experiments are specifically designed to eliminate elastic properties. This omission is practically universal, in spite of the fact that it is clear that one cannot predict these measures of function based on muscle fiber architecture and sarcomere dynamics derived from isolated single muscle fibers, in large animals as it can in the smaller animals such as the mouse, rat and guinea pig. The formula classically used to calculate physiological cross-sectional area of a muscle provides highly variable estimates of maximum force and velocity of shortening in human muscles. This limitation suggests that there are some novel fundamental design strategies that have been used in the evolution of larger animals. For example, the difference in body and muscle volumes in the human and the cat may differ 50-fold, whereas the lengths of the fibers in homologous muscles are approximately the same in many cases.

For the physiological cross-sectional area of a muscle to represent its maximum force potential, it must be assumed that the force generated by a single fiber is independent of its length, which in turn implies that all forces among the sarcomeres are transmitted in series and entirely to the end of the muscle fiber to the myotendinous junction, which then transmits the forces to the aponeurosis and/or tendon. It is quite clear now that this is not the case. Muscle forces are transmitted from sarcomeres along the entire length of muscle fibers laterally to the interfiber matrix, and the matrix in turn transmits these forces to connective tissues that form



**Skeletal Muscle Architecture. Figure 6** Example of the maximum displacement at various regions of interest along the aponeurosis-tendon of the gastrocnemius muscle (GM) for one subject during four trials (contractions) in one session. Displacement was calculated using cine phase-contrast magnetic resonance images. Note the nonuniformity in the strain along the aponeurosis-tendon complex. (Taken from [9], Fig. 4).

fascicles, aponeuroses and eventually a tendon. In effect, in large muscles this lateral transmission of forces from sarcomeres along the length of fibers will require much more detailed and sophisticated models of force transmission than is represented by the simpler, traditional models which assume transmission of forces only from sarcomere to sarcomere along the length of the fibers and eventually only to the myotendinous junction. Other sections in this series have addressed some of these issues, demonstrating the potential importance of mechanical interactions from muscle to muscle via the connective tissue sheets that surround them, as well as the interactions of the connective tissues within the muscle, including the interfiber connective tissue matrix (►see Chapter xxx by Huijing in this book).

Obviously, the ability to monitor sarcomere dynamics, muscle fiber shortening and orientation and strains among and within the different levels of organization of the connective tissues that encase the muscle fibers to form a muscle is a technological challenge, even for small muscles in small animals. Some progress has been made in attempting to monitor in vivo sarcomere dynamics in a fish during swimming, in human muscles during normal voluntary isometric activation of selected muscle groups as well as during dynamic jumping movements using ultrasound and magnetic resonance imaging [8]. The initial examinations of the intramuscular dynamics during isometric contractions of the triceps surae in humans demonstrate a remarkable complexity and spatial heterogeneity in the strain of events that occur throughout the triceps surae and particularly the soleus muscle. It is also evident that the strain that occurs within the aponeurosis of the Achilles tendon varies along its length during an isometric contraction **(**Fig. 6**)**. These studies represent only a beginning of the efforts that are likely to reveal important new basic concepts in muscle design, which will enable us to more accurately predict the physiological potential of a given muscle-tendon complex. This information could also be important in efforts to design artificial muscles that can be used to assist or replace dysfunctional muscles.

## Therapeutic Interventions

The consideration of muscle architecture has become prominent in the area of tendon transfers in patients with a variety of musculoskeletal diseases [10]. In instances where a muscle or muscle group has become dysfunctional, it is a common procedure to transfer the tendon of a nearby muscle to compensate for the loss of specific movements. Lieber and colleagues have clearly shown that a crucial consideration in these procedures is the operating range of the musculoskeletal unit to be transferred, i.e. the architectural features of the unit should closely match the kinematics of the desired movements.

►Coordination

## Skill Learning

### Definition

Skill learning is learning of behavioral procedures or "how to." Examples of skill learning are learning to ride a bike, learning to touch type, learning to play a musical instrument or learning to swim. This learning proceeds implicitly and unconsciously by using feedback information. Skill learning can reflect acquisition of an "internal model" of an external object to control. For instance, in the cerebellum, movement trajectories of limb or eye directed to an object are computed by an "inverse model" which transforms from desired trajectory input to motor command output to skeletal muscles.

►Internal Models
►Sensorimotor Learning and the Basal Ganglia

## Skin Photoreceptor

### Definition

Photoreceptors in the skin (or dermal photoreceptors) in non-mammalian vertebrates that regulate some non-image forming photoresponses. An opsin-like molecule in photosensitive pigment cells known as melanophores of Xenopus laevis was named melanopsin. The photoreceptor(s) in the skin of fish exhibits several properties of the opsin family of photopigments, but is not yet identified.

## Sleep

### Definition

Sleep is a state of rest in animals that is characterized by behavioral quiescence and decreased responsiveness to environmental stimuli. The timing of sleep is controlled by an animal's internal biological clock and sleep occurs mostly during the night (diurnal species) or during the day (nocturnal species). Other aspects of sleep behavior (e.g., daily sleep amounts, specific sleep

postures, preference to sleep in a protected environment such as a nest) vary considerably across species.

Common to all species is the expression of rebound increases in sleep amount when animals are deprived of sleep during all or part of their normal rest period.

# Sleep – Developmental Changes

Daniel A. Cohen
Harvard Medical School, Beth Israel Deaconess Medical Center, Department of Neurology, Brigham and Women's Hospital, Division of Sleep Medicine, Boston, MA, USA

## Definition

Sleep undergoes characteristic changes across the developmental progression from birth to early adulthood, including total sleep time, the proportion and timing of rapid eye movement (REM) and non-rapid eye movement (NREM) sleep, and electrophysiological features of sleep. These features may serve as markers of nervous system development, and sleep itself may be critical for normal development.

## Characteristics

### Introduction

Sleep is a complex, highly organized state associated with reversible changes in consciousness, neuronal network firing properties, cerebral blood flow, gene expression profiles, brain chemistry, and autonomic nervous system activity. The precise functions of sleep remain poorly understood, but it is likely that a prominent function of sleep is to promote neuronal repair and reorganization in the brain [1]. Therefore, "sleep is of the brain, by the brain, and for the brain" [2]. With this framework in mind, it is not surprising that the most rapid changes in the organization and physiology of sleep occur during development.

### Total Sleep Time

In the neonatal period (first 28 days of life) in humans, total sleep time tends to occupy 16 or more hours per day, declining to roughly 13 h at 6 months, 10 h at 2 years, and 9 h by age five. Shortly after birth, a large proportion of sleep occurs during the daytime, and with age sleep gradually becomes primarily a nocturnal phenomenon. This is likely due to maturation of the ►circadian pacemaker and the endogenous rhythm of ►rest-activity cycles [3].

### Sleep States: Rapid and Non-Rapid Eye Movement Sleep

Sleep is not a homogenous state and is generally divided between ►rapid eye movement (REM) sleep and stages of ►non-rapid eye movement (NREM) sleep. Sleep stages are defined by the patterns of electrical activity recorded over various scalp locations, changes in muscle tone or body movements, eye movements, and in infants the regularity of the respiratory pattern. Visual scoring has been used to characterize behavioral states in neonates into active and quiet sleep. Active sleep is characterized by: closed eyes, rapid eye movements, irregular respirations, and body twitches, and this is likely the precursor to REM sleep. Quiet sleep is characterized by: closed eyes, minimal eye and body movements, and regular respirations. This is likely the precursor to NREM sleep. In neonates, a substantial proportion of sleep may not be easily recognized as active or quiet sleep, and the term indeterminate sleep may be used.

During the first few months of life NREM sleep becomes divided into stages of lighter sleep, stage 1 and stage 2 sleep, as well as deeper stage 3 and stage 4 sleep (now generally combined as ►slow wave sleep). The depth of NREM sleep relates to the ease at which an environmental stimulus can cause an arousal from sleep to wakefulness. Sleep architecture, or the orderly progression of sleep stages across the night, changes significantly during development.

During early infancy, the oscillations between REM and NREM occur at roughly 60 min cycles, lengthening to about 90 min in the adult. Newborns and infants in the first month of life make the transition from wakefulness to sleep through REM or with only a few minutes of intervening NREM sleep prior to the first REM period [4]. After about 2–3 months of age, sleep is generally entered through NREM sleep through adulthood except under abnormal conditions such as: narcolepsy, the withdrawal of REM suppressing medications, or significant prior sleep restriction. The proportion of REM sleep is roughly 50% of sleep in the newborn, gradually declining to roughly 15–20% by the end of puberty [5]. The proportion of slow wave activity during NREM sleep declines sharply during adolescence.

### Electrophysiological Changes during Development

The electrophysiological patterns recorded by the electroencephalogram (EEG) undergo characteristic changes across gestational age, which is the time elapsed since the first day of the mother's last normal menstrual cycle. EEG patterns have been characterized in normal premature infants as early as 25–27 weeks

gestational age [6]. The EEG is initially discontinuous, with relatively long periods of electrical silence for periods of 30 s or more mixed with bursts of relatively high voltage activity lasting up to 20 s. It was previously felt that before 32 weeks, distinguishing ►waking and ►sleep states by EEG was not possible, but EEG differentiation may be possible as early as 28 weeks [6]. By 31–32 weeks, active sleep, quiet sleep, and wakefulness reliably show differential activity patterns. The EEG becomes more continuous, with general continuity in active sleep and wakefulness. During quiet sleep, the *trace alternant* pattern emerges with bursts of large slow frequency waves and relatively short periods of EEG quiescence. This generally disappears by 47 weeks development at which time the EEG becomes continuous in all behavioral states. ►Sleep spindles, which are short, high frequency bursts generally in the 12–14 cycles per second frequency range, begin to develop by 2–3 months post term. Sleep spindles are the hallmark of stage 2 NREM sleep. Spindles are initially asymmetric, but they become synchronous over both hemispheres during infancy. Generally by 3 months of age, the proportion of slow waves increases and starts to become similar to adult slow wave sleep [7]. Generally by 4 months of age, spindles and slow wave activity are present to a degree that allows confident segmentation of NREM sleep into its component stages. ►K complexes, another feature of Stage 2 NREM sleep, are present generally by 6 months of age. These are waves with a characteristic biphasic shape (negative then positive polarity). The posterior dominant rhythm of relaxed wakefulness gradually increases in frequency from 3 to 4 cycles per second at 3 months, 5–6 cycles per second at 6 months, 7–8 cycles per second by age three, and 8–10 cycles per second by age 15 [4]. Attenuation of the posterior dominant rhythm aids in the recognition of the transition from wake to sleep. Detailed descriptions of the electrophysiological changes of sleep across development have been documented elsewhere [4,7]. The key concept is that changes in the electrophysiological features of sleep are intimately coupled to gestational age and the level of maturation of the nervous system.

## Sleep and Developmental Milestones

The electrophysiological changes that occur during maturation reflect changes in network firing properties and patterns of depolarization and hyperpolarization of cortical neurons. The precise changes in the nervous system associated with the developmental progression of the sleep EEG are poorly understood. It has long been speculated that increasing myelination of the brain during development is a key factor in the timing and characteristics changes of the sleep EEG. Other mechanisms are possible as well. For example, in developing neurons there may be a shift in the post-synaptic receptor profiles and responsiveness to various neurotransmitters [5]. The changes in sleep behavior and physiology across development may be considered milestones of brain maturation, similar to other milestones such as the disappearance of various reflexes, development of fine motor skills, or language development. As such, features of the sleep EEG may be associated with the brain's capacity for information processing. For example, the precise electrophysiological characteristics of sleep spindles may be markers of general cognitive ability [8].

## Sleep may Influence the Development Process

Sleep may not only serve as a useful marker of the developmental state of the brain, but sleep may be a critical process to promote normal nervous system development. There is a growing body of literature for the role of sleep in the off-line processing of memories during a period of consolidation. This is an example of the role of sleep in plasticity, or the experience dependent changes that occur at the synaptic level. Changes in synaptic connections may increase or decrease the probability of activating particular neural networks, shaping the information processing capabilities of the brain.

The proportion of REM sleep is highest in the neonatal period, the phase of the life cycle associated with the most rapid re-organization of the brain. REM sleep deprivation experiments in animals have been used to determine the influence of this sleep stage on neural network connectivity. A particularly influential model for understanding development of neural connectivity has been monocular visual deprivation in developing animals. When one eye is deprived of visual input during a critical period of development, the brain undergoes reorganization so that cortical structures involved in visual processing become more heavily connected to the open eye. REM sleep deprivation during this critical period shifts the balance further, enhancing connections to the open eye at the expense of the visually deprived eye [9]. This has been interpreted to signify that normal REM sleep provides an opportunity for the deprived eye to compete for cortical connectivity despite the lack of external visual input. REM sleep is a state of high neuronal firing rates and brain metabolism that is similar to waking levels, and there is particular activation of visual processing areas such as occurs during ►dreams. Endogenous neuronal activity of visual pathways during REM sleep may enhance connectivity, so that maturation of the visual system may occur during sleep when there is no visual sensory input through closed eyes. Promoting use dependent plasticity in the visual system

during REM sleep is one example of how sleep processes can interact with the brain to promote normal connectivity. Slow wave sleep may also provide an opportunity for the brain to strengthen specific networks, for example, during the neuronal re-play of recently acquired memory traces during slow wave sleep.

### Clinical Implications

The sleeping brain reflects a highly organized pattern of neural activity, involving both cortical and subcortical structures. Changes in sleep behavior and physiology are intimately coupled with nervous system development. As an extension of the neurological examination, improved methodology to capture the physiological processes of sleep may provide sensitive markers of brain maturation. Therefore, sleep analysis may become a valuable tool for predicting neurological prognosis. Sleep is not only a window to the organization of the brain, but sleep may also be critical for its development. Cognitive and emotional difficulties later in life may result from abnormal sleep quantity or quality during development. For example, early REM deprivation may lead to mood disorders such as depression [10]. Sleep is important for the consolidation of memories and may have other benefits on cognitive function. Public health education to foster optimal sleep habits for children and effective screening tools for childhood sleep disorders may improve school performance, social functioning, and overall wellbeing.

## Definition

The inter-relationships of hormone concentrations, sleep and circadian rhythms. The frequency and/or amplitude of pulsatile hormone release may be affected by sleep, specific sleep stages and/or circadian rhythms. In turn, hormone concentrations may affect sleep and the circadian timing system.

## Characteristics

### Introduction

A hormone is a chemical messenger that carries its signal via the blood. Many hormones are rhythmically released. Their periodicity can be ►ultradian (i.e., with a period shorter than 24 h, e.g., ~90 min pulses of thyrotropin [TSH]), circadian (i.e., with a period close to 24 h, e.g., melatonin), or infradian (i.e., with a period longer than 24 h, e.g. sexual hormones such as Luteinizing Hormone or Follicule Stimulating Hormone) or combinations of these periodicities; one example is circadian variation in ultradian pulse frequency or amplitude.

Daily oscillations of endocrine activity are driven by mechanisms that can be endogenous (internal), exogenous (environmental), or by a combination. In addition to the conventionally considered biochemical regulatory mechanisms for each hormone's synthesis, release and clearance, other influences include the endogenous circadian biological clock, located in the ►suprachiasmatic nuclei (►SCN) of the ►hypothalamus, and endogenous sleep/wake-related processes) [1]. Environmental factors that are known to affect hormone release are: posture changes, physical activity, food intake, temperature, and light. In individuals living in real life conditions, endogenous and exogenous factors are usually confounded. For example, sleeping usually occurs a specific circadian phases and is not only a change in conscious state, but also is usually accompanied by a change in posture, feeding/fasting, light levels and social contacts, all of which may individually affect hormones. Only controlled laboratory studies allow for separation of those factors, and permit to infer controlling mechanisms of hormonal release.

The most thoroughly studied hormone-sleep interactions are those of the pituitary hormones. Early studies have described three categories of sleep-hormone

interactions: (i) hormones weakly influenced by sleep, such as adrenocorticotropic hormone (ACTH), cortisol and ►melatonin, (ii) hormones strongly influenced by sleep as a whole, such as prolactin (PRL) and TSH; (iii) hormones influenced by a particular stage of sleep, such as growth hormone (GH) [2]. More recently, a variety of protocols have been used to investigate the relationships between hormones and sleep and circadian systems, including: complete and partial sleep deprivation, acute or chronic shifts of the sleep time, administration of pharmacological agents which disturb either sleep or hormone secretion, and the use of pathologies in which either endocrine or sleep disturbances are observed [1,3,4]. Using frequent blood sampling rates, sensitive hormonal assays, and controlled protocols, those studies have found that, most hormones are influenced, with different respective contributions, both by circadian and sleep-related processes.

## Specific Relationships between Sleep and Hormones

### *Prolactin (PRL)*

Under baseline conditions, 24-h profiles of PRL show low levels during daytime and high levels during sleep. Studies using experimental strategies such as shifts of the sleep episode have shown a close association between sleep and the increase in PRL release. Figure 1a illustrates the effect of an 8-h shift in the sleep period on the 24-h PRL profiles in a group of young subjects. In order to differentiate circadian influences from sleep-related effects, day-active subjects were studied once under a normal 24-h ►sleep-wake cycle (sleep from 2300 or 23 to 0700 or 7 h), and once under a 24-h cycle where sleep was delayed by 8-h (sleep from 0700 or 7 to 1500 or 15 h). In both conditions, PRL is high during sleep time and low during waketime, showing the strong influence of sleep on PRL release. It is important to note that, a systematic PRL pulse was found in all subjects during the night of ►sleep deprivation, at the time of habitual sleep. This pulse, also observed in ►jet lag studies, is thought to reflect an influence of the circadian timing system on PRL release, independent of sleep [4].

The search for an association between the internal sleep structure and the episodic PRL pulses has led to conflicting reports. A relationship between the alternation of ►REM and ►NREM sleep episodes and the occurrence of nadirs and peaks, respectively, in plasma PRL levels has been described in some studies, but not in others. Using spectral analysis of the sleep EEG, however, a clear temporal link between PRL release and the ►electroencephalographic activity (►EEG) during sleep has been described. PRL secretory rates have been found to be positively correlated with delta wave activity (also called ►slow wave activity, ►SWA, 0.5–3.5 Hz), an indicator of sleep depth, and negatively correlated with alpha (8–12.5 Hz) and beta frequency bands (13–35 Hz), indicators of relaxed wakefulness, and active wakefulness respectively (Fig. 1b) [3].

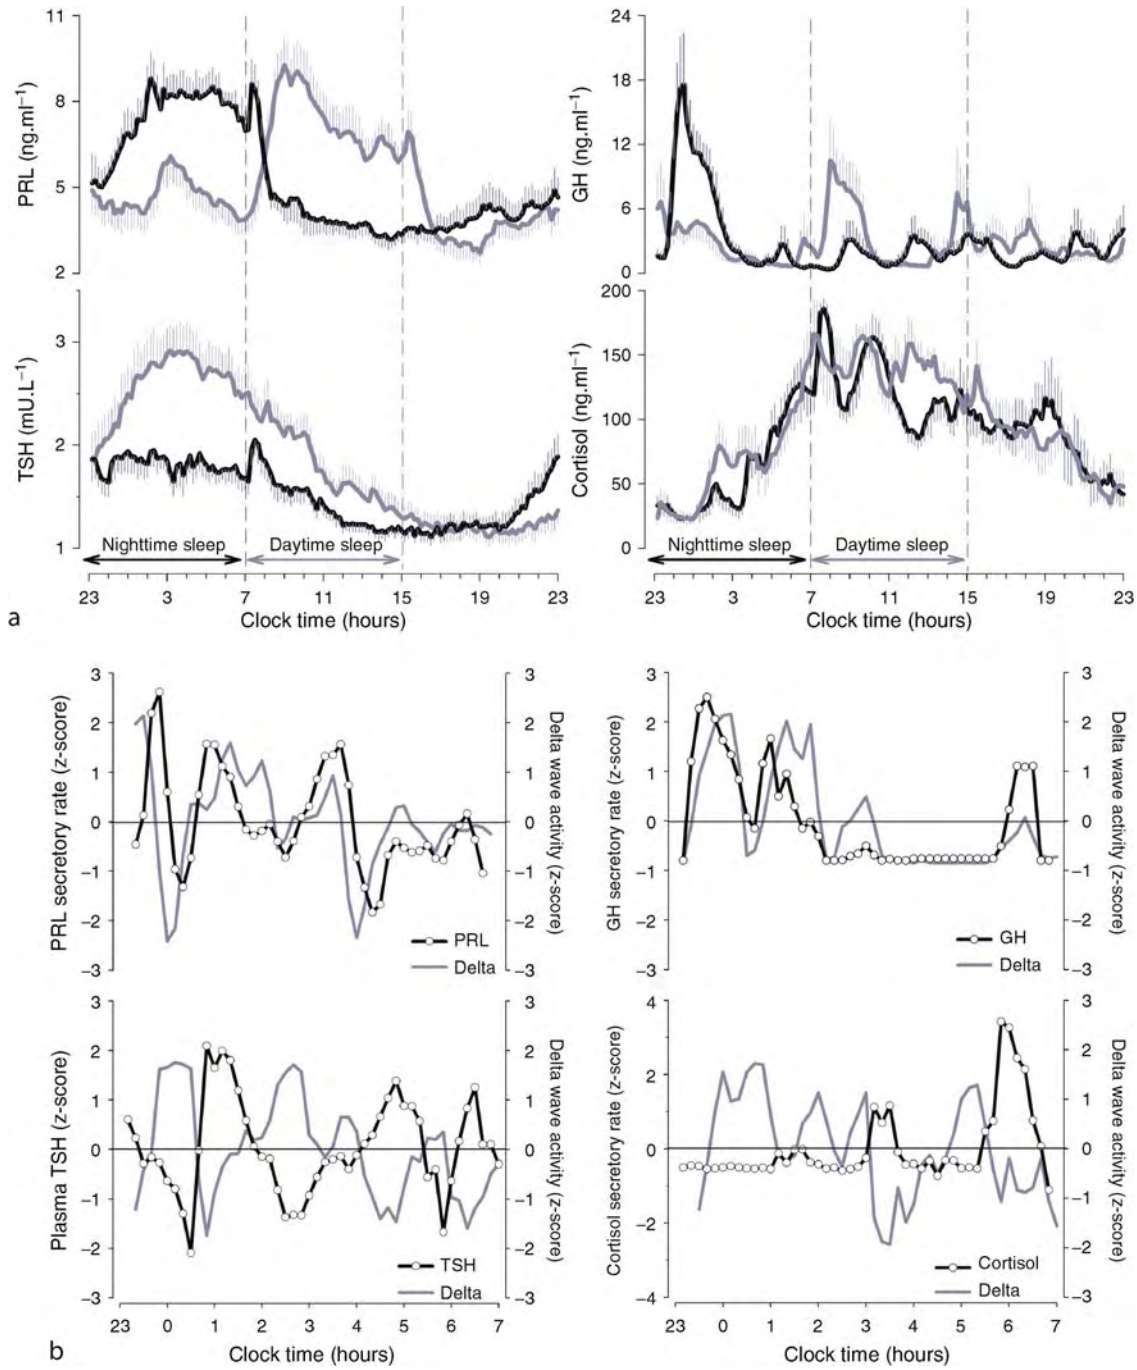
### *Growth Hormone (GH)*

The 24-h profile of GH is characterized by a sleep-dependent rhythm, with a large secretory episode occurring just after sleep onset, temporally related to the first episode of ►slow-wave sleep (SWS). Other pulses may occur later during sleep and during wakefulness, especially in women. Figure 1a illustrates the mean GH profiles during a normal 24-h period, and during a 24-h period where sleep was delay shifted by 8-h. In both conditions, a large GH pulse is measured just after sleep onset. This hormone is therefore clearly controlled by sleep mechanisms. A weak circadian influence on GH release has been proposed, as GH pulses are usually observed during sleep deprivation at the habitual sleep time [4].

Despite the large number of studies, the underlying mechanisms coupling GH and SWS have not yet been clearly identified. Some authors have concluded that the temporal association observed between GH pulses and the first episode of SWS may be fortuitous. In more recent studies, however, a close temporal relationship has been found between SWS and GH secretory rates. In addition, a significant correlation has been described between the amount of GH secreted during SWS and the duration of the associated SWS episodes, under normal conditions, as well as after pharmacological enhancement of SWS with gamma-hydroxybutyrate [4]. This result has been confirmed by another study describing a quantitative relationship between the amount of GH secreted and the concomitant amount of delta wave activity (Fig. 1b). Interestingly, when sleep is enriched in SWS by ritanserin (a 5-HT2 receptor antagonist), an equivalent increase in delta wave activity and GH secretion is found [5]. Taken together, these results suggest that the regulatory mechanisms involved in the control of delta wave activity and GH secretion share common pathways. In rodents, growth hormone releasing hormone (GHRH) neurons could be the common link between GH release by the pituitary and SWS generation.

### *Thyrotropin (TSH)*

TSH exhibits a 24-h rhythm generated by amplitude and frequency modulation of secretory pulses. TSH has low daytime values which begin to increase in the late afternoon, reaching maximum levels around the time of sleep onset. Subsequently, a slow decline, generally attributed to an inhibitory influence of sleep, occurs during the night. Figure 1a illustrates 24-h profiles of TSH both during a normal 24-h period and a sleep shift. During sleep deprivation, TSH levels continue to rise, peaking later in the night. It is generally admitted that sleep exerts an inhibitory influence on TSH secretion,



**Sleep – Endocrine Changes. Figure 1** (a) 24-h profiles of PRL, GH, TSH and cortisol in a group of eight healthy young subjects, measured once under a normal 24-h sleep-wake cycle (sleep from 23 to 7 h, dark line), and once under a 24-h cycle after a delay shift of the sleep episode by 8-h (sleep from 7 to 15 h, gray line). (b) Nocturnal hormonal profiles of PRL, GH, TSH, and cortisol (dark line with open circles) and concomitant with delta wave activity, as a marker of sleep depth (gray line). Adapted from [3].

and that sleep deprivation removes that inhibition. It is considered that the 24-h TSH profile results from an interaction between the endogenous circadian timing system and a sleep-related inhibitory effect. When the depth of sleep at the habitual time is enhanced by prior sleep deprivation, the nocturnal TSH rise is markedly reduced, suggesting that SWS is probably the primary determinant of the sleep-associated fall [3,4].

A temporal association has been described between the internal sleep structure and TSH pulses, such that

SWS is associated with declining plasma TSH levels, and awakenings with rising levels. These relationships have been confirmed using spectral (frequency) analysis of the sleep EEG, which demonstrated that the nocturnal TSH profile was negatively correlated with the delta wave activity. Figure 1b shows that increases in TSH levels are linked to decreases in delta wave activity, and conversely, that decreases in TSH levels are associated with increases in delta wave activity. The nocturnal TSH profile closely reflects variations of sleep EEG activity. Whether EEG activity has a modulatory role on TSH levels, or inversely, whether TSH variations could influence sleep structure, remains to be clarified. However, the fact that sleep deprivation is associated with an increase in TSH release favors the hypothesis that it is SWS that inhibits TSH secretion [3].

### *ACTH/Cortisol*

The 24-h cortisol rhythm is generally considered to be mainly under endogenous circadian control, and therefore to be relatively independent of sleep. Indeed, it is only slightly affected by short-term manipulations of sleep such as sleep reversal, selective and total sleep deprivation, and abrupt shift in the sleep period (Fig. 1a). However, temporal relationships between cortisol and sleep have been found, and sleep has been proposed to exert an inhibitory effect on cortisol release [6], particularly in the first few hours of the night. This finding has been challenged by other studies, which concluded that sleep does not inhibit cortisol since ►diurnal sleep does not suppress cortisol release [3].

Despite these discrepancies, temporal relationships between cortisol pulses and the internal sleep structure have been described. Awakenings or light sleep periods are associated with increasing plasma cortisol levels, whereas SWS is associated with low or decreasing cortisol levels. Using spectral analysis of the sleep-EEG and deconvolution procedures for estimation of cortisol secretory rates, an inverse relationship between cortisol secretory pulses and oscillations in delta wave activity during nocturnal sleep as well as during diurnal sleep was described. Increases in cortisol secretory rates were associated with decreases in delta wave activity, and conversely, peaks in delta wave activity occurred only during low cortisol secretion (Fig. 1b). It is possible that both sleep is inhibited by cortisol release and cortisol release is inhibited by sleep (SWS in particular). Cross-correlation analyses between delta wave activity and cortisol secretory rates revealed that cortisol oscillations precede the changes in EEG activity by about 10 min, suggesting that cortisol secretion or its secretory processes may modulate the EEG activity, rather than the inverse [3]. At the same time, this finding does not exclude that SWS exerts an inhibitory influences on cortisol release through delayed effects. Until new data is available, in particular from studies in which sleep and circadian influences can be separated (such as in ►forced desynchrony protocols), the safest statement that can be made at this point, is that reciprocal negative interactions exist between SWS and cortisol secretion.

### *Other Hormones and Neuropeptides*

Sleep is a strong modulator of glucose and insulin secretion, since high glucose and high insulin levels are seen during sleep, irrespective of sleep timing. Endogenous circadian rhythms of glucose and insulin secretion have been reported, but they are rather of low amplitude. The 24-h rhythm of satiety-sensing hormone leptin has a nocturnal increase that is under both circadian control (persisting during sleep deprivation) and sleep control (sleep deprivation dampens its amplitude) [4]. The appetite stimulant hormone ghrelin also shows a sleep-associated increase at night [4]. Recent studies have investigated the rhythmicity of ►orexin/hypocretin, a brain neuropeptide involved in sleep maintenance. Orexin levels increase during the day and decrease at night, under the dual control sleep/wake and circadian processes. Indeed, lesions of the SCN abolish the circadian rhythmicity of orexin, and sleep deprivation lead to subsequent increases in orexin levels [7]).

## Sleep Debt and Hormones/Metabolic Syndrome

Although the effects of inpatient short-term single episodes of sleep deprivation on brain functioning have been extensively studied, the consequences of chronic sleep restriction (insufficient sleep for multiple days) as experienced by millions of people, have received much less attention. During the past 5–6 years, however, a set of studies has demonstrated that the effects of sleep restriction is not limited to the executive performance and alertness functions of the brain, but also affects the entire body. Elegant studies have shown that sleep curtailment impacts the somatotropic (GH), corticotropic (cortisol) and thyrotropic (TSH) axes [8]). Interestingly, they also showed under a sleep restriction protocol, that leptin is decreased and ghrelin is increased, reducing the feeling of satiety and increasing the feeling of hunger [9]. Another group of studies, showed that short sleep duration is associated with reduced leptin, increased ghrelin and increased body mass index (BMI, an index of obesity) [10]. Taken together, these results suggest a causal relationship between sleep debt and metabolism impairment that has large implications for the health of sleep restricted individuals in industrial societies, in which the rate of obesity and metabolic illnesses such as type II diabetes is increasing dramatically.

## Conclusions

This chapter highlights the wide variety of relationships between sleep and hormonal activity. PRL and GH are increased during sleep (SWS in particular) and

mainly driven by sleep. In contrast, the circadian timing system is the main driving force of the 24-h rhythm of melatonin and cortisol, with, for the latter hormone an additional influence of the internal sleep structure on its pulsatile release. TSH lies on the boundary of these classes of hormones, as its 24-h rhythm is generated by the circadian system and by modulated (inhibited) by sleep (SWS).

Because of the intricate relationships among hormones, sleep, and the circadian timing system, alterations of hormonal release can impact sleep and its structure. Similarly, sleep loss and circadian misalignment, either due to pathologies (sleep apnea, ►insomnia, etc.) of real life situations (voluntary or socially induced sleep curtailment, jet lag, ►shift work) can have a detrimental impact of many endocrine systems. Further work is needed to detail the neuroanatomy and molecular mechanistic links between sleep and hormones that result in the observed interactions.

# Sleep – Motor Changes

Kenneth P. Wright Jr
Sleep and Chronobiology Laboratory, Department of Integrative Physiology, University of Colorado at Boulder, Boulder, CO, USA

## Synonyms

Descending Drive to motorneuron pool; Motor responsiveness; Sleep Movement Disorders

## Definition

Sleep associated motor changes reflect neurophysiological alterations in descending excitatory and inhibitory drives to the alpha ►motorneuron pool. Integration of descending excitatory and inhibitory drives determines net motor output during sleep.

## Characteristics

Sleep is characterized by specific postural changes, reductions in muscle tone, and changes in excitatory and inhibitory inputs to ►motorneurons that influence the likelihood of an action potential and therefore motor output. Motor output characteristically changes across wakefulness and sleep states such that muscle activity is highest during active wakefulness, decreases during quiet wakefulness and ►Non-REM sleep (NREM) sleep, and is minimal or absent during ►rapid eye movement (REM). Thus, measurement of gross motor activity, i.e., inactivity, has often been used as a proxy to assess wakefulness-sleep timing [1].

### Changes in Descending Drive to Motor Neurons During Sleep

In most mammals, activities of alpha motorneurons that innervate skeletal and respiratory ►muscle fibers may or may not be reduced during NREM sleep relative to quiet wakefulness, whereas during REM sleep motorneuron activity is actively reduced or inhibited. However, compared to active wakefulness when the ►alpha motorneuron membrane potential is most easily raised above threshold for the generation of action potentials, the membrane potential of motor neurons are ►hyperpolarized during NREM sleep. Motorneuron membrane potential becomes even more hyperpolarized during REM sleep making it even less likely that an action potential will occur. Sleep related changes in membrane potential are thought to be caused at least in part by a reduction or removal of excitatory drive to the motorneuron pool (i.e., ►disfacilitation) and by increased inhibitory drive at the level of the ►postsynaptic membrane. Excitatory drive is reduced to the greatest extent during REM sleep. Reductions in ►monoaminergic neuronal activity emanating from ►brain stem raphe serotonergic neurons and ►locus

coeruleus noradrenergic neurons are hypothesized to contribute to reductions in the excitatory drive to the motorneuron pool during sleep compared to wakefulness [2]. REM state specific activation of brain stem ►cholinergic neuronal cell groups and reductions in brain stem serotonergic and noradrenergic activity are reported to contribute to ►muscle atonia during REM sleep [3,4]. Findings from lesion studies indicate that damage to cell in the peri locus coeruleus [4] or ►sublaterodorsal tegmental nucleus [5] of the brainstem can result in a release from muscle atonia during REM sleep and as a result, animals appear to act out their dreams [6,7]. ►Gultamatergic cells within the sublaterodorsal tegmental nucleus of the brain stem are reported to project to ►spinal cord interneurons [5], and to actively inhibit alpha motor neuron action potentials though release of ►glycine and ►GABA [2,4,5]. In addition, during REM sleep there is an increase in small amplitude spontaneous as well as sensory stimulated ►inhibitory post synaptic potentials (IPSPs) in the motorneurons. These small amplitude IPSPs and REM state specific large amplitude IPSPs are reported to be associated with responses to sensory stimulation and ►pontine-geniculo-occipital (PGO) waves [8].

Although reduced, supraspinal excitatory drives to the motorneuron pool remain active even during REM sleep. Inhibitory drives generally predominate during REM sleep and thus muscle activation does not typically occur. However, twitches in skeletal muscle fibers take place during REM sleep and these brief increases in muscle activity are thought to be due to a temporary predominance of excitatory over inhibitory drives. Phasic muscle twitches that occur during REM sleep are reported to be associated with phasic activity in other systems such as rapid eye movements, PGO waves, and middle ear muscle activity. Some species, such as dogs and perhaps aquatic mammals like dolphins, appear to have less muscle inhibition during REM sleep.

## Behavioral Responses to Environmental Stimuli During Sleep

In humans, it has been demonstrated that behavioral responsiveness to stimuli can occur in all stages of sleep; however, the likelihood of a behavioral response is generally reported to be greatest in stages 1 and 2 sleep (reviewed in [9]). Behavioral responsiveness to stimuli during sleep is dependent on changes in sensory ►thresholds as well as the ability to perform and complete the behavioral response. For example, a button press in response to a tone is less likely to occur during the muscle atonia of REM sleep whereas taking a deep breath in response to an ►auditory tone can take place during REM sleep. In some cases, aborted attempts to respond with a button press can be observed in the ►electromyographic (EMG) activity of hand and forearm muscles during sleep. Findings from such studies demonstrate that complex motor behaviors are possible during sleep.

## Sleep Movement Disorders and Motor Phenomena During Sleep in Humans

A number of sleep movement neurological disorders have been identified. Examples include, periodic limb movements of sleep (PLMS), sleep bruxism, REM sleep behavior disorder (RBD), sleep walking, sleep related eating disorder, and obstructive sleep apnea. Periodic limb movements during sleep are characterized by periodic (i.e., every ~20–90 s), rapid flexion of the foot or knee and hip, or the extension of the big toe. Although less common, movements of the arms can also occur during sleep. Sleep bruxism – grinding or clenching of the teeth during sleep – has been reported to occur during all sleep stages but most predominantly in stages 1 and 2 of NREM sleep. Patients with REM sleep behavior disorder exhibit episodes of REM sleep without muscle atonia and therefore these patients appear to act out their dreams. Often, REM sleep behavior disorder can be seen in patients with neurological disorders such as Parkinson's disease. Sleep walking is an arousal out of deep NREM sleep and neurophysiologically the cortical EEG shows signs of wakefulness and sleep. Presumably, sleep related eating disorder is similar to sleep walking. Reductions in respiratory muscle activity during REM sleep also contribute to the cessation of breathing that is observed in the sleep disorder obstructive sleep apnea [10]. Sleep apnea is often worst during the muscle atonia of REM sleep. Many of the complex motor behaviors that take place during sleep are often unremembered because formation of "new" memories appears to be inactive during sleep. Effective treatments are available for patients with movement disorders during sleep. One last sleep related motor phenomena to be mentioned is the hypnagogic jerk, also referred to as a sleep start. The hypnagogic jerk is a sudden, non-periodic, involuntary contraction of the appendicular and/or axial muscles of the body during the transition (►transitions) from wakefulness to sleep. Hypnagogic jerks are usually considered to be benign motor behavior unless they occur multiple times per night and cause sleep onset insomnia. The common sensation of falling during a hypnagogic jerk may be the reason for the colloquialism "falling asleep." The neurophysiology of hypnagogic jerks is not well understood but is likely to be related to changes in inhibitory and excitatory drive to the motorneuron pool.

In summary, motor activity during sleep is determined by the summation of excitatory and inhibitory inputs to ►motorneurons. Inhibitory influences generally predominate during sleep. Furthermore, muscle activity is actively inhibited during REM sleep. Odd motor behaviors during sleep may be related to neurological disorders.

# Sleep – Sensory Changes

Kenneth P. Wright Jr
Sleep and Chronobiology Laboratory, Department of Integrative Physiology, University of Colorado at Boulder, Boulder, CO, USA

## Synonyms

Sensory Information Processing; Sensory Responsiveness

## Definition

Sleep associated changes in sensory physiology reflect neurophysiological alterations in ascending arousal systems and activation of sleep promoting systems.

## Characteristics

Sleep was once thought to be caused by a lack of environmental stimulation and sensory systems were thought to be relatively inactive during sleep. We now know that sleep is actively promoted by the brain and that processing of sensory information remains active during sleep [1–3]. However, neurophysiological changes during sleep are associated with alterations in sensory information processing and reductions in responsiveness to external stimuli. For example, arousal ►thresholds are higher during sleep than wakefulness and sensory physiology is different between stages of ►non-REM (NREM) and ►rapid eye movement (REM) sleep. In general, arousal thresholds progressively increase from light stage N1 through deep stage N3 of NREM sleep whereas arousal thresholds during REM sleep have been reported to be similar to those observed during deep NREM sleep or lighter stage N2 sleep depending on the amount of prior deep NREM sleep, time of night and/or ►circadian time [4,5].

### Brain Sensory System Activity During Sleep

The vast majority of studies that have examined the activity of sensory systems during sleep have examined exposure to ►auditory stimuli. In the 1930s, Loomis and colleagues first described ►electroencephalographic (EEG) activation and the ►K-complex EEG response to environmental stimuli during sleep [6]. More recent studies have reported that a meaningful stimulus, such as the person's name, produces more K-complexes than do less important stimuli. Brain imaging studies indicate that activation of the auditory ►cortex, the ►thalamus and the ►caudate nucleus occurs in response to auditory stimuli during NREM sleep [7] suggesting that some level of cortical processing takes place during sleep. Exposure to most odors alters EEG activity during sleep even if the odor is below detection threshold during wakefulness. Exposure to painful stimuli such as electric shock, hot and cold water applied to the skin, and infusion of saline into muscle have been reported to result in EEG ►arousals and increased heart rate responses during sleep (reviewed in [2]). Behavioral button switch press responses to photic flash stimuli during stages 1 and 2 sleep and also REM sleep have been reported. To date, brain EEG arousals have been reported in response to auditory, ►olfactory, ►somatosensory, ►visual, and ►taste stimuli.

### Sensory Information Processing During Sleep

The finding that sensory information can be processed during sleep is also supported by findings from evoked or ►event related potential studies. Early components of the ►evoked potential are linked to the sensory processing of stimuli and later components are linked to cognitive processing of stimuli. In general, the early ►brain stem components of the evoked potential

are similar between sleep and wakefulness whereas the later cognitive components are altered by sleep [8]. The cognitive evoked potential referred to as the ►P300 is elicited during wakefulness when stimuli are both detected and attended. The P300 is present during sleep but the latency of the P300 is delayed and the amplitude is reduced [9]. Other auditory evoked components such as the ►N1 and ►P2 are altered during sleep compared to wakefulness [8]. Changes in evoked potentials measured by EEG and ►magneto-encephalography (MEG) [3] between wakefulness and sleep and among NREM and REM sleep stages have been reported in response to auditory, somatosensory and visual stimuli. Although sensory processing can occur during sleep the neurophysiology of sleep does not appear to be conducive to the formation of new memories, with the exception of ►classical conditioning [2].

### Synaptic Excitability During Sleep

Neurophysiologically, the intrinsic and ►synaptic excitability of cortical and thalamic neurons changes between wakefulness and sleep, and between NREM and REM sleep. Wakefulness and REM sleep are associated with EEG activation caused by brainstem and ►forebrain arousal systems, whereas during deep NREM sleep the EEG is characterized by ►slow oscillations and ►synchronization. Relatedly, the transmission of sensory information from the thalamus to the cortex is enhanced during wakefulness and REM sleep compared to NREM sleep [10]. ►Field potentials between the thalamus and cortex that are evoked by stimulation of sensory pathways are reduced during NREM sleep. In addition, when a ►sleep spindle is generated – spindles are a hallmark of NREM stage N2 sleep in humans – there is an inhibition of sensory information transfer from the thalamus to the cortex. Such blockade of sensory information transfer during NREM sleep appears to occur at the level of the thalamus and ►GABA is thought to be a primary neurotransmitter involved in this process.

### Inhibition of Ascending Arousal Systems During Sleep Influences Sensory Information Processing

Reductions in activity of a multitude of brain stem, ►midbrain and forebrain arousal systems critically involved in attention and memory processes, likely contribute to alterations in sensory processing during sleep. In general, sleep promoting regions of the brain actively inhibit activity of ascending arousal systems including ►locus coeruleus noradrenergic neurons, ►raphe serotonergic neurons, ►basal forebrain and brain stem ►cholinergic neurons and ►hypothalamic orexigenic and histaminergic neurons (►histamine). Activities of ►monoaminergic neurons are even further reduced, if not completely silent, during REM sleep, whereas ►REM on cells actively promote REM sleep.

In summary, all sensory systems studied to date show that sensory processing take place during sleep, yet information processing and behavioral responsiveness to external stimuli are altered during sleep. Information transfer from the thalamus to cortical areas is blocked during synchronizing events, such as the generation of sleep spindles, during NREM sleep. Furthermore, there exist differences in sensory processing among NREM and REM sleep states that are likely related to changes in modulatory neurotransmitter brain stem, forebrain and midbrain arousal systems, which widely innervate cortical and subcortical structures.

## Synonyms

Sleep regulating mechanisms; Sleep onset mechanisms

## Definition

Neuronal and neurochemical mechanisms that actively promote sleep onset, function to maintain sleep continuity, and regulate sleep depth in response to homeostatic and circadian demands.

## Characteristics

### Sleep as an Active Process

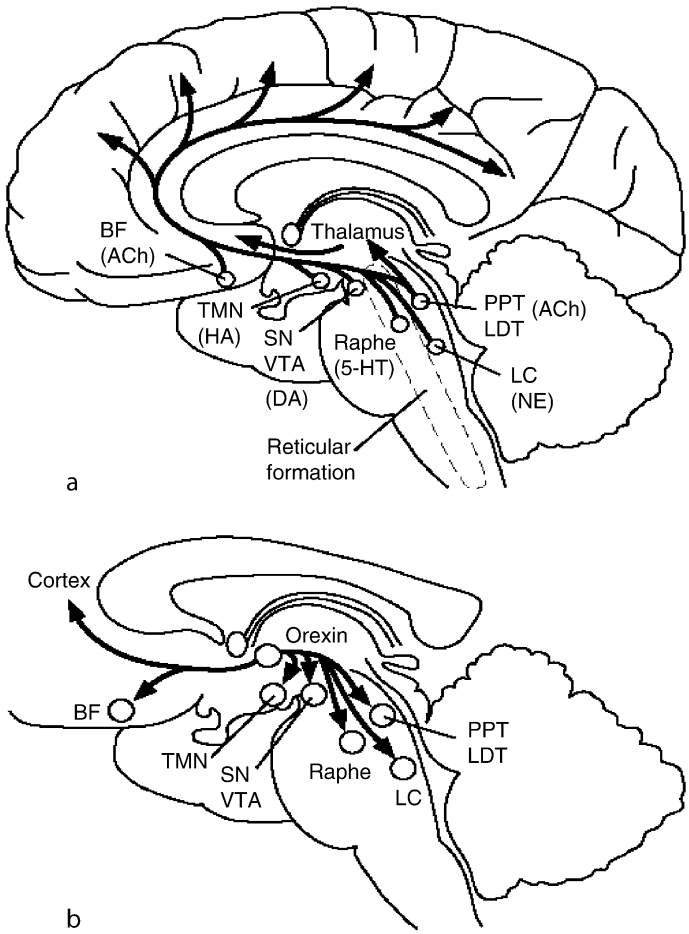
The prevailing view among physiologists during the first half of the twentieth century was that waking brain activity depended upon sensory stimulation. ►Sleep was believed to occur as a passive consequence of diminished sensory input that accompanied instinctual sleep preparatory behaviors (e.g., behavioral rest, eye closure, selection of a warm, quiet environment, etc.). Within this conceptual framework, then, the existence of brain mechanisms that actively generated sleep was not required [1].

This concept of sleep as a passive process was undermined by the following findings (i) sleep consists of an active cycling between ►nonREM and ►REM sleep, (ii) electrical stimulation of the midline thalamus or of the basal forebrain elicits sleep and (iii) brainstem transactions at the midpontine level or discrete lesions of the rostral hypothalamus cause chronic sleep suppression [2]. As will be described in this essay, the existence of neuronal mechanisms that function to actively generate and maintain sleep is now firmly established.

### Sleep Generation Entails Coordinated Inhibition of Arousal Systems

During the past 50 years, researchers have focused on identifying specific neuronal groups and pathways in the brain that interact to generate arousal states. Multiple chemically-defined neuronal systems located in the brainstem and posterior hypothalamus function to promote both behavioral and electrographic aspects of arousal. These arousal systems include monoaminergic neurons in the rostral pons, midbrain and posterior hypothalamus, cholinergic neurons in the brainstem and basal forebrain, dopaminergic neurons in the ventral tegmentum and ►orexin - (hypocretin-) containing neurons in the lateral hypothalamus (Fig. 1) [3]. Most of these arousal systems are characterized by localized aggregations of cell bodies with long axonal projections that have widespread forebrain targets, including the thalamus, limbic system and neocortex (Fig. 1). Descending projections from the arousal systems (not all of which are shown in Fig. 1) regulate muscle tone and autonomic nervous system activity at the level of the brainstem and spinal cord.

The characterization of these neuronal groups as "arousal systems" is an over-simplification, as each regulates various aspects of waking brain function. However, the collective activity in these neuronal systems during waking imparts a tonic background level of arousal/activation that is reflected in low voltage, fast frequency cortical EEG patterns. Neuronal activity in these arousal systems is characterized by high levels of tonic or phasic discharge during ►waking behaviors, and comparative quiescence during sleep.



**Sleep Generating Mechanisms. Figure 1** Ascending arousal systems in the brainstem and posterior hypothalamus. (a) Schematically depicted are (i) acetylcholine (Ach) neurons in the pedunculopontine and laterodorsal tegmental areas (PPT/LDT) and the basal forebrain (BF); (ii) noradrenergic (NE) neurons in the locus coreuleus (LC); (iii) serotonergic (5-HT) neurons in the dorsal raphe nucleus; (iv) histamine (HA) neurons in the tuberomammillary nucleus (TMN); (v) dopamine (DA) neurons in the substantia nigra and ventral tegemental area (SN/VTA). (b) Localization and projections of orexin neurons in the perifornical lateral hypothalamus From [3] with permission.

Some arousal systems (e.g., cholinergic) exhibit elevated discharge during waking and REM sleep and minimum activity during nonREM sleep. Others (e.g., the monoaminergic systems) display discharge rates during REM sleep that are as low or lower than that observed during nonREM sleep (so-called "►REM-off" discharge pattern) [3,4]. What is common to nearly all of the arousal systems schematized in Fig. 1, is a rapid decline in neuronal activity just prior to, or at the time of sleep onset.

A critical task, therefore, for brain mechanisms that generate sleep is to achieve a coordinated inhibition and/or disfacilitation of these disparate arousal-regulatory neuronal groups. There are three interrelated cellular and neurochemical mechanisms that accomplish this. First, is a system of neurons located in the preoptic hypothalamus that is activated during sleep and that exerts sleep-related inhibitory influences over several of the arousal systems through synaptic connectivity with these systems. Second, are endogenous sleep factors (e.g., adenosine) that exert inhibitory neuromodulatory effects on one or more arousal systems. Third, in all mammals, the timing of sleep and waking is controlled by the circadian clock in the brain. Thus, a third aspect of sleep generation involves regulation of the excitability of the arousal systems by the circadian clock in the ►suprachiasmatic nucleus of the hypothalamus.

## Sleep Generating Neurons in the Preoptic Hypothalamus

The preoptic area of the hypothalamus was initially identified as a potential site of sleep generating mechanisms on the basis of stimulation and lesion studies. Electrical or chemical stimulation of this area can

acutely evoke sleep onset and experimental damage to the preoptic hypothalamus yields profound and persistent insomnia [4]. Recordings of neuronal activity during natural sleep and waking identify neurons in the preoptic area that display elevated discharge rates during nonREM and REM sleep compared to waking. The activity of these "sleep-active" neurons increases prior to sleep onset during waking to sleep transitions. The sleep-wake discharge pattern of these preoptic neurons is the reciprocal of the REM-off discharge pattern observed in several of the arousal systems [4].

In addition to single unit recordings, sleep-active neurons can be identified by immunostaining for the protein product of the *c-fos* gene. *c-fos* gene expression is a validated marker of neuronal activation. By comparing immunoreactivity for the c-Fos protein in the brains of animals that are predominately asleep or predominately awake during the 1–2 h prior to sacrifice, the anatomical distribution of sleep-active neurons in the brain can be determined. This approach identifies two subregions of the preoptic area in the rat that contain high densities of sleep-active neurons; the ►ventrolateral preoptic area (►VLPO) and the median preoptic nucleus (MnPN) [4,5]. Combined staining for sleep-related Fos protein and neurotransmitter makers reveals that most sleep-active neurons in the MnPN synthesize the inhibitory neurotransmitter GABA, and that sleep-active neurons in the VLPO contain both GABA and the inhibitory neuropeptide, galanin.

Mechanisms of sleep induction by preoptic area neurons entail GABA-mediated inhibition of multiple arousal systems. Anatomical studies demonstrate direct projections from the VLPO and MnPN to all of the ascending monoaminergic arousal systems and to the orexin neuronal system. Particularly dense are the projections from the VLPO to histaminergic neurons in the tuberomammillary nucleus of the posterior hypothalamus (Fig. 1) [5]. The functional importance of this pathway is demonstrated by the ability of electrical stimulation of the VLPO to evoke GABA-mediated inhibitory postsynaptic potentials in histamine neurons. Activation of sleep-active neurons in the preoptic area by local thermal stimulation suppresses waking activity in serotonergic neurons in the dorsal raphe nucleus. Evidence also supports functional inhibition of orexin neurons by sleep-regulatory cells in the preoptic area. MnPN and VLPO neurons projecting to the orexin neuronal field in the lateral hypothalamus exhibit sleep-related c-Fos expression. Electrical or chemical activation of the MnPN evokes suppression of waking neuronal discharge in the lateral hypothalamus [4]. Collectively, findings support the hypothesis that deactivation of several functionally important arousal systems during sleep is due to GABA-mediated inhibition originating in the preoptic hypothalamus.

A mechanism that may help stabilize sleep-waking transitions arises from mutually inhibitory interactions between VLPO neurons and the monoaminergic arousal systems. VLPO neurons are inhibited by ►serotonin and noradrenalin. Thus, waking-related monoaminergic activity prevents inappropriate activation of VLPO sleep-generating cells during the active phase of an animal's day. At wake to sleep transitions during the rest phase, activation of VLPO neurons is reinforced by disinhibition as monoaminergic activity wanes. The mutual inhibitory interactions between sleep- and arousal-regulatory neurons function like a bi-stable switch (or flip-flop switch), and can help promote rapid and stable transitions between wakefulness and sleep [5].

GABAergic neurons in the preoptic area also participate in regulating homeostatic increases in sleep amount and sleep depth that occur as a consequence of sleep deprivation [4]. MnPN GABAergic neurons are progressively activated during a period of sleep deprivation, as sleep propensity (i.e., the tendency to fall asleep) increases. Activity of VLPO neurons is enhanced during recovery sleep following sleep deprivation.

## Endogenous Sleep Factors

Humoral theories of sleep generation have a long history, and are appealing because the cycling between waking and sleep seems consistent with the waxing and waning of an endogenous sleep-regulatory substance [1]. The search for, and characterization of endogenous sleep factors remains an active area of contemporary sleep neurobiology [6]. Most candidate sleep factors are implicated in a key feature of sleep regulation, namely the homeostatic control of sleep. A defining feature of sleep in mammals is that deprivation or restriction of sleep is followed by increased sleep drive (sleepiness) and, when sleep is permitted, rebound increases in sleep amount and sleep depth. There is evidence that putative sleep factors such as adenosine (see below) accumulate during sustained waking and dissipate during recovery sleep, thereby contributing to homeostatic aspects of sleep regulation.

A large body of evidence supports a role for adenosine as a sleep generating neurochemical [6,7]. Acting through the $A_1$ receptor, adenosine has inhibitory effects on multiple neuronal types in several brain regions. Adenosine is a by product of brain metabolism, and AD levels are elevated in response to intense brain activation (e.g., seizures) and as a consequence of sustained waking. Sleep deprivation is accompanied by elevated adenosine levels in the basal forebrain, followed by a decline in these levels during recovery sleep [7]. Administration of $A_1$ adenosine receptor agonists promotes sleep and enhances EEG slow-wave activity. The stimulant, caffeine, is an $A_1$ receptor antagonist. Collectively, these findings impli-

cate adenosine in homeostatic sleep regulation. Sleep generating effects of adenosine entail $A_1$ receptor mediated inhibition of arousal systems, including basal forebrain cholinergic neurons and orexin neurons in the lateral hypothalamus. Adenosine may activate sleep regulatory neurons in the VLPO as well, due to $A_1$ receptor mediated disinhibition and to excitatory actions mediated by $A_{2A}$ receptors.

While adenosine is arguably the most completely characterized putative sleep factor, other candidate substances are being actively investigated. Several cytokines, including, interleukin-1β and tumor necrosis factor-α, are sleep promoting and augment EEG slow-wave activity during sleep [6]. Antagonism of these cytokines can disrupt normal sleep and impair homeostatic responses to sleep deprivation. Cytokines are pivotal to the sleep enhancement that accompanies immune system activation and are implicated in normal sleep generation as well. Cellular mechanisms of cytokine-mediated sleep generation are not completely understood, but may involve a combination of arousal system inhibition and activation of preoptic sleep regulatory neurons. Additional candidate sleep factors include prostaglandin-$D_2$ and growth hormone releasing hormone [3,6].

### The Suprachiasmatic Nucleus and Sleep Generation

As Borbely articulated in his two-process model 25 years ago [8], the generation of sleep is under both circadian and homeostatic control. Homeostatic pressure for sleep increases in proportion to prior time awake, but the circadian system regulates the timing of sleep, such that it is largely confined to the species-appropriate time of day. The cellular and neurochemical details of how the mammalian suprachiasmatic nucleus (SCN) interacts with sleep generating mechanisms are far from completely understood. The SCN may regulate the timing of sleep primarily through modulation of activity in one or more arousal systems [9]. Ablation of the SCN in primates, while eliminating free running circadian rhythms in rest and activity, causes a significant increase in daily total sleep time, suggestive of an arousal deficit. The intact SCN has few direct efferent projections to hypothalamic or brainstem arousal systems. SCN modulation of arousal systems may involve neurohormones, since transplantation of SCN tissue can restore rest-activity rhythms in rats with SCN ablation. A multisynaptic pathway, involving the hypothalamic subparaventricular zone and the dorsomedial hypothalamic nucleus (DMH), links the SCN with the orexin arousal system [9]. The final link in this pathway is an excitatory glutamatergic projection from the DMH to the orexin neurons in the lateral hypothalamus [9]. SCN influences on sleep generation may also entail inhibition of preoptic area neurons. GABAergic projections from the DMH to the VLPO could covey inhibitory effects from the SCN [9]. Direct SCN to VLPO pathways may also play a functional role. A recent finding in a horizontal hypothalamic slice preparation, demonstrates that electrical or chemical activation of the SCN evokes inhibition in VLPO neurons [10]. Thus, SCN control of the timing of sleep generation may involve a combination of excitatory modulation of the arousal systems and inhibition of VLPO neurons.

### Synonyms

Homeostatic regulation of sleep need; Pressure; Intensity; Debt; Propensity, or duration; Process S; Sleep recovery process

### Definition

Homeostatic regulatory processes strive to maintain physiological variables constant or within an acceptable range thereby ensuring optimal functioning of the

organism. Sleep is thought of as a behavior that subserves a homeostatic process; a need or pressure for sleep accumulates during wakefulness and this need can only be alleviated efficiently during sleep. When sleep need exceeds optimal levels, such as occurs under conditions of sleep loss or sleep restriction, it negatively impacts cognitive performance and ultimately will lead to diminished health and well-being. The effects of sleep loss or sleep restriction can be countered by sleeping longer and/or by intensifying sleep. In particular, the observations that sleep time and/or intensity increase after sleep loss led to the notion that sleep is homeostatically regulated.

## Characteristics

The concept of homeostasis was first formulated by the French physiologist Claude Bernard (1813–1878). He stated that the constancy of the internal environment ("*le milieu intérieur*") is the condition for "a free and independent life." The term homeostasis itself was later coined by the American physiologist Walter Cannon (1871–1945). Homeostatic regulation has been extensively documented for, e.g., blood glucose levels and body temperature. The physiology behind sensing and evaluating these variables, as well as how effector mechanisms are activated and act to counter deviations from "set-point," is well understood. Its application to sleep-wake regulation is, however, problematic for several reasons: (i) When describing sleep phenomenology at least three main processes have to be considered that all interact and of which the respective contributions sleep are difficult to separate in normal, daily life conditions. Thus a ►circadian process interacts with the homeostatic process enabling us to stay awake and alert throughout the day and to remain asleep through the night. A third regulatory process underlies the more or less rhythmic alternation between the two main sleep states [i.e., ►rapid-eye-movement (REM) sleep and ►non-REM (NREM) sleep] also known as the NREM-REM sleep cycle. (ii) Both sleep states can be said to be homeostatically regulated since deprivation of sleep leads to increases in the duration of both. However, the regulation of the duration of NREM sleep differs from that from of REM sleep. Furthermore, different aspects of one state, such as the duration and intensity of NREM sleep, are regulated differently. (iii) The regulated variable and the neuro-physiological function of sleep remain elusive which makes it difficult to study the homeostatic control circuitry of sleep. Consequently, most concepts of the homeostatic regulation of sleep have been based on behavioral and EEG studies. The search for the neuro-chemical, neuro-anatomical, and molecular-genetic substrates of sleep homeostasis is the focus of intense research in various organisms. Homeostatic regulation of sleep also has been observed in invertebrates. The fruit fly, in particular, provides a powerful model system to dissect the molecular-genetic underpinnings of sleep function.

## The Homeostatic Regulation of NREM Sleep

In mammals, the homeostatic regulation of NREM sleep has been extensively studied and consists of changes in both duration and intensity. One widely used measure of NREM sleep intensity or depth that can be extracted from the electroencephalogram (EEG) is power in the delta frequency range (1–4 Hz). This measure is referred to as ►slow-wave activity (SWA) or ►EEG delta power and quantifies the prevalence and amplitude of slow waves that are characteristic of the NREM sleep EEG. When EEG slow waves are prevalent and SWA is high, arousal thresholds also are high (i.e., it is more difficult to awaken a subject) and sleep is more consolidated (i.e., less brief awakenings). SWA in NREM sleep typically declines over the course of the daily sleep period, increases as waking proceeds and is reduced after excess sleep. These changes in SWA are highly reliable and predictable and can be closely approximated through mathematical simulations. Because of this, much attention has been focused on this aspect of sleep and often the homeostatic regulation of sleep is equated with the sleep-wake dependent changes in SWA. These changes in SWA played a central role in the conceptualization of Alexander Borbély's ►two-process model of sleep regulation [1]. In this influential model a homeostatic process, "►Process S," reflected by SWA, in interaction with a circadian process, "►Process C," regulates the timing and intensity of NREM sleep. Many aspects of sleep regulation can be understood in the context of this model. Among those are the recovery from sleep deprivation, the dependence of sleep duration on circadian phase, sleep during shift work, sleep fragmentation during continuous bed rest, and ►internal desynchronization in the absence of time cues. That SWA can be used to index sleep need has been demonstrated in most, if not all mammalian species investigated to date.

Initially, the state of Process S was monitored only during NREM sleep by quantifying SWA. This measure is interpreted and used to index sleep need. In addition, it is thought that changes in SWA determine the efficiency with which sleep need is recovered during the sleep period. The initial part of the night during which NREM sleep SWA is high and rapidly declines, is therefore considered especially recuperative in terms of reducing the need for sleep. Suppressing EEG slow waves during this part of the night by presenting

acoustic stimuli (that did not awaken the subjects) led to a intra-night SWA rebound in the second, undisturbed half of the night indicating that the recovery process can be delayed and that the expression of EEG slow waves are functionally relevant. Meanwhile, EEG measures reflecting changes in sleep need have also been identified in the waking EEG.

Also the duration of NREM sleep is considered to be homeostatically regulated because increases in time spent in this state are observed after sleep deprivation (provided the experimental protocol allows for sleep extension). These "►rebounds" in NREM sleep duration are, however, usually less precise, depend on circadian phase at which sleep occurs, make up only a fraction of NREM sleep time lost, and can take place over a longer time span as compared to the immediate and highly predictable changes in SWA. Nevertheless, even small increases in NREM sleep duration can importantly affect SWA which poses the question of which aspect of sleep is homeostatically defended. Results of a sleep deprivation study in rats illustrate this issue. Twenty-four hours without sleep resulted in the expected and immediate increase in SWA that quickly subsided over the first 4 h of the recovery period. The duration of NREM sleep was also increased but this increase lasted for most of the 48 h for which recovery was monitored. As a result of the increase in NREM sleep time, SWA fell to values below those reached under baseline conditions (i.e., "►negative rebound"). Although both the positive and negative rebound in SWA in this study could be explained based on the altered sleep-wake distribution, the following question presents itself: If SWA indeed reflects sleep need then why should animals continue to sleep more (compared to baseline) when SWA is below baseline? The issue of the homeostatic regulation of NREM sleep time versus NREM intensity (i.e., SWA) is also relevant in the context of development; rats younger than 24-days old seem not yet able to compensate for sleep time lost by intensifying sleep and, in contrast to older rats, they compensate almost all of the sleep lost by sleeping more.

## The Homeostatic Regulation of REM Sleep

Although EEG measures indicative of REMS intensity have been proposed, losses in REM sleep seem to be primarily compensated by increases in REM sleep time as has been observed after selective REM sleep deprivation or total sleep deprivation in a variety of mammalian species. In particular, several studies in rats, cats, and mice indicate that the REMS increase during recovery from REM sleep deprivation, varying in length from 1 to 24 h, is proportional to the loss incurred by that deprivation (for references see [2]). This suggests that the daily amount of REM sleep is accurately regulated in these species. Strong evidence for a homeostatic regulation of REM sleep in humans is less well established as usually only small and/or delayed rebounds have been reported. Based, in part, on these discrepancies among species, James Horne argued that REM sleep is a "default" state and as such its duration is not homeostatically regulated [3]. On the other hand, based on data obtained in rats, Allan Rechtschaffen went so far as to suggest that REM sleep is the only sleep state that is homeostatically defended [4].

## The NREM-REM Sleep Cycle

Because both NREM and REM sleep seem homeostatically regulated, because their regulation differs, and because these two states greatly differ in many electro-physiological and neuro-chemical aspects, it is plausible to assume that they fulfill specific functions. During a sleep episode both NREM and REM sleep needs have to be fulfilled, an assumption supported by the observation that the two behaviors seem to compete for expression; i.e., a selective high pressure for one sleep state has repercussions for the expression of the other (reviewed in [2]). The alternation between NREM and REM sleep, i.e. the NREM–REMS cycle, can thus be viewed as a way "the system" ensures that the need for both behaviors is addressed efficiently within the circadian time frame allotted for sleep. The process underlying the more or less regular NREM–REMS alternation during sleep is thought to be a sleep-dependent oscillator; or, in other words, a homeostatic need to express REM sleep increases as a function of time spent in NREM sleep. Evidence for such need is based on the observation that the number of attempts to enter REM sleep increase as a function of the time-spent-asleep without REM sleep.

### *Homeostatic versus Circadian Processes*

Apart from the homeostatic process ("Process S") that is activated by and counters the effects of sleep loss, an equally important, circadian process ("Process C") determines the time-of-day sleep preferably occurs. Their interaction is described in the two-process model [1] and the fine-tuned, opposing influence between the two enables us to stay awake and alert throughout the day and to remain asleep at night [5]. Despite this close interrelationship it is widely believed that the two processes operate independently. This notion is based on observations in animals that lost circadian rhythmicity, sleep deprivation still elicits an intact homeostatic response in sleep time and intensity. Moreover, in humans it has been demonstrated that the daily, sleep–wake dependent variation in SWA is little affected by

circadian factors. More recent observations challenge this notion and suggest a direct cross-talk between the two regulatory systems. Thus, sleep deprivation was found to affect the phase of circadian rhythms and high levels of SWA seem to suppress neuronal activity in the ►supra-chiasmatic nucleus (►SCN), the hypothalamic structure that contains the circadian pacemaker. Finally, animals that lack circadian rhythms through genetic lesioning (i.e., "knock-outs") of one or more core circadian clock genes, also have altered sleep homeostasis (reviewed in [6]).

### Functional Considerations

After having established that sleep is homeostatically regulated the next obvious question to ask is what is being regulated or what function does sleep subserve. Given the complexity of sleep and its regulation it is likely that sleep fulfills more than one function. Several functions have been proposed over the years. Most have in common that sleep fulfills a function specifically benefiting the brain (*"Sleep is of the brain, by the brain, and for the brain!"*). This assertion is based on a variety of observations. Prominent among those are the facts that brain electrical and metabolic activity dramatically differs between NREM sleep and wakefulness, that falling asleep is associated with a loss of consciousness, that loss of sleep affects first and foremost cognitive performance, vigilance, and alertness, and that the variable that most reliably indexes the time-spent-awake and -asleep (i.e., SWA) is of cortical and thalamo-cortical origin.

The analysis of SWA reveals that sleep need is a local and use-dependent process [7,8]. SWA exhibits a frontal predominance both under baseline conditions, as well as after sleep deprivation. Local changes in SWA can be induced by engaging volunteers in tasks that activate specific brain areas. Thus vibration of one hand, which stimulates the somato-sensory cortex during wakefulness, leads to an increase in SWA in the contra-lateral sensorimotor cortex. Similarly, in rodents, regional activation of the barrel-cortex by unilateral whisker stimulation is followed by an increase of SWA in the stimulated cortex, specifically. Perhaps the most striking example of SWA's local and use-dependent aspects has been observed in the bottlenose dolphin. This mammal displays unilateral slow-wave sleep (NREM sleep with high SWA) and depriving one hemisphere of slow-wave sleep resulted in an increase in SWA in that hemisphere only. An extension of the use-dependent regulation of SWA is the association between local increases in SWA and the consolidation of particular forms of memory. The highly predictive sleep-wake dependent changes in SWA as observed in the EEG and its local and use-dependent nature gave rise to the notion that slow waves are closely linked to a recovery process that occur during NREM sleep and that this recovery is linked to the neuronal activation during wakefulness.

Neuronal activation during wakefulness is associated with synaptic rearrangement or strengthening at the level of individual neurons and/or at the level of brain micro-circuitry [7,8]. Extended periods of wakefulness would result in levels of synaptic weight that cannot be sustained or allow for further plastic events. The regular hyperpolarizing-depolarizing membrane potentials that underlie slow waves and/or associated changes in growth factors may reverse the detrimental effects of wakefulness on synaptic weight and brain micro-circuitry. Through such mechanisms SWA could restore performance and plasticity for the subsequent wake episode. Such detailed account on the hypothetical restorative function of SWA are still lacking for the other homeostatically regulated aspects (i.e., duration of NREM sleep and of REM sleep).

### Molecular and Genetic Correlates

SWA and its regulation by the duration of wakefulness are under genetic control. The dynamics of the sleep homeostatic process in mice were found to differ with genetic background and a QTL (Quantitative-Trait Locus) region on chromosome 13 was identified that could explain 50% of the variance in this trait between two inbred strains of mice (reviewed in [9]). In humans, a polymorphism in the circadian ►clock gene *Period-3* has been show to affect SWA and waking performance. Previously, studies in mice had demonstrated that the clock genes ►*Cryptochrome-1* and *-2*, ►*Bmal1*, ►*Clock*, and *Npas2* affect expression and regulation of SWA and NREM sleep (reviewed in [6]). The involvement of genes that play a key role in the generation of circadian rhythms in the regulation on SWA and NREM sleep seems at odds with the notion that the sleep homeostatic process and the circadian timing system are considered separate processes (see above). These results also demonstrate that genetic factors contribute to the considerable individual differences observed in the expression and regulation of SWA.

With the development of the techniques that allow for high-throughput assessment of gene expression; i.e., "microarrays," (►microarray, DNA Chip) genome-wide expression profiling has been performed to investigate which genes change their expression with time-spent-awake or -asleep. Instead of focusing on individual genes such approach allows for the identification of pathways that are activated with sleep loss. Stress-induced transcripts such as heat-shock proteins, genes encoding molecules involved in synaptic plasticity, and, more general, genes coding for enzymes involved in biosynthesis were found to change expression with sleep and waking in the few available studies. Progress on high-throughput techniques to investigate changes in proteins levels is being made

and preliminary studies using these techniques in sleep research have been published (see [9] for review).

## Sleep Inertia

### Definition

Interval of reduced alertness, cognitive performance impairment, grogginess, and tendency to return to sleep, which occurs immediately after awakening. The impairment from sleep inertia is normally mild and short-lived (less than half an hour), and is believed to be affected by the structure of the prior sleep period (non-REM sleep and rapid eye movement (REM) sleep amounts), the sleep stage from which awakening occurs, and the timing of the awakening relative to the circadian cycle. The magnitude and duration of sleep inertia are enhanced by prior sleep loss, such that the effect may become as substantial as the cognitive impairment normally seen after a night of total sleep deprivation and may take up to 2 h to dissipate.

## Sleep Movement Disorders

►Sleep – Motor Changes

## Sleep-onset Mechanisms

►Sleep Generating Mechanisms

## Sleep-onset REM Period

### Definition

Abnormally rapid transition from wakefulness to REM sleep, skipping the period of non-REM sleep that normally characterizes the beginning of the sleep period. Sleep-onset REM periods (SOREMs) are a symptom of narcolepsy and as such can be considered in the diagnosis of this disorder.

## Sleep Paralysis

### Definition

Sleep Paralysis is an inability to move occurring either at sleep onset or upon awakening from sleep. Episodes last a few minutes and are usually accompanied by intense feelings of fear and/or anxiety. Isolated sleep paralysis can occur in up to 25% of healthy, normal individuals and may be precipitated by sleep deprivation. Sleep paralysis is more commonly found in patients with narcolepsy.

# Sleep Phylogeny

Jerome M. Siegel
Center for Sleep Research 151A3, Department of Psychiatry, UCLA School of Medicine, Veterans Administration Greater Los Angeles Health Care System, North Hills, CA, USA

## Definition

►Sleep phylogeny refers to the variation in the nature and amount of sleep across species.

## Characteristics

A primary motivation for the study of sleep in various animals is to gain some insight into the function(s) of sleep. What aspects of sleep, if any, are present in all mammals? What aspects of sleep differ between animals? Why are there two kinds of sleep, ►REM sleep and ►nonREM sleep?

The amount and nature of sleep are correlated with age, body size and ecological variables, including life in the terrestrial vs. aquatic environment, diet and the safety of the sleeping site. The sleep phylogeny literature suggests that sleep reduces activity to the amount needed for feeding and species reproduction, and maximizes energy conservation, thereby furthering genetic survival. Theories of REM sleep function have suggested that in addition to these functions, this state may have a role in periodic brain activation during sleep, in localized brain and body recuperative processes and in emotional regulation.

### Sleep Studies in Terrestrial Mammals

Daily sleep amounts vary substantially throughout the mammalian class. Some animals, such as bats and opossums, sleep for 18–20 h/day, whereas others, such as the elephant and giraffe, sleep as little as 3–4 h/day. One might expect that species in each mammalian order would have a similar pattern of sleep because of their defining genetic, behavioral, and anatomical similarities. However, this is not the case. Primates as a group (or carnivores as a group, or rodents as a group) do not have a characteristic sleep duration. Sleep time in these various orders overlaps extensively and any "order related" contribution to sleep duration must be small relative to other factors [1]. Human sleep does not appear to be quantitatively unique in its duration or in the proportion or absolute amount of REM sleep.

Daily sleep amounts are highest in carnivores, lower in omnivores, and lowest in herbivores. Sleep time is inversely correlated with body mass in herbivores. This correlation is responsible for a significant overall correlation between body mass and sleep time over all mammals studied to date [1].

Most studies of mammalian sleep have been performed on placental (eutherian) or marsupial mammals. The third subclass of mammals is the monotremes, found in Australia and New Guinea. These egg-laying mammals have more genetic and physiological similarities to reptiles and birds than do other mammals and are thought to have more characteristics of the common mammalian ancestor. Both the echidna and platypus show evidence of ►brainstem activation during sleep, with the platypus displaying intense rapid eye, limb, and bill movements periodically during sleep. However, the low voltage neocortical EEG typically seen in placental and marsupial mammals during REM sleep is not consistently present during sleep in either the echidna or platypus during these motor activities. Instead the neocortical EEG may resemble that of nonREM sleep [2,3]. Thus, these "primitive" mammals appear to have a form of REM sleep largely localized to the brainstem.

### Sleep in Marine Mammals

All terrestrial mammals show relatively high voltage low frequency (slow) neocortical electrical brain waves (EEG) bilaterally during the behavioral state that is recognized as nonREM sleep. In contrast, cetaceans (whales and dolphins) almost never have high voltage slow waves in both hemispheres at the same time. The eye contralateral to the hemisphere with slow waves is almost always closed while the other eye is almost always open. There have been no published reports documenting REM sleep in cetaceans, making them the only studied mammals in which this state has not been observed.

The bottlenose dolphin (*Tursiops truncatus*), when not floating or resting on the bottom, generally swims in a single direction (usually counterclockwise) even as the brain hemisphere with slow waves alternates. Some smaller cetacean species are rarely, if ever, immobile, moving and avoiding obstacles 24 h a day from birth until death, even during unihemispheric slow wave activity; these animals may never exhibit the immobility that is used in terrestrial mammals to define the state of sleep [4].

### Postpartum Sleep Behavior in Cetaceans

Further evidence for the unique properties of "sleep" in cetaceans are the phenomena of a near absence of sleep behavior in neonates and a postpartum reduction of sleep behavior in their mothers [5]. All studied terrestrial mammals have shown minimal activity and maximal total sleep and REM sleep amounts at birth, with sleep gradually decreasing and activity gradually increasing to adult levels as the animals grow to maturity. This is not the pattern in cetaceans. Killer whales (*Orcinus orca*) and dolphins have minimal amounts of sleep behavior (i.e., immobility or eye

closure) at birth, with sleep behavior slowly increasing to adult levels over a period of months. This minimal amount of sleep behavior occurs during the period of most rapid growth of body and brain for the newborn, during a period of bonding to the mother and learning how to nurse, find food, avoid predators, and swim efficiently. The continuous activity of cetaceans has adaptive value in allowing the neonate, which is much less insulated by body fat than the adults, to thermoregulate in cold ocean water. The suppression of sleep behavior also allows the neonate to swim with and be protected by its mother during development. As the animal gains mass and blubber and approaches adult size, adult-like "sleep" or rest behavior, including periods of immobility, emerges. Both mother and calf go without substantial amounts of immobility and without substantial amounts of the eye closure linked to unihemispheric slow waves during the postpartum period. Keeping rats awake for comparable periods is lethal. Neither cetacean mother nor calf show any rebound increase in the amount of sleep behavior following this period.

## Neocortical Activity and Sleep

Although neocortical EEG changes are the most easily observed electrical correlate of nonREM sleep, as they are recordable from scalp electrodes in humans and from electrodes placed on the surface of the cortex in other animals, sleep produces large changes in the rates and patterns of neuronal activity in nearly all brain regions. Cortical EEG phenomena are controlled by and reflect activity in thalamic, hypothalamic and brainstem reticular regions. The cellular activity changes underlying the changes in neocortical EEG include calcium fluxes into and hyperpolarization of neocortical and thalamic neurons that are synchronized in large populations, producing high voltage brain waves. But neocortical size does not correlate positively with sleep amount. Both total brain weight and encephalization correlate poorly and negatively with total nonREM and REM sleep amounts [1]. The elephant, which has the largest neocortex of any terrestrial mammal, has one of the smallest sleep amounts. Conversely, the rat and the platypus, which have smooth cortices with small total neocortical volumes, have extremely large amounts of nonREM and REM sleep, with the platypus having more REM sleep than any other animal studied to date [3].

Although neocortical size does not appear to be a major determinant of either nonREM or REM sleep amounts, recent work has indicated that neocortical activity during sleep may be altered by prior waking activity. Some such changes dissipate with continued ►waking, suggesting that localized recuperative processes may occur during either waking or sleep in systems projecting to, or within, the neocortex.

Sleep may be adaptive because it conserves energy and suppresses behavior across portions of the ►circadian cycle, just as ►hibernation does across certain seasons. Large herbivores may have evolved reduced sleep amounts because they are more vulnerable to predators than small herbivores. A second hypothesis is that these grazing animals may need to spend more time awake in order to eat, because of the low caloric density of their food. A complementary hypothesis is that small herbivores and other mammals may need to maximize sleep amounts in order to conserve energy, because their relatively high surface area to body mass ratio makes it costly to maintain their body temperature, but retreating to a warm, protected nest may minimize this cost. A striking feature of sleep in animals with small daily sleep amounts, such as many herbivores, is that sleep depth, as judged by EEG and sensory response threshold, appears to be less than that in animals requiring more sleep; i.e., animals with reduced sleep amounts do not appear to "make up" for reduced sleep by sleeping more "deeply."

Energy conservation may be particularly important in newborns. Their high surface area to body mass ratio and need for rapid growth makes the energy conservation achieved by sleep highly adaptive. Furthermore, animals that are immature at birth benefit from the sleep-induced reduction in exposure to danger. When body size increases and sensory-motor systems mature, young animals derive greater benefits from waking activities and can begin to defend themselves, consistent with the developmental decrease in sleep time.

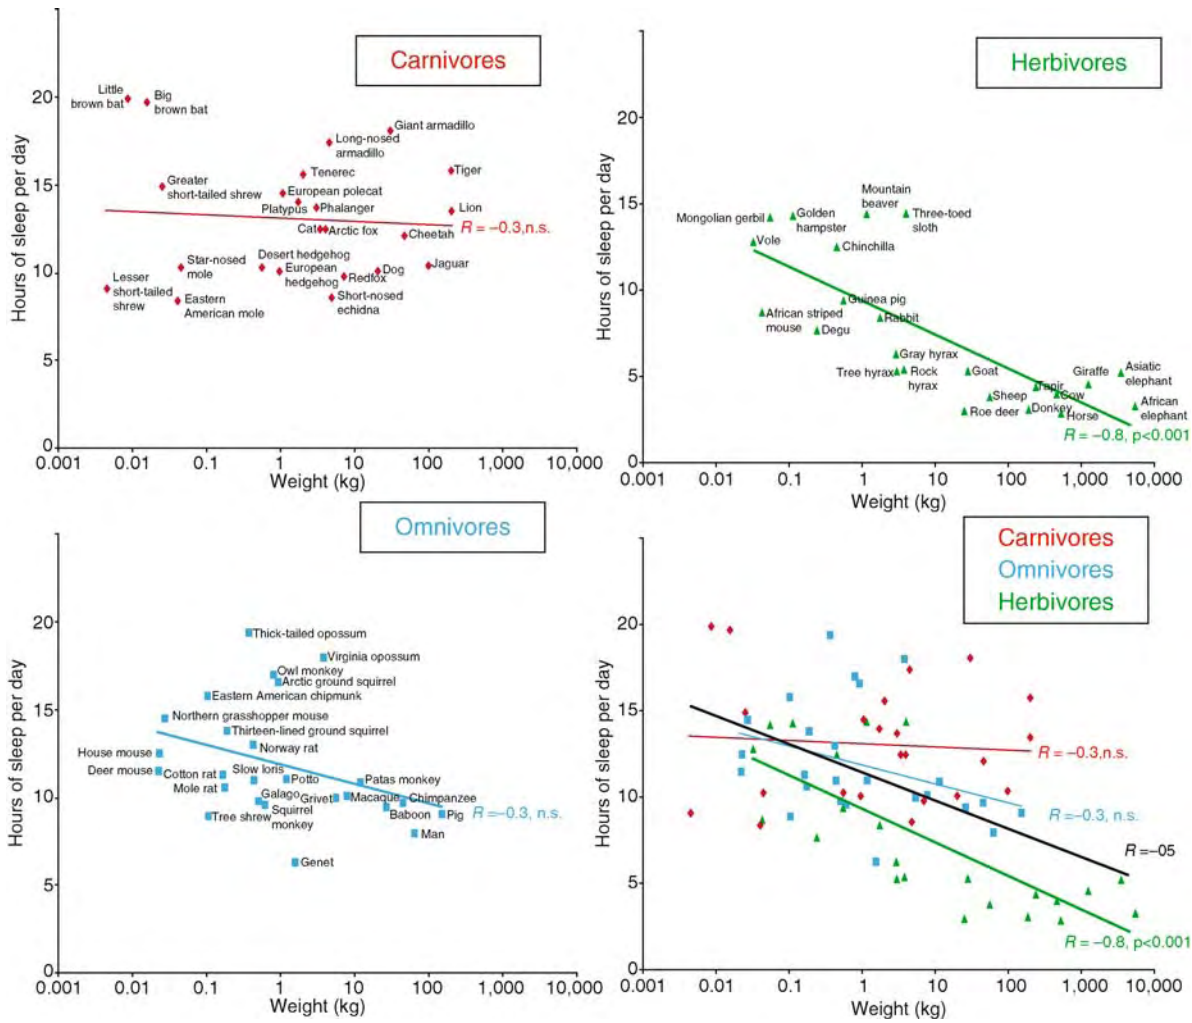
## Body Mass, Metabolism and Sleep Control

One of the best established relations in mammalian biology is the inverse relationship between body mass and mass specific metabolic rate. Small animals have high metabolic rates per gram of weight; large animals have low metabolic rates. Brain metabolic rate is correlated with body metabolic rate. Elevated metabolism is linked to a number of biochemical changes, several of which have been linked to sleep control.

Sleep time may be related to defense against oxidative stress. A high metabolic rate results in the generation of high levels of reactive oxygen species (ROS) by mitochondria. This ROS generation has been linked to normal aging. Sleep deprivation in the rat is accompanied by indications of increased oxidative stress and evidence of membrane disruption in the hippocampus, subcortical brain regions and peripheral tissues [6–8]. There appear to be no such changes in the neocortex [7,9]. Higher brain metabolic rates may require longer periods of sleep to interrupt ROS induced damage to brain cells, facilitate the synthesis and activities of molecules that protect brain cells from oxidative stress, allow sufficient time for the repair or replacement of essential cellular components in neurons and glia, and deal with other biochemical consequences of ►waking metabolic activity.

One may hypothesize that the "ratio" of the energy conservation benefit of sleep to the waking metabolic activity-derived need for sleep for brain recuperation varies across species. Carnivores and omnivores, which tend to have more sleep than predicted on the basis of body mass, may make more use of the energy conservation aspects of sleep; their generally safe sleep places and their ability to eat meals with high caloric density may make continuous activity unnecessary. In such a situation, genetic fitness might best be served by energy conservation, which would reduce the need for hunting, aid nurturing of the young, speed development and generally aid in reproductive success.

Protein synthesis in the brain is increased during ►slow wave sleep. New neurons are generated in adult animals in the olfactory bulb, the subventricular zone lining the lateral ventricles, and in the subgranular cell layer of the dentate gyrus of the hippocampus, in a process that produces functional neurons in 3–4 weeks. It has been shown that this neurogenesis is facilitated by exercise and blocked by stress. Short term (2–3 day) total sleep deprivation, even done when controlling for other forms of stress, also blocks subsequent neurogenesis in the dentate gyrus [10]. Thus, sleep may have a general role in allowing or facilitating neurogenesis.



**Sleep Phylogeny. Figure 1** Sleep time in mammals: Carnivores are in *red*, herbivores in *green* and omnivores in *blue*. Sleep times in carnivores, omnivores and herbivores significantly differ ($p < 0.0002$, $F$ test, df 2, 68), with carnivore sleep amounts significantly greater than those of herbivores ($p < 0.001$, $t$ test, df 24, 22). Sleep amount is an inverse function of body mass over all terrestrial mammals (*black line*). This function accounts for approximately 25% of the interspecies variance in reported sleep amounts (Regression of log weight against sleep amount, $R = -0.5$, $p < 0.0001$, $N = 71$). Herbivores are responsible for this relation, since body mass and sleep time were significantly and inversely correlated in herbivores ($R = -0.77$, $p < 0.001$, df 24), but were not in carnivores ($R = -0.28$, df 24) or omnivores ($R = -0.25$, df 25).

### REM Sleep

REM sleep amount is positively correlated with total sleep amount and negatively correlated with body weight. However, if one statistically controls for body weight or brain weight, REM sleep amount is most strongly correlated with immaturity at birth [1]. Altricial animals, those that are immature at birth, tend to have more REM sleep than animals that are mature at birth, or precocial. This tendency is marked in the neonatal period. But perhaps more remarkable is that altricial mammals continue to have more REM sleep as adults. The platypus has 8 h of REM sleep per day as an adult. The platypus neonate cannot thermoregulate, locomote, acquire food or defend itself at birth, and lives attached to its mother. The ferret, likewise, is immature at birth and the adult has over 6 h of REM sleep per day. In contrast, the guinea pig has only 1 h of REM sleep per day as an adult. The guinea pig is born with teeth, claws, fur and eyes open; it thermoregulates at birth, locomotes within an hour of birth and eats solid food within a day of birth. Similarly, the sheep and giraffe are relatively mature at birth and have little REM sleep (less than one h/day) at maturity [1]. The extremely high levels of REM sleep seen at birth, followed by a slow decrease to adult levels in altricial terrestrial animals, must be an important clue to its function. This time course, combined with the observation that neuronal activity levels are high in REM sleep, led to the hypothesis that this sleep state is involved in the development of the brain.

Dolphins, which can be continuously mobile while having unihemispheric slow waves must have continuous brainstem activity to control this movement, since the brainstem is the final path for motor control. This contrasts with the situation in land mammals, all of which have bilateral slow waves and immobility during sleep and greatly reduced brainstem activity. The absence or reduction of REM sleep in marine mammals displaying unihemispheric slow waves supports the hypothesis that the stimulation of brainstem activating systems is an important function of REM sleep. Similarly, the manifestation of REM sleep in monotremes as a largely brainstem state, without marked neocortical activation, suggests that REM sleep may have evolved as a state of brainstem activation, with cortical stimulation functions added later in evolution. The cold-induced increase in REM-sleep amount in the isolated brainstem, the increased REM-sleep amount at the minimum of the circadian brain, and body temperature cycles and the increase in the temperatures of brain regions during REM sleep are consistent with this brainstem activation hypothesis.

### Concluding Paragraph

The nature and duration of sleep are important factors in determining genetic fitness. In sleep, animals realize benefits from reducing energy expenditure, confining behaviors to periods when it is most efficient to find food, avoiding predators and tending to their young. The expression of sleep varies across animals with some being able to sleep deeply and for long durations and others who cannot sleep in safe places evolving to be somewhat responsive for 24 h aday (Fig. 1). Several species are able to greatly reduce sleep time during the postpartum period and during long migrations. Sleep is best viewed as an adaptive state, furthering survival. REM sleep appears to have originated as a brainstem state providing periodic activation of this vital region. In most placental mammals this activation also includes forebrain regions, with increased brain metabolism and neuronal activity. It has been suggested that REM sleep helps maintain neural function during sleep and prepares the brain for rapid awakening [11].

## Sleep Rebound

### Definition

Sleep rebound is a term used to describe the increase of a sleep variable above normal (or baseline) levels after a period of sleep restriction or deprivation. Rebounds have been observed for many aspects of sleep (e.g.

electroencephalographic (EEG) delta power, non-rapid eye movement (NREM) and rapid eye movement (REM) sleep duration) and are interpreted as an effort to compensate for the incurred loss of sleep and as proof that sleep is homeostatically regulated. Such initial (positive) rebounds can be followed by subsequent negative rebounds when variables reach below-baseline levels as has been documented for EEG delta power.

►Sleep Generating Mechanisms

## Sleep Spindles

### Definition

Sleep-related electroencephalographic (EEG) events characterized by 1–2 s burst of nearly sinusoidal 12–15 Hz activity. There is a waxing and waning of amplitude across the duration of the event, giving it a characteristic "spindle" shape. During transitions from waking to stable sleep, sleep spindles are among the first EEG events to appear that exhibit high intra- and inter-hemispheric coherence. Sleep spindles are a defining feature of Stage 2 nonREM sleep in humans.

### Synonyms

Vigilance states; Arousal states

### Definition

Sleep states refer to distinct constellations of physiological, behavioral and neurological variables that alternate with wakefulness and are periodically expressed during the 24-h day. The primary defining features of sleep across the animal kingdom include (i) an increase in arousal thresholds; (ii) stereotyped behaviors (e.g., sleep postures, sustained quiescence, avoidance of sensory stimulation); and (iii) homeostatic regulation. Subsidiary features of sleep that are found in some species include (i) changes in autonomic/endocrine function; (ii) alterations in brain rhythms; and (iii) strong circadian regulation [1,2].

### Characteristics

Sleep is one of several core behaviors that, like feeding, drinking and reproduction appears to be ubiquitous among higher organisms. It is considered an appetitive behavior vital for life because a need for sleep accumulates in its absence, and prolonged sleep loss is fatal in vertebrate and invertebrate species [3]. In placental mammals and birds, sleep is divided into two principal states of non-rapid-eye-movement (non-REM) and REM (or "►paradoxical") ►sleep. ►REM sleep, however, is not typically observed in reptiles and amphibians or invertebrates which instead display a single sleep state that behaviorally resembles mammalian ►non-REM sleep [1,2]. In most species, sleep is regulated by distinct homeostatic and circadian mechanisms. The homeostat governs the accumulation and compensatory discharge of sleep need; a process commonly detected by increases in sleep time and intensity following extended wakefulness. In contrast, the biological clock provides signals that offset the accumulation of sleep need and influences sleep onset and arousal [4].

### Human Sleep

The mammalian states of non-REM and REM sleep can be further divided into sub-stages that are entered and exited in an orderly fashion across the major rest (or inactive) phase. In humans, sleep is entered through non-REM sleep which progresses from "light" to "deep" stages. Each stage is accompanied by a rise in arousal thresholds and characteristic changes in brain

rhythms that reflect increasing levels of neuronal hyperpolarization [5]. These include thalamocortical spindles, a slow neocortical wave, and delta waves. Non-REM sleep is also accompanied by a slowing of respiration and heart rate, a drop in core temperature and a peak in growth hormone secretion [3–5]. The descent into stage 4 sleep is followed by periodic ascents into REM sleep. REM sleep is characterized by several peculiar neurological and physiological changes including paralysis of skeletal muscles, REMs, a "waking"-like electroencephalogram (EEG), suppression of monoaminergic neurotransmission and irregular patterns of respiration and heart rate. REM sleep is sometimes further divided into sub-stages which refer to periods with or without phasic events (e.g. REMs). In healthy humans, approximately 4–5 NREM-REM cycles occur during the night [5].

## Phylogenic Studies of Sleep States

The basic properties of sleep observed in humans are also observed in placental and marsupial mammals and birds [1,2]. There are however, important differences as the amounts of total sleep and/or REM sleep vary among different species and the distinct sub-stages of sleep typical of humans are not always observed. In addition, endocrine changes observed in humans are not always detected in other mammals and REM sleep is accompanied by certain types of brain activity (e.g., hippocampal theta rhythms and pontine-geniculate-occipital waves) that may not occur in humans [1,2]. Birds are also quite peculiar in that REM sleep amounts represent a much smaller fraction of total sleep time in comparison to mammals [1].

Sleep has also been studied in several non-mammalian vertebrates, including lizards, snakes, crocodiles, turtles, frogs and salamanders [1,2]. In these species, a state that exhibits the primary features of sleep has been observed, but no convincing signs of REM sleep have been reported. Moreover, the brain rhythms typical of mammalian sleep are absent and instead sleep is accompanied by bursts of neuronal activity that appear as a train of unitary spikes in the EEG. In other cases a slow oscillation is occasionally observed that bears some resemblance to the mammalian slow wave. Similar phenomena are reported during sleep in terrestrial invertebrates (insects and arachnids) [2,6]. Overall, however, neurophysiological changes in sleep in these species are not as distinct as those reported in mammals and birds. This may reflect the fact that these species lack the neurological structures necessary for the generation of mammalian brain rhythms.

## Ontogenetic Studies of Sleep States

There are dramatic changes in sleep expression and regulation across the lifespan [7]. These can be summarized as follows. First, recordings of EEG and autonomic activities in very young, developing mammals do not reveal clear signs of REM and non-REM sleep, reflecting the extreme immaturity of the nervous system. Second, once sleep emerges its amounts are very high and then decline with subsequent development. In mammals, these changes are predominantly due to an initial abundance of REM sleep, which is progressively replaced by non-REM sleep. Sleep amounts eventually stabilize by early adult-hood at which time REM sleep and "deep" non-REM sleep begin to slowly decline, reaching their nadir in senescence [5]. A similar pattern has been reported in fruit flies, where newly hatched flies have much more sleep than adult flies [6]. Third, circadian regulation and homeostatic regulation are quite different in early life. Infant animals do not respond to sleep loss as adults do and circadian rhythms are absent until a certain stage of development [7].

## Sleep State Mechanisms

Non-REM and REM sleep are generated by distinct neural circuits and brain regions. Although the precise mechanisms have not been completely determined, there is consensus that non-REM sleep is generated by hypothalamic and forebrain regions whereas REM sleep is chiefly controlled by brainstem circuits [8]. The forebrain contains populations of neurons that secrete the inhibitory neurotransmitter GABA onto other neurons important in maintaining arousal. The hypothalamus contains several nuclei (e.g. the ►VLPO) that induce sleep when stimulated or in some cases, when warmed (i.e., are temperature sensitive) [9]. These nuclei secrete the inhibitory neuropeptide Galinin onto posterior hypothalamic structures also important in arousal [10]. Within the brainstem are regions that when stimulated produce REM sleep in its entirety, or separate components of REM sleep. These regions include cholinoceptive neurons and glutamatergic and GABAergic circuits. Stable state expression appears to be controlled by the peptide hypocretin/►orexin because in its absence the normal alternation of sleep and wakefulness is highly disturbed (e.g., in ►narcolepsy) [9,10].

Sleep-wake modulation of visceral function

## Definition

Across the ►sleep-wake cycle, functions of the viscera (internal organs) are modulated together with those of the soma (body) in an integral manner. Visceral functions (involving smooth muscles of blood vessels, bronchi, gastrointestinal tract and glands) are generally regulated in an automatic or involuntary manner by the autonomic nervous system. In contrast, somatic functions (involving the skeletal muscles) can be controlled in a voluntary manner through input from the brain to the somatic motor neurons. The autonomic nervous system serves to maintain ►homeostasis (constant state) of the internal milieu, including blood pressure, $O_2/CO_2$ concentrations, osmolarity and sugar, while responding to metabolic needs for energy within the organism. In this process, it regulates the cardiovascular, respiratory, endocrine and digestive systems. These in turn also allow the maintenance of a relatively constant body temperature and associated basal metabolism in mammals and birds. The autonomic nervous system controls these systems through its two reciprocally functioning components: the sympathetic and the parasympathetic. Generally, the sympathetic system supports action of the somatic system by catabolism and mobilization of energy stores to increase energy supply to the skeletal muscles for movement. In contrast, the parasympathetic system functions during rest of the somatic system and is responsible for anabolism and restoration of energy stores. Across sleep-wake states, the sympathetic and parasympathetic systems assume different levels of control and activity such that sleep-wake cycles, as well as their ►circadian organization, permit periods of maximal action during wake and periods of maximal rest during sleep for long term homeostasis of the organism.

There are three distinct states in mammals and birds: ►wake (W), ►slow wave sleep (SWS) and ►paradoxical sleep (PS) or ►rapid eye movement sleep (REMS). Through these states, homeostasis is maintained within an appropriate range of physiological parameters by afferent feedback from receptors and efferent adjustments through the sympathetic or parasympathetic systems. During W, autonomic regulation depends upon behavior, foraging, fighting, fleeing, breeding or eating and resting. During SWS, it is predominated by the parasympathetic division which supports rest and restoration. During PS or REMS, despite continued parasympathetic activity, storms of sympathetic activity occur. Moreover, whereas feedback control is generally robustly exerted during W and SWS, it is blocked or dampened during PS or REMS. This state is called "paradoxical," since despite inactivity and maximal rest in the somatic postural muscles, phasic bursts of activity occur in the somatic eye, facial and distal flexor muscles in the form of twitches and in the cardiovascular system in the form of blood pressure surges. This phasic activity is similar to bursts of somatic and sympathetic activities which can occur during waking behaviors and thus could reflect ►dreaming activity.
