diameter innervates Merkel cells in the field of about 100 × 300 µm, and their terminals make expanded and fattened disks (about 7 µm in diameter and 1 µm thick). The nerve disks are located on the dermal side of the Merkel cells, making synapse-like contacts with the latter. Merkel cells contain clear and dense-cored vesicles, mitochondria and Golgi apparatus in the cytoplasm, and vesicles (125,000–200,000) [2] are gathered between the nucleus and cell membrane facing the nerve disk, and the latter also contains mitochondria.

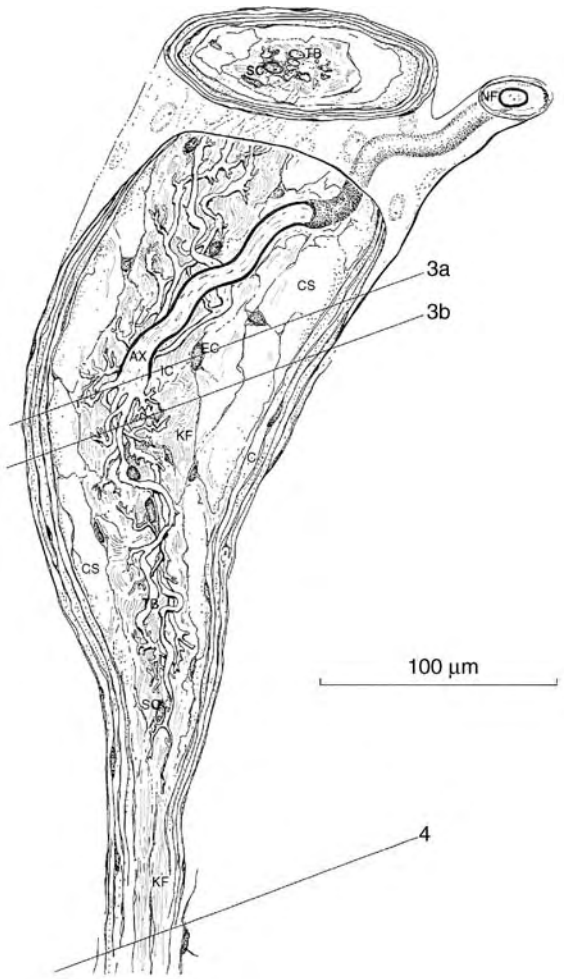
## Merkel Disk Receptors

Merkel disk receptors are encapsulated and often called *Grandry corpuscles* after Grandry (1869) who first described the receptor. They have been found in the dermis in the bill and tongue of aquatic birds, but are absent from Japanese quail and the domestic hen. The receptor is spherical with a mean diameter of 30–80 µm and has a single-layered capsule. Two to seven Merkel cells (i.e., Grandry cells) or satellite cells (hemispherical, 50 × 15 µm in size) are present inside the capsule. The number of Merkel cells contained varies with different species [7]. The nerve terminal of a flattened disk form (40 µm in diameter × 20 µm in thickness in duck) is sandwiched between two Merkel cells [8]. Merkel cells in this receptor show three morphological features similar to that of Merkel cells in the mammalian Merkel cell-neurite complex, as follows; (i) there are numerous finger-like cytoplasmic protrusions on the hemispheric surface of the cell, the processes that interdigitate with Schwann satellite cells surrounding the cells. Merkel cells in this receptor have desmosome with Schwann cells but the desmosome is absent in the processes. (ii) The cytoplasm contains osmiophilic dense-cored vesicles (120–250 nm in diameter) scattered throughout the cytoplasm, although the vesicles are concentrated adjacent to the nerve endings in the mammalian Merkel cells. (iii) Junctional zones are formed between the Merkel cell and the nerve terminal. It is argued to classify satellite cells in this receptor as Merkel cells, although they are differentiated on the basis of whether they are located in the epidermis or dermis and whether they are encapsulated or not [2].

## Pacinian Corpuscles

Lehman and Vater (1741) first described this corpuscle. The corpuscle is present deep in the subcutaneous tissue, at the interosseous membrane and at the mesentery in primates and non-primates. The perineural or outer lamella, made of 20–70 layers, forms a thick capsule and contains an inner core with many Schwann cells (inner lamella). An unmyelinated nerve terminal occupies the center of the inner core. The receptor is oval and rice-seed sized; the overall size ranges from 0.5 to 2 mm in length and is about 0.7 mm in diameter,

so large that it is visible when it presents at the mesentery or interosseous membrane. The lamellated structure looks like a section through an onion (Fig. 3). A single nerve fiber enters at one end of the corpuscle. After giving rise to a single Ranvier's node, it gets unmyelinated and travels to the other end of the corpuscle along the longitudinal in the inner core. The inner core lamella has a profile of semicircles with gaps between the half circles aligned so as to produce two clefts, with 180° apart, into which the unmyelinated nerve terminal with oval appearance at cross section projects the footlike extensions [9]. Nerve terminals are densely packed with a large number of mitochondria.



**Cutaneous Mechanoreceptors, Anatomical Characteristics. Figure 5** Schematic illustration of Ruffini ending. (Reproduced from Andres and von During (1973) Handbook of sensory physiology, vol. 2 somatosensory system, (ed. A Iggo), Springer Verlog, Berlin Hiedelberg New York, Fig. 5).

## Ruffini Endings

These receptors were originally described by Ruffini (1983). Ruffini endings are spindle-shaped with the length ranging from 0.5 to 2 mm, and lie in the dermis both in the glabrous and hairy skin. A schematic illustration of the receptor is shown in Fig. 5.

The outer capsule of 3–5 lamella, originating from perineural cells, surrounds the fluid-filled space between the capsule and inner core, and the space is divided into several compartments. The inner core is filled with collagen fibers running continuously, and supplied by a large myelinated axon which breaks up to form a dense brush-work of fine branches and terminals [10]. A single axon innervates several endings.

## Sinus Hair Follicles

Sinus hairs are present in the skin of mammals: they are vibrissae or whiskers in the face, carpal sinus hairs on the foreleg, tactile hairs or ►tylotrich hairs in other parts of the body. They are characterized by their large diameter and the length of the hair, the presence of a vascular sinus in a large bulbous capsule, associated erectile muscles, and a rich innervation. Nerve terminals are present in the midregion of the follicle below the sebaceous gland. The four kinds of nerve terminals are noted in the facial sinus hairs [1]: (i) Merkel cells around the perimeter of the hair in the basal stratum adjacent to the glassy membrane, (ii) lanceolate nerve terminals lying in the inner hair follicle on the other side of the glassy membrane from the Merkel cells, (iii) small lamellate corpuscles, and (iv) fine nerve terminals. Carpal sinus hairs lack lanceolate nerve terminals but are associated with Pacinian corpuscles clustered around them. Tylotrich hairs have lanceolated nerve terminals but no Merkel cells, however, they are associated with Merkel cells in the epidermis to form hair disks.

## Synonyms

Tactile afferents; Low-threshold cutaneous mechanoreceptors; Cutaneous receptors

## Definition

The skin is the largest organ of the body and is richly supplied with specialized sensory endings of low mechanical threshold. These cutaneous mechanoreceptors allow us to feel the weak forces generated by a slight breeze and to differentiate between the textures and shapes of objects we touch and manipulate; they also contribute to ►proprioception. Yet the tactile system subserves not only the sense of "touch" in the broadest interpretation of the word, which implies that a stimulus can be felt; cutaneous mechanoreceptors are also important in fine motor control (particularly of the hand), which – depending on the task – may or may not require conscious attention. The remarkable versatility of the human hand depends not just on its anatomical structure but, in particular, on the sophisticated neural machinery that controls it. We use our hands to explore the physical world within our reach and, with tools, the world beyond our reach, and to act on the world through manipulation of environmental objects. To control both the exploratory and manipulatory functions of the hand, the brain must obtain accurate descriptions of various mechanical events that take place when objects are brought into contact with the hand, or when the fingers make contact with an object. Cutaneous mechanoreceptors in the fingers play crucial roles in providing such information. The glabrous (hairless) skin of the human hand contains approximately 17,000 low-threshold mechanoreceptors that provide us with our remarkable capacities to discriminate shape, texture and force [1]. This chapter deals only with the functional properties of human cutaneous mechanoreceptors, assessed via the technique of ►microneurography.

## Characteristics

### Quantitative Description

#### *Glabrous Skin*

Four types of specialized mechanoreceptor terminal can be identified histologically in human hairless (glabrous) skin – two located superficially and two deeper [1]. In the upper layers of skin there are groups of expanded disc-like endings that arise from branched axons and which are closely associated with specialized cells in the basal layer of the epidermis (Merkel cell-neurite complexes); within the intradermal papillae lay elipsoidal encapsulated endings (Meissner's corpuscles), the long axis of which is oriented normal to the skin. In the subpapillary dermis one finds the encapsulated Ruffini and Pacinian corpuscles, both endings originating from a single axon. The Ruffini corpuscle, which is morphologically similar to the Golgi tendon organ, is oriented with its long axis in the plane of the skin and forms mechanical linkages with the longitudinally arranged collagen fibers that course through the dermis. The Pacinian corpuscle, which is composed of concentric lamellae around a central core, is situated in deeper layers of the dermis and subcutaneous tissues: the lamellae effectively serve as a high-pass filter, preventing all but the most brisk mechanical events from reaching the generator region of the axon terminal. As discussed below, it is terminal specializations like this that determine how a given sensory axon encodes mechanical stimuli. In addition to these specialized mechanoreceptors, however, free nerve endings – some of which have low thresholds to mechanical stimuli (►tactile C fibers) – are found within the epidermis and dermis. In support of the histological findings, microelectrode recordings from the median and ulnar nerves have also revealed the existence of four classes of low-threshold mechanosensitive afferent in the glabrous skin of the human hand, defined according to their responses to sustained indentation and to the sizes of their receptive fields: two classes of afferent adapt rapidly (►rapidly-adapting afferents type I & II) to a sustained indentation of the skin ("fast-adapting") – types FAI and FAII –and two classes of afferent adapt slowly (►slowly-adapting afferents type I & II) and are referred to as SAI and SAII. Type I afferents possess small, well-defined receptive fields, whereas the receptive fields of the type II afferents are large with poorly defined borders. The most common class encountered in recordings from the median nerve,

which supplies most of the glabrous skin of the hand, is the FAI class, followed by (in descending order) the SAI, SAII and FAII classes [1]. Based on their behavioral similarities with afferents recorded in the cat and monkey it is believed that the FAI afferent – referred to as "RA" (rapidly adapting) in the cat and "QA" (quickly adapting) in the monkey – supplies the Meissner corpuscle, and the SAI afferent the Merkel cell-neurite complex. The receptors belonging to the FAII and SAII afferents are believed to correspond to the Pacinian corpuscle ("PC") and Ruffini ending, respectively.

### *Non-Glabrous Skin*

The hairy skin covers much of the body, and the properties of cutaneous mechanoreceptors supplying this tissue are probably more representative of the "tactile sensory sheet" than those of the glabrous skin – which is rather more specialized. In agreement with the types of receptors found in hairy skin of the cat, five classes of myelinated tactile afferent have been recorded from the lateral antebrachial cutaneous nerve, which supplies the hairy skin of the human forearm: two types of slowly-adapting afferent (SAI & SAII) that can classified in a similar fashion to those in the glabrous skin, and three types of rapidly-adapting afferent – hair units, field units and Pacinian units [2]. Hair units respond specifically to movements of individual hairs and air puffs onto the receptive field, whereas field units respond to actual skin contact; the behavior of the SAI, SAII and FAII units is similar to that observed in glabrous skin, with 80% of the SAII endings presenting a low-level background discharge in the absence of stimulation. The afferent innervation of the skin on the dorsum of the hand, which is supplied by the superficial branch of the radial nerve, is similar to that of the volar surface of the hand: SAI, SAII, FAI and FAII afferents have been identified [3]. However, differences do exist between the two cutaneous regions. Unlike glabrous skin, in which the dominant species of cutaneous afferent is the FAI afferent, two-thirds of the afferents in the hairy skin of the hand are slowly adapting. A further difference lies in the relative proportions of SAI and SAII afferents: in the glabrous skin there are more of the former, whereas there are equivalent numbers in the hairy skin. There are also difficulties in differentiating between SAI and SAII units in the hairy skin, whereas the classifications are quite distinct in glabrous skin. Although few endings associated with hairs have been recorded from the radial nerve this may simply reflect the lower density of hairs on the back of the hand compared with that of the forearm. Nevertheless, a common feature shared by glabrous and non-glabrous skin is the relative paucity of FAII afferents. Microelectrode recordings from the infraorbital nerve have demonstrated that the hairy skin of the human face is innervated by rapidly-adapting and slowly adapting afferents with properties identical to those of the FAI and SAI afferents found in the hand [4]. A distinct population of slowly-adapting afferents that present a very regular discharge characteristic of SAII endings has also been found, although their responsiveness to skin stretch could not be tested. Interestingly, no FAII afferents were encountered; this suggests an absence of Pacinian corpuscles in the human face, and fits with the low sensitivity of the face to high-frequency vibration.

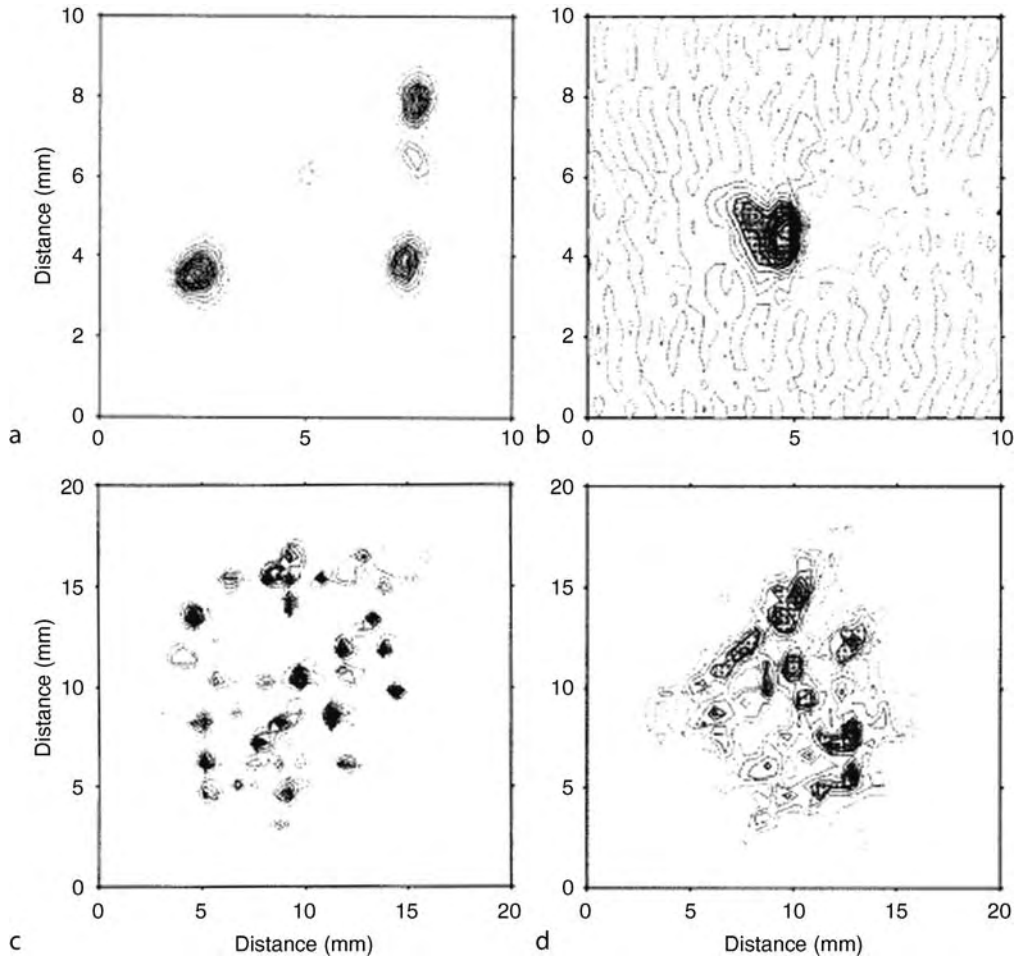
## Lower Level Components

### *Glabrous Skin*

Type I tactile afferents have small circular or ovoid receptive fields with distinct borders, and have a higher innervation density in the tips of the digits than more proximally within the hand [1]. In addition, receptive fields are smaller on the distal phalanx of the fingers than on the palm. The receptive field is composed of multiple "hot-spots" in which mechanosensitivity is maximal: FAI afferents contain 12–17 such zones – corresponding to the individual Meissner corpuscles supplied by a single axon – whereas SAI afferents contain only 4–7, corresponding to the individual Merkel cell neurite complexes. Type II afferents have large, poorly-defined receptive fields with obscure borders and, usually, a single zone of maximal sensitivity. In addition, their density is fairly uniform throughout the hand, with the exception of a specific representation of SAII afferents associated with the medial and lateral borders of the nail beds. As noted above, both classes of type II afferent can respond to stimuli applied outside their receptive field: FAII afferents respond to brisk mechanical stimuli and SAII afferents respond to lateral skin stretch; despite their small receptive fields, type I afferents can also respond to stimuli that do not directly engage their receptive field, such as stimuli that compress the finger pad. The mechanical thresholds of each class of afferent, as assessed with calibrated filaments (von Frey hairs), are fairly uniform throughout the glabrous area of the hand, but the rapidly adapting receptors have the lowest thresholds: median thresholds to punctate stimulation are lowest for the FAII (0.54 mN) and FAI (0.58 mN) afferents, and highest for the SAI (1.3 mN) and SAII (7.5 mN) afferents [1].

### *Non-Glabrous Skin*

Receptive field maps of four single cutaneous mechanoreceptors in the hairy skin of the forearm are illustrated in Fig. 1. The fields of the SAI afferents consist of 2–4 distinct islands of high sensitivity separated from each other by 3 mm on average; these spots presumably correspond to the touch domes overlying clusters of Merkel cells (Fig. 1a). On the dorsum of the hand, however, most of the SAI fields (like their



**Cutaneous Mechanoreceptors, Functional Behavior. Figure 1** Receptive field maps of single cutaneous mechanoreceptors in the hairy skin of the forearm: (a), SAI afferents with three zones of maximal sensitivity; (b), SAII afferent with single zone of maximal sensitivity; (c), hair unit and, (d), field unit with multiple zones of sensitivity. Note the different scales in C and D. Receptive fields were mapped by scanning the skin with a probe via a computer-controlled X-Y plotter. Reproduced from [2].

rapidly-adapting counterparts) consist of a single spot of maximal sensitivity. Overall, the number of these zones in the hairy skin is lower than in the glabrous skin. Apart from their higher representation in the hairy skin, the SAII afferents are similar to those in the glabrous skin, usually having a single zone of high sensitivity to punctate stimulation (Fig. 1b). Hair units have large ovoid or irregular receptive fields composed of multiple sensitive spots that corresponded to individual hairs (Fig. 1c). On average, each afferent innervates 20 hairs [2]. The field units show a similar arrangement of 10–12 high sensitivity spots encompassed by a similarly large area, although the individual spots are larger and less isolated than those of the hair units. By contrast, on the dorsum of the hand and the hairy skin of the face, the rapidly-adapting afferents have small receptive fields, usually with only a single zone of uniform sensitivity. Mechanoreceptors in the hairy skin of the forearm are exquisitely sensitive, even more so than those in the glabrous skin: after the hair units the afferents with the lowest threshold to von Frey stimulation are the field units, with a median threshold of 0.1 mN; the SAI and SAII afferents have median thresholds of 0.45 and 1.30 mN, respectively [2]. Mechanical thresholds of afferents on the dorsum of the hand and on the face are similar to those in the glabrous skin of the hand [3,4].

## Higher Level Processes

Selective stimulation (►microstimulation) of single FAI, FAII and SAI afferents innervating the glabrous skin of the hand evokes elementary sensations of a specific quality [5]. A single pulse delivered to a single FAI afferent can be detected if the subject's attention is directed to it, whereas an SAI afferent requires more

impulses and greater attention. This also fits with the lower mechanical threshold of FAI afferents and confirms an earlier interpretation of psychophysical thresholds that subjects can detect a single impulse generated by a single FAI receptor. Stimulating a single FAI afferent with a low frequency train generates a percept of intermittent tapping that, as the frequency of stimulation increases, becomes one of flutter or vibration; stimulation of a single FAII afferent with a train of pulses always generates a frequency-dependent perception of mechanical vibration. Percepts of sustained pressure can be evoked by selective stimulation of SAI afferents, the magnitude of which increases with increasing stimulation frequency. It would appear that the impulse codes utilized by rapidly and slowly adapting tactile afferents are quite distinct: increasing frequency of stimulation signaling increasing vibration with the former, and increasing pressure with the latter. Stimulation of a single SAII afferent with a train of pulses usually does not elicit a sensation.

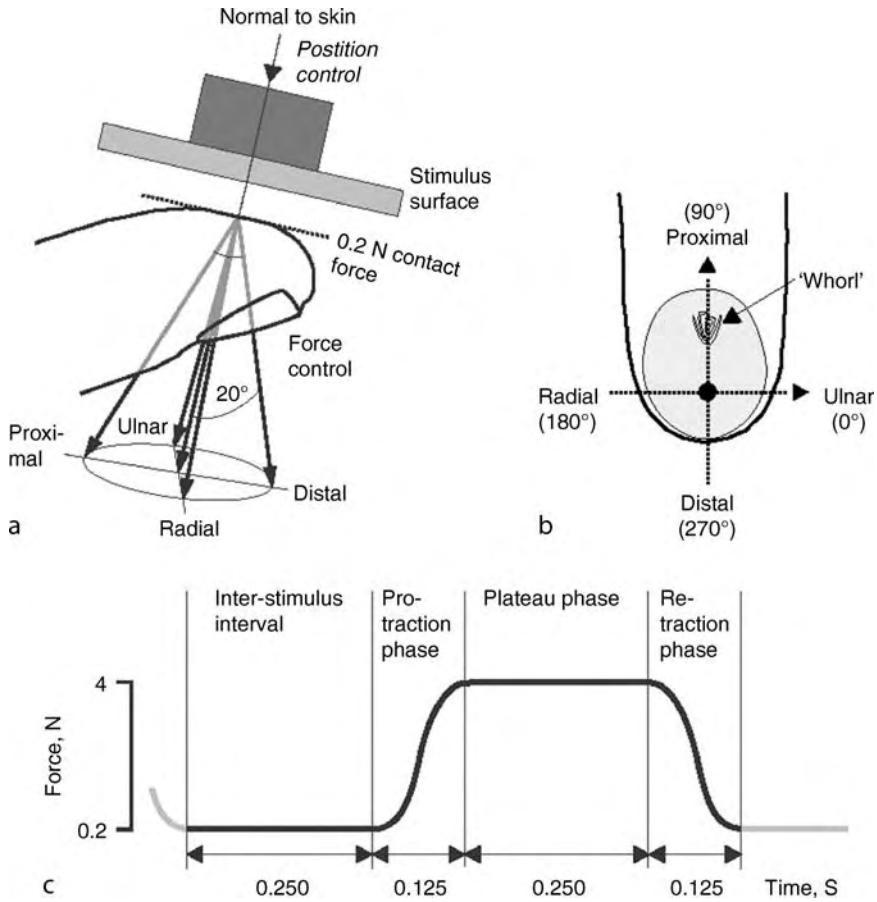
## Function

### *Tactile Sensibility*

Because of their low mechanical thresholds, and functional specializations related to anatomic specializations of the receptor endings, tactile afferents contribute importantly to the sensory picture of the body. The afferent innervation of human skin is characterized by regional variations in receptor types and densities that indicate specializations of the "tactile sensory sheet." In the glabrous skin of the hand the tips of the digits contain a high proportion of rapidly-adapting afferents (FAI) with small receptive fields, low mechanical thresholds, and – based on the robust perceptual responses to microstimulation – a secure transmission to the sensory cortex, whereas on the dorsum of the hand these afferents have a much lower representation. FAI afferents can be activated by discrete punctate stimuli in a small, well-defined area of skin; they are particularly sensitive to light stroking across the skin, responding to local shear forces and incipient or overt slips within the receptive field. The rapidly-adapting type II (FAII) afferents, like their PC counterparts in experimental animals, are exquisitely sensitive to brisk mechanical transients: typically, FAII afferents respond to tapping over areas remote from the site of maximal mechanosensitivity, or to blowing over the skin. Instantaneous firing rates are typically higher for the FAII afferents than for the FAI afferents. In all skin areas the numbers of FAII (Pacinian) afferents is low, but given their large field sizes, low thresholds, exquisite sensitivity to mechanical transients and high security transmission to the sensory cortex, their number need not be so high anyway. The slowly-adapting type I afferents (SAI) characteristically have a high dynamic sensitivity to indentation stimuli applied to a discrete area, and often respond with an off-discharge during release. In the glabrous skin of the hand, the SAI endings appear to be of particular importance in encoding shape and – together with the FAI afferents – in fine tactile discrimination. Furthermore, the SAI afferents in the finger pads signal with high fidelity the changes in grip force associated with manipulation of held objects. While the SAII afferents do respond to forces applied normal to the skin, a unique feature of these afferents is their capacity to respond also to lateral skin stretch. Many possess directional sensitivity, the discharge of some afferents increasing with stimuli applied in certain directions, but decreasing in others. And, because SAII afferents possess lower dynamic sensitivity, peak firing rates are typically lower for the SAII afferents than for the SAI afferents. A proportion of SAII afferents are spontaneously active at rest, presenting a characteristically regular discharge. Given their high sensitivity to forces tangential to the skin and poor capacity in spatial discrimination, it is reasonable to conclude that the specific contribution of SAII afferents may lie in signaling changes in conformation of the hand and the load forces (tangential to the skin) encountered during manipulation. The hairy skin of the forearm, which probably typifies the skin of much of the body, has its own specializations: in addition to two classes of very sensitive receptors with large receptive fields (hair units and field units), this region is endowed with non-myelinated mechanosensitive endings of very low threshold (►tactile C fibers).

Although the two classes of rapidly adapting afferent have the lowest thresholds to mechanical stimulation, the slowly adapting type I afferent shares a property with the FAI afferents that effectively increases its mechanosensitivity: FAI and SAI afferents are especially sensitive to edges of a contact surface that crosses the afferent's receptive field. The finger pads have the highest density of FAI and SAI endings; it is this property that endows the finger pads with their exquisite tactile discrimination, and the reason the finger pads are used for tactile exploration and manipulation.

Human subjects have a remarkable capacity to discriminate small differences in forces applied to the finger pad, forces of magnitudes typically associated with manipulation. Recent studies on the responses of tactile afferents in the finger to compression forces applied to the centre of the finger pad (Fig. 2) have emphasized the need to consider receptors in the entire terminal phalanx as providing tactile information on mechanical events in the centre of the pad [6]. Indeed, SAI and SAII endings, as well as FAI receptors, on the end and sides of the terminal phalanx can respond vigorously to stimuli applied at locations remote to their receptive fields, and each of these classes of tactile afferent can contribute to encoding the direction of fingertip forces [6] and the curvature of

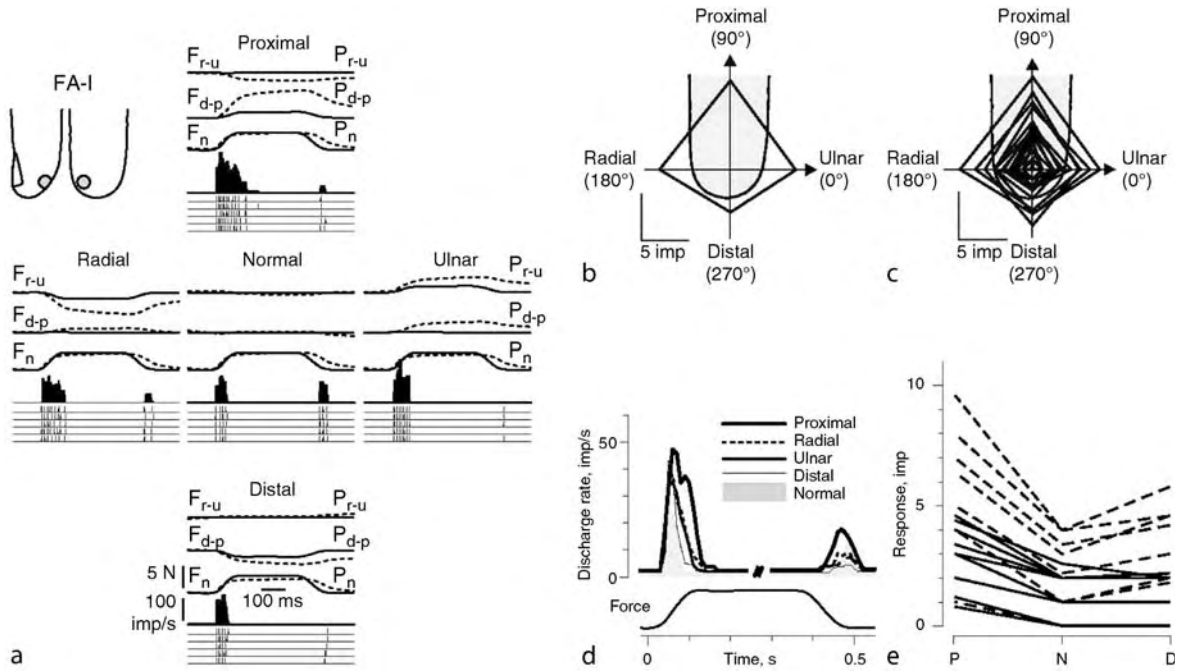


**Cutaneous Mechanoreceptors, Functional Behavior. Figure 2** Method of delivering forces to the fingertip in five different directions. (a), The stimulus surface was oriented parallel to the flat portion of skin at the fingertip. Force stimuli were superimposed on a 0.2 N background contact force and delivered in the normal direction and at an angle 20° to the normal with tangential components in the distal, radial, proximal, and ulnar directions as indicated by the *five arrows*; the normal force was always 4 N. (b), Outline of a generic finger showing the stimulation point and the approximate skin area (*shaded*) in contact with the stimulus surface for a 4 N normal force. (c), Temporal profile of the applied forces. Each stimulus consisted of a protraction phase, a plateau phase, and a retraction phase. Reproduced from [6].

objects applied to the finger pad [7]. Directional sensitivity has significant implications for functional specialization and, surprisingly, is present for each class of tactile afferent. Figure 3 show the directional sensitivity of FAI afferents in the distal phalanx of the finger to forces applied to the centre of the finger pad according to Fig. 2.

### Sensorimotor Control of the Hand

Cutaneous mechanoreceptors in the fingers are critical for fine sensorimotor control of the hand. People with impaired tactile sensibility of the fingers (including that associated with aging) show clumsiness during object manipulation tasks: objects are frequently dropped, fragile objects may be crushed, and they have severe problems in stereognostic discrimination of objects. Most previous studies of afferents from the glabrous skin of the human hand have addressed issues related to use of the hand in exploratory tasks, with comparatively little research devoted to the tactile encoding of the various mechanical fingertip events critical for the control of dextrous manipulation. The responses of human tactile afferents in relation to discrete motor control events were demonstrated for the first time during object lifting [8] and restraint tasks [9]. The neural programs involved in the sensorimotor control of manipulation are tuned parametrically to the physical properties of the object, whether this be surface friction and object mass, mass distribution or the shape of grasped surfaces. Through *Anticipatory Parameter Control* people use implicit memories from previous manipulatory experiences to retrieve internal models pertaining to the relevant properties of the target objects. Importantly, tactile signals from the

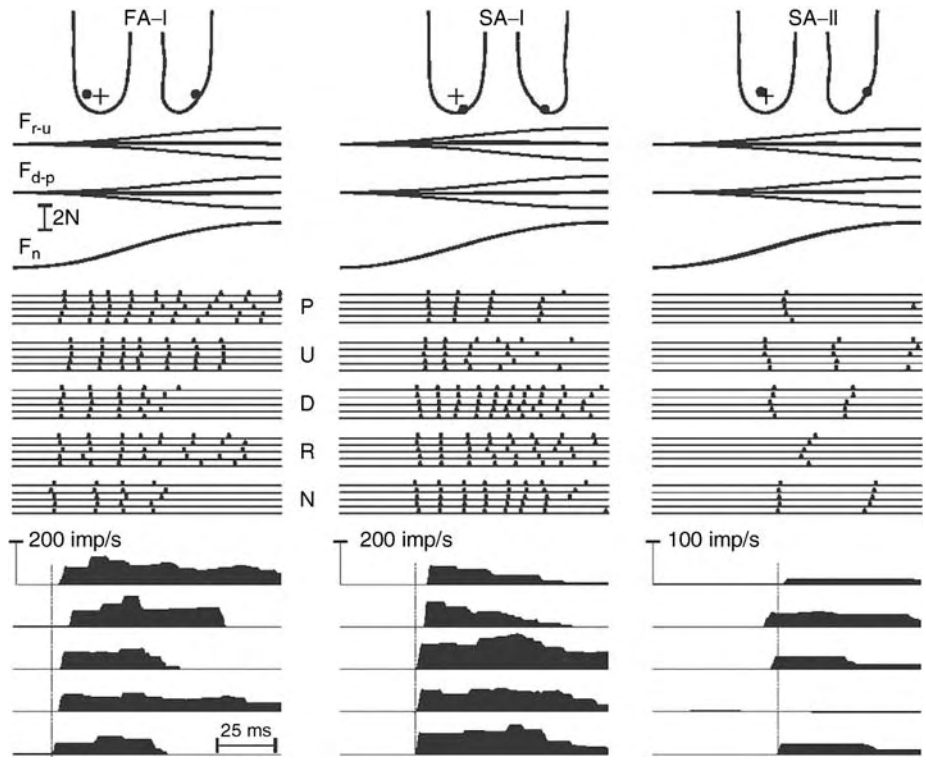


**Cutaneous Mechanoreceptors, Functional Behavior. Figure 3** Responses of FAI afferents to servo-controlled forces applied in five directions. (a), Responses of a single FAI afferent which responded preferentially to forces delivered in the proximal direction (b), The generic finger outline shows a polar plot for the afferent illustrated in A. (c–e), Data from 21 afferents for which response was greatest when the tangential component of force was in the proximal direction. (c), Overlaid polar plots, superimposed on the generic finger, for the 21 afferents for which responses were greatest when the tangential component of force was in the proximal direction. (d), Instantaneous firing rates, averaged over the five trials, for the same 21 afferents as in C, shown for forces with tangential components in the four directions and for normal force stimulation. (e), For each of the 21 afferents in C, lines join three data points representing the response, averaged over the five trials, to forces in the proximal (P), normal (N), and distal (D) directions. Reproduced from [6].

fingertips play a key role for the forming and updating those models. Through *Discrete Event, Sensory-driven Control* the time-varying tactile inflow is compared with an internal signal representing the predicted sensory outcomes (also generated by the active sensorimotor program). Disturbances in task execution due to erroneous parameter specification are reflected in a mismatch between predicted and actual sensory input; discrete tactile events may not occur when expected, or alternatively, they may occur unexpectedly. When such a mismatch is detected, pre-programmed patterns of corrective responses are triggered, along with an update of the parameter specification of the relevant internal model. For friction and aspects of object shape this updating primarily occurs during the initial contact with the object; tactile afferents in the finger pads provide this information.

An astonishing feature of sensorimotor control of hand is the speed with which motor commands are parametrically updated in response to discrete mechanical events during object manipulation. It appears that tactile information from the fingertips is already available when most afferents would have had time to fire only one nerve impulse. Thus, besides traditional coding mechanisms based on rate codes requiring several or at least two impulses per afferent, a new much faster coding mechanism based on first spike latencies has been proposed [10]. This study demonstrated that the sequence in which different afferents initially discharge may provide information about the force directions and shape of grasped surfaces faster than any rate code and matches the speed with which this information is utilized by the sensorimotor control loops. Signals provided by FAI afferents are most efficient in this capacity, followed by the SAI afferents (Fig. 4).

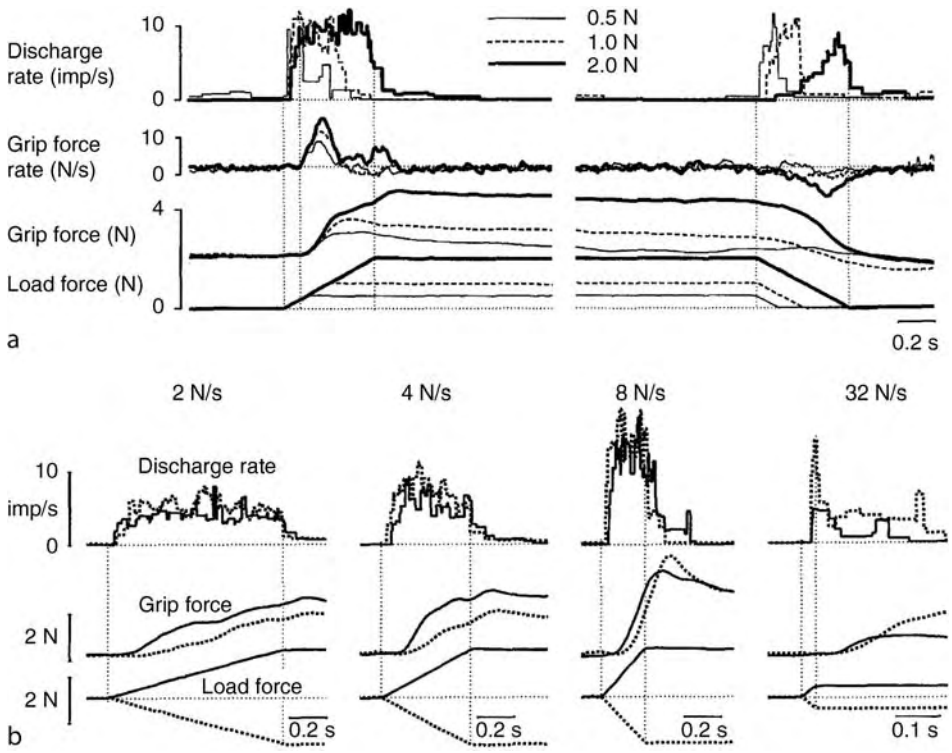
When holding an object between the fingers and thumb there are two primary forces that act at the skin: a compressive component normal to the skin and a shear component tangential to the skin. The first is brought about by the grip forces exerted by the muscles acting on the digits, the second by the effect of gravity on the held object or any other net force imposed by the object or hand on the object. Johansson and colleagues



**Cutaneous Mechanoreceptors, Functional Behavior. Figure 4** Modulation of first spike latencies by direction of fingertip force. Responses of single afferents of each type to the proximal ("P"), ulnar ("U"), distal ("D"), radial ("R") direction and with normal force ("N") only (see stimuli in Fig. 2). Impulse ensembles show responses to the repeated stimuli (n = 5). Traces above show the normal force ($F_n$) and tangential forces in the radial-ulnar ($F_{r-ul}$) and distal-proximal ($F_{d-p}$) directions, superimposed for all trials; traces below show the instantaneous discharge frequency averaged over the five trials. Vertical lines indicate the response onset latency for stimulation with normal force, i.e., the condition labeled "N." Symbols on the finger outlines indicate the centers of the afferents' receptive fields. Reproduced from [10].

have shown that cutaneous afferents in the glabrous skin of the digits are capable of encoding the grip and load forces associated with grasping and lifting an object, and that the information provided by tactile afferents to the central nervous system is of paramount importance in the fine coordination of load and grip forces [8]. When grasping and lifting a passive object between finger and thumb the type I afferents (FAI and SAI) in the tips of the digits respond with high firing rates at the moment of contact and in the early part of the loading phase, during which the grip force increases in parallel with the load force at a rate sufficient to prevent slipping of the object. The FAI and SAI afferents also respond to local mechanical disturbances during the lifting and hold phases, such as incipient or overt slips. FAII afferents respond to the mechanical transients associated with initial contact and release of the object, and they are especially sensitive to the acceleration (and deceleration) signals related to the start and end of a grip and lift (or replace) movement sequence. The SAII afferents generally respond to the grip force during the loading and hold phases of the lift, and also to the tangential loads generated at the skin during the hold phase.

Similar behavior is observed when subjects attempt to prevent escape of a manipulandum from the grasp during unexpected increases or decreases in tangential force: the FAI, SAI and SAII afferents in the finger pads respond to the shear forces generated between the skin and the manipulandum, but the FAII afferents do not respond to these slow events. While the slowly-adapting afferents also respond during the subsequent increases in grip force that serve to restrain the manipulandum, as shown in Fig. 5, FAI afferents respond only during the dynamic phases of the stimulus, i.e., during the loading and unloading ramps, and less to the normal forces associated with the increase in grip force [9]. Tactile afferents also provide information on the rotational forces associated with manipulation of held objects. Indeed, torque loads tangential to the fingertips are common in the majority of natural manipulatory tasks. Everyday tasks, such as lifting a book from the shelf by its spine, would not be possible if the motor control system did not automatically coordinate grip forces with torsional



**Cutaneous Mechanoreceptors, Functional Behavior. Figure 5** Mean responses of 8 FAI afferents in the finger pads to tangential loads applied to the receptor-bearing digit at, (a), a constant ramp rate delivered at three different amplitudes (0.5–2.0 N) and, (b), at four ramp rates (2–32 N/s) delivered at a constant amplitude (2 N). Subjects gripped an instrumented manipulandum which delivered, at unexpected times, tangential loads in the distal (upward = pulling) or proximal (downward = pushing) direction. Reproduced from [9].

loads. Torque loads depend on rotational (torsional) friction between the fingertips and the object, which arises because the normal force is distributed across the skin-object contact area, rather than focused at a point. Thus, to prevent an object from slipping under combined linear force and torque loads, we need to apply a grip force that is higher than that required to prevent slips due to the linear load force only. Surface curvature parametrically scales the relationship between the grip force and tangential torque: the grip force at any given tangential torque increases with increasing surface convexity and thereby prevents rotational slips. Again, tactile afferents in the finger pads provide this information.

## Pathology

Loss of cutaneous (and proprioceptive) sensibility can occur in rare large-fiber sensory neuropathies. Patients loose all discriminative touch and their capacity for fine motor control, relying on vision as the only source of feedback. Nevertheless, in the hairy skin they do have preserved C-fiber function and, because of the low-threshold C-fibers (▶tactile C fibers), can sense light stroking on the skin.

## Cutaneous Reflexes

### Definition

An automatic and stereotypical response to cutaneous stimulation that is mediated through a polysynaptic set of interneurones in the spinal cord. A cutaneous reflex may be elicited by stimulation of any cutaneous sensory organs, broadly classified as innocuous mechanoreceptors, innocuous thermoreceptors, and nociceptors.

►Integration of Spinal Reflexes

## CVA Brain Attack

►Stroke

## Cyborg

### Definition

Contraction of Cybernetic Organism. Organism composed of a living and an artificial portion, in close bidirectional interaction. The term was first introduced in 1960 by Clynes and Kline in the context of the debate on humans colonizing space. If man in space, in addition to flying his vehicle, must continuously be checking on things and making adjustments merely in order to keep himself alive, he becomes a slave to the machine. The purpose of the Cyborg, as well as his own homeostatic systems, is to provide an organizational system in which such robot-like problems are taken care of automatically and unconsciously, leaving man free to explore, to create, to think, and to feel (Clynes & Kline 1960).

►Computer-Neural Hybrids

## Cycle

### Definition

The complete sequence of values of a periodic quantity that occur during a period.

## Cyclic AMP

### Definition

3-5-cyclic adenosine monophosphate (cAMP, formed from adenosine triphosphate, ATP, by the action of the enzyme adenylyl cyclase) is a second messenger, used for intra-cellular signal transduction of some inter-cellular messages (some hormones and neurotransmitters) or sensory messages such as odorants which cannot get through the cell membrane. These messages are also called “first messengers”.

## Cyclic AMP- and cGMP-dependent Protein Kinases (cAKs, cGKs)

### Definition

These enzymes are activated by the binding of cAMP or cGMP. When activated cAKs and cGKs phosphorylate specific serine or threonine residues in target proteins and thereby control the activity of these proteins.

►Cyclic Nucleotide-regulated Cation Channels

## Cyclic AMP-binding Guanine Nucleotide Exchange Factors (cAMP-GEFs)

### Definition

In the cAMP-bound conformation cAMP-GEFs specifically bind to Ras-like small G proteins and activate these proteins by profoundly accelerating the exchange of GDP for GTP.

►Cyclic Nucleotide-regulated Cation Channels

## Cyclic GMP

### Definition

Cyclic guanosine monophosphate (cGMP) is an intracellular second messenger generated by guanylyl cyclase from guanosine triphosphate (GTP).

## Cyclic GMP-regulated Phosphodiesterases

### Definition

Phosphodiesterases represent a multi-gene family of enzymes that hydrolyze the second messengers cGMP and cAMP. The hydrolytic activity of several subfamilies of these enzymes is regulated in an allosteric manner by the binding of cGMP. Notably, the cyclic nucleotide binding site present in cGMP-regulated phosphodiesterases is not homologous to that found in most other cyclic nucleotide-binding proteins.

►Cyclic Nucleotide-regulated Cation Channels

## Cyclic Nucleotide-binding Domain (CNBD)

### Definition

In cyclic nucleotide-regulated channels this domain serves as a high-affinity binding site for 3–5 cyclic monophosphates. The CNBD of channels has significant sequence similarity to the CNBDs of most other classes of eukaryotic cyclic nucleotide receptors and to the CNBD of the prokaryotic catabolite activator protein (CAP). The primary sequence of CNBDs consists of approximately 120 amino acid residues forming three α-helices (αA–αC) and eight β-strands (β1–β8).

►Cyclic Nucleotide-Regulated Cation Channels

## Cyclic Nucleotide-gated Cation Channel

### Definition

►Cyclic Nucleotide-regulated Cation Channels

## Cyclic Nucleotide-regulated Cation Channels

Martin Biel
Department Pharmazie, Zentrum für Pharmaforschung, Ludwig-Maximilians- Universität München, München, Germany

### Synonyms

CNG channels; HCN channels

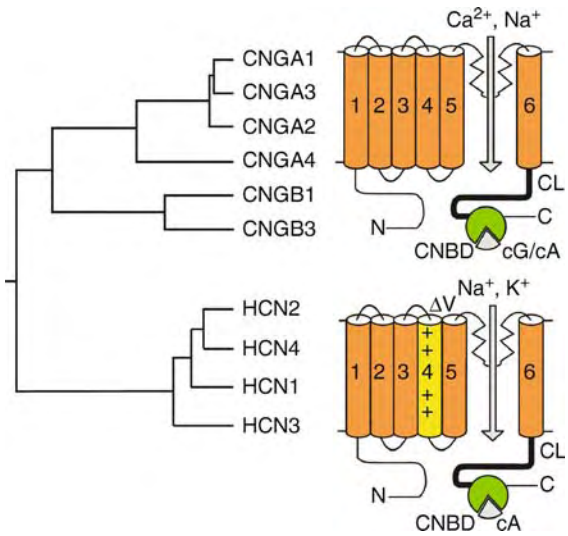
### Definition

Cyclic nucleotide-regulated cation channels are ion channels whose activation is regulated by the direct binding of cyclic AMP or cyclic GMP to the channel protein. Two families of channels regulated by cyclic nucleotides have been identified, the cyclic nucleotide-gated (CNG) channels [1,2] and the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels [3–5]. CNG channels require the obligatory binding of a cyclic nucleotide in order to be activated. In contrast, HCN channels are activated by membrane hyperpolarization. Cyclic nucleotides enhance HCN channel activity by affecting the voltage-dependence of channel activation.

### Characteristics

Cyclic nucleotides exert their cellular effects by binding to four major classes of cellular receptors: ►Cyclic AMP- and cGMP-dependent protein kinases (cAKs, cGKs), ►Cyclic GMP-regulated phosphodiesterases, ►Cyclic AMP-binding guanine nucleotide exchange factors (cAMP-GEFs) and cyclic nucleotide-regulated cation (CNG and HCN) channels. Cyclic nucleotide-regulated cation channels are unique among these receptors because their activation is coupled to the influx of extracellular cations into the cytoplasm and to the depolarization of the plasma membrane. CNG channels pass monovalent cations, such as $Na^+$ and $K^+$, but do not discriminate between them. Calcium is also permeable but at the same time acts as a voltage-dependent blocker of monovalent cation permeability. By providing an entry pathway for $Ca^{2+}$, CNG channels control a variety of cellular processes that are triggered by this cation. HCN channels conduct $Na^+$ and $K^+$ with permeability ratios of about 1:4 and are blocked by millimolar concentrations of $Cs^+$. Despite this preference for $K^+$ conductance, HCN channels carry an inward $Na^+$ current under physiological conditions. HCN channels can also conduct $Ca^{2+}$, but not as well as CNG channels. At 2.5 mM external $Ca^{2+}$, the fractional $Ca^{2+}$ current of HCN2 and HCN4 is about 0.5%, whereas for native CNG channels it is in range between 10 and 80%.

CNG and HCN channels belong to the superfamily of ►voltage-gated cation channels. The proposed structure of the channels is shown in Fig. 1. The transmembrane channel core consists of six α-helical segments (S1 –S6) and an ion-conducting ►pore loop between the S5 and S6. The amino- and carboxy-termini are localized in the cytosol. CNG and HCN channels contain a positively charged S4 helix carrying three to nine regularly spaced arginine or lysine residues at every third position. In HCN channels, as in most other members of the channel superfamily, the S4 helix functions as "voltage-sensor" conferring voltage-dependent ►gating. In CNG channels, which are only slightly voltage-dependent, the specific role of S4 is not known. In the carboxy-terminus, CNG and HCN channels contain a ►cyclic nucleotide-binding domain (CNBD) that is homologous to CNBDs of cAKs, cGKs and cAMP-GEFs. In CNG channels, the binding of cGMP or cAMP to the CNBD initiates a sequence of allosteric transitions that lead to the opening of the ion-conducting pore. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage-dependence of channel activation to a more positive membrane potential and thereby facilitate voltage-dependent channel activation. CNG and HCN channels are tetramers. In native tissue, HCN channel subunits can assemble to form either homo- or heteromeric complexes. By contrast, all known native CNG channels are heterotetramers.



**Cyclic Nucleotide-regulated Cation Channels.**
**Figure 1** Phylogenetic tree and structural model of cyclic nucleotide-regulated cation channels. The CNG channel family comprises six members, which are classified into A subunits (CNGA1 –4) and B subunits (CNGB1 and CNGB3). A "CNGB2" subunit does not exist. The HCN channel family comprises four members (HCN1 –4). CNG and HCN channels share the same transmembrane topology, consisting of six transmembrane segments (1 –6), a pore loop and a cyclic nucleotide-binding domain (CNBD). CNG channels conduct $Ca^{2+}$ and $Na^{+}$ whereas HCN channel mainly conduct $Na^{+}$ and $K^{+}$. CNG channel are activated *in vivo* by binding of either cAMP (cA) or cGMP (cG), depending on the channel type. HCN channels activate on membrane hyperpolarization (ΔV), and are enhanced by binding of cAMP. The positively charged amino acid residues in the S4 segment of HCN channels are indicated by + symbols. CL, C-linker involved in activation gating of CNG and HCN channels.

## CNG Channels

CNG channels are expressed in retinal photoreceptors and olfactory neurons and play a key role in visual and olfactory signal transduction. In addition, CNG channels are found at low density in some other cell types and tissues such as brain, testis and kidney. While the function of CNG channels in sensory neurons has been unequivocally demonstrated, the role of these channels in other cell types where expression has been observed remains to be established. Based on their phylogenetic relationship, the six CNG channels identified in mammals are divided in two subfamilies, the A-subunits (CNGA1 –4) and the B-subunits (CNGB1 and CNGB3). When expressed in ►heterologous expression systems, A-subunits, with the exception of CNGA4, form functional homomeric channels. In contrast, B-subunits do not give rise to functional channels when expressed alone. However, together with CNGA1 –3 they confer novel properties (e.g. single channel flickering, increased cAMP sensitivity) that are characteristic of native CNG channels. In native tissues, CNG channels are heterotetramers with different heteromers displaying distinct nucleotide sensitivity, ion selectivity and modulation by $Ca^{2+}$. Recent genetic studies in mice indicate that B-subunits play a key role in principal channel formation and channel targeting in native sensory neurons. For example, mice lacking the CNGB1 subunit fail to express substantial amounts of CNG channels in rod outer segments and olfactory cilia, respectively. The physiological role and subunit composition is known for three native channels: the rod and cone photoreceptor channels and the olfactory channel. The CNG channel of rod outer segment consists of the CNGA1 subunit and the CNGB1a subunit (3:1 stoichiometry). The cone photoreceptor channel consists of the CNGA3 and the CNGB3 subunit (2:2 stoichiometry). CNG channels control the membrane potential and the calcium concentration of

photoreceptors. In the dark, the channels are maintained in the open state by a high concentration of cGMP. The resulting influx of $Na^+$ and $Ca^{2+}$ (dark current) depolarizes the photoreceptor and promotes synaptic transmission. Light-induced hydrolysis of cGMP leads to the closure of CNG channels. As a result the photoreceptor hyperpolarizes and shuts off synaptic glutamate release. Mutations in human CNG channel genes have been linked to retinal diseases. Mutations in the CNGA1 and CNGB1 subunits have been identified in the genome of patients suffering from ►retinitis pigmentosa. The functional loss of either the CNGA3 or the CNGB3 subunit causes total color blindness (achromatopsia) and degeneration of cone photoreceptors.

The olfactory CNG channel consists of three different subunits: CNGA2, CNGA4 and the CNGB1b subunit (2:1:1 stoichiometry). The channel is activated *in vivo* by cAMP which is synthesized in response to the binding of odorants to their cognate receptors. The olfactory CNG channel mainly conducts $Ca^{2+}$ under physiological ionic conditions. The increase in cellular $Ca^{2+}$ activates a $Ca^{2+}$-activated $Cl^-$channel which further depolarizes the cell membrane. $Ca^{2+}$ is not only a permeating ion of the olfactory CNG channel, it also represents an important modulator of this channel. By forming a complex with calmodulin, which binds to the CNGB1b and CNGA4 subunit, $Ca^{2+}$ decreases sensitivity of the CNG channel to cAMP. The resulting inhibition of channel activity is the principal mechanism underlying fast odorant adaptation.

## HCN Channels

A cation current that is slowly activated by membrane hyperpolarization (termed $I_h$, $I_f$ or $I_q$) is found in a variety of excitable cells including neurons, cardiac pacemaker cells and photoreceptors. The best understood function of $I_h$ is to control heart rate and rhythm by acting as "pacemaker current" in the sinoatrial (SA) node. $I_h$ is activated during membrane hyperpolarization following the termination of an action potential and provides an inward $Na^+$ current that slowly depolarizes the plasma membrane. Sympathetic stimulation of SA node cells raises cAMP levels and increases $I_h$ by a positive shift of the current activation curve, thus accelerating diastolic depolarization and heart rate. Stimulation of muscarinic receptors slows down heart rate by the opposite action. In neurons, $I_h$ fulfills diverse functions, including generation of pacemaker potentials (neuronal pacemaking), control of membrane potential, generation of rebound depolarizations during light-induced hyperpolarizations of photoreceptors, dendritic integration, and synaptic transmission.

HCN channels represent the molecular correlate of the $I_h$ current. In mammals, the HCN channel family comprises four members (HCN1 –4) that share about 60% sequence identity to each other and about 25% sequence identity to CNG channels. The highest degree of sequence homology between HCN and CNG channels is found in the CNBD. The crystal structure of this domain has been determined for HCN2 and a bacterial CNG channel. When expressed in heterologous systems all four HCN channels generate currents displaying the typical features of native $I_h$: (i) activation by membrane hyperpolarization, (ii) permeation of $Na^+$ and $K^+$ with a permeability ratio $P_{Na}/P_K$ of about 0.2, (iii) modulation of voltage-dependence of channel activation by direct binding of cAMP, (iv) channel blockade by extracellular $Cs^+$.

HCN1 –4 mainly differ from each other with regard to their speed of activation and the extent by which they are modulated by cAMP. HCN1 is the fastest channel, followed by HCN2, HCN3 and HCN4. Unlike HCN2 and HCN4, whose activation curves are shifted by about +15 mV by cAMP, HCN1 and HCN3 are only weakly, if at all, affected by cAMP.

Site-directed mutagenesis experiments have provided insight into the complex mechanism underlying dual HCN channel activation by voltage and cAMP. Like in other voltage-gated cation channels, activation of HCN channels is initiated by the movement of the positively charged S4 helix in the electric field. The resulting conformational change in the channel protein is allosterically coupled by other channel domains to the opening of the ion-conducting pore. Major determinants affecting channel activation are the intracellular S4 –S5 loop, the S1 segment and the extracellular S1 –S2 loop. The CNBD fulfils the role of an autoinhibitory channel domain. In the absence of cAMP the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel core and, thereby, shifting the activation curve to more hyperpolarizing voltages. Binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal gating. It remains to be determined if the inhibitory effect of the CNBD is conferred by a direct physical interaction with the channel core domain or by some indirect pathway. There is evidence that the so-called C-linker, a peptide of about 80 amino acids that connects the last transmembrane helix (S6) to the CNBD plays an important role in this process. The C-linker was also shown to play a key role in the gating of CNG channels, suggesting that the functional role of this domain has been conserved during channel evolution.

HCN channels are found in neurons and heart cells. In mouse and rat brain all four HCN isoforms have been detected. The expression levels and the

regional distribution of the HCN channel mRNAs vary profoundly between the respective channel types. HCN2 is the most abundant neuronal channel and is found almost ubiquitously in the brain. In contrast, HCN1, HCN3 and HCN4 are enriched in specific regions of the brain such as thalamus (HCN4) hippocampus (HCN1) or olfactory bulb and hypothalamus (HCN3). HCN channels have also been detected in the retina and some peripheral neurons such as dorsal root ganglion neurons. In SA node cells, HCN4 represents the predominantly expressed HCN channel isoform. In addition, minor amounts of HCN2 and HCN1 are also present in these cells. Insights into the (patho) physiological relevance of HCN channels have been gained from the analysis of mouse lines lacking individual HCN channel isoforms. Disruption of HCN1 impairs motor learning but enhances spatial learning and memory. Deletion of HCN2 results in absence epilepsy, ataxia and sinus node dysfunction. Mice lacking HCN4 die *in utero* due to the failure to generate mature sinoatrial pacemaker cells. The key role of HCN4 in controlling heart rhythmicity is corroborated by genetic data from human patients. Mutations in the human HCN4 gene leading to mutated or truncated channel proteins have been found to be associated with sinus bradycardia (S672R, 573X) and complex cardiac arrhythmia (D552N).

## Drugs Acting on CNG Channels

Several drugs have been reported to block CNG channels. The most widely used among these drugs is L-*cis* diltiazem which blocks CNG channels in a voltage-dependent manner at micromolar concentrations. The D-*cis* enantiomer of diltiazem, which is an important therapeutic blocker of the L-type calcium channel, is much less effective than the L-*cis* enantiomer in blocking CNG channels. High affinity binding of L-*cis* diltiazem is only seen in heteromeric CNG channels containing the CNGB1 subunit. CNG channels are also moderately sensitive to blockage by some other inhibitors of the L-type calcium channel (e.g. nifedipine), the local anesthetic tetracaine and calmodulin antagonists. Interestingly, LY83583 [6-(phenylamino)-5,8-quinolinedione] blocks both the soluble guanylyl cyclase and some CNG channels at similar concentrations. H-8 [N-2-(methylamino)ethyl-5-isoquinolinesulfonamide], which has been widely used as a non-specific cyclic nucleotide-dependent protein kinase inhibitor, blocks CNG channels, though at significantly higher concentrations than needed to inhibit protein kinases. The most potent blocking agent for CNG channels is pseudechetoxin. This toxin inhibits homomeric CNGA2 channels with a $K_i$ of 5 nM and the homomeric CNGA1 channel with a $K_i$ of 100 nM. The peptide is several orders of magnitude less effective in blocking the heteromeric channels.

## Drugs Acting on HCN Channels

Given the key role of HCN channels in cardiac pacemaking, these channels are promising pharmacological targets for the development of drugs used in the treatment of cardiac arrhythmias and ischemic heart disease. HCN channels are not expressed in vascular and airway smooth muscle. As a consequence, specific HCN channel blockers are expected to have no side effect on the peripheral resistance. Importantly, unlike the well-established β-adrenoceptor blockers, HCN channel blockers would not impair pulmonary function in patients with asthma or obstructive pulmonary disease. Recently, ivabradine (S16257, Procoralan) was approved as the first therapeutic $I_h$ blocker. Ivabradine blocks cardiac $I_h$ at low micromolar concentrations and is used in the treatment of stable angina pectoris. Other known $I_h$ blockers with blocking mechanisms related to that of ivabradine are ZD7288 [4-(N-ethyl-N-phenylamino)-1,2-dimethyl-6-(methylamino)pyrimidinium chloride], zatebradine and cilobradine. These blocker were not introduced into therapy because they either lacked specificity or exerted unacceptable side effects, in particular visual disturbances due to the inhibition of retinal $I_h$. Interestingly, the well-known $\alpha_2$ adrenoceptor agonist clonidine also effectively blocks HCN channels. The block of cardiac $I_h$ (mainly conferred by HCN4) contributes significantly to the bradycardic effect of clonidine. Modulation of $I_h$ may also be a promising approach for treatment of disease processes in central and peripheral nervous system. For example, $I_h$ is upregulated in dorsal root ganglion neurons in response to nerve injury making HCN channels interesting candidates for therapeutic modulation of inflammation and neuropathic pain. Moreover, agents acting on HCN channels may be utilized in the treatment of epilepsies. Finally, HCN1 and HCN2 channels are inhibited by clinically relevant concentrations (≤0.5 mM) of the inhalational anesthetics halothane and isoflurane. Similarly, the intravenous anesthetic propofol inhibits and slows the activation of native and expressed HCN channels. Thus, modulation of $I_h$ may contribute to clinical actions of anesthetic agents.

## Cyclins

### Definition

Family of proteins that regulate the progress of cells through the cell cycle.

## Cyclooxygenase-2

### Definition

The cyclooxygenase (COX)-2 enzyme catalyzes the conversion of arachidonic acid into prostaglandins. The type-2 isoform of COX is induced during injury and infection. COX-2 generated prostaglandins induce inflammatory pathways, pain and fever.

►Central Nervous System Inflammation: Astroglia and Ethanol

## Cys-Loop Receptors

### Definition

Members of the Cys-loop receptor class are ligand-gated ion channels that open in response to binding of ACh, 5-HT (serotonin), Glycine, GABA. Cys loop receptor channels form from homo- or hetero-tetrameric arrangement of subunits surrounding an aqueous pore. Each subunit consists of an extracellular aminoterminal domain, followed by four transmembrane segments. They harbor a signature sequence of 13 residues flanked by cysteins which form a closed loop linking the extracellular ligand binding and channel domains.

## Cystometry

### Definition

Cystometry is the study of urinary bladder activity by recording the intravesical pressures exerted at varying degrees of bladder filling with water or gas.

►Micturition, Neurogenic Control

## Cytoarchitecture

### Definition

Refers to the morphological characteristics of cells.

►Evolution of the Brain: in Birds

## Cytokines

### Definition

The loose definition of cytokines is that they are proteins made by cells that affect the behavior of other cells through actions on specific cytokine receptors. The term is often used in a narrower sense as messages produced by white blood cells that affect the behavior of other blood cells and other non-blood cells. The term can therefore encompass neurotrophic factors, or may be used to refer only to cells released by lymphocytes, macrophages/microglia and polymorphs. In neurobiology the term is increasingly being used to refer to all small, low-molecular-weight (usually less then 30 kDa in size) protein messengers for inter-cell communication. Cytokines are also involved with inflammatory and hypersensitive reactions. They are critical to the functioning of both the innate and adaptive immune responses to injury in

many cell and tissue types. Usually cytokines are not produced at high levels in normal resting conditions but are rapidly and transiently up-regulated following appropriate stimuli. Cytokines exert their biological effect by interacting with high-affinity cell surface metabotropic receptors, leading to an intracellular cascade of signalling events and activation of transcription factors.

►Neurofilament

## Damping

### Definition

Damping denotes the proportionality constant for a linear dynamical system that relates the force (or torque) produced in response to an imposed velocity. The term viscosity is frequently used synonymously. In motor control, damping characterizes the ability of the system to attenuate the speed of deviation from an equilibrium or current position elicited by external perturbations; together with stiffness, damping is required for stability of posture and movement.

►Equilibrium Point Control
►Impedance Control

## Damping Ratio

### Definition

A parameter that indicates how quickly oscillations are attenuated following transient disturbances of a second-order linear dynamical system. It is defined as $\varsigma = B/2\sqrt{(KI)}$, where $B$ is damping, $K$ is stiffness and $I$ is inertia.

►Impedance Control

## Dandy-Walker Syndrome

### Definition

Characterized by enlargement of all four brain ventricles resulting from obstruction of the outflow of the cerebrospinal fluid from the fourth ventricles (through the foramina of Luschka and Magendie).

## Danger Signals

### Definition

Pathogens and toxic cell debris (apoptotic/necrotic cells) express molecules that will alert the innate immune response, the first line of defense of the host, against infection and tissue injury.

►Neurodegeneration and Neuroprotection – Innate Immune Response

## Dark-induced REM

### Definition

In certain strains of rats, rapid eye movement (REM) sleep can be triggered by turning off the environmental lights. The manner of testing is as simple as turning the room lights on for 30 min, followed by turning them off for 30 min for many hours, if desired. REM is initiated very shortly after the lights go off. Thus, light controls, at least to some degree, the expression of REM. It is not known what other brain structures connected to the pretectal regions responsible for dark-induced REM, although the IGL is a logical candidate.

►Rapid Eye Movement (REM) Sleep

## Darkness Hormone

►Melatonin

## De Novo Protein Synthesis

### Definition

The term “de novo protein synthesis” in neurons refers to protein synthesis that takes place outside the

boundaries of the soma or cell body. Such "extrasomal" protein synthesis can take place in both the dendritic and axonal compartments of neurons.

►Extrasomal Protein Synthesis in Neurons

## Deactivation

### Definition

Ion channels, such as sodium ion channels, have three structural states, open, close and inactivated. Deactivation is the direct change in state of an ion channel from open to close that does not involve the inactivation pathway. Unlike inactivation, there is no refractory period after deactivation which allows the channel to rapidly open and close.

►Action Potential
►Ion Channels from Development to Disease

## Dead Reckoning

### Definition

Synonym for path integration.

►Path Integration
►Spatial Learning/Memory

## Dead Zone

### Definition

Portion of the Phase Response Curve (PRC) during which light has no effect on rhythm phase. There are two major parts in the PRC derived from tests with light pulses. During the "subjective night," light induces phase shifts (except at the "crossover" point), but during most of the "subjective day," circadian rhythm phase is generally not modified by light. This portion of the PRC during which light has no effect on rhythm phase is known as the "dead zone."

►Circadian Rhythm
►Phase Response Curve (PRC)

## Deafferentation

### Definition

Loss of sensory nerve input to the central nervous system.

►Proprioception: Effect of Neurological Disease

## Deafferentation Pain

►Central Pain

## Deafferented Subjects, Deafferentation

### Definition

Characterized by the loss or degeneration of afferent fibers carrying somatosensory and proprioceptive information to the spinal cord in humans; responsible for the lack of sensation of positions of body segments and marked motor deficits, especially in the absence of vision. Complete deafferentation is extremely rare.

►Equilibrium Point Control

## Debt

►Sleep Homeostasis

## Decerebrate Animals

### Definition

Animals with a complete section of the encephalon performed between the diencephalon and the midbrain

followed by removal of the whole anterior part of the brain. In this preparation the postural tone is abnormally high and the thermoregulation is abolished, while the control of blood pressure and breathing is preserved.

## Decerebrate Rigidity

### Definition

Characterized by extension of the elbows and wrists with pronation of the lower arm, indicating damage in the ►midbrain or caudal ►diencephalon. Strong spontaneous extensor rigidity occurs in ►metabolic encephalopathy, particularly after acute hypoxia.

►Encephalopathy (or Acute Organic Brain Syndrome)

## Decibel (dB)

### Definition

Ten times the log (base 10) of the ratio of two intensities, two powers, or two energies and 20 times the log of the ratio of two pressures.

►Acoustics

## Decision Neurons

### Definition

Neurons that are able by their discharge to discriminate between several behavioral options and to respond best to a specific stimulus.

## Decision-making Strategy

### Definition

A strategy for choosing action based on information about a current situation. A strategy often optimizes certain criteria such as expected total reward in the future.

►Competitive Learning Theory

## Declarative Learning

### Definition

Learning events, facts and rules. Learning "that" rather than learning "how". Declarative learning is typically contrasted with "procedural learning" or "knowing how". In humans declarative learning is, roughly, learning that we can describe (declare) in language. Declarative learning is often subdivided into the learning of semantic information, facts, and the learning of episodic, autobiographical experiences. Because the definition and identification of declarative learning is tied to language, identifying declarative learning in animals is problematic. Amnesia is loss of declarative memory.

►Spatial Learning/Memory

## Declarative Memory

### Definition

Declarative memory refers to the everyday sense of memory, the learning and remembering of events and facts. Namely, declarative memory literally includes what can be declared or brought to mind as a proposition or an image. Declarative memory indicates memory for facts and events, which depends integrity of hippocampus and related structures.

►Amnesia
►Long-Term Memory
►Recognition Memory
►Sensory Plasticity and Perceptual Learning

## Declive

### Definition

Part of the vermis cerebelli lying below the primary fissure. Belongs to the posterior lobe. Like the entire

D

vermis cerebelli, the declive receives its afferents primarily from the spinal cord. Hence it is part of the so-called spinocerebellum – palaeocerebellum.

►Cerebellum

## Decorrelation

►Contrast Enhancement

## Decorticate Rigidity

### Definition

Characterized by stereotyped arm and leg movements, spontaneous or in response to stimuli: flexion of the elbows and wrists and supination of the lower arm, suggesting severe bilateral brain damage above the ►midbrain.

## Decrease of Synaptic Effectiveness

►Presynaptic Inhibition

## Decussation

### Definition

A decussation (Latin for crosswise division in the shape of an X) refers to a crossing of fibers from one side of the brain to the other, e.g., the decussation of the superior cerebellar peduncle in the midbrain, or the pyramidal decussation in the medulla.

## Deep Somatic Pain

►Muscle Pain, Including Fibromyalgia

## Defecation Reflex

### Definition

The defecation reflex involves the evacuation of fecal material from the rectum in response to stimulation of afferent nerves in the distal bowel. Afferent activity is carried in the pelvic nerves to the sacral spinal cord where it stimulates parasympathetic reflex pathways to elicit a contraction of the smooth muscle of the colon and rectum. Simultaneous inhibition of somatic efferent pathways to the external anal sphincter permit concurrent opening of the anal canal.

## Defense

### Definition

Behavior to ward off danger by fight or flight; protection from harm.

## Defense Mechanism

### Definition

Defense mechanism denotes the special unconscious behavior used to protect the ego against emotions like anxiety, sense of guilt, shame or other psychical contents. There is a variety of available defense mechanisms, examples are: repression, displacement, projection, introjection, isolation, reaction formation, denial, intellectualization, negation, rationalization, reversal into the opposite, undoing.

►Personality Disorder

## Defense Musculaire

### Definition

Defense musculaire refers to rigidity of body wall muscle overlying painful viscera. Also known as “muscle guarding” or “muscular guarding,” this is a

familiar concomitant of disorders such as peritonitis and appendicitis. In pronounced cases, the rigidity is described as "board-like." The term defense musculaire implies an adaptive function. Nonetheless, muscle hypertonicity may be relatively mild, even in the presence of significant visceral inflammation. The likely mechanisms of defense musculaire include spinally-mediated viscerosomatic reflexes. However, in the conscious patient, voluntary mechanisms also play a role.

## Defense Reaction

### Definition

The defense reaction is an "alerting" or "aversive" response to a threat and is characterized by coordinated changes in autonomic, respiratory, and other somatomotor functions, and by changes in the level of cortical arousal and attention to the external environment.

## Deflation Reflex

►Respiratory Reflexes

## Deformation

### Definition

A function specifying the correspondence between the positions of each particle of a material body in two different configurations.

►Mechanics

## Deformation Gradient

### Definition

The derivative of the deformation. Mathematically, it is represented by a tensor associated with each point of the body.

►Mechanics

## Degenerative

### Definition

In neurology, these are disorders in which there is a (usually unexplained and progressive) loss of neural tissue (e.g., cerebellar degenerations, Alzheimer's disease).

►Alzheimer's disease

## Degrees of Freedom

### Definition

The number of degrees of freedom of a mechanical system is given by the number of variables required to uniquely define the system's motion.

►Coordination
►The Distribution Problem in Biomechanics

## Degu

### Definition

Octodon degus, Order Rodentia, Suborder Histricomorpha, Family Octodontidae. A precocial species.

►Neural Correlates of Imprinting

## Deiter's Cell

### Definition

Deiter (a nineteenth century German anatomist) published a variety of materials on the inner ear. His name is attached to the outer phalangeal cell on the basilar membrane of the inner ear's Organ of Corti. It is also attached to the lateral vestibular nucleus of the 8th (cochleovestibular) cranial nerve.

## Déjérine's Syndrome

### Definition

(aka Medial medullary syndrome). Caused by occlusion of the vertebral or anterior spinal artery resulting in deviation of the tongue to the side of the lesion, weakness on the side of the body contralateral to the lesion without affecting the face, loss of vibration and proprioception on the side of the body ipsilateral to the lesion.

►Ischemic Stroke
►Stroke

## Dejours Test

### Definition

The magnitude of the ventilatory depression caused by hyperoxia, often used as an index of carotid body sensitivity.

►Carotid Body Chemoreceptors and Respiratory Drive
►Development of the Respiratory Network

## Delay Eyeblink Conditioning

### Definition

The eyeblink classical conditioning paradigm in which the conditioned stimulus is followed by and coterminates with the unconditioned stimulus. This paradigm is distinct from the trace conditioning paradigm in which the conditioned stimulus terminates before the onset of the unconditioned stimulus.

►Classical Conditioning (Pavlovian Conditoning)
►Motor Learning

## Delayed Depolarization

### Definition

►Action Potential

## Delayed Excitation

### Definition

After many neurons are hyperpolarized, they show a long delay with a slow repolarization, before they resume firing action potentials. The delay arises from activation of subthreshold potassium currents such as IA, while the excitation arises from subthreshold inward currents such as Ih, ICa(T) and INa(P).

►Action Potential
►Neuronal Potassium Channels
►Stomatogastric Ganglion

## Delayed Match-to-Sample Task

### Definition

Generally abbreviated as DMS, the delayed match-tosample paradigm is often used in studies of working and recognition memory. The DMS task includes three distinct phases. In the first phase, a sample stimulus is studied. In the second phase, the encoded information must be maintained through a delay interval. The final, or choice, phase, requires the subject to indicate which of a series of choices matches the initially studied item.

►Recognition Memory

## Delayed Non-match-to-Sample Task

### Definition

Similar in design to the delayed match-to-sample (DMS) task, the delayed non-match-to-sample (DNMS) paradigm is employed in studies of working and recognition memory. Taking advantage of a general inherent preference for novelty found in both human and non-human species, experimenters using this paradigm ask subject to encode a sample object, remember it through a delay period, and then select the item that was not shown in the study phase.

►Recognition Memory

## Delayed Rectifier Current

### Definition

Depolarization-activated outward $K^+$ current similar to that of the squid axon; it activates with a delay and relatively slowly, and inactivates minimally or very slowly. These channels may significantly contribute to the repolarizing phase of the nerve action potential.

►Action Potential
►Neuronal Potassium Channels

## Delayed-rectifier $K^+$ Channels

### Definition

Delayed-rectifier potassium channels activate with a delay and mediate outwardly-rectifying potassium currents. These channels may make a significant contribution to the repolarizing phase of nervous action potentials.

►Neuronal Potassium Channels

## Delayed Response Task

### Definition

A behavioral task in which a delay is interposed between when the cue is presented and the subsequent response is permitted. The cue is not present during the delay period so that this information must be stored in memory in order to guide future responding. Alterations in the duration of the delay period adjust the mnemonic load of the task.

## Delayed Saccade

### Definition

Delayed saccades are saccadic eye movements that are voluntarily withheld, after a targeting eccentric stimulus appears, until a central fixation stimulus is turned off. The temporal overlap between the time of target appearance and the turning off of the fixation point is called the delay period.

►Saccade, Saccadic Eye Movement

## Delayed Saccade Task

### Definition

A visual target is presented and the subject is required to maintain fixation for a variable amount of time. Next, a second target is presented at another location, while the fixation target remains on. Finally, the fixation target is extinguished, and the subject must make a saccade to the location of the second target. This task is used to create a temporal dissociation between the visual target and the saccade.

►Saccade, Saccadic Eye Movement

## DeltaF/F

### Definition

Many functional imaging studies work with changing light. For example, a calcium -sensitive dye such as calcium green increases its fluorescence with increasing calcium concentration. However, the fluorescence increase also depends on the available quantity of dye in the first place. Therefore, the absolute change in fluorescence is not relevant, but the relative change is: and this magnitude is deltaF/F, i.e. the absolute change in fluorescence (deltaF) divided by the background magnitude of fluorescence (F).

►Functional Imaging

## Delta Function

### Definition

A signal whose integral over time is unity, while its width approaches zero (which implies that its height approaches infinity).

►Signals and Systems

## Delta Waves/Rhythms

### Definition

Slow oscillatory bursts of electroencephalogram (EEG) activity (1–4 Hz) observed during deep stages of non-REM sleep.

►Brain Rhythms
►Electroencephalography
►Non-REM Sleep

## Dementia

### Definition

A progressive neurodegenerative condition that compromises neurologic functioning in individuals who have attained adult levels of intact cognition.

►Memory and Dementia

## Dementia Paralytica

### Definition

Dementia paralytica results from diffuse chronic inflammation entailing degenerative sclerotic alterations in meninges, dura mater and brain with a predominance in the ►frontal lobes. The first symptom may be a generalized convulsion. Other main symptoms include headache, insomnia, personality changes (such as impaired judgment, altered emotional responses, delusions of greatness and tendencies towards sexual obscenities), slurring speech, tremors; later progress into dementia.

## Dementia Praecox

### Definition

This is the historic definition for psychotic diseases that was created by E. Kraepelin at the beginning of the last century. It was later replaced by Bleuler with the term "schizophrenia."

►Schizophrenia

## Demyelinating Neuropathies

### Definition

Subgroup of ►peripheral neuropathies and feature a degeneration of ►myelin sheaths, whereby the ►conduction velocity of the afflicted fibers is reduced, which in turn leads to many sensory and motor disturbances.

►Action Potential Propagation
►Large Fiber Sensory Neuropathy
►Myelin

## Demyelination

### Definition

Demyelination is the removal of an existing myelin sheath in the peripheral or central nervous system. It may be caused by immune processes, as in multiple sclerosis, by factors initiated by trauma, by the action of toxins, by genetic conditions and numerous other causes. The damaged myelin is usually removed by the action of macrophages/microglia and other cells, while the oligodendrocyte or Schwann cell may survive.

►Multiple Sclerosis
►Myelin
►Oligodendrocyte
►Schwann Cell

## Dendrite

### Definition

The dendrite (Greek for tree-like branching) is the branching process of the neuron that receives most of the synaptic input from axons of other neurons.

## Dendritic Field of Retinal Ganglion Cell

### Definition

Retinal ganglion cells collect light from photoreceptors (via bipolar retinal cells) through their dendrites, which extend away from the cell body. Since each class of retinal ganglion cells covers the entire retina, numerous cell types, such as the midget cell, have very small dendritic fields, whereas sparse cell types, like the P giant cell, have large dendritic fields.

►Retinal Bipolar Cells
►Photoreceptors

## Dendritic Growth

Shigeo Okabe
Department of Cellular Neurobiology, Graduate school of Medicine, University of Tokyo

### Definition

Increase in Total Length, Branching and Complexity of Dendritic Structures During Development and Reorganization of the Nervous System.

The basic pattern of morphological changes in dendrites in the course of nervous system development is described in this essay. After defining the four major stages in dendritic growth, the molecular mechanisms of growth regulation at each stage are discussed. The extent and pattern of dendritic growth show great variability among different cell types even within the same brain region. Specific patterns of dendritic growth have been used to illustrate the extent of divergence.

### Characteristics

#### Quantitative Description

The extent of dendritic growth is variable among different neuron types. The total dendritic length of typical CA1 pyramidal neurons in the rat hippocampus is 12–17 mm and they receive 30,000 excitatory and 2,000 inhibitory inputs after maturation (Fig. 1c) [1].

Immediately after the final mitosis in these cells in embryonic days 15–19, they have a few immature processes of lengths less than 50 μm [2]. Postnatal dendritic growth is therefore a process of massive increases in surface area, in amount of cytoplasmic organelles and in synaptic junctions with other excitatory and inhibitory neurons. Similar significant increases in the size and the complexity of dendrites are observed in a wide range of neuronal populations, including cortical pyramidal cells, ►cerebellar Purkinje cells, retinal ganglion cells and spinal cord motor neurons. There are several types of neurons showing less prominent dendritic growth. For example, some types of midget bipolar cells in the retina develop a few dendrites with individual processes of less than 20 μm and receive synaptic input from only one to five photoreceptors (Fig. 1a). Cerebellar ►granule cells are another example of cells forming a simple dendritic structure (Fig. 1b). These cells have fewer than five short dendrites. The simple dendritic structure of granule cells contrasts with the highly branched dendrites of nearby Purkinje cells in the cerebellar cortex [3].

#### Description of the Process

Dendritic growth involves multiple mechanisms, which tend to be in parallel operation even in a single neuron at a given time point [4]. However, to simplify the questions related to dendritic growth, it will be convenient to separate the time-course of dendritic growth into four essential stages. First, early postmitotic neurons (Fig. 2a) Start to extend two types of processes, axons and dendrites (Fig. 2b).

Second, dendrites extend, branch and increase the volume they occupy (Fig. 2c). Third, dendrites interact with incoming axons and form synaptic junctions (Fig. 2d). Finally, dendrites stop their growth and are stabilized. They can even show regressive changes, frequently associated with functional competition among different afferents (Fig. 2e).

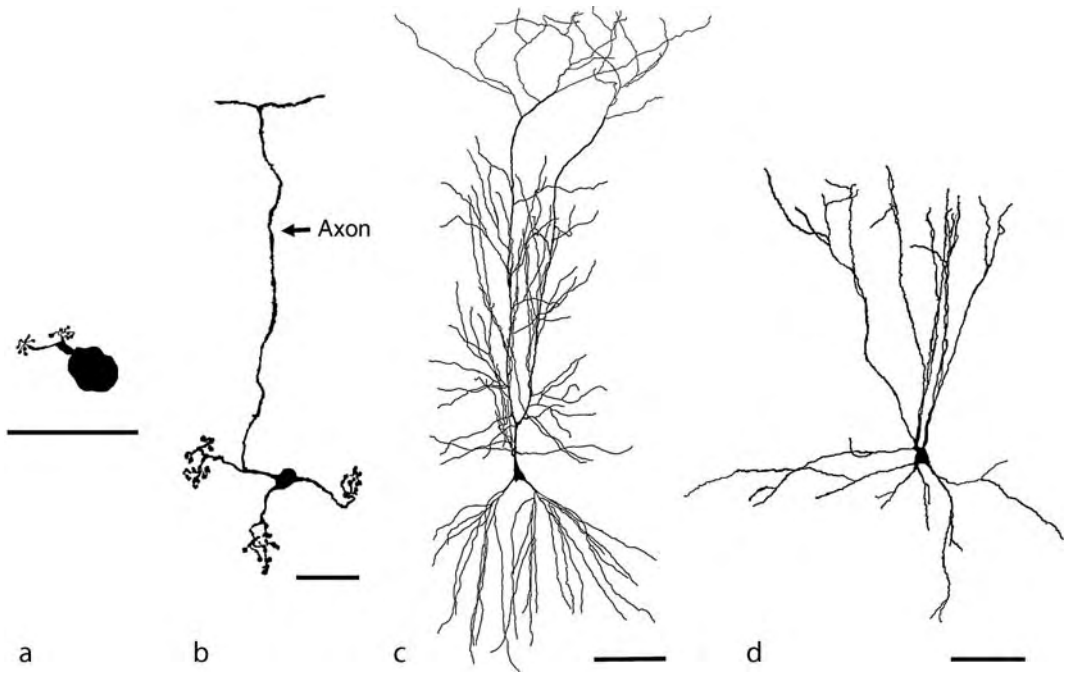
#### Differentiation of Axons and Dendrites

Extensive culture studies of the rodent embryonic hippocampus identified the time-course of axon-dendrite differentiation in isolated neurons [2]. After the initial stage of slow outgrowth of several short processes from the cell body, a single process commences to elongate rapidly and later becomes the axon. Outgrowth of the other processes remains slower than that of the axon, but they branch more frequently to develop a typical dendritic structure.

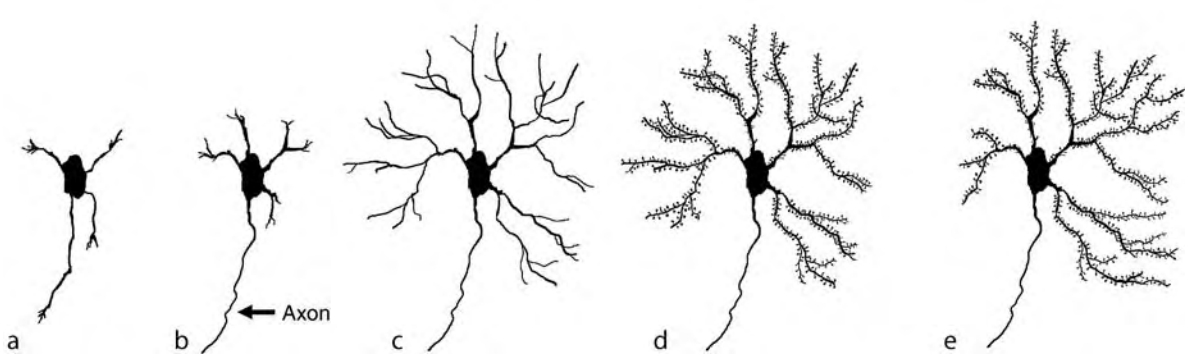
It is generally accepted that a similar sequential differentiation of axons and dendrites takes place in vivo. Differential development of axons and dendrites is evident in specific neurons that extend their axons much earlier than the arrival of afferents at their dendrites, such as cerebellar Purkinje cells. The Purkinje cell axons already exist at birth in the rat, but dendrites grow slowly in postnatal days 4 to 21 [3].

#### Process Extension and Branching

From short dendritic processes in immature neurons, a complex structure of highly branched dendrites



**Dendritic Growth. Figure 1** Diversity of dendritic structure for four different neuron types in three brain regions. (a) Morphology of a midget bipolar cell in the marmoset retina. Only the dendritic structure is shown and the axon is omitted from this drawing. The dendrite is short and bifurcated, contacting with two cone photoreceptors by multiple terminal branches. Bar, 20 μm. (b) Morphology of a cat cerebellar granule cell. This neuron type contains less than five short dendrites with multiple terminal branches. These terminal branches contact with the mossy fiber terminals. Bar, 20 μm. (c) Dendritic structure of a rat hippocampal CA1 pyramidal neuron. The cell body is a pyramidal shape and has both apical dendrites and basal dendrites. Both dendritic structures are highly branched. Bar, 100 μm. (d) Dendritic structure of a rat hippocampal CA1 interneuron. This neuron belongs to a parvalbumin-immunopositive sub-class of hippocampal inhibitory neurons. Although the degree of extension of single dendritic branches is comparable to that of pyramidal neurons, the dendrites show less branching. Bar, 100 μm.



**Dendritic Growth. Figure 2** Developmental stages of dendritic growth. (a) Stage before determination of axons and dendrites. (b) Stage of axon/dendrite determination. A single neurite starts to extend rapidly and acquires features of the axon. (c) Stage of dendrite extension and branching. Massive increase in the dendritic cytoplasm takes place. (d) Stage of synapse formation. Dendrites start to make contact with incoming axons and form synapses. Synapse formation is often associated with formation of dendritic spines. (e) Stage of selective stabilization. Selective stabilization and additional growth of dendritic branches take place. Concomitantly, dendrites with less trophic support start to regress.

gradually develops. This structural development is driven by both increases in length of dendritic segments and in number of branching points. It should be emphasized that these two parameters determine the final size and shape of the dendritic arborization, which are specific for different types of neurons. The dendritic cytoplasm is the extension of the cell body. It contains the usual membrane organelles such as mitochondria, rough/smooth endoplasmic reticulum (ER), Golgi apparatus and free ribosomes. The presence of protein synthesis machinery in dendrites contrasts with the scarcity of ribosomes in axons. Another distinction between dendritic and axonal cytoplasm is the presence of microtubules with mixed polarity in the dendrites [4]. The axonal cytoplasm contains only microtubules with their plus ends distal to the cell body. The presence of microtubules with mixed polarity is important for dendritic morphogenesis, as suppression of a key molecule for the maintenance of the mixed polarity results in suppression of dendritic growth [4]. As in the case of growing axons, the tips of growing dendrites develop growth cones, which are highly motile structures with an enriched actin cytoskeleton. New dendritic branches are generated either by splitting of advancing dendritic growth cones or by de novo formation of processes in the middle of dendritic segments [5].

## Synapse Formation

In many brain regions, synapse formation occurs concomitantly with process extension and branching. A typical example is the synchronized formation of cerebellar Purkinje cell dendrites and their synaptic contacts with two distinct presynaptic components, the parallel fibers of granule cells and ►ascending fibers from the ►inferior olive [3]. The formation of specific types of synapses is known to be behind the peak of dendrite morphogenesis. For example in mossy fiber synapses onto the hippocampal CA3 pyramidal neurons [6], on postnatal day 7 the proximal segment of the apical dendrites is already established in the CA3 region. The development of presynaptic specialization in the incoming mossy fibers from the ►dentate gyrus granule cells starts only after day 7 and the number of synaptic contacts increases gradually until postnatal day 21.

Synapse formation is associated with morphological changes in the dendritic surface. The most prominent morphological change is spine formation, which takes place in most of the excitatory neurons in the cortex and the hippocampus [7]. Spine formation is not restricted to excitatory neurons. Several GABAergic ►Golgi type I neurons, such as cerebellar Purkinje cells and striatal medium spiny neurons, also generate prominent spines with high density. Real-time imaging of pyramidal neuron dendrites in the neocortex in vivo and in slice preparations revealed rapid morphological change in spines. This motility is driven by assembly/disassembly of filamentous actin, which is highly concentrated in the spine cytoplasm. Another characteristic structure on the surface of dendrites during the period of synaptogenesis are dendritic filopodia. A possible role of dendritic filopodia is to initiate contact with nearby axons. Stochastic extension and reabsorption of dendritic filopodia are consistent with their role in sampling the environment. The distinction between thin spines and filopodia with synaptic contacts is not self-evident and sometimes they are considered to be the same entity. Electron microscopic reconstruction studies revealed the appearance of dendritic filopodia at the early stage of synaptogenesis and their reduction at the later stage with an increase in dendritic spines. However, evidence for direct morphological transition from filopodia to spines is relatively scarce. Alternatively, dendritic filopodia can be stabilized by synaptic contacts and subsequently transformed into new dendritic shafts without losing the established synaptic contacts. This scenario has been confirmed by in vivo imaging of the postsynaptic specialization in zebra fish embryos [5].

## Growth Termination and Regression of Existing Dendrites

Extension of dendritic processes is usually limited at the border of brain territories. Apical dendrites of both CA1 pyramidal neurons and dentate granule cells receive inputs from the ►entorhinal cortex. These two types of apical dendrites extend toward the border of the stratum lacunosum-moleculare of CA1 and the stratum moleculare of the dentate gyrus from the opposite directions and there exists a clear demarcation between these dendritic fields [1]. Dendritic fields of individual neurons can also form clear borders in specific brain regions. For example, retinal ganglion cells stop extending dendritic processes once they make contact with adjacent ganglion cells to form mutually exclusive dendritic territories.

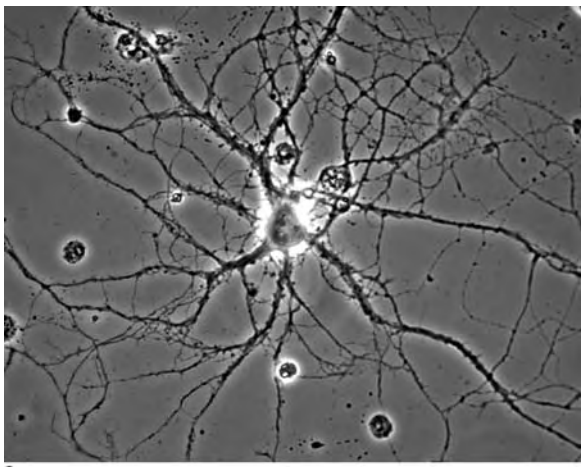
## Higher Level Processes

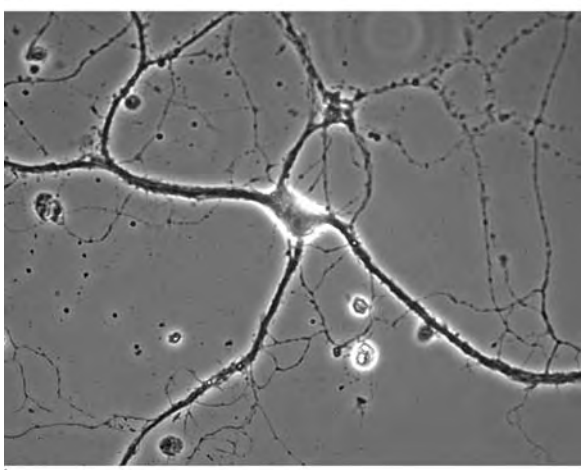
The pattern of dendritic growth is one of the key factors influencing the higher order organization and local connectivity in specific brain regions. As will be discussed in the following section, dendritic growth is regulated by multiple factors. Therefore, causal relationships between specific dendritic patterns and the overall organization of the local circuit are difficult to determine in many cases. Spiny neurons in the barrel field of the rodent somatosensory cortex show dendritic growth confined to individual barrel structures [8]. Development of barrel structure is dependent on the sensory afferents and activation of NMDA receptors in the sensory cortex. This is a clear example in which incoming axons and their synaptic connectivity control

postsynaptic dendritic growth. The barrel cortex is a typical example of topographic maps present in sensory systems and controlled growth of dendrites is important in proper processing of sensory information.

## Regulation of the Process

Dendritic growth is the product of both cell autonomous mechanisms and extrinsic influences. When neurons are placed in an artificial environment, such as in dissociated culture, they still grow to resemble their normal counterparts in vivo (Fig. 3) [1].





**Dendritic Growth. Figure 3** Dendritic morphology of hippocampal neurons maintained in dissociated culture. Without native cell-to-cell contacts, extracellular matrix and soluble factors, isolated neurons can establish the characteristic morphology of dendrites on culture substrate. Highly branched dendrites of a pyramidal shaped neuron (a) and less-branched straight dendrites of an inhibitory neuron (b) preserve the basic morphological characteristics of their in vivo counterparts shown in Fig. 1c,d.

On the other hand, detailed dendritic branching patterns of individual neurons with the same genetic composition and in close vicinity still show clear differences. Either intrinsic or extrinsic mechanisms or a combination of them play specific roles in certain stages of dendritic development [5].

## Intrinsic Mechanisms

Both extension of dendritic processes and branching are mediated by motile protrusions such as dendritic growth cones and filopodia. The actin cytoskeleton is enriched in these structures. Local assembly of the actin cytoskeleton is regulated by the Rho-family of small GTPases [7]. By increasing the activity of the small GTPase Rac1, initial growth of dendrites and dendrite branching are enhanced. Manipulation of Rac activity can also change the density of dendritic spines, where actin-dependent morphological change takes place. Another GTPase RhoA shows the opposite effects, reducing dendrite growth and branching. Dendritic growth is also mediated by assembly of microtubules, a major cytoskeletal component in the dendritic shaft. Proper organization of microtubules is also important for the addition of new plasma membrane, which is transported along the dendrites via microtubule-dependent motors. Dendritic cytoplasm contains abundant polyribosomes and protein synthesis within the dendritic compartment is another key factor for both dendritic growth and synapse maturation. Mutations affecting functions of several RNA-binding proteins impair dendritic growth and synapse formation.

## Exogenous Trophic Factors

A variety of soluble factors can influence the shape of dendrites [4]. Sema 3A was originally identified as having a collapsing activity on axonal growth cones. This collapsing effect can be reversed when the intracellular concentration of the cyclic nucleotide guanosine 3′/5′-monophosphate (cGMP) is elevated. Sema 3A attracts apical dendrites of neocortical pyramidal neurons, where the local cGMP level is high. Axons from the same pyramidal neurons show a repulsive response, because the local cGMP concentration is low. BDNF and NT-3, members of the neurotrophin family of growth factors, are important in promoting growth of dendrites from pyramidal neurons in specific cortical layers. Neurotrophins are synthesized in the cell body, transported down the axon and synaptically released to the postsynaptic neurons. The effect of BDNF on pyramidal neurons is also dependent on synaptic activity. This is one example of the interplay between distinct extrinsic signals on the growth of dendrites. Osteogenic protein 1 (OP-1), a member of the bone morphogenic protein (BMP) family, shows strong and specific effects on dendritic growth from sympathetic neurons.

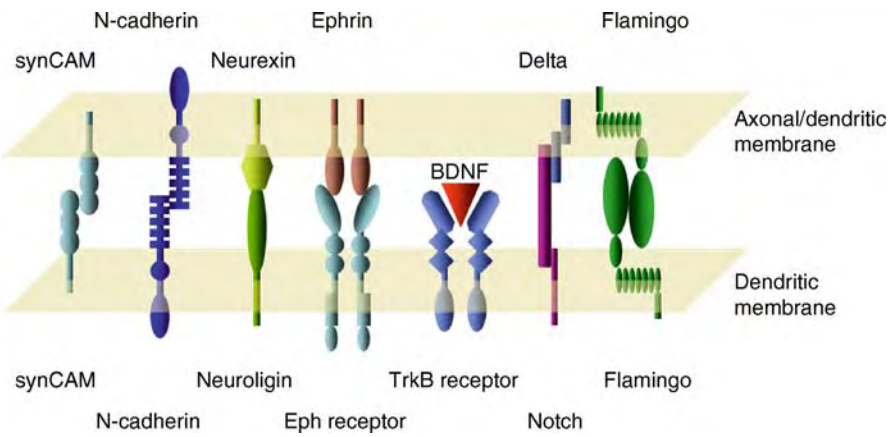
### Cell-to-cell Interactions (Fig. 4)

As already mentioned, dendritic growth is coupled with synapse formation. In this sense, molecules involved in synapse formation also play important roles in dendrite morphogenesis. Cell adhesion molecules present on the postsynaptic membrane, such as N-cadherin ►synCAM and neuroligin, are important in induction and/or maturation of synaptic structure [9]. N-cadherin and synCAMs are homophilic cell adhesion molecules. Neuroligin associates with presynaptic β-neurexin molecules to induce both presynaptic and postsynaptic specialization. Eph receptors are receptor tyrosine kinases (RTKs) activated by interaction with their ligands ephrins. Several members of both Eph receptor and ephrin ligand families are present in synaptic contact sites and positively regulate the process of synapse formation by accumulating key molecules such as NMDA receptors.

Several other membrane proteins, such as Notch and Flamingo, exert negative effects on dendrite outgrowth [4]. Notch is a cell surface protein originally identified in Drosophila as a regulator of cell fate specification. In the mammalian neocortex, Notch is expressed in neurons and its activation by its ligand Delta or Jagged suppresses neurite extension. Flamingo is a ►seven-pass transmembrane protein with the N-terminal extracellular domain homologous to cadherin molecules. In both Drosophila and mammalian neurons, the presence of Flamingo is important in proper morphogenesis of dendrites.

### Electrical Activity

Dendritic morphology is remarkably resistant to the treatments that reduce the overall level of synaptic activity or neuronal firing. In contrast, differential activity plays an important role in the process of competition among groups of afferents. For example, loss of sensory input from one eye dramatically alters the synaptic organization in the visual cortex. If input from both eyes is eliminated, the reorganization does not take place. Both synaptic activity and neuronal firing can induce an increase in intracellular calcium levels. Subsequent activation of intracellular effectors is responsible for the morphological alterations of dendrites [8]. As already mentioned, preferred



**Dendritic Growth. Figure 4** Membrane proteins involved in the regulation of dendritic growth. *SynCAM* belongs to the immunoglobulin superfamily of cell adhesion molecules. The extracellular region contains three immunoglobulin-like domains, which mediate calcium-independent homophilic interaction. The carboxy-terminal PDZ-binding motif of synCAM binds to synaptic PDZ domain-containing proteins. *N-cadherin* contains five cadherin repeats in the extracellular domain. The most amino-terminal cadherin repeat is responsible for the calcium-dependent homophilic interaction. The cytoplasmic domain of N-cadherin interacts with α-catenin and β-catenin to organize the submembranous actin cytoskeleton. *Eph receptors* form a large group of receptor tyrosine kinases and show high affinity with their ligands, ephrin molecules. Eph receptors are divided into two sub-families, EphA and EphB. EphB receptors are localized at the postsynaptic membrane and their roles in synaptic functions have been extensively studied. EphB2 receptor activation can induce clustering of EphB2 together with NMDA receptors at the postsynaptic membrane. *TrkB receptors* are members of the Trk family of neurotrophin receptors. TrkB receptors belong to receptor tyrosine kinases and bind specifically to BDNF and NT-4/5. BDNF has been shown to be released from presynaptic terminals in an activity-dependent manner. *Notch* is a large membrane protein with 36 EGF-like domains in the extracellular region. The cytoplasmic domain of Notch is cleaved and transported to the nucleus to activate Notch-response genes. Delta is one of the Notch ligands and also contains EGF-like repeats in the extracellular region. *Flamingo* belongs to a family of seven-pass transmembrane proteins. The amino-terminal extracellular region of Flamingo contains eight cadherin domains, which are responsible for homophilic association. Knockdown of Celsr2, a mammalian homologue of Drosophila flamingo, impairs normal development of dendrites in cortical pyramidal neurons and cerebellar Purkinje cells.

development of dendrites within the barrel structure is dependent on the NMDA receptor, which is a major mediator of calcium influx. Calcium/calmodulin-dependent protein kinases (CaMKs) are one of the major targets of calcium influx. CaMKIIα and CaMKIIβ have opposing roles in dendritic growth. CaMKIIα activation stabilizes dendrites and limits their growth. In contrast, CaMKIIβ activation facilitates filopodia extension and dendrite development. A local increase in calcium in specific dendritic segments should be important in the process of competitive pruning, as dendritic segments receiving more active synaptic input should be selectively stabilized. Indeed, in retinal ganglion cell dendrites, a local increase in calcium in small dendritic segments specifically stabilizes developing dendrites [10]. Downstream signaling cascades involved in local stabilization of dendritic segments are not yet clarified, but selective activation of CaMKs is a candidate for this process.

## Denervation

Loss of nerve (innervation) to cell, tissue, organ.

## Dental Implant

### Definition
A replacement for lost root(s) of a tooth, upon which a new, artificial tooth is fabricated and attached.

►Tactile Sensation in Oral Region

## Dentate Gyrus

### Synonyms
Gyrus dentatus

### Definition
The dentate gyrus (dentate fascia) is an important part of the hippocampus, retrocommissural part. Rostrally, it joins Giancomini's band and caudally, the fasciolar gyrus. Afferents come from the hypothalamus and via the entorhinal area from the cerebral cortex. Efferents of the granular cells pass exclusively to the cell layers CA3 and CA4 of Ammon's horn, forming the dense mossy-fiber system.

►Telencephalon

## Dentate Nucleus

### Synonyms
Nucl. dentatus

### Definition
Measuring about 1 cm in length, the dentate nucleus is the largest cerebellar nucleus. With its typical, saw-toothed shape it lies in the medulla of the cerebellar hemisphere. Afferents: (i) Purkinje fibers of the cerebellar hemisphere, lateral part, (ii) collaterals of the pontocerebellar projection.

Efferents: via superior cerebellar peduncle to the ventral lateral thalamic nucleus. A few fibers terminate in the red nucleus.

►Cerebellum

## 2-Deoxy-Glucose Experiment

### Definition
Nerve cells need glucose as their source of energy. They take up 2-deoxy-glucose (2-DG) like normal glucose which, in contrast to normal glucose, is only slowly metabolized and therefore its degradation products are accumulated in the cell. Therefore radioactive 2-DG allows the visualization and measurement of the localized spontaneous or evoked activity of the whole brain by adequate electronic equipment, or by exposing radioactive brain slices of experimental animals to Xray film.

## Depolarization

### Definition
Depolarization is a change in the polarity of the membrane from changes in ionic distribution, that results in the membrane potential becoming more positive. A depolarization that raises the membrane potential above a threshold will fire action potentials. In many cases, depolarizations are generated by the influx of sodium ions through voltage-gated sodium channels, but the influx of calcium or potassium ions as a charge carrier can also cause depolarizations.

## Depolarization Block

### Definition
Depolarization block longer-lasting depolarizations may lead to accommodation which occur in a number of clinical conditions. These may come about, for example, by changes in ion concentration gradients across the cell membrane. An elevated extracellular $K^+$ concentration (hyperkalemia) shifts the $K^+$ equilibrium and the coupled resting membrane potential to

depolarized levels (for instance after crush injuries liberating great amounts of intracellular $K^+$ into the extracellular space; during epileptic discharges, during impairment of the $Na^+$-$K^+$ pump (Ion transport) by metabolic impairment, anoxia etc.; mistreatment by overinfusion of $K^+$). In anesthesia and surgery, succinylcholine is used to depolarize the muscle fiber membrane and thus block the generation of action potentials for some time (depolarization block).

►Action Potential

## Depth Perception

### Definition

The ability to perceive that objects are positioned at different distances form the observer. There are monocular and binocular cues to provide absolute and relative depth information.

►Binocular Vision

## Depth Perception Disorders

### Definition

These patients are unable to perceive the three-dimensionality of the world and instead see all objects as flat. There is also a substantial proportion of people who cannot discriminate selectively "near" or "far" stimuli from monocular stimuli.

## Derived Characters/Traits

### Definition

Derived characters/traits are states of a character that are advanced over the primitive condition. Where such a trait is shared by one or more lineages it is said to be a synapomorphy.

## Descending Modulation of Nociception

Peggy Mason
Department of Neurobiology, Pharmacology and Physiology, University of Chicago, Chicago, IL, USA

### Synonyms

Nociceptive modulation; Pain modulation; Endogenous analgesia system; Descending pain modulation

## Definition

Descending pain modulation encompasses pathways that descend from the forebrain and brainstem to the spinal cord and trigeminal sensory complex to modify incoming somatosensory information so that the perception of and reactions to somatosensory stimuli are altered, resulting in either less or more pain.

## Characteristics

That mammalian sensory systems do not record the world faithfully is so obvious as to border on the cliché. Visual, auditory and somatosensory illusions are clear evidence that what we perceive differs from what exists externally. In the case of pain, a function absolutely critical to survival, it is remarkable that a given stimulus (or lack of stimulus) does not reliably evoke a predictable sensation. Under some circumstances, sensory perception is dominated by ascending nociceptive pathways as one may expect; however, there are a myriad of circumstances when sensory perception follows primarily from the effects of descending sensory modulation. Descending pain modulation can make one perceive and react to an innocuous stimulus as though it were painful. Holding a cold can of beer – the same can that felt ever so good on a hot summer day – in sub-freezing temperatures is unpleasant and even painful and chances are, you will drop the can. Pathological examples of "false positive" pains abound in the realm of the spontaneous pain that accompanies a number of neuropathic conditions, at least some of which depend on descending modulation for their initiation and maintenance. Examples of "false negatives" – noxious stimuli that fail to elicit a sensation of pain – also abound. One of the best articulated examples of this is David Livingstone's feeling of "a sort of dreaminess, in which there was no sense of pain," after being mauled by a lion (who Livingstone had just shot and injured), to the extent that his bone was splintered and skin permanently scarred [1]. These two examples represent two extremes on a continuum of sensitivity to cutaneous stimulation that ranges from insensitive (Livingstone) to inappropriately sensitive (holding cold beer on a freezing day).

The disconnect between the somatosensory worlds, outside and perceived, does not result from errors in the faithful, labeled-line, ascending sensory pathways, but rather from modulation of these same systems. Pain modulation happens at every level of the sensory pathway: at the peripheral terminal, the nerve, dorsal horn and on up the neuraxis. Touching one's skin before and after basking in the sun for hours elicits very different sensations because a number of inflammatory chemicals modulate the sensitivity of peripheral afferents. Yet, the exquisite sensitivity to touch resulting from a sunburn is not very different under different contexts. In order for modulation to be context-specific, the modulatory signal must arise from regions rostral to the spinal cord where information about context is available. Thus modulatory signals that alter nociceptive processing in accordance with context or meaning descend from the brainstem and forebrain. While some modulation ascends to modify thalamo-cortical processing of sensory input, it is clear that most pain modulation descends to the dorsal horn where it modifies the discharge of dorsal horn neurons that respond to nociceptor activation. In this way the dominant mode of pain modulation is to modify transmission at the earliest central synapses in the dorsal horn.

The primary direct (monosynaptic) sources of descending input to the dorsal horn arise from: (i) the medullary raphe magnus and adjacent reticular region; (ii) the locus coeruleus and neighboring catecholaminergic neurons in the dorsolateral pontine tegmentum; and (iii) motor cortex. Di- or oligo-synaptic connections from the midbrain periaqueductal gray, anterior hypothalamus and prefrontal cortex to the dorsal horn also figure prominently in the modulatory control of incoming sensory information. The raphe magnus and surrounding region, also known as the rostroventromedial medulla (RVM) or ventromedial medulla (VMM), has the strongest anatomical connection to the dorsal horn and receives input from virtually every other spinopetal afferent source. Thus, raphe magnus is considered to be the final common pathway for descending pain modulation and has been the focus of hundreds of studies. Much has been written about raphe magnus' contributions to descending modulation and many reviews are available on the subject [2]. Therefore only a few key points will be discussed here:

- Raphe magnus can either inhibit or facilitate nociceptive transmission. Under normal circumstances and in healthy animals, the inhibitory effects predominate. However, descending facilitation from raphe magnus is a necessary component for certain neuropathic pain syndromes [3]. It is interesting to note that under these same circumstances, descending inhibitory influences from the medullary raphe also appear to be enhanced, perhaps in an attempt, albeit unsuccessful, to suppress the on-going neuropathic pain signal [4].
- The medullary raphe suppresses low threshold as well as nociceptive responses in dorsal horn neurons [5]. Raphe magnus stimulation also modulates thermoreceptive responses in the superficial dorsal horn [6]. Thus, descending modulation from raphe magnus likely targets a variety of sensory inputs rather than only nociceptive ones.
- Medullary raphe and ventral reticular neurons project heavily to the intermediate gray, including the thoracic and sacral intermedio-lateral and medial cell columns and to the central canal region. These cells also project oligosynaptically to

sympathetically- and parasympathetically-innervated tissues as well as to some somatomotor muscles, all of which are involved in maintaining homeostasis [7]. Activation of medullary raphe neurons results in a number of homeostatic adjustments, evidence for a role beyond one of simple sensory modulation.

Descending modulation from sensorimotor cortex warrants mention here as it is the most under-studied and unrecognized component of descending pain modulation. Contrary to the textbook version of corticospinal axons targeting one motoneuron pool and associated motor interneurons in order to control a muscle's activity, corticospinal axons collateralize in multiple spinal segments and in dorsal and intermediate gray as well as in ventral horn [8,9]. In fact, there is a strong projection from sensorimotor cortex to the medial superficial dorsal horn, laminae I and II, where cells have distal receptive fields. As Shinoda and colleagues speculate [9], this projection may be important in modulating sensory inputs during self-generated movements. Thus, anticipated sensory inputs, such as the brush of whiskers on the paw during grooming, can be suppressed whereas unexpected inputs, such as a sharp object on the heel, which would be particularly harmful if encountered while stepping down, could be facilitated to ensure a brisk withdrawal. The projection of corticospinal neurons to the superficial dorsal horn may be the neural substrate by which motor cortex stimulation provides pain relief to patients with intractable pain [10].

## Detection of Tactile Stimuli

### Definition

Most tactile stimuli have multiple parameters each of which can be perceived separately from other parameters of the stimulus. For example, when we grasp an object, the position of the object on the skin and the contact force are perceived independently. The simplest judgment we can make is to detect the presence or absence of a particular stimulus or parameter. Psychophysics and clinical experiments have used von Frey monofilaments to establish absolute contact thresholds, sometimes referred to as touch thresholds. Another example of a tactile detection task is detecting the presence or absence of a micrometer sized raised bump when we rub our fingertips over a smooth surface. A higher level of judgment relates to the detection of a difference between two stimuli or discriminating the stimuli. Usually a difference in a single parameter is involved such as detecting a difference in the frequency of two vibrating probes (as opposed to a difference in their vibratory amplitude). An example of single parameter discrimination with a more complex multi-dimensional stimulus is discriminating the ripeness (compliance) of two peaches by grasping them.

Once an object is detected, we can make judgments about the magnitude of each of the stimulus parameters. In psychophysics experiments this process in known as scaling. For example, when grasping a sphere, we can independently scale the curvature of the sphere and the grip force used.

►Processing of Tactile Stimuli

## Detection of Tactile Stimuli, Effects of Attention

### Definition

When relying solely on tactile information, spatially selective attention is not essential in simple tasks such as detecting the presence or absence of surface texture but it plays a role in more complex tasks such as discriminating differences in surface texture. In contrast, when attention is manipulated across sensory modalities, such as between touch and vision, tactile performance of both simple detection tasks and more complex discrimination tasks is affected. Tactile performance is faster and more accurate when attention is not misdirected toward another modality. Such attention diversion produces a genuine perceptual impairment.

## Definition

Determinism is the metaphysical doctrine that the whole of world history is uniquely fixed by ►laws of nature and initial conditions. In science, "deterministic" is an epithet of theories or of laws that describe the temporal behavior of physical systems as strictly regular.

## Description of the Theory

### What is Determinism?

To a first approximation, determinism is the claim "that there is at any instant exactly one physically possible future" ([1] p 3). As such, determinism is a metaphysical doctrine about the course of the world as a whole, rather than a scientific theory. The French mathematician P. S. Laplace famously and vividly formulated metaphysical determinism in the early nineteenth century:

"An intelligence that, at a given instant, could comprehend all the forces by which nature is animated and the respective situation of the beings that make it up, if moreover it were vast enough to submit these data to analysis, would encompass in the same formula the movements of the greatest bodies of the universe and those of the lightest atoms. For such an intelligence nothing would be uncertain and the future, like the past, would be open to its eyes." ([2] p 2).

In his appeal to a superhuman intelligence, later called *the Laplacean demon*, Laplace merged the idea that the future is definitely fixed with the idea that it can be predicted. Predictability, even predictability in principle, is an *epistemic* notion, which relates to the question what can be known, not to the question what is the case. It is advisable to disentangle the metaphysical claim of Laplacean determinism from the idea of predictability, because the latter poses additional problems. For example, the superhuman intelligence must not obtain his knowledge about the present state of the universe in the normal way. In the actual world, any detection of information involves the consumption of energy and thus would alter the physical data supposedly available to the demon. If the doctrine of determinism is not disentangled from predictability, then it can easily shown to be untenable, as Popper did for what he called "scientific determinism" [3].

The Laplacean idea that the course of the world is fixed once and for all can be reformulated in the jargon of ►possible worlds. Following Montague, determinism has been defined as the doctrine that two possible worlds which instantiate the same laws are alike throughout all of time or never, "The world W is *Laplacean deterministic* just in case for any (possible world W′ which satisfies the natural laws obtaining in the actual world), if W and W′ agree at any time, then they agree for all times" ([4] p 13; cf [5]).

Laplacean determinism makes a *modal* claim, i.e., a claim about what *must* be the case, not simply a claim about what will in fact be the case. In this respect, it differs from so-called *logical determinism*, as encapsulated in the formula "Que sera, sera." Being a tautology, this

dictum does not say what is *bound to* happen, as a matter of physical necessity. By contrast, Laplacean determinism does comprise an inevitability claim. It is taken to express a causal, physical or metaphysical kind of necessity, not a logical one. As to the question where its modal force stems from, there remains just one serious candidate. While *theological determinism*, i.e., the doctrine of divine predestination draws its modal force from God's intentions or commands, scientifically minded Laplacean determinism takes it from the laws of nature. If determinism is true, it owes its truth to the existence of certain laws that "govern" everything. Given this bond between determinism and lawfulness, some philosophers apply the epithet "deterministic" primarily to some sets of laws and only derivatively to the course of the world. The following definition, which echoes Earman's quoted above, reflects this idea: "A *deterministic* system of laws is one such that, whenever two possible worlds both obey the laws perfectly, then […] they are alike always or never" ([6] p 37). The connection between the world related and the laws related formulations of determinism is provided by the deductive-nomological account, according to which deterministic laws, taken together with complete antecedent conditions, *logically entail* a description of the total state of the world at any other time.

Laplacean determinism is sometimes called *causal* determinism. While this locution helps to distinguish the doctrine from logical and from theological determinism, it is infelicitous in that it takes for granted a contentious conception of ►causality. Some authors simply equate determinism with the principle of universal causation, i.e. with the thesis that every event has a cause. This equation rests on the preconception that causality is a deterministic relation. But since nondeterministic accounts of causation have been developed, such an identification is unadvisable. Laplace himself chose a causal formulation when he suggested "consider[ing] the present state of the universe as the effect of its previous state and as the cause of that which is to follow" ([2] p 2). This view assumes an unusual conception of causal relata, according to which ►causal relations do not hold between ordinary events, but only between total states of the universe.

While determinism, in making a stronger claim about lawfulness, should not be identified with the principle that every event has a cause, it does exclude uncaused events, miracles and interventions by immaterial soul substances. Thus determinism is intimately linked with the principle of the ►causal closure of the physical domain (see also ►completeness of the physical domain). This association is due to the demand that one set of laws describe happenings completely and uniquely. If a miracle is defined as a violation of the laws of nature (Hume), it follows immediately that determinism rules out miracles. Whether determinism rules out *mental causation* is more difficult to decide. Accounts of mental causation that do not contest the claim that one set of physical laws fixes the course of events uniquely, e.g., supervenience theories of the mental, should be compatible with determinism.

Determinism is closely linked with the ►physicalistic assumption that whatever happens must supervene on the lawful behavior of microphysical entities. While the principle of the nomological primacy of the micro-level as it may be dubbed, is arguably not part of the *meaning* of "determinism," it is hard to see how it could work the other way round, i.e., how higher level laws could uniquely fix the behavior of microphysical entities. Note, however, that microphysical laws do not *causally determine* the behavior of the systems they describe. Laws are abstract entities; they do not make anything happen. Causal determination is a relation in time, which holds between events or states that follow each other. To say that laws "govern" events is already metaphorical.

*Hard determinism* and *soft determinism* are not further variants of determinism, but views about the compatibility issue in the free will debate. Soft determinism holds that determinism and free will are compatible. Hard determinism denies it. It is widely agreed that no kind of determinism is compatible with one core element of a "strong" conception of freedom, the principle of alternative possibilities, according to which the agent could have acted otherwise under the same circumstances.

## Is Determinism True?

Is determinism a scientific or a metaphysical theory? The issue hinges on the kind of evidence available. The natural assumption is that any scientific evidence for Laplacean determinism must come from physics, the most fundamental science. Now the determinism problem is by no means a dead issue in the philosophy of physics. In recent years, long established assumptions have been called into question. It is no longer uncontroversial that classical mechanics is a deterministic theory, nor that quantum mechanics is indeterministic [4,8]. Since Newtonian mechanics knows no upper bound on the velocities of moving particles, it does not rule out objects which "escape to infinity" nor the inverse phenomenon of "space invaders." The latter at least violate determinism. Moreover, Newtonian mechanics does not yield empirically correct solutions for a number of collision phenomena. As for quantum theory, its orthodox interpretation is indeterministic, but in recent years, deterministic interpretations have been developed which also seem to be consistent.

How could physics prove or disprove Laplacean determinism? The main obstacle to a scientific test is the global character of the doctrine. Laplacean determinism says something about the course of the world as a whole. Now take the laws related formulation that a

deterministic system of laws is one such that whenever two ►possible worlds both obey these laws, they coincide throughout all of time or never. The question whether determinism is true then seems to boil down to the question whether the fundamental laws of physics or the theories of which they form part are deterministic in character or not. A law of physics is deterministic if it is strict, i.e., if it admits no exceptions, is not probabilistic and does not contain open ended *ceteris paribus* clauses. Given that the book of nature is written in mathematicalese, as Galileo proclaimed, a physical law's being deterministic is a mathematical property of certain sets of equations (roughly, the property of having a unique solution for future times). In quantum mechanics, for example, the Schrödinger equation, which describes the evolution of the wave function, is taken to express a deterministic law. However, the deterministic character of fundamental laws and the theories to which they belong does not by itself license the inference that the *world* is deterministic, i.e., that Laplacean determinism is true. The problem with this inference can been described as follows: "The best approach to the question whether a world is deterministic is to analyze the laws or theories that pertain to it. The claim that not only the theory but also the world it pertains to is deterministic (or indeterministic) is however a further claim that needs to be established separately, e.g., by arguing that the relevant theory describes the whole universe in all its detail" ([9] p 12). A deterministic theory would have to tell the *whole truth* about the course of the world. It would have to be a final "theory of everything." Unless it is such a complete theory, any regular succession of phenomena predicted by the theory is susceptible to interferences that are due to the superposition of physical forces about which the theory is silent. As Russell puts it: "All causal laws are liable to exceptions, if the cause is less than the whole state of the universe" ([10] p 230). Lacking an all-encompassing theory, deciding whether certain laws of a physical theory are deterministic or not is immaterial to the question of whether Laplacean determinism is true. There is "a large gap between the determinism of a given physical theory and the bolder, vague idea that motivated the traditional formulations, the idea that the world in itself is deterministic" ([8] p 33).

By the same token, the existence of counterinstances to alleged deterministic laws or theories does not by itself *refute* Laplacean determinism. In order to put Hume's principle "same cause, same effect" to the test, the antecedent conditions of the entire system, i.e., of the universe, would have to be the same on two occasions: "As long as it is not the case that the entire universe was in perfectly identical states $t$ and $t'$, [an object] O's different behavior at those two points in time can always be attributed to different causes acting on it. […] Thus we could suggest that the doctrine of determinism implies that if the total state of the universe was ever identical with a state that had obtained at any time in its past, the universe would from then onward go through eternally recurring cycles" ([7] p 341 f). This intimate connection between Laplacean determinism and the ancient doctrine of eternal recurrence was already acknowledged by J. S. Mill, who framed the hypothetical principle: "If the whole prior state of the universe could again recur, it would again be followed by the present state". Now as far as is known, history does not repeat itself. And worse yet, the more precisely the antecedent of an alleged law is specified, the less probable it is that such a state will be instantiated more than once. There is an inverse relation between exactness and repeatability, as described by Russell: "As soon as the antecedents have been given sufficiently fully to enable the consequent to be calculated with some exactitude, the antecedents have become so complicated that it is very unlikely they will ever recur" ([11] p 188). This being the case, the deterministic idea that like states follow like states after definite time intervals can only be preserved in a counterfactual version, as in Mill's principle, if a state of the universe *were* ever to recur, history *would* repeat itself down to the last detail.

Science has no option but to study systems that are not causally closed. Within the actual world, no physical system is completely isolated. The very procedures of taking measurements and making observations constitute causal interactions between the observed system and its environment. The above mentioned principle that the physical domain as a whole is causally closed does not change the situation, for even if the physical realm were a deterministic system, this property would not be passed on to partial systems within the physical. As a remedy, it has been suggested "to formulate determinism in terms of completely isolated systems," thinking of theories as "describing single completely isolated systems, each alone in the universe" ([8] p 36 f). This move is however just another version of Mill's escape to counterfactuality. Restricted to isolated systems, determinism would become a counterfactual claim and perhaps even a counter*legal* one, in devising worlds which are nomologically impossible. The salient point is that positing physical systems that are each alone in the universe would deny the existential presuppositions of the remaining laws of physics, thus making it impossible for all of the laws to hold in the same actual world ([12] p 778).

In sum, evidence from physics can neither conclusively verify nor falsify Laplacean determinism. Its assertion transcends empirical evidence and this is precisely what makes determinism a metaphysical doctrine.

Now what about the whole array of domain-relative determinisms? Talk of psychological, biological, genetic, historical, economic or cultural determinism

carries the suggestion that these respective factors strictly determine say, the nature and the behavior of human beings. Genetic determinism, for instance, has been described as the view that "human lives and actions are inevitable consequences of the biochemical properties of the cells that make up the individual and these characteristics are in turn uniquely determined by the constituents of the genes possessed by each individual" ([13] p 3). Now it is simply not the case that genetic factors fix human behavior uniquely. In order to make a domain-relative determinism true, strict, exceptionless laws would have to exist that link say, the genetic set up of individual organisms with their behavior. No weaker correlation would do. In particular, making the system *disposed* to react in a certain way does not constitute a deterministic relation. In the absence of such strict laws, either all these domain-relative determinisms are plainly false, or a weaker reading of "determinism" must be developed.

## Determinism in the Neurosciences

In the neurosciences, "determinism" is not a well-defined theory. Theories in the neurosciences can be called "deterministic" if they treat their objects of research, i.e., the brain or the neural system, as deterministic systems. What does it mean that the brain "works deterministically" or that it is a "►deterministic automaton"? A deterministic automaton is one whose computational output is completely determined by the starting state, the input and the program. If the brain is such a system, its causal output must be fixed uniquely by these three factors. This could only be the case if the operation of the brain were causally isolated, i.e., if after the processing of some input begins, no further factor could ever disturb the dynamics of the brain from outside. Now surely more things can happen between brain input and output than are dreamt of in our neuroscientific textbooks. This is why neuroscience is hardly ever concerned with finding strict causal laws, i.e., causally sufficient conditions for the occurrence of a certain phenomenon. For example, the readiness potential, which "initiates" voluntary acts in the brain, according to B. Libet, is not a causally sufficient condition for the onset of movement and no one argues that it is. Just like any other physical system, the brain is susceptible to interferences of many kinds, including the sudden death of the organism that houses it, which ends all brain activity. Now systems that are not causally isolated cannot exhibit local determinism unless global Laplacean determinism is also true. (There is however one sense in which domain-relative determinisms could be true while Laplacean determinism is not; physical systems can be described at different levels and with different degrees of precision. If there is genuine randomness at the quantum level, this quantum indeterminacy may average out at the macro level. In that restricted sense, the world could contain deterministic systems even if the course of events is fundamentally indeterministic.)

It has been suggested that biological systems, while not being causally or energetically closed, are "operationally" or "organizationally closed" (Maturana/Varela). ►Operational closure means that certain relations and processes define the system as a unity, in determining the dynamics of interaction and transformations that the system may undergo. This kind of closure is however, immaterial to the issue of determinism. It is one thing to identify principles that restrict the number things that can happen within the system unless it is destroyed. It is another thing to reduce the number of possibilities to one. In order for the brain to be a deterministic system, its initial state, its input and its *modus operandi* would have to fix its causal output *uniquely* and as a matter of physical necessity.

The observation that neural activity is neither completely predictable nor purely random has led a number of authors to invoke the notion of ►deterministic chaos to describe the dynamics of the brain. Deterministically chaotic systems are extremely sensitive to initial conditions, which makes their dynamics unpredictable in the long run, while they still instantiate deterministic laws. In such systems, same causes still have same effects, but similar causes do not have similar effects. The response of nerve cells to periodic stimulations for instance, has been described as such a deterministically chaotic process. The philosopher Robert Kane invokes chaotic neural processes sensitive to quantum events in order to explain the possibility of free, undetermined decisions [14].

In the life sciences, the notions of determinism and determination are often used in a loose, informal sense. For example, talk of "neural determinants" of thought and behavior typically does not commit the speaker to determinism proper. But while the verb "to determine" is an ordinary English term that is not associated with a particular philosophical or scientific theory, it is questionable whether a weak sense of "determinism" really exists or should be introduced. Insisting that the brain "works deterministically" often just has the function of indicating that no causal gaps, no miracles and no intrusions by immaterial soul substances should be expected. These views are better expressed without the notion of determinism. In particular, the view that all mental phenomena are physically *realized* in the brain has nothing to do with determinism, the latter describing a *temporal* relation. One can believe in the causal closure of the physical, reject Cartesian dualism and repudiate obscure pseudo-explanations without adhering to Laplacean or neurobiological determinism. Consciousness, thought and behavior arguably have neural correlates and even neural "determinants," even if determinism is not true.

# Deterministic Automaton

### Definition

A deterministic automaton is a finite state computing system whose output is completely determined by the starting state, the input and the program.

►Determinism

# Deterministic Causation

### Definition

A relation between cause and effect such that a complete statement of the laws of nature together with a complete description of the condition of the entire universe at the time the cause occurs logically entails that the effect occurs.

►Freedom of Will

# Deterministic Chaos

### Definition

Deterministically chaotic systems are extremely sensitive to initial conditions. The dynamics of such systems is unpredictable in the long run, while they still instantiate deterministic laws.

►Determinism

# Detour Learning

### Definition

The ability to learn an efficient path to a goal that takes into account the presence of an obstacle or barrier to reaching the goal. This ability is difficult to explain by route navigation or dead reckoning navigation without a map. Similarly, route navigation and dead reckoning without a map make it difficult to take a newly available shortcut path to a goal. In contrast, a map-like representation of an environment contains the information that is needed for a subject to take efficient novel detour and shortcut paths. Thus the observation that rats can take detours and shortcuts was regarded as strong evidence that animals possessed an internal map-like representation of their environments. Such a representation is called a cognitive map and whether or not animals had one was the subject of the place versus response controversy.

►Navigation
►Spatial Learning/Memory

# Developing Nociceptive System

### Definition

An immature system in which the basic nociceptive connections (formed before birth) exhibit increased responsivity in comparison to the adult animal. The conduction velocity of afferent fibers, action potential shape, receptor transduction, firing frequencies and receptive field properties change substantially over the postnatal period.

## Synonyms

Developmental aspects of pain; spinal reflex; C fiber; nociceptor; spinal cord; neuropathic pain; chronic pain; medulla; cortex; receptive field; inhibitory circuits; hyperalgesia; analgesia

## Definition

The developmental aspects of pain concern the growth and maturation of neural pathways and mechanisms that result in nociceptive behavior and pain sensation in response to tissue damage in the fetus, infant and child.

Newborn infants show strong nociceptive behavior, but the nature of their pain sensation is poorly understood and as a result infant pain has, historically, been under-treated [1].

This essay will discuss our current understanding of mammalian pain development from both laboratory and clinical studies. It will show that

- Early pain behavior is restricted to reflex responses, but cortical pain responses are evident in the youngest preterm infants.
- Peripheral nociceptive neurons are specified early in development, and key molecular pathways that control this have been identified.
- Newborn nociceptive circuits are more excitable than in adults and receptive fields gradually become tuned during the postnatal period. This tuning arises from the refinement of afferent excitatory inputs and the maturation of inhibitory processes, both locally and descending from the brainstem.
- Nociception and ►primary hyperalgesia can be observed at an earlier age than ►secondary hyperalgesia and chronic ►neuropathic pain, suggesting that ►central sensitization pathways require postnatal maturation.
- Both non-noxious and noxious sensory activity can influence the development of pain processing.

## Characteristics

### The Onset of Nociceptive Reflexes and Pain Processing

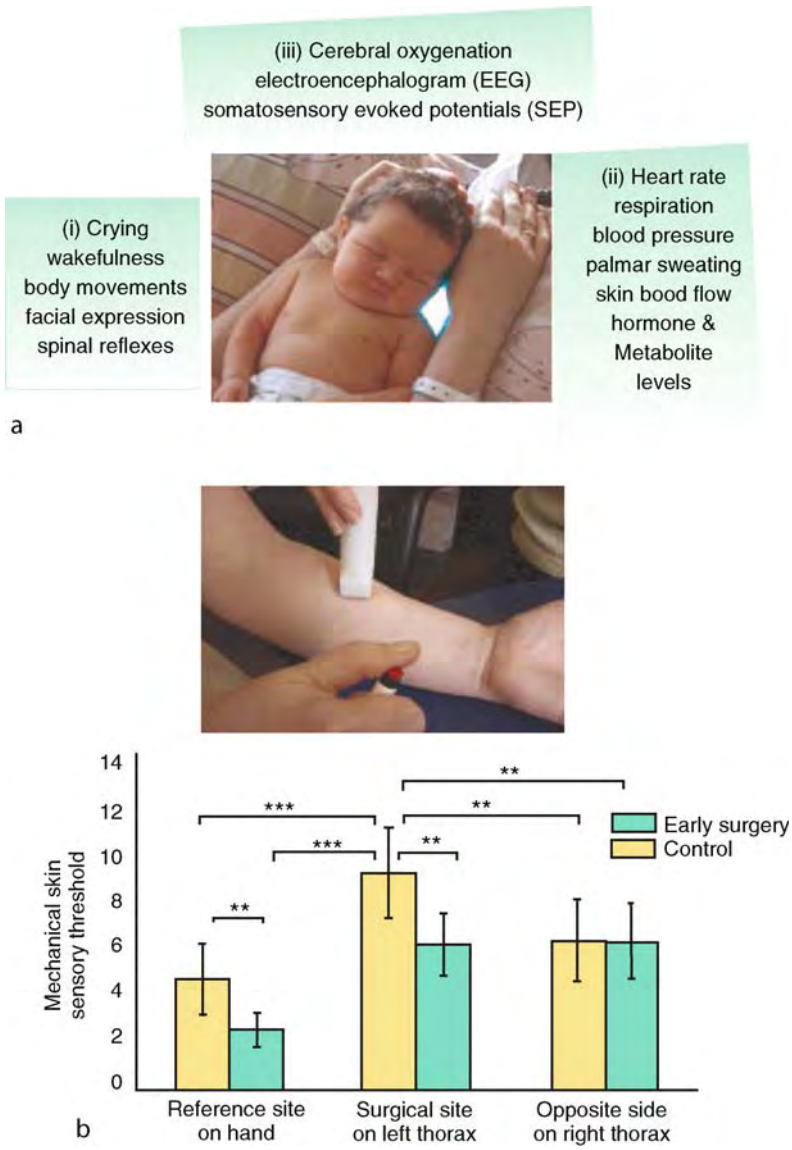
Nociceptive behavior in fetal life begins with the appearance of reflex reactions to noxious sensory stimuli. These responses are not, in themselves, evidence of pain perception or "feeling" pain, but do provide information about the ability of the fetal spinal cord and brainstem to respond to brief mechanical stimulation of the skin. These begin at 15 days of gestation in the rat fetus (E15, where gestation is 21.5 days) and coincide with the onset of spontaneous movements in the absence of any obvious external stimulation. These spontaneous movements are first observed by real-time ultrasound at 7–8 weeks of fetal life in humans, but it is not known whether reflex responses to skin stimulation begins at the same stage. However, it is clear that the youngest premature babies, born at 22 weeks gestation, display robust reflex limb withdrawal to lancing the foot (for clinical blood sampling) as well as cardiovascular and hormonal responses, crying and facial expressions associated with pain. Recently ►near-infra red spectroscopy has demonstrated neural activity in the contralateral somatosensory cortex in response to noxious stimulation in infants from 25 weeks showing that pain is potentially processed at cortical levels in very young infants [2,3]. (Fig. 1a) summarizes current methods of measuring pain in infants.

### Postnatal Maturation of Nociceptive Behavior

Spinally-mediated nociceptive reflexes are exaggerated in magnitude and duration compared to the adult, but they lack functional precision [3]. Considerable fine tuning occurs over the postnatal period, and as a result reflex responses cannot be interpreted in exactly the same way at each stage of development. A noxious prick on the foot of a very young rat pup or human infant can cause movements of the whole body and simultaneous responses from all four limbs, but these gradually mature into restricted limb or foot movements over the postnatal period. This is because neonatal spinal withdrawal reflexes have lower ►cutaneous thresholds, are easily sensitized by repeated stimulation and consist of more synchronized and prolonged muscle contractions than those of adults. Furthermore, reflex ►receptive fields are large and disorganized such that the withdrawal itself can be evoked from a wider area of the limb and is not always appropriate to the stimulus. For the first 10 days after birth, rat pups have a 75% error rate in the direction of a tail flick to noxious stimulation of the tail, and this gradually improves to the adult rate of less than 10% by P21. Preterm human infant limb and abdominal ►withdrawal reflexes show analogous lack of tuning [4]. This increased excitability and lack of focussed, directed response to a noxious stimulus in the newborn can be explained by the different sensory circuit properties in the infant spinal cord and brainstem. At birth, ►dorsal horn cell cutaneous receptive fields, particularly those in the deep dorsal horn, are relatively larger than in adults and decrease rapidly in size over the first two postnatal weeks.

### Development of Peripheral Nociceptors

Primary sensory neurons in the dorsal root ganglion are born early in embryonic life, but the small diameter



**Development of Nociception. Figure 1** (a) Measuring pain in human infants. Since infants cannot communicate their pain, other meadures are used: (i) motor reflexes and behaviour (ii) automatic changes and hormonal levels and (iii) cortical activity. (b) Quantitative sensory testing in children. Children that have undergone early pain and surgery are less sensitive to mechanical skin stimulation than their age-matched controls. Upper panel shows skin temperatures sensitivity testing on a child. Lower panel shows the mean meachanical sensivity in three skin areas in children that underwent thoracic surgery as neonats and age-matched controls. Note that the early surgery group have a higher threshold and are therefore are less sensitive to touch than the control group (adapted from ref 10).

C cells, most of which are future nociceptors, are in the last wave of neurogenesis. Their specification as a separate subgroup of sensory neurons is dependent on a member of the neurogenin family of ►transcription factors, ngn1. The final numbers of nociceptors are determined by the balance between cell birth and subsequent cell death, which in turn is regulated by access to peripheral neurotrophic factors that regulate the survival of immature nociceptors via signaling at receptor tyrosine kinases (►trks). In early life, all nociceptor neuron express trkA receptors and these require activation by the neurotrophin nerve growth factor (NGF) if the neurons are to survive. After birth, a subset of these neurons down-regulate trkA receptors and become dependent on a different neurotrophin called glial cell line-derived neurotrophic factor (GDNF) via the expression of the GDNF receptor Ret. The emergence of this sub-group of ret-expressing nociceptors is coordinated by a Runt domain transcription factor, called Runx1. In this way, two clear

subgroups of nociceptors emerge over the perinatal period: the trkA expressing group, which contain the neuropeptides, substance P and calcitonin gene related peptide (CGRP), and the ret expressing group which do not contain neuropeptides [5]. Both are important for the full range of mechanical, thermal and chemical nociceptive transduction.

Mechanical, thermal and chemical nociceptive transduction depends upon expression of the TRP (transient receptor potential) channel family and the maturation of differential expression of these channels determines the functional heterogeneity of nociceptor responses. The sequence of development of different TRP channels determines the onset of heat sensitivity in the mouse at E12.5 followed by cold sensitivity at E16.5 and finally sensitivity to mustard oil, a pungent irritant [6].

## Development of Spinal Nociceptive Circuits

C fiber nociceptor terminals grow into the superficial laminae of the dorsal horn of the spinal cord just before birth in the rat and their arrival coincides with a period of rapid synaptic CNS growth and reorganization. The larger diameter, myelinated ►A fibers, which convey a sense of touch and pressure from peripheral tissues, have already grown into the cord and in doing so have formed widespread connections over much of the target area. The earlier maturation and widespread presence of functional A fiber terminals in the first weeks of life means that dorsal horn pathways which, in the adult, are only triggered by noxious inputs, can also be activated by touch and pressure in the newborn. As ►C fiber inputs proliferate and strengthen over the postnatal period, the influence of A fibers over nociceptive circuits declines through what appears to be a competitive mechanism and A fiber terminals gradually withdraw to deeper laminae [4].

The postnatal period is marked by important changes in excitatory and ►inhibitory synaptic signaling in immature nociceptive circuits. Synaptic inputs from nociceptive fibers are not simply getting stronger over the postnatal period, they are changing their signaling properties. The major excitatory neurotransmitter is glutamate and its receptors (AMPA, NMDA, kainate and metabotropic receptors) are made up of subunits that are all developmentally regulated over the postnatal period in the sensory circuits of the dorsal horn. Overall, glutamatergic activity in the newborn seems to lead to longer channel opening times and greater calcium influx than in adults, properties that are thought to be critical for growth and synaptogenesis, but will also impact upon nociceptive transmission. The development of inhibitory connections is as important as the excitatory input. The main inhibitory neurotransmitters, GABA and glycine and their receptors (GABAR and GlyR) are also postnatally regulated in the postnatal dorsal horn. Initially, virtually all the inhibitory activity in the newborn dorsal horn is mediated by GABA, and there is little or no glycinergic activity, despite the presence of functional GlyR. Since glycinergic inputs mediate fast inhibitory events, their slow maturation relative to GABA inputs will affect the timing and synchronization of inhibition. In addition, GABA excitation is evident in the very newborn spinal cord, due to high intracellular $Cl^-$ concentrations $[Cl]_i$ in immature neurons, although inhibition predominates [7].

A further factor contributing to the balance of excitation and inhibition in spinal nociceptive circuits is descending activity from the brainstem. The brainstem is known to exert powerful descending control over spinal nociceptive processing in adults, largely through projections from the rostroventral medulla (RVM) and ►periaqueductal grey (PAG) traveling down the spinal cord in the dorsolateral funiculus (DLF). The role of this system in modulating spinal sensory processing in the neonate is less clear. Electrical activation of the periacqueductal gray (PAG) does not produce analgesia and stimulating the DLF does not inhibit the firing of dorsal horn neurons until at least P10. Recently, it has become evident that there is, in fact, powerful tonic supraspinal excitatory control over nociceptive circuits in the newborn, which shifts to inhibition after several postnatal weeks.

## Development of Persistent and Chronic Pain Mechanisms

Tissue injury and inflammation can lead to persistent pain and ►hyperalgesia that lasts for days, weeks or months due to sensitization of peripheral nociceptor terminals in the injured area and central sensitization of nociceptive neurons in the spinal cord and higher centers.

Hyperalgesia can also be produced by experimental inflammation in newborn rats and hypersensitivity to tissue damage can also be measured in human infants, where “tenderness” or a fall in reflex thresholds is established for days and weeks in the presence of local skin or deep visceral tissue injury. The effect is small in the youngest infants and increases with age in both rats and humans. Secondary hyperalgesia, which spreads into an area surrounding the original injury, appears to develop later than primary hyperalgesia in newborn rats [8].

Immature C fibers are capable of peripheral sensitization from before birth, but the release of the neurotransmitter substance P from their terminals is likely to be low in the neonate and substance P receptors (NK1) undergo substantial postnatal reorganization. In slice preparations, NMDA dependent C-fiber evoked depolarization of spinal cord cells and “wind-up” of cells to repeated C-fiber stimulation has been

demonstrated in the young (8–14 day) spinal cord, but it is not clear that it occurs earlier than that. In any event, it is evident that different protein kinase C-mediated pathways are triggered in the dorsal horn of young versus old rats by inflammation.

The development of neuropathic pain in infants and children is not well understood. Brachial plexus injuries occurring in infants during delivery do not appear to result in chronic neuropathic pain and peripheral nerve injuries do not evoke neuropathic pain behavior in neonatal rats in contrast to the pronounced behavioral changes seen in adults. Mechanisms underlying neuropathic pain, such as the activation of microglia in the dorsal horn, are absent in the early postnatal period and further studies of their development may aid our understanding of chronic pain in adults [9].

### Sensory Experience and the Development of Pain Processing

There is increasing evidence that the normal maturation of nociceptive systems is influenced by exposure of the infant to sensory stimulation. Sensory activity could arise from nociceptive or non-nociceptive inputs, but under normal physiological circumstances nociceptor activation would be rare in the first postnatal weeks while tactile stimulation would be considerable. Whereas daily noxious stimulation does not affect postnatal tuning of the nociceptive tail reflex, blocking low intensity tactile inputs from the tail with local anesthetic, during a critical ten day period, prevents it [6]. Regular tactile input can arise from spontaneous twitching during sleep in both rats and human infants and this has been proposed to be responsible for shaping nociceptive circuits in early life.

There is evidence that C fiber activity influences synaptic organization in the spinal dorsal horn. Neonatal destruction of C fibers by systemic administration of the neurotoxin capsaicin prevents or delays the development of a number of synaptic processes and increased C fiber input early in development is also likely to alter the normal development of nociceptive circuits [3]. The well-documented numerous invasive procedures that preterm infants undergo in intensive care, where it is not always possible to achieve adequate levels of analgesia, could produce increased C fiber activity, which in turn could alter the subsequent development of the nervous system. There are reports that children who were in intensive care as infants do have altered somatosensory processing [10] (Fig. 1b). In animal models, neonatal hindpaw inflammation has a pronounced effect on the central terminal fields of C fibers and the dorsal horn cell response to a second inflammatory challenge is increased well into adulthood. Similarly, neonatal skin wounds have prolonged effect long after the wound has healed and the skin remains hypersensitive and dorsal horn receptive field sizes expanded for at least six weeks [3]. This is an area that requires more research before firm conclusions can be drawn.

## Development of the Respiratory Network

Hugo Lagercrantz, Malin Rohdin
Karolinska Institute, Astrid Lindgren Children's Hospital, Stockholm, Sweden

### Synonyms

Respiratory network growth and maturation

### Definition

The respiratory network consists of clusters of neurons in the brain stem that receives afferents from central

and peripheral chemoreceptors, mechanoreceptors in the lung and also from the cortex, hypothalamus and cerebellum. This structure generates the respiratory rhythm and forms the pattern of breathing movements. It used to be named the respiratory center. However, this term is not really appropriate since the forebrain, the hypothalamus and other suprapontine nuclei can override the respiratory network in the brain stem for example during talking and singing (Euler) [1].

## Characteristics

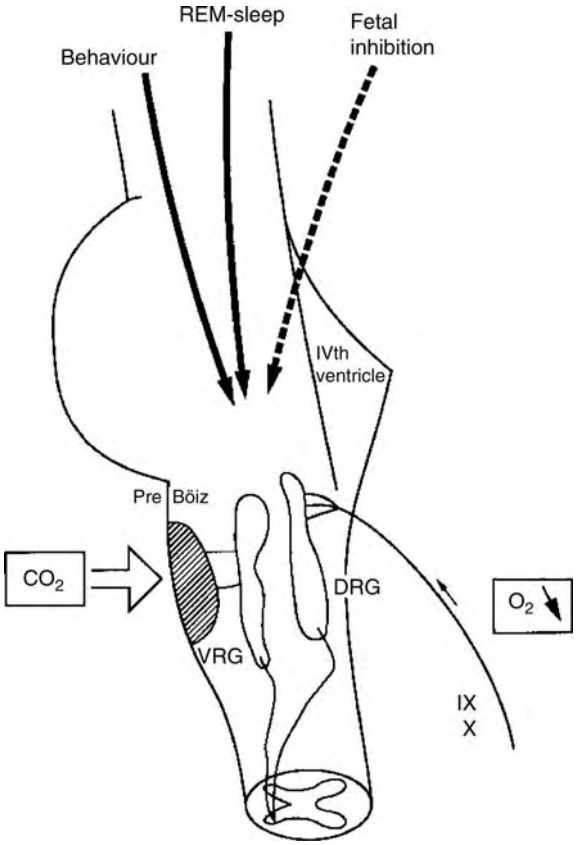
Respiratory movements can be observed by ultrasound already during the 11th gestational week in the human fetus. Respiratory related rhythm activity can be recorded from the isolated ►brainstem via C3 and C4 from the rat fetus at the 16th gestational day. These findings suggest that the respiratory rhythm generator localized in the ►pre-Bötzinger complex is developed at an early stage long before air breathing commences. However, the first respiratory-like activity is rather ataxic and a more rhythmic pattern emerges first after the inspiratory activity is inhibited by pontine structure, which is evident around E 18 in the rat fetus.

## Embryology/Anatomy

The respiratory rhythm generator is localized in the so-called pre-Bötzinger complex, which is a part of the nucleus tractus solitarius. The ►nucleus Ambiguus is also involved. The ►Kölliker-Fuse Nucleus, which is a part of the ►Locus Coeruleus, executes switching off the inspiration. Both clinical evidence and observations on transgenic mice indicate that inactivation of the genes encoding for the making of nuclei of the cranial nerves may cause aberrant respiratory patterns after birth [2].

## Neurochemistry

►Glutaminergic neurons within the pre-Bötzinger complex can generate this activity. Glutamate seems to be essential for sharpening the central pattern generator acting via ►AMPA receptors and ►NMDA receptors. There are also subpopulations of neurons expressing opioid and substance P receptors in these structures. Substance P is the most abundant neuropeptide in the ►respiratory kernels and it has been found to affect the patterning of the respiration. ►GABA is an excitatory neurotransmitter in fetal life, but switches to an inhibitory neurotransmitter during maturation due to the expression of ►KCC2. Adenosine, prostaglandin and endogenous opioids inhibit breathing and may be responsible for suppression of breathing before and after birth. Blocking the action of endogenous adenosine is probably the mechanism by which theophylline and caffeine exert their clinical effects in the treatment of ►apnea of prematurity [3,4].



**Development of the Respiratory Network.**
**Figure 1** Organization of the neuronal groups and drive mechanisms controlling respiration. The $CO_2$ drive is mediated by the central chemoreceptive area at the ventral surface. The hypoxic drive is mediated by the cranial nerves iX and X) which terminate at the dorsal respiratory group (DRG). The respiratory rhythm generator is assumed to be located in the pre-Bötzinger complex of the ventral respiratory group (VRG).

## Fetal Respiratory Movements

During the fetal period the respiratory system is fluid-filled and the fetus performs intermittent breathing efforts from 10 to 11 weeks of gestation [5]. Fetal respiratory movements are promoted by activity in the reticular system during rapid-eye-movement (REM) sleep, as identified by low-voltage cortical electrical activity [5]. In contrast, fetal breathing is inhibited during quiet sleep.

However, if the brainstem is transected above pons in the fetal sheep the breathing becomes continuous, indicating the existence of a suprapontine inhibition [5]. ►Hypoxemia also causes arrest of respiratory movements in the fetus due to central inhibition. Hypercapnia ►stimulates fetal breathing only during active sleep but has no effect during quiet sleep. The fetal respiratory movements are less frequent towards the end of gestation.

## Transition at Birth

The fetal respiratory movements are inhibited during labor, although severe hypoxemia may trigger gasps, which can lead to meconium aspiration. The mean time for the onset of respiratory effort is about 10 s, although there is great variability. The factors responsible for the onset of breathing can be divided into extrinsic (e.g. skin cooling and painful stimuli) and intrinsic influences (e.g. removal of respiratory inhibitory mechanisms including adenosine and ►prostaglandins, increased wakefulness, level of catecholamines and activation of $CO_2$ drive). The respiratory pattern is very irregular at birth, probably caused by incomplete neuronal interconnection and integration of signals.

Inspiratory pressure and volume are similar in newborn infants delivered by cesarean section compared to infants born vaginally. However, the expiratory and delivery pressures are often smaller and the functional residual capacity is formed less frequently after cesarean section than in the vaginal delivery. This is due to the fact that the lung liquid is less rapidly removed, probably caused by lower levels of catecholamines [3].

## Arousal and the Forebrain Drive

Respiration is governed by a number of regulating mechanisms hierarchically arranged to ensure behavioral and metabolic demands [1]. The breathing pattern during the awake state is rather irregular and influenced by sensory input and behavior. In contrast, the respiration is determined by the $CO_2$ drive during quiet sleep and by reticular firing during ►REM sleep.

## Thermodrive

The only way to elicit breathing movements in the fetal sheep during apnea is by cooling. There are also anecdotal evidences that cooling of the newborn infant, due to evaporation of the amniotic fluid, is an important trigger of the first breaths of air. Increasing the skin temperature of the preterm infant is a well-known factor causing apnea. It has also been assumed that some infants dying of ►SIDS have been too warm, particularly when they sleep in prone position.

## Central and Peripheral Chemoreceptor Drive

►Central chemoreceptors in the brain stem are continuously regulating the breathing through the partial pressure of carbon dioxide ($PCO_2$) and pH in the blood. The partial pressure of oxygen ($PO_2$) on the other hand, will only stimulate respiration when it reaches hypoxemic levels ($PO_2 < 20$ mmHg) through the ►peripheral chemoreceptors located in the carotid and aortic bodies. The peripheral receptors are set at a lower $PO_2$ level in the fetal sheep, probably adapted to the low $O_2$ in the fetus (Mount Everest in utero). The sensitivity is increased a few days after birth. This has been tested by the so-called ►Dejours test, i.e. exposing the infants briefly for 100% oxygen. Normally, this results in a ~10% decrease of ventilation corresponding to the hypoxic drive. However, newborn infants do not respond until after a few days of age. Dopamine is probably involved in this process, since dopamine turnover decreases after birth.

## Respiratory Pattern

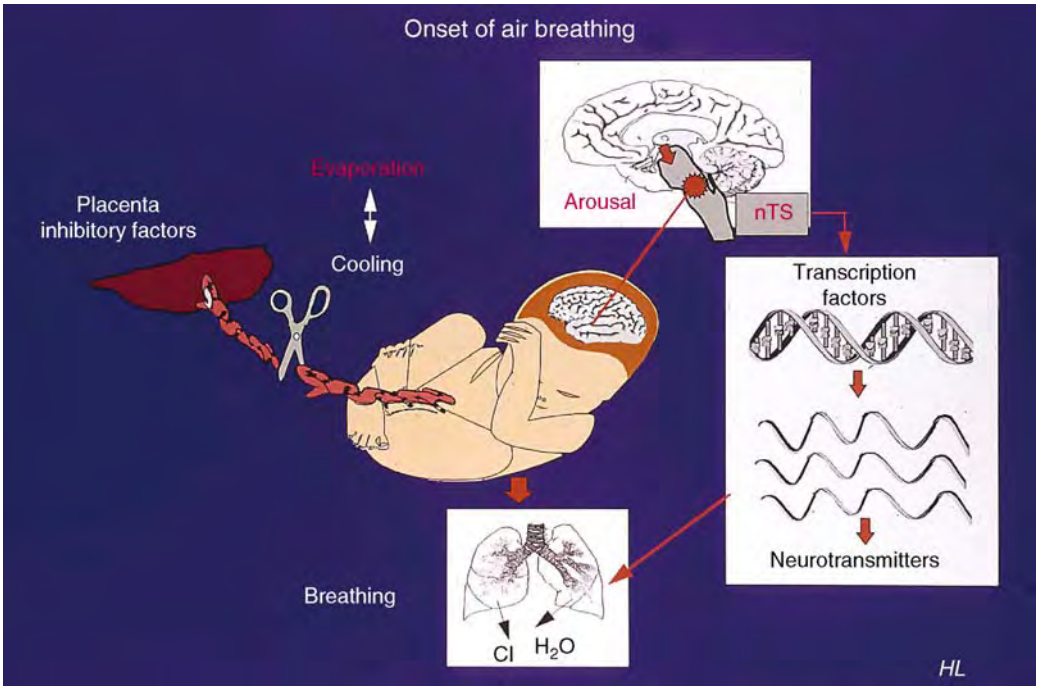
Maintenance of continuous, regular and effective breathing is dependent on a number of factors: the intricate balance of suprapontine influence on respiratory activity, chemoreceptor activity, neuromodulators, airway patency and stretch receptors in the lungs [1]. The precise integration of these various inputs is of particular importance to the infant [3].

In the neonatal period the breathing pattern is more influenced by respiratory reflexes than during childhood and adulthood. The respiratory reflexes are initiated by stretch receptors in the airways or the chest wall. Breuer and Hering found that inflation of the lung leads to apnea. The ►Hering-Breuer reflex prevents overinflation of the lungs and appears to be more important during the neonatal period than later in life. Pulmonary stretch receptors, present in the smooth muscle of the airways, respond to excessive stretching of the lung during large inspirations. The stretch receptors send action potentials to the apneustic center of the pons, inhibiting the inspiratory neurons present there, allowing expiration to occur. The Hering-Breuer reflex is active within tidal breathing range and increases progressively in strength from FRC to approximately 4 ml/kg above FRC. There is a significant relationship between strength of the reflex and respiratory rate, suggesting that the reflex modifies the breathing pattern in the neonatal period.

## Apnea

Apnea of prematurity represents a major medical concern in the neonatal population [6]. Clinical apnea in infants is defined as a pause in breathing for more than 20 s or a briefer pause if associated with bradycardia. Apneas are more common in preterm than in term infants [4], probably due to brainstem immaturity. The incidence of apnea of prematurity is inversely related to gestational age [7]. However, term infants apparently also have apnea exceeding 20 s, which has been detected by home monitoring.

Apneas can be divided into three different categories; central, obstructive and mixed apneas. Central apnea is defined as a complete cessation of inspiratory effort with no sign of obstruction of the upper airways. In the obstructive apnea, the infant tries to breathe against an obstructed upper airway resulting in chest wall/abdominal motion without nasal airflow. Mixed apnea is a combination of both



**Development of the Respiratory Network. Figure 2** Mechanisms involved in the initiation of the first breaths of air. Cooling at birth and arousal seem to be more important, than the $CO_2$ drive. Hypoxia inhibits the breathing of the fetus and the newborn, since the peripheral chemorceptors are not yet adapted. Immediate early genes and genes encoding for Substance P and other respiratory stimulating neurotransmitters seem to be switched on at birth.

central and obstructive apnea. There is often a central respiratory pause followed by an obstructed respiratory effort.

### Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) remains the most prevalent cause of post-neonatal infant mortality in developed countries. SIDS is defined as an abrupt death of an infant less than one year of age that remains unexplained after a thorough clinical history, death scene investigation and postmortem examination. Although the complete picture is yet to be drawn, a number of risk factors can be identified. SIDS is probably the result of an unfortunate combination of a critical time during maturational development, a congenital or acquired vulnerability and an acute stressor. SIDS occurs mainly during the first 6 months of age and the peak is between 2 and 4 months. Fetal exposure to nicotine seems to be the second most important risk factor. Nicotine affects the respiratory and arousal responses to hypoxia. It may also attenuate the ability to auto-resuscitate, possibly due to depleting of the catecholamine stores [8]. Failure of autoresuscitation mechanisms other than failure to initiate gasping may be characteristic of infants dying of SIDS. The most important environmental risk factor seems to be prone sleeping. By the back-to-sleep campaign the incidence of SIDS has been reduced from about 1 case per 500–1,000 live-born to less than 1/4,000 in many countries [9]. The mechanism has not yet been clarified but it is possible that prone sleeping affects the heat dissipitation and $CO_2$ removal. Another example of an acute stressor is an upper airway infection, which is a primary risk factor for SIDS, possibly mediated by interleukins, which inhibits breathing [10].

Sudden respiratory failure is currently viewed as the most likely cause of death in SIDS. Although sudden deaths in infants resulting from cardiac arrhythmias are well documented, these appear to account for no more than 5–10% of SIDS cases.

### Synonyms

Developmental disabilities

### Definition

Developmental Disorders are disorders that happen during infancy, childhood, or adolescence, and are typically accompanied with retarded development. They include psychological or physical disorders. In DSM-IV, the following disorders are listed; i) mental retardation, ii) learning disorders, iii) motor skills disorder, iv) communication disorders, v) pervasive developmental disorders, vi) attention-deficit and disruptive behavior disorders, vii) feeding and eating disorders of infancy or early childhood, viii) tic disorders, ix) elimination disorders, x) other disorders of infancy childhood, or adolescence [1].

### Characteristics

The neurodevelopmental disorders, whose primary causes are attributed to the nervous system, are focused on in this essay. Recently, molecular analyses of these disorders have achieved progress in cloning the causative genes. For example, methyl CpG-binding protein 2 (MeCP2) is responsible for Rett's disorder and SLITRK1 (Slit and Trk-like 1) for Tourette syndrome. DCDC2 (Doublecortin domain-containing 2), ROBO1 and KIAA0319 are likely to be responsible for dyslexia. A comprehensive list of genes useful for defining the diseases based on molecular understanding is not yet available.

In the subsequent chapters, the following neurodevelopmental disorders are discussed; i) mental retardation (MR), ii) learning disorders (LD), iii) pervasive developmental disorders (PDDs), and iv) attention-deficit hyperactivity disorder (AD/HD). In some cases, these disorders overlap with each other, and a single genetic mutation might present different clinical phenotypes in different persons. Some psychiatric diseases, including schizophrenia, whose onsets are considered to occur in the adolescent or adult period, are sometimes categorized into the developmental disorders, since their causes can be traced back into childhood.

Mental retardation (MR) is defined as a significant impairment of cognitive and adaptive function.

Intellectual developmental disorder, mental deficiency, and cognitive impairment are used as similar concepts. Learning disorders (LD) are defined as developmental impairment in a single area of development, such as reading, mathematics, or written expression. Pervasive developmental disorders (PDDs) are a class of neurodevelopmental disorders that emerge in childhood and involve impairments in the development of social reciprocity, communicative functioning, and/or a restricted range of interests and behaviors [2]. Five disorders are included in this category, namely i) Autistic Disorder, ii) Asperger's Disorder, iii) Rett's Disorder, iv) Childhood Disintegrative Disorder, and v) Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS). Age of onset, natural course, and individual symptom patterns are important for a precise diagnosis. Attention-deficit hyperactivity disorder (AD/HD), one category of attention-deficit and disruptive behavior disorders, results in symptoms of inability to maintain attention, impulsive behaviors and/or motor restlessness.

## Developmental Disorders: Mental Retardation (MR)

MR is diagnosed in individuals who have significantly subaverage intellectual function, existing concurrently with related limitations in two or more of the following applicable adaptive skill areas: communication, self-use, home living, social skills, community use, self-direction, health and safety, functional academics, leisure and work. IQ score is usually defined as lower than 70. It is called mild when IQ is 50–55 to 70, moderate when IQ is 35–40 to 50–55, severe when IQ is 20–25 to 30–40 and prefound when IQ is below 20–25. It is subdivided into syndromic and non-specific when associated with distinct dysmorphic, neurological, behavioral or biometric abnormalities and when it is the only abnormality, respectively.

### *Prevalence*

1–3% of individuals in the general population. Sex ratio (male:female) is 1.5:1.

### *Pathology*

It is divided into four groups according to whether the causal diagnosis is i) genetic, ii) multifactorial, iii) environmental, or iv) unknown etiology. The most common known cause of MR is genetic etiology, which accounts for roughly 40% of the entire group. In this group, chromosomal abnormalities, including 21 trisomy, 18 trisomy, are the most common, and account for 20% of cases of MR. Other monogenic causes of MR include Fragile X syndrome, which is caused by FMR-1 gene mutations and occurs mainly in men, and Rett's syndrome, which is caused by mutations of the MECP2 gene in females. The latter disease is also classified as one of the PDDs, which are described later. Hundreds of genetic diseases can cause MR. Among them, X-linked MR (XLMR) is important because it accounts for 10% of all MR. One-third of the estimated 165 genes associated with syndromic MR have been shown to reside on the X chromosome, and one-fourth of the estimated 100 genes causing non-specific MR are mapped on the X chromosome.

Multifactorial reasons have been suspected as causes of malformations of the central nervous system such as hydrocephalus and spina bifida. Drug-induced embryopathy and infection in the uterus are some of the possible environmental causes. Perinatal asphyxia causes 5% of all MR. In our present medical diagnostic situation, the largest part of MR (about 60% of all patients) is of unknown etiology. Two-thirds of them are syndromic and one-third is nonspecific. In the future, this category might be re-classified and include the former three groups.

## Learning Disorders (LD)

Specific ability, such as the mathematics ability, reading ability or writing ability, of individuals suffering from this LD is substantially below their expected potential.

Following the DSM-IV, the diagnostic criteria are as follows [1]

Reading Disorder

A. Reading achievement, as measured by individually administered standardized tests of reading accuracy or comprehension, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.
B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living that require reading skills.
C. If a sensory deficit is present, the reading difficulties are in excess of those usually associated with it.

### *Mathematics Disorder*

A. Mathematical ability, as measured by individually administered standardized tests, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.
B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living that require mathematical ability.
C. If a sensory deficit is present, the difficulties in mathematical ability are in excess of those usually associated with it.

### *Disorder of Written Expression*

A. Writing skills, as measured by individually administered standardized tests (or functional assessments of writing skills), are substantially below those

expected given the person's chronological age, measured intelligence, and age-appropriate education.

B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living that require the composition of written texts (e.g., writing grammatically correct sentences and organized paragraphs).

C. If a sensory deficit is present, the difficulties in writing skills are in excess of those usually associated with it.

### Prevalence

Approximately 2–10% of children.

### Pathology

Several genes have been reported as candidate genes for LD. FOXP2, mapped at 7q31, was mutated or duplicated in several families with speech and language impairment [3]. FOXP2 is a transcription factor containing the forkhead DNA-binding domain and is expressed broadly in the brain.

## Pervasive Developmental Disorders (PDDs)

The prevalence of PDDs is about 60 cases per 10,000 children. The largest proportion (~70%) of individuals with PDD have mild disorders-showing high IQ score, such as Asperger's Disorder and PDD-NOS. By contrast, the more severe regressive disorders (Childhood Disintegrative Disorder, Rett's Disorder) represent only about 2% of the cases of PDD.

### PDDs: Autistic Disorder

This disorder is characterized by the following three features:

(1) Deficits in social relating and reciprocity.
(2) Impaired language and communication skills.
(3) Restricted range of interests and activities.

Following the DSM-IV, the diagnostic criteria are as follows [1]

A. A total of six (or more) items from (1), (2), and (3), with at least two from (1), and one each from (2) and (3): Qualitative impairment in social interaction, as manifested by at least two of the following: (i) marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction, (ii) failure to develop peer relationships appropriate to developmental level, (iii) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest), (iv) lack of social or emotional reciprocity.

(1) Qualitative impairments in communication, as manifested by at least one of the following: (i) delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime), (ii) in individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others, (iii) stereotyped and repetitive use of language or idiosyncratic language, (iv) lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level.

(2) Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following: (i) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus, (ii) apparently inflexible adherence to specific, nonfunctional routines or rituals, (iii) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements), (iv) persistent preoccupation with parts of objects.

B. Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years: (i) social interaction, (ii) language as used in social communication, or (iii) symbolic or imaginative play.

C. The disturbance is not better accounted for by Rett's Disorder or Childhood Disintegrative Disorder.

### Prevalence

Autistic disorder develops before 36 months of age and is typically diagnosed by 18 months of age. Prevalence is approximately 20–60 per 10,000 births and 4–5 times more common in males than females.

### Pathology

Primary responsible region has not been identified, although deficits in the reticular activating system, structural cerebellar changes, forebrain hippocampal lesions, and neuroradiologic abnormalities in the prefrontal and temporal lobe areas, as well as the cingulate cortex, have been documented, and abnormal neurochemical findings have also been shown to be associated with autism, with dopamine, catecholamine, and serotonin levels or pathways implicated. However, the literature on brain structure and function in autistic children is conflicting and there is no diagnostic imaging or other test for autism at present.

The cause of autism is multifactorial [4]. There is a 60–90% concordance rate for monozygotic twins and less than 5% concordance rate for dizygotic twins. Anomalies have been reported in all but three chromosomes. Most promising may be the maternal but

not paternal duplication in chromosome 15q11-q13. Autism sometimes co-occurs with a variety of neurological disorders, such as tuberous sclerosis, phenylketonuria, fragile X syndrome, and neurofibromatosis. Approximately 25% of individuals with autism develop seizure disorders during their lifetime.

In addition, it has been reported that there are several symptoms associated with some patients with this spectrum; multisensory defects, selective dominance of visuospatial functions, high incidence of subthreshold EEG abnormalities, comorbidities with sleep-wake cycle anomalies, frank epilepsy (~15–25%) and MR (~50%) [5].

Individualized educational and behavioral treatments are essential for promoting optimal functioning for persons with autism. Recent research suggests that specialized early intervention (before 3 years old) can be extremely effective in promoting significant gains in social, communicative, and cognitive functioning. The TEACCH (Treatment and Education of Autistic and Communication Handicapped Children) model, which aims to improve the quality of the treatment program and the adaptation of individuals with autism with severe disabilities, was proposed and developed at Division TEACCH, University of North Carolina [6].

Antipsychotics, including haloperidol and risperidone, are the most widely studied drugs for reducing symptoms in children and adolescents with autism. When administered at relatively low dosages, antipsychotics have been shown to reduce repetitive behaviors and social withdrawal, as well as a number of related symptoms, such as hyperactivity, aggression, self-abusive behavior, temper tantrums, liability of mood and irritability [7].

### PDDs: Asperger's Disorder

This disorder is characterized by the following three features:

1) Qualitative impairments in social interaction.
2) Restricted patterns of behavior or interests.
3) Average language and cognitive development.

Following the DSM-IV, the diagnostic criteria are as follows [1]

Qualitative impairment in social interaction, as manifested by at least two of the following: (i) marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction (ii) failure to develop peer relationships appropriate to developmental level (iii) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people) (iv) lack of social or emotional reciprocity.

A. Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following: (i) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus (ii) apparently inflexible adherence to specific, nonfunctional routines or rituals (iii) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements) (iv) persistent preoccupation with parts of objects.
B. The disturbance causes clinically significant impairment in social, occupational, or other important areas of functioning.
C. There is no clinically significant general delay in language (e.g., single words used by age 2 years, communicative phrases used by age 3 years).
D. There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood.
E. Criteria are not met for another specific Pervasive Developmental Disorder or Schizophrenia.

### Prevalence

Approximately 8–30 per 10,000 children, but the border between Asperger's disorder and autism is not clear and may cause an error in statistics.

### Pathology

The diagnosis is mainly based on behavioral assessment and developmental history, therefore, it is usually made at least 5 years after birth. Group social skill training is an important therapy, although children with this disorder have a high risk for other psychiatric disorders.

### PDDs: Rett's Disorder

This is a syndrome involving progressive psychomotor deterioration, stereotypic movements of the hands, loss of acquired language and decreased cranial growth. Several diagnostic criteria have been proposed [8].

### Pathology

A gene that encodes the methyl CpG-binding protein 2 (MeCP2) on the X chromosome is the gene responsible for this disorder. Recently a second gene, CDKL5, responsible for the disease was reported.

### PDDs: Childhood Disintegrative Disorder

Also called Heller dementia. Patients develop normally up to 2–4 years, and then exhibit severe deterioration of mental and social function. Language, social skills, and imagination are profoundly affected. Seizures are often present.

### PDDs: Pervasive Developmental Disorder Not Otherwise Specified (PDDNOS)

Individuals who have severe impairments in social relating and reciprocity, but who do not meet the diagnostic criteria for any of the other Pervasive Developmental Disorders. In addition to social deficits, patients with PDDNOS must demonstrate either impairments in communication development or restricted, repetitive interests and activities. The diagnosis of PDDNOS is based primarily on behavioral observations and developmental history. Educational and behavioral treatments are essential for promoting optimal functioning for persons with PDDNOS.

### Prevalence

PDDNOS is the most common of the PDDs. Approximately 36 per 10,000 births.

## Attention-Deficit Hyperactivity Disorder (AD/HD)

Criteria for AD/HD according to DSM-IV are as follows [1]

A. Either (1) or (2):
   (1) Inattention: six (or more) of the following symptoms of inattention have persisted for at least six months to a degree that is maladaptive and inconsistent with developmental level: (i) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities. (ii) often has difficulty sustaining attention in tasks or play activities. (iii) often does not seem to listen when spoken to directly. (iv) often does not follow through on instructions and fails to finish school work, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions). (v) often has difficulty organizing tasks and activities. (vi) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework). (vii) often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools). (viii) is often easily distracted by extraneous stimuli. (i) is often forgetful in daily activities.
   (2) Hyperactivity-impulsivity: six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least six months to a degree that is maladaptive and inconsistent with the developmental level.

   Hyperactivity
   (i) often fidgets with hands or feet or squirms in seat. (ii) often leaves seat in classroom or in other situations in which remaining seated is expected. (iii) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness). (iv) often has difficulty playing or engaging in leisure activities quietly. (v) is often "on the go" or often acts as if "driven by a motor." (vi) often talks excessively. Impulsivity (vii) often blurts out answers before questions have been completed. (vii) often has difficulty awaiting turn. (i) often interrupts or intrudes on others (e.g., butts into conversations or games).

B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before age 7 years.
C. Some impairment from the symptoms is present in two or more settings (e.g., at school [or work] and at home).
D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.
E. The symptoms do not occur exclusively during the course of a Pervasive Developmental Disorder, Schizophrenia, or other Psychotic Disorder and are not better accounted for by another mental disorder (e.g., Mood Disorder, Anxiety Disorder, Dissociative Disorders, or a Personality Disorder).

### Prevalence

5–8% of children.

### Pathology

Twin studies suggested substantial genetic influences ranging from 60 to 90%, and non-shared environmental influences ranging from 10 to 40% [9]. This disorder is also considered to be a polygenic trait. From clinical observations of drug effects, this disorder was proposed to result from dysregulation of dopamine and norepinephrine circuits. Based on association and linkage studies, a relationship with *DAT1* (the dopamine transporter gene), *DRD3* and *DRD4* (the dopamine receptor *D3* and *D4* genes), alpha 2A adrenergic receptor (*ADRA2A*), *HTR1β* (the *serotonin 1β* receptor gene), etc., was proposed; however, the strength of the relationship is not so evident at present.

Several drugs were tried historically, including stimulant drugs such as methylphenidate, as reviewed by Biederman and Faraone (2005) [10].

## Developmental Plasticity

### Definition

Neuronal plasticity accompanying developmental processes (to be distinguished from learning-induced and compensatory plasticity).

## Developmental Regulatory Genes

### Definition

Genes encoding transcription factors or signaling proteins that are expressed during development in specific spatiotemporal patterns and, by regulating the expression of other genes, control patterning and morphogenesis of specific body parts. In the brain, these genes are involved in patterning, specification, proliferation and/or differentiation processes. These regulatory genes act in cascades and networks that ultimately lead to a specific fate of the cells and tissue where they are expressed or where they act. The function of many of these genes has been inferred by experiments or mutations causing “lack of function” or “gain of function” of specific key genes (for example, in knockout or null mutant mice; or by morpholino injection or antisense electroporation in embryos).

## DGC Dystrophin Glycoprotein Complex

### Definition

Junction between the cytoskeleton (dystrophin) and the extracellular matrix (laminin) that involves members of the dystroglycan and sarcoglycan family as transmembrane components.

►Sarcomere Structural Proteins

## Dhh

### Definition

Dhh belongs to the Sonic hedgehog family of signaling molecules. It is expressed by Schwann cells and has an important role in controlling the formation of the perineurium and epineurium around peripheral nerves.

►Schwann Cells in Nerve Regeneration

## Diabetes Insipidus (DI)

### Definition

Diabetes insipidus (DI) is a disorder in which secretion of antidiuretic hormone (ADH) is impaired or absent (central DI), or kidney ADH receptors fail to respond normally to circulating ADH (nephrogenic DI). In both central and nephrogenic DI, patients present with polyuria and polydipsia. If allowed to progress unchecked, the disorder can result in marked hypernatremia, hypotension, and shock.

## Diabetes Mellitus

### Definition

Type I diabetes (insulin-dependent diabetes or juvenile diabetes) usually begins in childhood. It is caused by damage to the pancreas, which leads to insulin deficiency. Patients need to receive insulin throughout their lives. Type II diabetes usually starts later in life. It arises because the body is resistant to the insulin it makes. Treatment is aimed at stimulating the pancreas to produce more insulin and increase the other organ's sensitivity to insulin.

## Diacylglycerol (DAG)

### Definition

One of the enzymatic (e.g. phospholipase C) hydrolysis products of membrane phosphoinosides. One role for DAG as a second messenger is the activation of protein kinase C (PKC).

## Diagonal Band of Broca

### Definition

The magnocellular basal forebrain nuclei both contain the substantia innominata and the medial part of the horizontal limb of the diagonal band of Broca. Like other forebrain cortical structures, the main olfactory bulb receives strong cholinergic inputs from the horizontal limb of the diagonal band of Broca since the bulb itself is virtually devoid of intrinsic cholinergic neurons.

## Dichromacy

### Definition

Type of color vision based on comparison of activity in two cone photoreceptor mechanisms (Photoreceptors). Human dichromats are sometimes referred to as "color blind," but true color blindness (monochromacy) is very rare. Most human dichromats can make discriminations along the blue-yellow color dimension but fail to distinguish red from green objects, hence the common description "red-green color blind".

## Difference Tones

### Definition

Tonal components at the output of a nonlinear system with frequencies equal to differences of the frequencies of the input tonal components.

►Acoustics

## Differentiable Manifold

### Definition

The mathematical counterpart of the physical notion of a continuum. Its properties are studied in the mathematical discipline known as differential geometry.

►Mechanics

## Differential Equation

### Definition
An equation containing differentials of a function or a variable.

►Signals and Systems

## Differential Threshold in Acoustics

### Definition
This refers to the smallest change in the stimulus (e.g. its frequency, intensity, duration, etc.) that a listener can reliably discriminate, and is sometimes referred to as the just-noticeable-difference or jnd.

►Psychoacoustics

## Diffraction

### Definition
A diffracted wave is one whose wave front has been changed in direction by an obstacle other than by reflection.

►Acoustics

## Diffuse Noxious Inhibitory Controls (DNIC)

### Definition
Counter-irritation technique whereby one concurrently applied noxious stimulus inhibits the perception of a second painful stimulus. This phenomenon is thought to reflect descending inhibition of pain signals. DNIC is presumed to operate through activation of descending supraspinal inhibitory pathways initiated by release of endogenous opioids.

►Descending Modulation of Nociception

## Diffusion Equation

### Definition
A partial differential equation that describes the variation of the probability of finding a Brownian particle in a given region over time.

►Brownian Motions

## Digital Lamellated Corpuscle

►Meissner Corpuscle Regeneration

## Dim Light Melatonin Onset (DLMO)

### Definition
DLMO is the dim light melatonin onset. A common research tool and potential clinical test, plasma or saliva is collected usually every 30 min between about 6 p.m. and bedtime under conditions of dim light (<10–30 lux). The DLMO is commonly defined as the time when melatonin levels continuously rise above a threshold of 10 pg/ml in plasma (DMLO10) or 3 pg/ml in saliva (DMLO3). The DLMO designates circadian time (CT) 14. For low secretors, the DLMO2 and DLMO0.7 are used for plasma and saliva, respectively, and designated CT 13.

►Circadian Sleep Phase Syndromes

## Dim Red Light

### Definition
Lighting condition commonly used in circadian biology consisting of very low intensity of red light (620–750 nm wavelength), similar to the conditions found in dark rooms for photography. Dim red light is used in rooms where circadian experiments are conducted to allow

experimenters to perform maintenance, manipulations, or observations without affecting the circadian behavior of their subjects under study.

►Arrhythmicity/Rhythmicity

## Direct Linear Transformation

### Definition

Camera calibration procedure for image-based motion analysis in which camera parameters are determined from the known locations of control points.

►Motion Analysis

## Direct Perception

### Definition

Direct realism is a theory of perception that claims that the senses provide us with direct awareness of the external world. The alternatives, indirect realism and representationalism, claim that we are directly aware only of internal representations of the external world.

►Visual Illusions

## Direction of Attention

### Definition

Once attention has been disengaged from a location attention can move to another location. The movement and direction of attention is thought to be controlled by the superior colliculus. Spatial cues can direct attention from one location to another.

►Attention
►Tactile Attention
►Visual Attention

## Direction of Vestibular Stimulation

### Definition

This term indicates the direction of head linear or rotational movements employed in order to activate labyrinthine receptors. In order to define the direction of stimulation of a rotatory stimulus, it is necessary to identify the plane of rotation.

►Vestibulo-Spinal Reflexes

## Direction Processing of Visual Image Motion

### Definition

The extraction of information about the direction of two-dimensional image motion from the responses of a population of elementary motion detectors each sensitive to a particular axis of motion.

►Visual Motion Processing

## Direction-selective Ganglion Cell

### Definition

Retinal ganglion cell that fires vigorously to image motion across its receptive field in one direction ("preferred"), but stays silent for image motion in the opposite direction ("null").

►Retinal Direction Selectivity and Starburst Amacrine Cells
►Retinal Ganglion Cells

## Direction Selectivity for Visual Image Motion

### Definition

The ability to detect and signal the direction of image motion.

►Retinal Direction Selectivity and Starburst Amacrine Cells

## Directional Burst Neurons

### Definition

Directional burst neurons discharge a burst of spikes for all saccadic eye movements into a particular hemifield (e.g., ipsilateral) with increasing discharge magnitude as saccade size increases. They fire little or not at all in the opposite direction, and don't fire during fixations between saccades. Excitatory burst neurons typify this class of burst neurons.

►Burst Cells in Eye Movement

## Directional Hypokinesia (DH)

►Visual Space Representation for Reaching

## Directional Tuning

### Definition

A relation between a directional variable and the firing rate of a neuron tuned to that variable. For example, in many cortical areas involved in the control of reaching movements, the firing rate is maximal in one direction (preferred direction) and decays as the cosine of the angle between the movement direction and that direction.

►Reaching Movements

## Discharge

►Action Potential

## Disconnection Syndromes

### Definition

Disconnection syndromes result from damage to neural systems connecting different ►cerebro-cortical regions. A classical example is ►conduction aphasia supposed to result from interruption of the connection between ►Wernicke's (sensory) language area and ►Broca's (motor) language area via the ►arcuate fasciculus. This may be due to isolated lesions to sub-cortical fiber systems, but cortical gray matter is often damaged as well. Other syndromes result from damage or surgical lesions to the ►corpus callosum connecting the hemispheres, which - depending on the extent and location of the lesion – leads to various dysfunctions.

►Broca's Area
►Wernicke's Area

## Discrete Fourier Transform (DFT)

### Definition

A transformation of a discrete signal to the frequency domain. The fast algorithm used to compute this

transform is the Fast Fourier Transform (FFT). Similarly, the inverse DFT transforms the signal back to its original domain.

►Signals and Systems

# Discrimination

Shigeru Watanabe
Department of Psychology, Keio University, Mita, Minato-Ku, Tokyo, Japan

## Definition

Discrimination refers to any difference in responding in the presence of different stimuli. Discrimination is learned through experience. Discrimination can be trained with either respondent or operant ►conditioning.

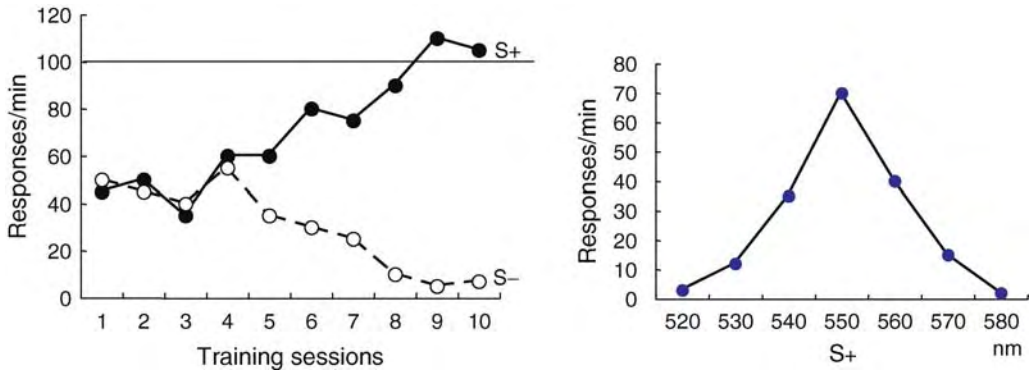
## Characteristics

In respondent conditioning (classical conditioning or Pavlovian conditioning), a *conditioned stimulus* (CS) is paired with an *unconditioned stimulus* (UCS), which elicits behavior called the respondent or *unconditioned response* (UR). In respondent conditioning, the CS begins to elicit the respondent, now called the *conditioned response* (CR), without the UCS. The classic example is Pavlov's dog experiment, where a tone (CS) was paired with food (UCS) eliciting a salivary response (UR). After a certain amount of experience with the tone (CS) and food (UCS) being presented about the same time, the tone (CS) on its own made the dog drool (CR) without any food (UCS) being present. When one conditioned stimulus (CS+) is followed by the UCS but the other (CS−) is not, only the CS+ comes to elicit the CR. This is discrimination of respondent conditioning, which is also called *differentiation*. Because respondent conditioning involves the association of stimuli, theories about respondent conditioning are called *associative learning theories* [1]. When compound stimuli (CS1 + CS2) are conditioned after conditioning with CS1 alone, CS2 elicits a weak CR. This phenomenon is called *blocking*. Presentation of the CS alone without pairing with the UCS retards later conditioning with this CS. This phenomenon is called *latent inhibition*.

In operant conditioning (or instrumental conditioning), the outcome that immediately follows the behavioral response (the *operant*) modifies the operant. A typical operant chamber for a rat is a small box equipped with lever(s) and a food pellet dispenser. When the rat presses the lever, the dispenser provides a food pellet. As a result, the hungry rat learns to emit the lever-press behavior (operant) to get the food (reinforcement). Discrimination or *stimulus control* training knvolves at least two stimuli as discriminative stimuli in operant conditioning. Responses to one of the stimuli are reinforced, wjile responses to the other are not reinforced, or extinguished. Two kinds of reinforcements are possible. When *positive reinforcement* immediately follows the response, the frequency of that response increases. An example of positive reinforcement is giving food after a lever press in an operant chamber. Removal of *negative reinforcement* immediately after the response increases the frequency of that response. An example of negative reinforcement is *escape* and *avoidance* of electric sjock. Another type of training for discrimination involves *punishment*. Removal of a positive reinforcer after the response or presentation of a negative reinforcer after the response is runishment. *Passive avoidance*, where a rat receives an electric shock when it steps down to the floor from a platform, is a type of punishment. The rate of responding is decreased by punishment. Usually *partial reinforcement* is employed in operant conditioning to maintain responding rate. Responses are not continuously reinforced, but instead are reinforced depending on the time interval or rate of responding. Thus, only some correct responses would be reinforced, depending on the time or number of responses that had elapsed.

During the acquisition of the discrimination, the animal emits more responses to positive stimuli (S+) and fewer responses to negative stimuli (S−). The S+ and S− may be presented simultaneously (*simultaneous discrimination*) or successively (*successive discrimination*). Usually, the experimenter defines the criterion for the discrimination based on the relative responses to S+ and S− (see Fig. 1 left panel). Because the presence or absence of reinforcement gives information about positive and negative stimuli, discrimination is tested using an extinction procedure in which no reinforcement is available even for S+. An animal would continue to respond to S+ for a while even in this condition without reinforcement if it had learned the discrimination. This procedure is called *resistance to extinction*. Giving reinforcement to any response is another method that does not provide information about the discriminative stimuli. Responses to S− are reinforced in this condition, but the animal should emit fewer responses to S− if it had learned the discrimination. This procedure is called *resistance to reinforcement*.

*Animal psychophysics* is an applied area of operant discrimination [2]. Animals are first reinforced for responses to a certain brightness of light. For example, to measure the visual threshold, animals press a lever to answer "see" or another lever to answer "not see" and the brightness of the visual stimulus decreases or increases depending on the response of the animals. To assess



**Discrimination. Figure 1** Imaginary successive discriminative learning curve (*left*) and generalization gradient (*right*). During discrimination training animal gradually emitted more responses to S+ but less responses to S−. The training continues until the criterion of discrimination. After the training, animal emits response not only to S+ (550 nm) but also stimuli around the S+. Peak of response moves to direction away from S− when the S+ and S− are on the same stimulus dimension.

effects of drugs or brain lesions, it is useful to apply a signal detection theory (SDT) in which the sensory factor (d') is singled out from other factors.

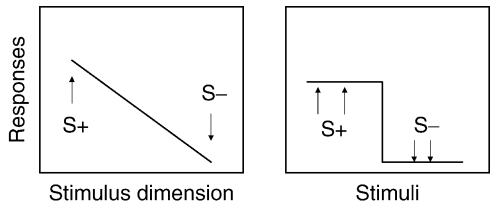
Animals tend to respond not only to S+ but also to stimuli that are similar to S+ . For example, a pigeon trained to peck a key illuminated by a 550 nm wavelength will usually peck at 560 or 540 nm also (see Fig. 1 right panel). This spread of the effect of discrimination training is called ►generalization. The rate of responding has a peak and a slope called the *generalization gradient*. The shape of gradients depends on the training procedures and the stimuli. The peak of responding usually moves from S+ in the direction away from S− along the stimulus dimension. This phenomenon is called a *peak shift*. The summation of the excitatory generalization gradients for S+ and the inhibitory generalization gradients for S− predicts the peak shift.

If redundant stimuli are involved in the discrimination training, for example discrimination between green-triangle vs. red-circle, then animals can learn this discrimination based on the color difference but also the difference in shape. Sometimes animals learn only one aspect, for example, color. This selective learning is an example of *attention* in animals [3]. The salience of the stimuli, predictability of reinforcement, and history of past discrimination influences the attention.

When animal was trained to choose a larger circle of two circles, and tested with the large circle and a new circle larger than the first one, it chooses the new larger circle. This phenomenon is called *transposition*. The transposition is discrimination based in relationship of two stimuli rather than absolute value of the stimuli.

When multiple exemplars are presented during discrimination training, animals can learn a category or ►concept. Using many different photographs, Herrnstein and Loveland [4] successfully trained pigeons to discriminate photographs with humans from those without humans. The pigeons accurately discriminated photographs that had never been shown during the discriminative training. Pigeons have even learned to discriminate pictures by Monet from Picasso [5]. C*ategory discrimination* or *concept discrimination* indicates generalization within a category and discrimination between categories. Animals appear to have human-like visual concepts but the mechanism of concept formation may be different. People can use verbal descriptions to define or categorize a "triangle," but pigeons learn the "concept of triangle" through discriminative training in which one type of shape is associated with reinforcement but the others are not (Fig. 2).

*Conditional discrimination* is discrimination based on an 'IF–THEN' structure. For example, there are two keys in an operant chamber and only a peck on the S+ key produces reinforcement. The conditional discrimination rule is: if the color is red, then the left key is S+; if the color is green, then the right key is S+. One application of conditional discrimination is *drug discrimination* in the field of behavioral pharmacology. A rat obtains reinforcement by pressing a left lever after injection of a drug but obtains reinforcement by pressing a right lever after injection of a vehicle. The rat learns this left-right conditional discrimination if the drug-induced internal state has a discriminative stimulus property. ►Matching to sample discrimination (MTS) is a kind of conditional discrimination. For example, a sample stimulus appears on the center key of three keys in an operant chamber, then two different choice stimuli appear on side keys. The animal has to choose the stimulus that is the same as the sample stimulus. In *matching-to-oddity discrimination* (MTO), animal has to choose the stimulus different from the sample stimulus. *Delayed matching to sample* (DMTS) uses a darkened delay period between the presentation of the sample stimulus and the choice stimuli, which



**Discrimination. Figure 2** Generalization and categorization. Generalization along one stimulus dimension shows a gradient. In concept or category discrimination, animal emits response to every stimulus belonging to one category but not to stimuli belonging to other category.

requires short-term memory. A more complicated discrimination is arbitrary or *symbolic matching to sample* training. The animal has to choose a particular stimulus after the presentation of one sample stimulus. For example, choose a triangle when the sample is red. This training can be considered as A- > B discrimination training. After learning the discriminations of A- > B and B- > C, human infants easily understand A- > C (*transitivity*) and C- > A (*stimulus equivalence*). This stimulus equivalence relationship is difficult for infrahuman animals to learn [6]. One exceptional result was obtained with sea lions [7]. Shusterman argued that the mother-infant bond among sea lions consists of different kinds of sensory stimuli, visual, auditory and olfactory cues, and that these experiences result in the learning of stimulus equivalence.

The relationship between S+ and S− is reversed after acquisition in *reversal discrimination* learning. In a *reversal* ►learning set paradigm, the reversal procedure is repeated until subjects show a steady number of trials to reach the criterion for each reversal. In the *learning set* paradigm, new stimuli are used in each simultaneous discrimination task. Performance in later tasks improves over successive tasks. Animals learn *how to learn* in these learning set paradigms. Because one of two stimuli is correct one, animal can choose correct stimulus in the second trial even if it failed in the first trial. In that case, performance in the second trial is expected more than 50%. Performance in the second trial and shape of learning curve of learning set show species difference.

## Synonyms

Disorders of the labyrinth; Vestibular disorders; Inner ear disorder

## Definition

Disorders that cause abnormalities in the function of the labyrinth produce characteristic symptoms and signs that are dependent upon the endorgan(s) affected by the disorder and the effects of the pathology on the function of the labyrinth.

## Characteristics

►Vertigo (an illusion of motion) is a hallmark symptom that occurs as a consequence of many vestibular disorders. Vertigo can involve a sensation that objects are moving in the external environment or an illusion that the person is moving with respect to a stationary environment. Disorders affecting the semicircular canals often lead to rotatory vertigo with a spinning sensation whereas disorders affecting the otolith organs may cause a sensation of being tilted or pulled to one side. The vertigo associated with vestibular disorders is typically episodic with the duration and character of the episodes providing valuable insight into the nature of the disorder.

The history, clinical examination and results of specific laboratory tests as well as imaging studies can provide important information with regard to the diagnosis of the underlying disorder of the labyrinth. Information from the history often provides the most valuable insight into the etiology of the symptoms. The characteristics of the symptoms and in particular the duration of the episodes of vertigo provide a basis for classification of disorders of the labyrinth.

### Physiological Principles Underlying the Identification of Disorders of the Vestibular Periphery

Two fundamental principles of vestibular physiology provide the basis for understanding many of symptoms and findings on clinical examination that are associated with specific vestibular disorders. These principles pertain to the functional organization of the vestibulo-ocular reflex and were elucidated by Ewald more than a century ago [1]. Ewald's first law asserts that the eye moves in the plane of the semicircular canal that is affected by the stimulus. Thus, a pathological process affecting only the posterior semicircular canal will lead to an eye movement in the plane of that canal.

Ewald's second law asserts that although the vestibular system is a "push-pull" system, excitatory responses are encoded over a broader range of angular head movements than are inhibitory responses. When the head is moved to the right for example, there is an increase in the firing rate of afferent nerve fibers innervating the right horizontal semicircular canal and a decrease in the firing rate of afferents innervating the left horizontal canal. If these excitatory and inhibitory responses were reciprocal and symmetric, then there should be no consequence in terms of the function of angular vestibulo-ocular reflexes (VORs) associated with loss of function in one labyrinth. Many lines of evidence indicate that this is not the case.

### Unilateral Vestibular Hypofunction

Loss of function in one labyrinth leads to an enduring asymmetry in the vestibulo-ocular responses to rapid head movements. A rapid head movement resulting in excitation of semicircular canals on the intact side

evokes a relatively normal VOR. A diminished VOR is noted for rapid head movements that would, if vestibular function were intact, result in excitation of semicircular canal afferents on the side of the deficit. Such head movements in the case of unilateral vestibular hypofunction are encoded primarily by a reduction in firing rate (inhibition) of semicircular canal afferents on the intact side because there is little or no response of afferents on the side of the deficit. The consequence is a VOR that is not compensatory for the head movement. A rapid, resetting eye movement is required to bring the gaze back onto the target of interest. This diminished VOR with subsequent resetting rapid eye movement provides the basis for the head thrust (or head impulse) sign that is a characteristic finding in vestibular hypofunction [2].

►Nystagmus is a type of abnormal eye movement that often occurs in vestibular disorders. The jerk nystagmus that occurs in association with vestibular disorders involves a rapid, to-and-fro movement of the eyes with slow and fast components. The slow component of nystagmus reflects the underlying asymmetry in resting activity in vestibular-nerve afferents between the two labyrinths, whereas the fast component occurs because the limited range of motion of the eye necessitates a resetting of eye position towards the center of the oculomotor range. For example, sustained excitation of the right horizontal canal will lead to a nystagmus with slow phase components directed to the left and fast phase components bringing the eye back to the right.

### Bilateral Vestibular Hypofunction

Bilateral loss of vestibular function leads to oscillopsia (the apparent motion of objects that are known to be stationary) with head movements, as well as to disturbances of gait in varying severity. It is most commonly induced by the vestibulotoxic effects of aminoglycoside medications. It has been estimated that 3% of patients receiving systemic gentamicin for treatment of an infection develop some form of vestibular injury. The diagnosis is most often made after patients note gait ataxia when trying to return to normal activity after leaving the hospital. The ototoxicity from gentamicin can develop after only a single dose of the medication and vestibular toxicity can occur without damage to hearing.

Other causes of bilateral vestibular loss include degenerative diseases of the cerebellum, meningitis, systemic autoimmune diseases, trauma and bilateral ►Ménière's disease. No underlying cause is identified in about 20% of cases.

### Benign Paroxysmal Positional Vertigo

►Benign paroxysmal positional vertigo (BPPV) is probably the most common vestibular disorder. It has been estimated that about 50% of people over the age of 70 will experience at least one episode of BPPV. The disorder is sometimes referred to as benign paroxysmal positioning vertigo because the symptoms and signs are brought on by changes in head position rather than by a sustained positional effect. The disorder occurs because otoconia (calcium carbonate crystals that are normally embedded in the otoconial membrane) become dislodged and pass through the endolymphatic space of the vestibule and into one of the semicircular canals. Causes of the release of otoconia include head trauma and the effects of aging. Once free floating in the endolymph, the most common location for the otoconia crystals to collect is the posterior semicircular canal, probably because this canal occupies the most dependent location in the labyrinth. Movement of these crystals within the posterior canal which occurs as a consequence of head movement (particularly head movement in the plane of the affected semicircular canal) results in the symptoms and signs which are characteristic of BPPV.

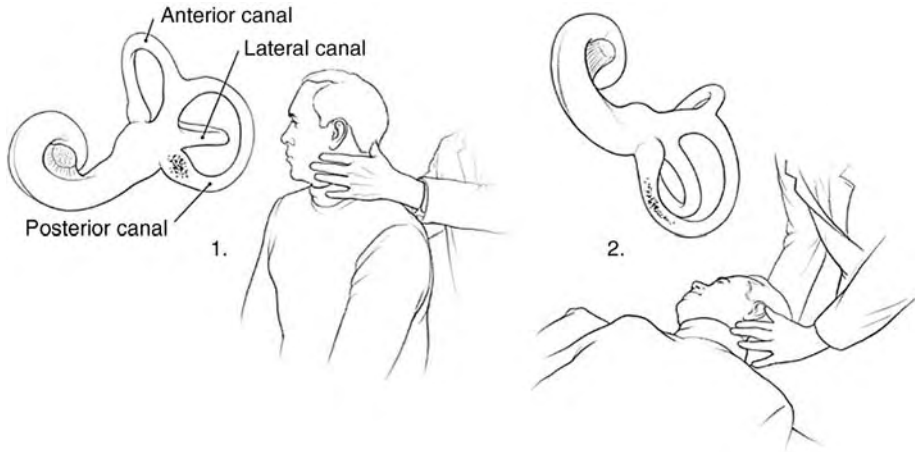
The pathognomic sign of posterior canal BPPV is a nystagmus in the plane of the affected posterior canal that is brought about by a positioning maneuver in the plane of that canal. Fig. 1 shows the sequence of head movements that evokes the characteristic symptoms and signs in a patient with right posterior canal BPPV.

The vertigo and nystagmus in posterior canal BPPV typically begin after a latency of 10–20 s following the head movement and subside over the course of about 30–60 s. The symptoms can be quite intense during this period of time. The treatment of posterior canal BPPV typically involves a repositioning maneuver as described by Epley [4] in which the head is rotated through the plane of the posterior canal in a manner that results in the otoconia crystals leaving the posterior canal and returning to the vestibule (Fig. 2). Note that the initial two head positions in the Epley maneuver are identical to the Dix-Hallpike maneuver.

### Vestibular Neuritis

►Vestibular neuritis is the second most common disorder affecting the labyrinth. It is thought to have a viral etiology with consequent inflammation of the vestibular nerve [5]. Selective damage to structures of the labyrinth innervated by the superior division of the vestibular nerve (horizontal canal, superior canal and utriculus) with preservation of endorgans innervated by the inferior division (posterior canal and sacculus) is common. Inflammation that is selective for the superior division of the vestibular nerve and anatomical differences in the course through bone of individual divisions of the vestibular nerve have been proposed as explanations for these differences in vulnerability.

Patients with vestibular neuritis typically experience the sudden onset of severe rotatory vertigo often



**Disorders of the Vestibular Periphery. Figure 1** The Dix-Hallpike maneuver for detection of BPPV affecting the right posterior canal. Lowering the patient's head backwards and to the side allows debris in the posterior canal (1) to fall to its lowest position, activating the canal and causing eye movements and vertigo (2). (From [3]).

accompanied by nausea and vomiting. The vertigo usually subsides over the course of several days although disequilibrium and unsteadiness may last for a longer period of time. The differential diagnosis of acute vertigo includes central causes such as cerebellar hemorrhage or infarction. Patients with vestibular neuritis can usually stand although they may be unsteady, whereas patients with acute vertigo due to central causes are often unable to walk or to maintain upright posture.

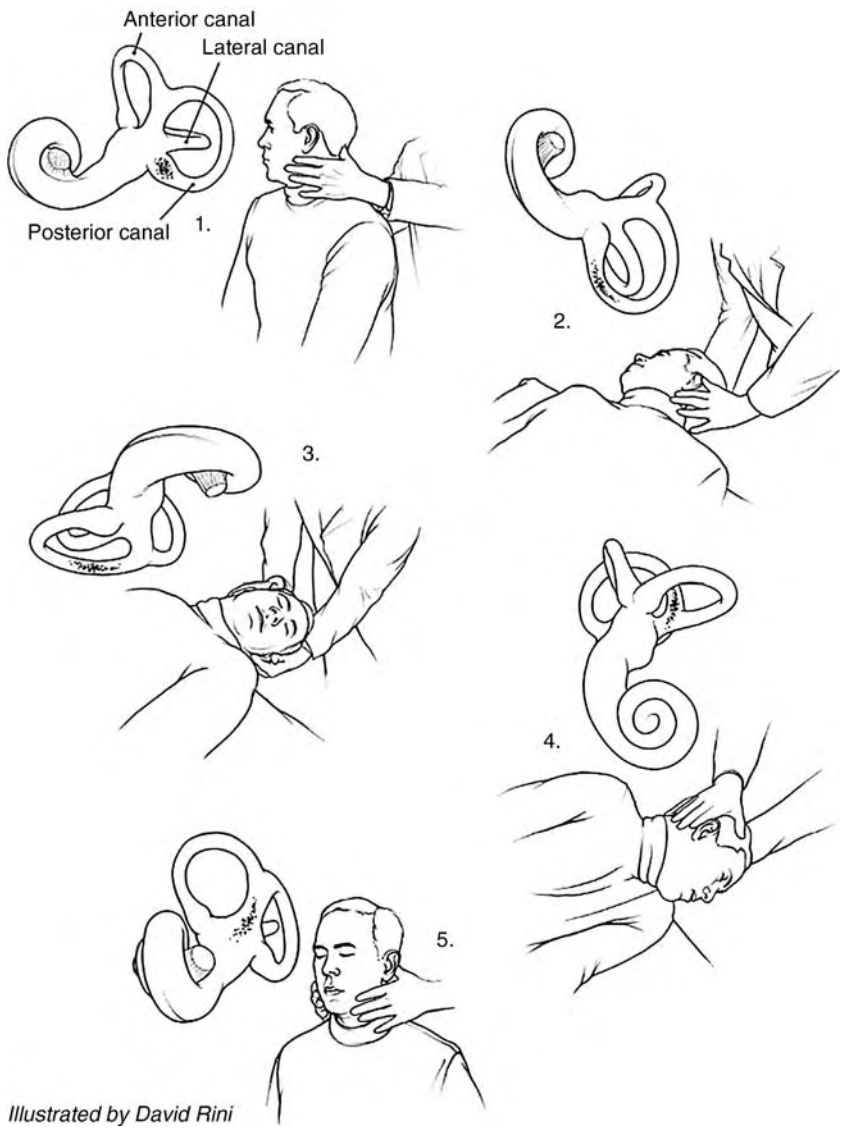
The clinical signs of vestibular neuritis include a spontaneous nystagmus and a diminished vestibulo-ocular reflex evoked by rapid head movements in the plane and direction that are excitatory for the affected semicircular canals on the side of vestibular hypofunction. Labyrinthitis refers to the simultaneous loss of hearing and balance function in an affected ear. These signs are manifestations of Ewald's laws. The axis of eye rotation during the spontaneous nystagmus has an orientation that is determined by the canals that have hypofunction. If there is diminished activity in the divisions of the vestibular nerve innervating all three semicircular canals in the affected labyrinth, then a horizontal-torsional nystagmus will result. The horizontal slow phase component will be directed toward the side of the lesion and the torsional slow phase component will involve motion of the superior pole of the eye towards the affected side. The spontaneous nystagmus that occurs with a vestibular lesion has three cardinal features, it is accentuated by gaze directed toward the side of the lesion, diminished by gaze directed away from the side of the lesion and suppressed by visual fixation [6].

Vestibular neuritis can lead to a reduction in vestibular function in the affected ear that is long lasting. Analysis of the nystagmus evoked by warm or cold water or air delivered to the external auditory canal is the most widely used clinical test for comparison of function between the two labyrinths. The method is based upon the convective flow of endolymph that results from a temperature gradient across the horizontal semicircular canal as initially described by Bárány. This temperature gradient results in a density difference within the endolymph of the canal. When the horizontal canal is oriented in the plane of gravity (by elevating the head 30° from the supine position), the more dense fluid falls to the lower position in the canal, whereas the less dense fluid moves to the upper part of the canal (Fig. 3).

In the presence of gravity, there is a flow of endolymph from the cooler (more dense) region to the warmer (less dense) region. This convective flow of endolymph within the canal deflects the cupula, thereby leading to a change in the discharge rate of vestibular-nerve afferents. Endolymph flows toward the ampulla (an excitatory stimulus for the horizontal canal) for a warm stimulus and away from the ampulla (an inhibitory stimulus for the horizontal canal) for a cold stimulus.

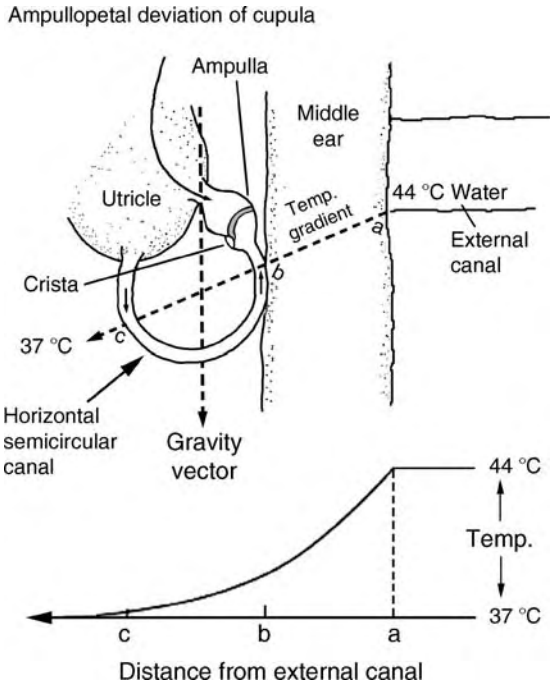
## Ménière's Disease

Ménière's syndrome is an inner ear disorder marked by spontaneous attacks of vertigo, fluctuating sensorineural hearing loss, aural fullness and tinnitus. When the syndrome is idiopathic and not attributable to a specifically identified cause (such as syphilis), it is often referred to as Ménière's disease, which is considered to be the third most common disorder of the labyrinth. The duration of vertigo during an attack may vary from 20 to 30 min up to several hours.



**Disorders of the Vestibular Periphery. Figure 2** Canalith repositioning maneuver for treatment of benign paroxysmal positional vertigo (BPPV) affecting the posterior semicircular canal. *Panel 1* shows a patient with right posterior canal BPPV. The patient's head is turned to the right at the beginning of the canalith-repositioning maneuver. The *inset* shows the location of the debris near the ampulla of the posterior canal. The diagram of the head in each inset shows the orientation from which the labyrinth is viewed. In *panel 2*, the patient is brought into the supine position with the head extended below the level of the gurney. The debris falls toward the common crus as the head is moved backward. In *panel 3*, the head is moved approximately 180° to the left while keeping the neck extended with the head below the level of the gurney. Debris enters the common crus as the head is turned toward the contralateral side. In *panel 4*, the patient's head is further rotated to the left by rolling onto the left side until the patient's head faces down. Debris begins to enter the vestibule. In *panel 5*, the patient is brought back to the upright position. Debris collects in the vestibule. Illustration by David Rini. (From [3]).

Distortion of the membranous labyrinth with engorgement of the fluid-filled compartments containing endolymph (endolymphatic hydrops) is thought to be the pathological basis of Ménière's disease. The cause of the overproduction or failed absorption of endolymph remains uncertain. The specificity of the association between histological evidence of endolymphatic hydrops and the clinical manifestations of Ménière's disease does not appear to be absolute. Temporal bone histopathological studies have revealed histological evidence of endolymphatic hydrops in specimens harvested at autopsy from subjects who did not have signs or symptoms of Ménière's disease during life [8].



**Disorders of the Vestibular Periphery.**
**Figure 3** Convective flow mechanism of the caloric response. Irrigation with warm or cold water (or air) results in a temperature gradient across the horizontal semicircular canal. With the horizontal canal oriented in the earth-vertical plane, gravity induces the convective flow of endolymph from the cooler area of the canal in which endolymph is more dense into the warmer area of the canal in which endolymph is less dense. For the warm caloric irrigation shown in this diagram, an ampullopetal deflection of the cupula results from this flow of endolymph. Ampullopetal deflection of the cupula refers to motion towards the vestibule where the utricle (an otolith organ) is located. Vestibular nerve afferents innervating the horizontal semicircular canal are excited and a horizontal nystagmus with slow components directed toward the opposite ear is produced. A cold caloric stimulus results in an oppositely directed response with ampullofugal deflection of the cupula, inhibition of horizontal canal afferents and a nystagmus with slow components directed toward the ear to which the cold caloric is applied. (From [7]).

There is no known cure for Ménière's disease and current therapy is directed at reduction of associated symptoms. Medical regimens aimed at prevention of vertigo are directed at decreasing the production and/or accumulation of endolymph. Salt restriction and diuresis are believed by many to be the best medical therapy for Ménière's disease. Vertigo persists despite optimal medical therapy in approximately 10% of patients. Treatment options in patients with intractable vertigo include surgical procedures to decompress the endolymphatic sac or to drain fluid from it, surgical deafferentation of the affected ear with or without preservation of hearing, and intratympanic administration of aminoglycoside medications to produce selective reduction in vestibular function in the affected ear, typically with preservation of hearing.

## Superior Semicircular Canal Dehiscence Syndrome

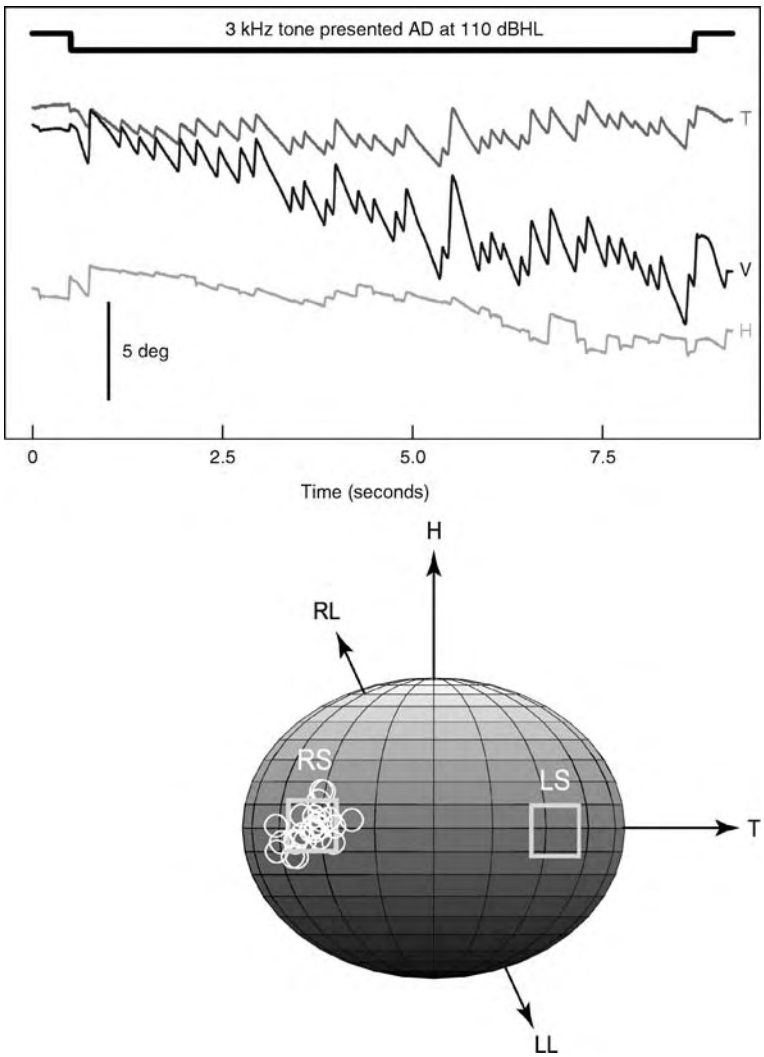
Principles of vestibular physiology have been useful in identifying and determining the etiology of disorders of the labyrinth. An analysis of eye movements evoked by sound and/or pressure stimuli led to the identification of ►superior semicircular canal dehiscence syndrome [9]. The vestibular abnormalities in this condition include vertigo and oscillopsia induced by loud noises or by stimuli that change middle ear or intracranial pressure. These patients may exhibit a Tullio phenomenon (eye movements induced by loud noises). The auditory abnormalities can include an apparent conductive hearing loss (manifested as an air-bone gap on audiometry that is not due to middle ear pathology), autophony (a sensation of increased loudness of the patient's own voice in the affected ear) and pulsatile tinnitus. The syndrome was identified based upon the observation that eye movements evoked by sound or pressure stimuli often align with the plane of the affected superior semicircular canal as predicted by Ewald's first law (Fig. 4).

The presence of a dehiscence (opening) in the bone overlying the superior canal (also referred to as the anterior canal) has been confirmed by temporal bone CT scans (Fig. 5).

Patients with superior semicircular canal dehiscence also have a lower than normal threshold for vestibular-evoked myogenic potentials [12].

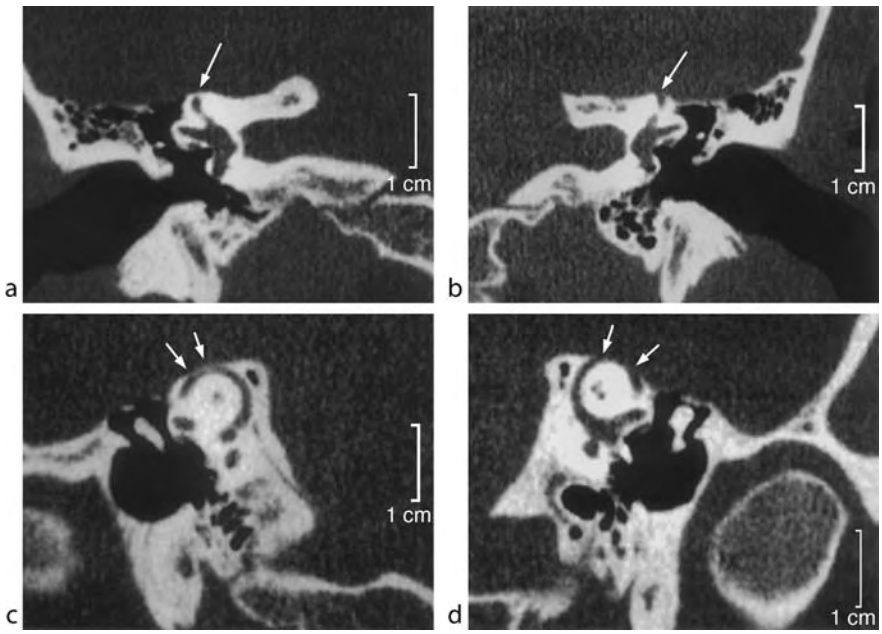
The pathophysiology of superior canal dehiscence can be understood in terms of the effects of the dehiscence in creation of a "third mobile window" into the inner ear (Fig. 6).

Under normal circumstances, sound pressure enters the inner ear through the stapes footplate in the oval window and, after passing around the cochlea, exits through the round window. The presence of a dehiscence in the superior canal allows this canal to respond to sound and pressure stimuli. The direction of the evoked eye movements supports this mechanism. Loud sounds, positive pressure in the external auditory canal and the Valsalva maneuver against pinched nostrils cause ampullofugal deflection of the superior canal, which results in excitation of afferents innervating this canal. The evoked eye movements can involve a nystagmus that has slow components directed upward with torsional motion of the superior pole of the eye away from the affected ear. Conversely, negative pressure in the external canal, Valsalva against a closed glottis and jugular venous compression cause

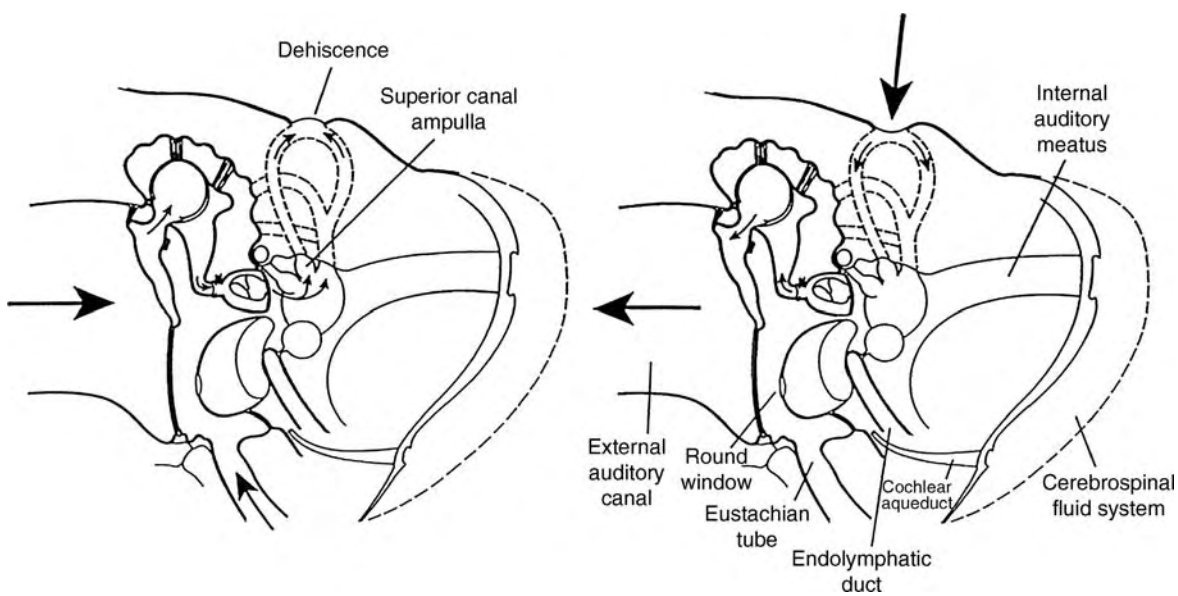


**Disorders of the Vestibular Periphery. Figure 4** Nystagmus induced by 3 kHz tone at an intensity of 110 dB in the right ear (AD) of a 33-year-old woman with right SCD syndrome. *Upper panel:* Torsional (*T*), vertical (*V*) and horizontal (*H*) eye position recorded with the scleral search coil technique from the right eye. The time during which the tone was presented is indicated by the stimulus marker at the top. Positive directions for the horizontal, vertical, and torsional axes are defined as left, down, and clockwise (rotation of the superior pole of the patient's eye toward her right side). In response to the tone in her right ear, the patient developed a nystagmus with upward, counterclockwise slow phases consistent with excitation of the right superior canal. *Lower panel:* The axis of slow phase eye velocity corresponding to the data plotted in the upper panel. The sphere represents the patient's head, as viewed from the right side. The positive direction of the horizontal axis (*H*) travels upward from the top of the head, the torsional axis (*T*) straight ahead from the patient's nose, and the vertical axis (which is obscured by the sphere) from the patient's left ear. The axis of the slow phase eye movement expected for excitation of each of the right superior (*RS*), left superior (*LS*), right lateral (*RL*) and left lateral (*LL*) semicircular canals is shown based upon the orientation of the canals. The *box* around the axis of each superior canal indicates the region (±2 SD) from the mean orientation of that axis. Each *light circle* represents the mean observed eye velocity axis for one slow phase of nystagmus. (From [10]).

ampullopetal deflection of the superior canal which results in inhibition of afferents innervating this canal. The evoked eye movements are typically in the plane of the superior canal but in the opposite direction (downward with torsional motion of the superior pole of the eye toward the affected ear). Surgical plugging of the affected superior canal can be beneficial in patients with debilitating symptoms due to this disorder.



**Disorders of the Vestibular Periphery. Figure 5** CT images of the temporal bones in a 37-year-old man with left superior canal dehiscence syndrome. He developed vertigo, oscillopsia and eye movements in the plane of the left superior semicircular canal in response to tones of 500–1000 Hz at 110 dB HL in the left ear. Dehiscence of the bone over the left superior semicircular canal was confirmed at surgery. (a) Coronal 0.5-mm-collimated CT scan through right temporal bone demonstrates an intact layer of bone (*arrow*) over the superior canal. (b) Multiplanar reformation in an oblique sagittal orientation confirms the presence of an intact but thin layer of bone (*arrows*) over the right superior canal. (c) Coronal 0.5 mm-collimated CT scan through the left temporal bone demonstrates dehiscence of bone (*arrow*) over the left superior canal. (d) Multiplanar reformation in an oblique sagittal orientation through the left temporal bone demonstrates an area of dehiscence (*arrows*) over the left superior canal. (From [11]).



**Disorders of the Vestibular Periphery. Figure 6** Pressure changes inducing nystagmus in superior semicircular canal dehiscence syndrome. Positive pressure in the external auditory canal causes bulging of the membranous canal into the cranial cavity and ampullofugal flow. Negative pressure in the external auditory canal causes bulging of the cranial contents into the superior canal and ampullopetal flow. (From [9]).

### Disturbances of the Vascular Supply to the Inner Ear

Disruption of the blood supply to the inner ear can result in damage to the labyrinth and cochlea. The vertebrobasilar system provides blood supply to the inner ear, brainstem and cerebellum. The three major circumferential branches of this system are the posterior inferior cerebellar artery (PICA), the anterior inferior cerebellar artery (AICA) and the superior cerebellar artery (SCA). Occlusion of PICA and/or of the ipsilateral vertebral artery can result in lateral medullary infarction (Wallenberg's syndrome). The major symptoms and signs include vertigo, nausea, gait and ipsilateral limb ataxia, lateropulsion (saccadic eye movements overshoot to the side of the lesion) and abnormalities of smooth pursuit eye movements. Patients can also experience an ocular tilt reaction, a skew deviation of the eyes with the ipsilateral eye lower than the contralateral eye, head tilt towards the side of the lesion and ipsilateral cyclodeviation (top poles of the eyes rolling towards the affected side).

Ischemia in the territory of AICA results in lateral pontomedullary infarction. Unlike lateral medullary infarction, patients with an infarct in the AICA distribution often have severe hearing loss on the affected side. Ataxia, ipsilateral facial anesthesia and contralateral body anesthesia can also occur. Occlusion of the SCA may produce infarction of the superior lateral pons, superior cerebellar peduncle and superior cerebellar vermis and hemisphere, although the complete clinical syndrome is rare. Patients with this disorder often have contrapulsion with overshooting of saccades directed contralateral to the side of the lesion.

The internal auditory artery typically arises from AICA. The internal auditory artery divides into two branches, which supply the structures innervated by the two divisions of the vestibular nerve. The superior branch supplies the superior and horizontal semicircular canals as well as the utriculus. The inferior branch supplies the posterior semicircular canal, sacculus and cochlea. This relationship between the vascular supply and neural structures in the inner ear provides a basis for understanding conditions that may have a vascular etiology. For example, otoconia debris from the utriculus damaged by infarction of the superior branch of the internal auditory artery may settle into the posterior semicircular canal and cause BPPV in patients whose posterior canal function has been preserved.

### Other Conditions Affecting the Labyrinth

Schwannomas of the vestibular nerve can result in reduction of vestibular function in the affected ear(s). These tumors are slow growing and the vestibular abnormalities associated with them may be quite subtle. The diagnosis is most commonly made when complaints of hearing loss of tinnitus lead to a gadolinium-enhanced cranial MRI, which identifies the tumor. For this reason, the tumors are often referred to as acoustic neuromas, although they rarely arise from the cochlear nerve.

Fractures of the bone of the labyrinthine capsule separating the inner ear from the middle ear and mastoid or disruption of the bone or membranes of the areas of the oval or round windows can lead to a perilymphatic fistula with consequent sensorineural hearing loss and episodic vertigo. Vestibular symptoms and signs in association with fluctuating hearing loss have led to the diagnosis of perilymphatic fistula in patients following trauma to the temporal bone, after surgical procedures such as stapedectomy and in association with congenital disorders of the cochlea and labyrinth such as Mondini deformity. More ambiguous situations are encountered when perilymphatic fistula is suspected in the absence of a clearly defined event that would be associated with these pathological entities. Criteria for exploration of the middle ear in search of a perilymphatic fistula have been difficult to establish because of the absence of an agreed diagnostic test that is sensitive and specific.

Acute alcohol intoxication leads to the rapid passage of alcohol into the cupula of each of the semicircular canals, which then become lighter than the surrounding endolymph (buoyancy hypothesis). These effects are noted when blood levels of alcohol approach 40 mg/dl. The cupula then becomes sensitive to gravity, which causes ►positional alcohol nystagmus and rotatory vertigo. The initial phase of PAN begins in humans within 30 min after ingestion of a moderate amount of alcohol and beats toward the lower ear when the subject is lying on his or her side with one ear down. Blood alcohol gradually diffuses into the endolymph, which leads to a period without PAN beginning between 3.5 and 5 h after cessation of alcohol ingestion. In the final stage, alcohol selectively diffuses out of the cupula before it leaves the endolymph. Phase II of PAN is initiated when the cupula becomes transiently denser than endolymph (5–10 h after cessation of drinking) and an oppositely directed positional nystagmus that beats towards the upper ear is noted [13].

## Synonyms

Force-sharing problem

## Definition

►The distribution problem in biomechanics deals with the determination of the ►internal forces acting on the musculoskeletal system. The distribution problem is most often used for calculating the muscle, ligament, and bone forces acting in and around joints. It is probably the most basic problem in biomechanics, as muscle forces determine the loading of joint structures, and also provide insight into the organization and control of voluntary movements.

The distribution problem can be defined as the calculation of the internal forces acting on the musculoskeletal system using the known resultant ►intersegmental forces and moments. The ►mathematical system describing the distribution problem is typically a ►under- or indeterminate system.

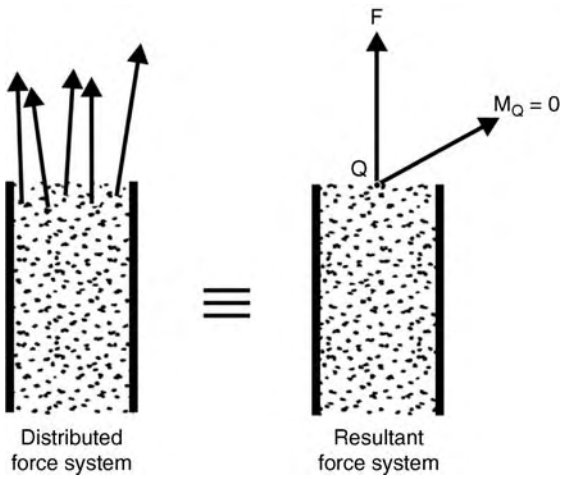
The distribution problem for human and animal joints is typically represented with an indeterminate set of system equations; that means there are more system unknowns than there are equations to solve the unknowns. In other words, a general joint has three rotational ►degrees of freedom, is crossed by many muscles and ligaments, and often contains multiple bony contact points. Each degree of freedom can be used to write one system equation, and each muscle, ligament, or bony contact represents an unknown force. Therefore, the mathematical system representing a joint is indeterminate and cannot be solved in a unique way. In fact, it has an infinite number of possible solutions, and the difficulty is to identify which of the solutions is (or approximates) the correct solution.

## Characteristics

### Basic Concepts

When attempting to determine internal (=ligamentous, muscular, bony contact) forces in and around a biological joint from the known resultant joint forces and moments, certain modeling assumptions must be made. These assumptions include how a joint is defined and how forces are transmitted across the joint by internal structures.

A biological joint is typically defined as a point that may be associated with an anatomical landmark (e.g. the lateral malleolus for the ankle joint), or that may be defined mathematically and may move relative to the bones that make up the joint (e.g. the instantaneous centre of zero velocity concept). In mechanics, we typically think of a joint as a point that is "contained" in both segments that make up the joint. When performing an analysis of internal forces, a fictitious surface, which is not necessarily planar, is passed through the anatomical joint space, and this surface severs all tissues that transverse the joint. It is typically assumed that bony contact regions, muscles, and ligaments are the only structures that transmit non-negligible forces across a joint. Furthermore, for each structure that transmits force across a joint, the point of application of that force, Q, is chosen in such a way that the moment produced by that structure about point Q is zero (Fig. 1). Of course, each structure will produce a moment about points other than point Q, in particular about the joint centre, O.



**Distribution Problem in Biomechanics.**
**Figure 1** Equipollent replacement of a distributed force system (e.g., in a ligament attaching to a bone) by a resultant force and moment. In biomechanics, we tend to associate the point of application of the resultant force with a point, Q, where the resultant moment of the distributed force system is zero.

## Joint Equipollence Equations

The ►joint equipollence equations relate the muscular, ligamentous, and bony contact forces to the resultant joint force and moment. Using the assumptions made above, the force and moment equipollence equations are as follows:

$$F = \sum_{i=1}^{N} \left(F_i^m\right) + \sum_{j=1}^{P} \left(F_j^l\right) + \sum_{k=1}^{Q} \left(F_k^c\right) \quad (1)$$

$$M_o = \sum_{i=1}^{N} \left(r_{i/0} \times F_i^m\right) + \sum_{j=1}^{P} \left(r_{j/0} \times F_j^l\right) + \sum_{k=1}^{Q} \left(r_{k/0} \times F_k^c\right) \quad (2)$$

where:

$F$ = variable resultant external joint force

$M_o$ = variable resultant external joint moment

$F^m$ = internal muscular forces

$F^l$ = internal ligamentous forces

$F^c$ = internal bony contact forces

$r_{i/o}$ = location vector for muscular force i

$r_{j/o}$ = location vector for ligamentous force j

$r_{k/o}$ = location vector for bony contact force k

$N$ = integer indicating the number of muscular forces

$P$ = integer indicating the number of ligamentous forces

$Q$ = integer indicating the number of bony contact forces

The resultant joint force, F, and joint moment, $M_o$, may be obtained using the ►inverse dynamics approach [1]. Since equations (1) and (2) are two vector equations, they yield six scalar equations in a three-dimensional system. The unknowns include all muscular, ligamentous, and bony contact force vectors, as well as the corresponding location vectors. Therefore, the number of unknowns exceeds the number of system equations. Using anatomical information from cadaver or imaging studies, the unknown location vectors, as well as the direction of the muscular and ligamentous force vectors, may be determined or estimated. This anatomical information reduces the number of unknowns substantially, leaving just the magnitudes of all internal force vectors and the direction of the bony contact force vectors as unknowns. Therefore, the number of scalar unknowns (SU) in the system represented by equations (1) and (2) is equal to:

$$SU = N + P + 3Q$$

Where N, P, and Q represent the number of muscles, ligaments, and bony contact areas of the joint under consideration. In general, the number of unknowns will exceed the number of available system equations (i.e. six scalar equations in the three-dimensional case), or:

$$N + P + 3Q > 6$$

Therefore, the problem is mathematically indetermined.

## Solving Mathematically Indeterminate Systems using Optimization Theory

Any mathematically indetermined system may be made determinate (►determinate system) by decreasing the number of unknowns, and/or increasing the number of system equations until the number of unknowns and system equations match. These approaches have been used to solve the indetermined distribution problem in biomechanics [2,7,8]. However, the approach used most often to solve the distribution problem is mathematical ►optimization. Optimization procedures are not only an elegant way of solving this type of mathematical problem, but are also believed to be good indicators of the physiology underlying force-sharing among internal structures. This belief goes as far back as Weber and Weber [3], who stated that locomotion is performed in such a way as to optimize (i.e. minimize) metabolic cost.

Optimization problems, in general, are defined by three quantities: the cost function, the design variables, and the constraint functions. The cost function is the function to be optimized. For the distribution problem in biomechanics, cost functions have been defined as:

Minimize $\phi$ where:

$$\phi = \sum_{i=1}^{N} F_i^m \quad [6] \quad (3)$$

or:

$$\phi = \sum_{i=1}^{N} \left(F_i^m / pcsa_i\right)^3 \quad [7] \quad (4)$$

or:

$$\phi = \sum_{i=1}^{N} \left(F_i^m / M_{max\,i}\right)^3 \quad [8] \quad (5)$$

where

$F_i^m$ = force magnitude of the ith-muscle

$pcsa_i$ = physiological cross-sectional area of the ith-muscle

$M_{maxi}$ = variable maximal moment that the ith-muscle can produce as a function of its instantaneous contractile conditions

$N$ = total number of muscles considered

Design variables are the variables that are systematically changed until the cost function is optimized and all constraint functions are satisfied. The design variables must be contained in the cost function, and for the distribution problem, they typically are the magnitudes of the individual (muscle) forces.

The constraint functions restrict the solution of the optimization approach to certain boundary conditions. For example, in the distribution problem, typical inequality constraints are:

$$F_i^m \geq 0, \text{ for } i = 1, \ldots\ldots, N \tag{6}$$

and typical equality constraints are:

$$M_o = \sum_{i=1}^{N} \left(r_{i/o} \times F_i^m\right) \tag{7}$$

Equations (6) and (7) indicate that muscular forces must always be zero or positive (tensile), and that resultant joint moments, $M_o$, are assumed to be satisfied by the vector sum of all moments produced by the muscular forces. An optimization problem may not have constraint functions, and is then referred to as an unconstrained problem.

### *Example Solution of a General Constrained Problem*

The distribution problem in biomechanics is typically solved by minimizing the cost function of a ►general constrained optimization problem. Specifically, suppose we want to minimize f(x) subject to the constraints $h_i(x) = 0 (i = 1, 2, \ldots\ldots, s)$ where f and $h_i$ are differentiable and $x = (x_1, \ldots., x_N)$ is a vector of design variables that are assumed to be non-negative. These non-negativity constraints $x_j \geq 0$ $(j = 1, 2, \ldots., N)$ make the problem of the "mathematical programming" type, and in certain cases, it can be solved via the Karush Kuhn-Tucker (KKT) conditions.

One such case, which we shall consider, is where f is convex and each $h_i$ is affine, i.e. $h_i(x) = a_i^T x + b_i$ for some (row) vector $a_i$ and constant $b_i$. In this case, the KKT conditions are necessary and sufficient for a ►global minimum, and they admit the following interpretation.

First, select the design variables which are zero, and label them $x_k$ (the other design variables are positive). Then solve the *equality* constrained problem of minimizing f(x) subject to:

$$\text{all } h_i(x) = 0 \text{ and all } x_k = 0 \tag{8}$$

This problem can be attacked by Lagrange multipliers $\lambda_i$ and $\mu_k$. Let:

$$L(x) = f(x) + \sum_{i=1}^{s} \lambda_i h_i(x) + \sum_k \mu_k x_k \tag{9}$$

and solve the mathematical system consisting of the stationary point condition:

$$0 = \frac{\partial L}{\partial x_j}(x) \; (j = 1, 2, \ldots., N) \tag{10}$$

together with the equality constraints of equation (8).

If N is large, the task of selecting which design variables should be zero can be formidable. For a small N, however, the problem may be tackled as follows: first try the case where no $x_k$ is zero (so all $x_j$ are positive and the final summation is absent from L (x)). If the system (i.e. equations 8 and 10) is soluble with all $x_j \geq 0$, then we have found the global minimum. If not, then we try the case where just one $x_k$ is zero. There are N such possibilities, and if any of the resulting systems has a solution with all $x_j \geq 0$, then again we have found the minimum. If not, then we try those cases where exactly two of the $x_k$ are zero, and so on.

## DNA Polymorphisms

### Definition

Alternate, but normal, usage of different nucleotide sequences at a given site in a DNA molecule across a population of individuals. DNA polymorphisms may occur in exons or noncoding regions of genes. DNA polymorphisms are used extensively in genetic analyses when tracking the genes underlying familial disorders, including for example Huntington's disease. Single nucleotide polymorphisms (SNPs) occur at a single nucleotide, and because of degeneracy of the genetic code, do not necessarily result in changes in the amino acid sequence of the encoded protein. The presence of a particular SNP may not in itself cause a disease, but the presence of several SNPs across a region of the chromosome (haplotype) can affect the likelihood of a disease occurring, the severity of the disorder, and the response of a disease to chemical interventions.

## DNA Transcription

Gabriel Bertolesi, Sarah McFarlane
The Hotchkiss Brain Institute, Department of Cell Biology and Anatomy, Faculty of Medicine, University of Calgary, Calgary, AB, Canada

### Synonyms

RNA synthesis

### Definition

►DNA Transcription is the process by which one strand of a ►DNA duplex serves as template to enzymatically generate a complementary strand of ►RNA. This reaction is catalyzed by enzymes called ►RNA polymerases.

Transcription refers to the conversion of a written source in another medium. For example, the digitization of a book is a transcription process since a specific written source is converted to a digitized one. In the context of the expression of genetic information, the conversion is from the template source of deoxinucleotides in the DNA, into a different form, ribonucleotides in the RNA. The stretch of DNA that is transcribed into an RNA molecule is called the ►transcription unit.

### Characteristics

#### RNA Polymerases Synthesize RNA From DNA

RNA polymerases are the enzymes responsible for RNA synthesis. Although RNA polymerases use double stranded DNA to make RNA, only one of the two stands of DNA acts as template as the double helix is transiently unwound. The RNA is complementary to the template strand. RNA polymerization proceeds only in the 5′→3′ direction while the template DNA is read in the 3′→5′ direcction (Fig. 1).

RNA polymerases have a very modest proofreading mechanism compared with the DNA polymerase, which is compatible with the idea that the consequences of misincorporated nucleotides in RNA are much less significant than in DNA replication. This is because many copies of an RNA are made, degraded and replaced while the DNA that serves as template is unique.

RNA and DNA are made from four different types of nucleotide units linked together by phosphodiester bonds, but RNA chemically differs from DNA in two aspects:

1. ribose rather than deoxyribose is the sugar contained in the nucleotides and,
2. while the bases adenine (A), guanine (G) and cytosine (C) are present in both RNA and DNA, the base uracil (U) replaces thymine (T) in RNA (Fig. 1).

The transcription process is similar between prokaryotes and eukaryotes with two main differences:

1. There is only one RNA polymerase in bacteria, while at least three RNA polymerases are present in eukaryotes.
2. DNA transcription and protein synthesis are coupled in prokaryotes while it is compartmentalized in eukaryotes. Thus, in bacteria, newly transcribed RNA can interact with ribosomes while RNA polymerase is still synthesizing the RNA strand. In eukaryotes, transcription and translation are time separated and occur in the nucleus and cytosol/endoplasmic reticulum, respectively.

Eukaryotic transcription utilizes three RNA polymerases characterized by their RNA product:

1. RNA polymerase I generates the pre 45S ribosomal RNA, which matures into the three mayor components of RNA in the ribosome, the 28S, 18S and 5.8S ribosomal RNA (rRNA). Most of the DNA transcribed in cells corresponds to rRNA.
2. RNA polymerase II synthesizes the messenger RNA (►mRNA) and small nuclear RNA (snRNA). Although, mRNA comprises less than 5% of the total RNA in the cell, RNA polymerase II is the most studied of the three polymerases. It interacts with a wide range of ►transcription factors, which modify its affinity and selectivity for specific regions of the genes named ►promoters. Thus, RNA polymerase II is responsible for gene expression and ultimately for its regulation.
3. RNA polymerase III synthesizes transfer RNAs (tRNA); rRNA 5S and other snRNA.

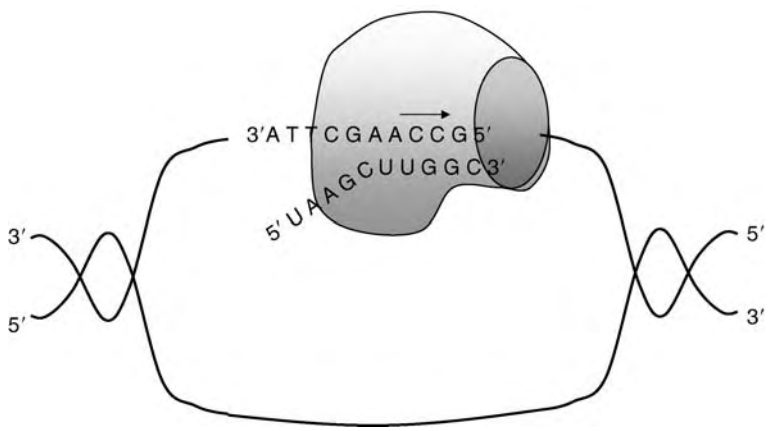
Other RNA polymerases are found in mitochondria and chloroplasts of eukaryotic cells and resemble in some aspects the bacterial polymerase.

## Initiation, Elongation and Termination of Transcription

Transcription occurs in three stages, ►initiation, ►elongation and termination.

### *Initiation*

The initiation step involves the binding of the RNA polymerase to the double strand DNA. The polymerase must recognize where to start transcription in the genome, and in a complex with multiple additional proteins determine which genes are to be transcribed and at what rate. In order to initiate transcription, RNA



**DNA Transcription. Figure 1** RNA synthesis by the RNA polymerase. The RNA polymerase moves, unwinding the DNA helix. RNA synthesis occurs at the active site (shown as internal circle) generating the addition of new nucleotides at the 3′ end. Thus, RNA polymerization occurs in the 5′→3′ direction. The RNA is single stranded and complementary to one of the two DNA strands used as template. The base uracil (U) replaces thymine (T) in the ribonucleotides.

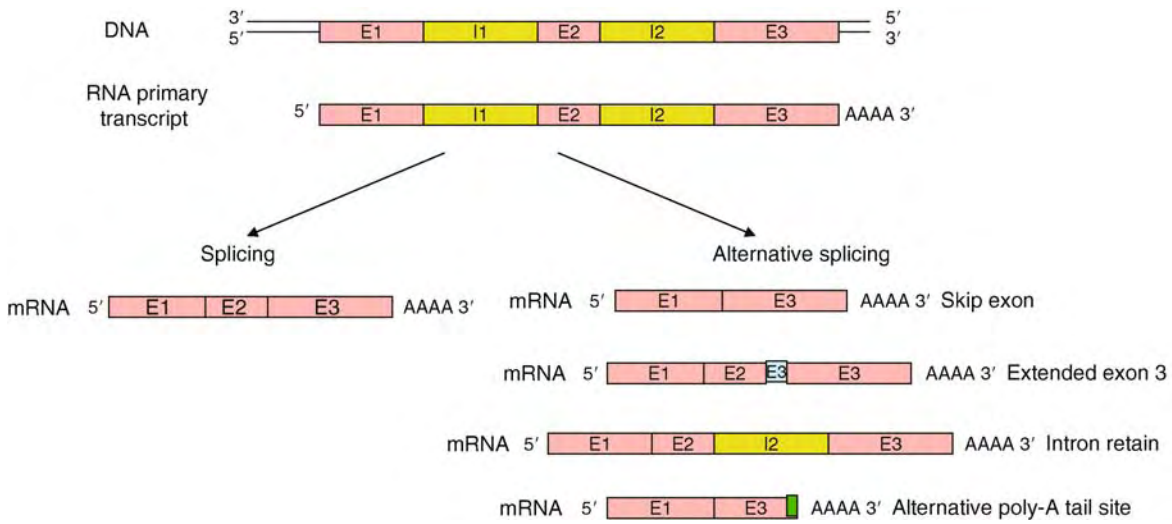
polymerases require the help of a large set of proteins called general ►transcription factors. These factors help the polymerase bind to the promoter, contribute to unwinding the DNA, and aid the transition of RNA polymerase II activities from initiation to elongation. General transcription factors are designated as TFII (transcription factors for polymerase II) plus an additional letter (TFIIA; TFIIB etc) and are "general" because they participate in the assembly of transcription complexes on all promoters used by RNA polymerase II.

Other transcription factors are specific and form part of the transcription complex on some but not all promoters. Further, other gene regulatory proteins can bind the DNA even thousand of bases away from the promoter and influence the rate of transcription. Initiation is a critical step in the regulation of gene expression. An example in the nervous system of how transcriptional regulation at the initiation level may define neuronal properties involves the control of the expression of ►Brain-Derived Neurotrophic Factor (►BDNF) by multiple promoters. BDNF is a member of the neurotrophin family that plays an important role in promoting neuronal survival, neuronal differentiation, and synaptic plasticity. Interestingly, four different promoters regulate the transcription of BDNF, with expression under the control of each promoter differentially regulated by calcium signals [1].

### Elongation

This step involves the covalent addition of new ribonucleotides to the 3′end of the growing RNA chain. The RNA synthesized by the RNA polymerase II in the nucleus of eukaryotes cells is called the ►primary transcript. Several of the modifications that occur on the primary transcript, commonly called "posttranscriptional modifications," are really coupled to the elongation process. The three main modifications of the primary transcript are:

1. ►5′ Cap: The 5′ end of the RNA (the first to be synthesized during transcription) is capped by the addition of a methylated G nucleotide, a process that is important for protein synthesis and to protect RNA from degradation. The 5′ capping occurs almost immediately after the elongation of the first 30 nucleotides and protects the growing RNA transcript.
2. ►3′ poly A tail: The 3′end of the RNA synthesized by polymerase II contains a poly-A- tail of about



**DNA Transcription. Figure 2** Splicing and alternative splicing. The double strand DNA is transcribed to a single strand primary transcript containing both exons (pink) and introns (yellow). During the splicing process, introns are removed and the exon sequences (E1 to E3) are joined into a continuous coding sequence (*left side*). The primary transcript can also be spliced in different ways generating alternative splice variants with different coding sequences in different ways, generating (*right side*). Skipping exon: internal exons (E2) can be removed together with the introns generating a shorter coding sequence. Extended exons: During intron removal a "cryptic" sequence inside the intron is recognized as an "exon-intron" boundary, removing a shorter intron and leaving an additional region (light blue) as part of the next exon. Intron retained: During intron removal, a boundary exon-intron sequence is not recognized and the intron is retained in a coding sequence. Alternative poly-A tail site: a different sequence for poly-A addition is recognized. This may occur on the last or internal exons, generating a shorter coding sequence or sometimes changing the RNA stability.

100–200 nucleotides, which is added during elongation after recognition of a specific sequence and before termination of transcription. Additional nucleotides incorporated after synthesis of the poly-A-tail are later removed. The poly A tail is important for RNA stability, contributes to the export of RNA from the nucleus and is recognized by the ribosome for protein synthesis.

3. ►Splicing: The primary transcript is synthesized as a long molecule containing ►exons and ►introns. Splicing events occur in the nucleus and involve cutting the intronic sequence out of the RNA and joining the exons to produce an mRNA molecule that codes directly for a protein (Fig. 2).

The mature mRNA is exported to the cytoplasm only once the splicing process is completed. The splicing process is carried out by a multicomponent ribonucleoprotein complex, called the ►spliceosome, which recognizes the specific sequences that determine the boundary region between exons and introns.

In evolutionary terms, the splicing process allowed some genes to evolve from a combination of exons coming from different genes. This idea is supported by the presence of specific protein domains with similar function in many different proteins. Splicing also facilitates the diversity of proteins obtained from one gene. This concept becomes clear with an understanding of alternative splicing (Fig. 2), which expands exponentially the number of functionally distinct proteins. In humans, approximately 75% of the genes which contain multiple exons are subject to alternative splicing [2]. There are multiples examples of alternative splicing in neurons. For example, several potassium and calcium voltage channels with different electrophysiological properties are generated by alternative splicing. The expression of these splicing variant subtypes changes between cellular types, as well as during the development of neuronal cells [3].

#### *Termination*

The RNA polymerase continues elongating the RNA until it finds a sequence in the DNA called the ►terminator. It then releases both the DNA template and the newly made RNA. These terminator sequences appear in the DNA as two fold symmetric sequences, which when transcribed into the RNA induce a secondary "hairpin" structure. The hairpin structure helps to destabilize the polymerase and the DNA-RNA hybrid, releasing the components. Because a large number of sequences have the potential to generate hairpin structures, terminator sequences are more heterogeneous and less well characterized than promoter sequences.

## DNA Vaccination

### Definition

DNA vaccines are plasmid DNA that encodes for an antigen expressed under the control of a mammalian enhancer/promoter. DNA vaccines also contain certain DNA sequences, CpG DNA motifs, that act as adjuvants and are recognized by the innate immune system. The encoded antigen is transcribed and translated into protein in vivo after immunization, and antigen-specific immune responses are subsequently induced.

►Neuroinflammation – DNA Vaccination against Autoimmune Neuroinflammation

## DNA Vaccination against Autoimmune Neuroinflammation

### Definition

To prevent or treat autoimmune neuroinflammation by vaccination with DNA encoding one or more autoantigen(s). The autoantigen, usually a myelin autoantigen, is transcribed and translated in vivo, processed and presented to T cells in the context of major histocompatibility complex after vaccination. Toll-like receptor 9 ligand CpG DNA within the plasmid backbone acts as adjuvant to activate the innate immune system. Presence of CpG DNA and the expressed autoantigen are both essential for the protective immune reaction to occur.

## Dominance Column

### Definition

In the primary visual cortex neurons receive information predominantly either from the left or the right eye. They are arranged in spatial regions which are called ocular dominance columns. In such a column cortical cells respond to visual input from a receptive field of one eye while cells in the adjacent dominance column respond to visual input from a corresponding receptive field of the other eye.

►Striate Cortex Functions

## Dominant Allele

### Definition

Dominant allele – a gene that is expressed even when its allele on the other homologous chromosome is dominant or recessive.

►GAL4/UAS

## Dominant Inheritance

### Definition

Pattern of inheritance that causes disease by a faulty dominant gene which overpowers the normal gene.

## Dominant Negative

### Definition

A mutant form of a protein that when expressed at high levels in a cell will interact with the endogenous protein, or its interactors, and block or poison the function of the protein.

## Domoic Acid Neurotoxicity

Douglas Steven Kerr
Department of Pharmacology & Toxicology, University of Otago School of Medical Sciences, Dunedin, New Zealand

### Synonyms

Excitotoxin; Amnesic shellfish poison

## Definition

The term "neurotoxicity" refers to the process whereby a drug or toxin causes a temporary or lasting change in neuronal function leading to the disability or death of an organism. Neurotoxicity may involve a discrete alteration of neuronal activity which in turn leads to changes in physiological control mechanisms and subsequent loss of health, without any demonstrable damage to the neuron itself. The marine algal neurotoxin saxitoxin is a good example of a neurotoxin which does not directly damage neurons *per se*, but which blocks voltage-sensitive sodium channels and the propagation of action potentials, leading to profound paralysis and death. Conversely, neurotoxicity may involve a direct damaging effect on the neuron itself with subsequent physiological dysfunction(s) which lead to disability or death.

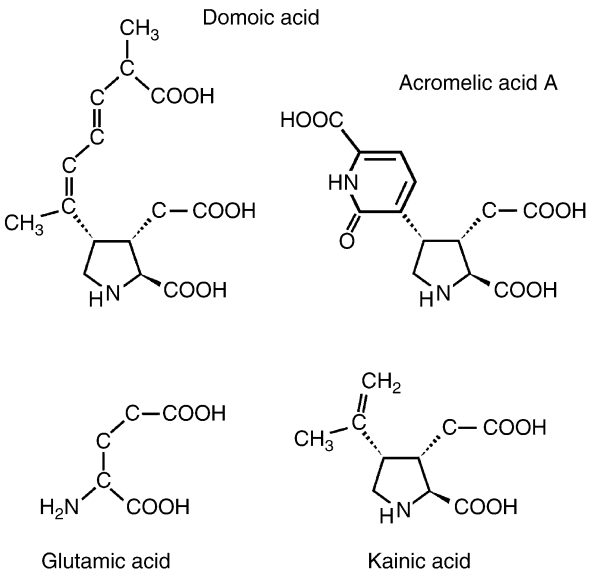
Domoic acid (also known as ►Amnesic Shellfish Poison; ASP) is a naturally occurring neurotoxin which, depending on dose and duration of exposure, can act by either of these two mechanisms. Domoic acid can cause a transient perturbation of neuronal function leading to cognitive disturbances, seizures and cardiac damage, or the neurotoxin can kill CNS neurons outright, leading to permanent and ongoing disabilities (epilepsy, anterograde amnesia) which persist even after the toxin has been cleared from the system. The following discussion will focus on domoic acid chemistry, toxicology, receptor sites and mechanisms of action, and central and peripheral pathophysiology. Interested readers are directed to recent reviews [1,2] for comprehensive treatments of the subject.

## Characteristics

### Source in the Environment and Chemistry of Domoic Acid

Domoic acid is produced by marine red algae in the genus *Chondria* and by marine diatoms in the genus *Pseudo-nitzschia*. In 1987 domoic acid was identified as the causative agent underlying an incident of human poisoning in Canada [3], and has since been responsible for episodes of pathological intoxication in animals as diverse as pelicans, sea lions and sea otters. Entry into food chains generally occurs during seasonal phytoplankton blooms, leading to bioaccumulation of domoic acid in numerous species of phytoplanktivorous shellfish, crustaceans and small finfish.

Domoic acid ((2S,3S,4R,5′R)-2-carboxy-4-(5′-carboxy-1′-methyl-1Z,3E- hexadienyl)-3-pyrrolidineacetic acid) is a tricarboxylic amino acid with structural homology to the endogenous CNS neurotransmitter glutamate and other excitotoxins, such as kainic acid (KA) and acromelic acid (from seaweed and fungi, respectively; Fig. 1). A number of natural isomers of domoic acid also exist (isodomoic acids-A through -H; Fig. 2). Although these isomers are generally detected in only trace amounts in the food chain, isodomoic acids-A and -C have been recently identified in high concentrations in New Zealand shellfish. Not surprisingly, the appearance of DA and its isomers are of concern to commercial shellfish industries and food safety authorities alike, and monitoring programs are now in place worldwide.

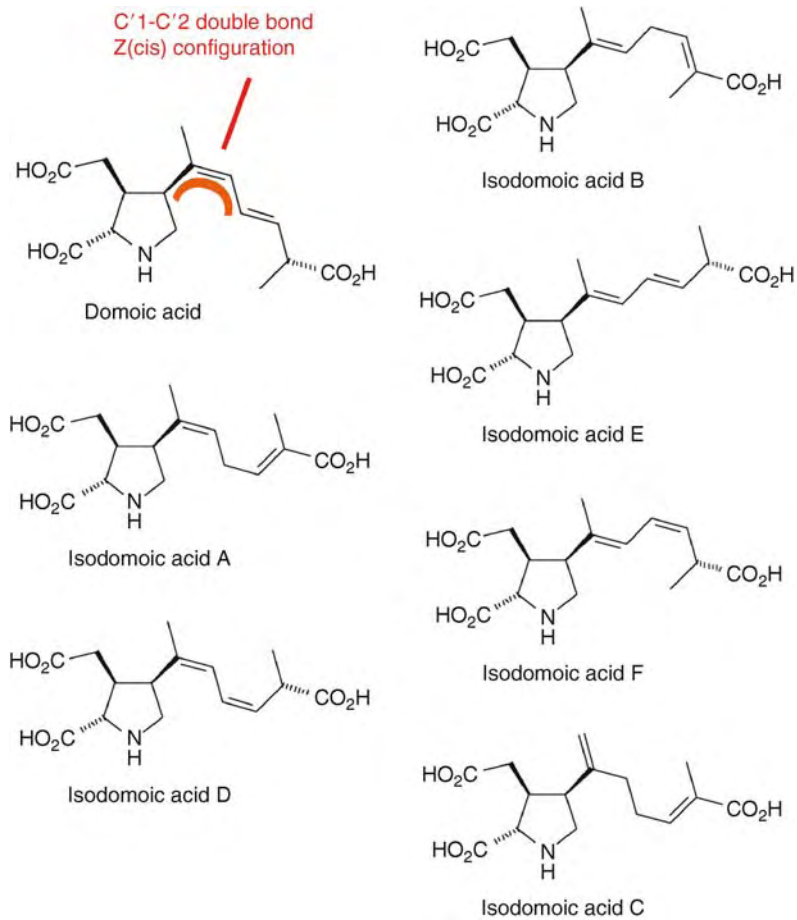


**Domoic Acid Neurotoxicity. Figure 1** Chemical structures of domoic acid and related compounds.

### Pharmacokinetics

Following oral ingestion, domoic acid undergoes limited absorption from the mammalian gut with up to 98% excreted unchanged in the faeces (depending on the species). Animal studies indicate that the small percentage of domoic acid which is absorbed is not metabolized and undergoes full renal clearance within a few hours of ingestion. Movement from the blood is considerably limited by the blood-brain barrier with only 4–6% of an injected dose apparent in most brain regions at 1–2 h postinjection. Behavioral observations in rodents and primates following intravenous, intraperitoneal or subcutaneous administration of domoic acid indicate mild to strong neurotoxicity in the range of 1–4 mg/kg body weight. Oral administration in animals generally produces minimal adverse effects at doses 20- to 80-fold higher than those producing comparable activity by systemic administration. Humans appear to be much more sensitive to domoic acid following dietary exposure.

Clinical studies of humans and laboratory studies in rats confirm an age-related supersensitivity to domoic acid and related kainoids. Numerous studies have shown that aged rats suffer more severe symptoms of toxicity



**Domoic Acid Neurotoxicity. Figure 2** Chemical structures of domoic acid and isodomic acids A through F. The isoforms shown on the left (domoic acid, Iso-A and Iso-D) contain a C'1–C'2 double bond with a Z (cis) side-chain configuration; each of these exhibits strong neurotoxic potency. The isoforms on the right exhibit either no C'1–C'2 double bond (Iso-C) or a C'1–C'2 double bond with an E (trans) side-chain configuration (Iso-B, -E and -F) and collectively exhibit little or no functional potency.

following administration of kainic acid relative to young, and behavioral studies of domoic acid in neonatal, young-adult and aged rats have shown that neonatal and aged animals are markedly more susceptible to domoic acid-induced seizures relative to young-adults across a wide range of intraperitoneal doses. This increased susceptibility appears to be a result of impaired renal clearance as opposed to increased blood-brain barrier permeability or differences in absolute neuronal sensitivity to the neurotoxin [4]. Although the precise kinetics of domoic acid transfer across the placenta are not known, domoic acid has been shown to adversely affect postnatal development following exposure of pregnant animals to seizurogenic doses of the neurotoxin. In addition, domoic acid has been shown to appear in the milk of lactating rats and can be detected in low levels in suckling offspring. Interestingly, a number of studies in rats have shown that postnatal exposure to even small doses of domoic acid can produce lasting changes in brain neurochemistry, anatomy and behavior which persist well into adulthood.

## Receptor Sites of Action and Pharmacodynamics

Domoic acid is a potent agonist of ionotropic glutamate receptors, exhibiting high affinity to a subset of ►KA receptors and moderately high affinity to a subset of ►AMPA receptors. Neither the parent molecule nor its isomers bind to NMDA or metabotropic glutamate receptors (mGluR's), or to any of a wide range of other CNS neurotransmitter or ion channel sites [5]. The considerable selectivity of domoic acid at KA and AMPA receptors has been demonstrated by radioligand binding, electrophysiology and functional *in vitro* toxicity studies. Binding affinity ($K_D$) at the KA receptor ranges from 1 to 5 nM and at the AMPA receptor from 10 to 100 nM, depending on receptor assay conditions. Whole cell neuronal recordings and *in vitro* cell culture studies have

confirmed this relative relationship for domoic acid potency (agonist activity) at KA and AMPA receptors.

A key feature leading to strong glutamate receptor binding by domoic acid and its isomers is a C'1–C'2 double bond with a Z (cis) side-chain configuration. In early radioligand binding studies, isodomoic acid-D and other cis-configuration isomers were shown to exhibit relatively high affinities for rat brain KA receptors, while isomers E and F (both trans-configuration) exhibited markedly lower affinities relative to DA [6]. The same relative structure-affinity relationship was recently shown for isodomoic acid-A (cis-configuration) and -C (trans-configuration) binding at KA receptors [7]. Studies of functional neurotoxicity in insects and recent electrophysiological analyses of isodomoic acids-A, -B and -C in rat brain, both *in vitro* and *in vivo* (8, and unpublished observations), have confirmed that strong agonist activity is associated with domoic acid isomers exhibiting a cis-configuration side chain.

## Mechanisms of Seizure Induction and Excitotoxicity

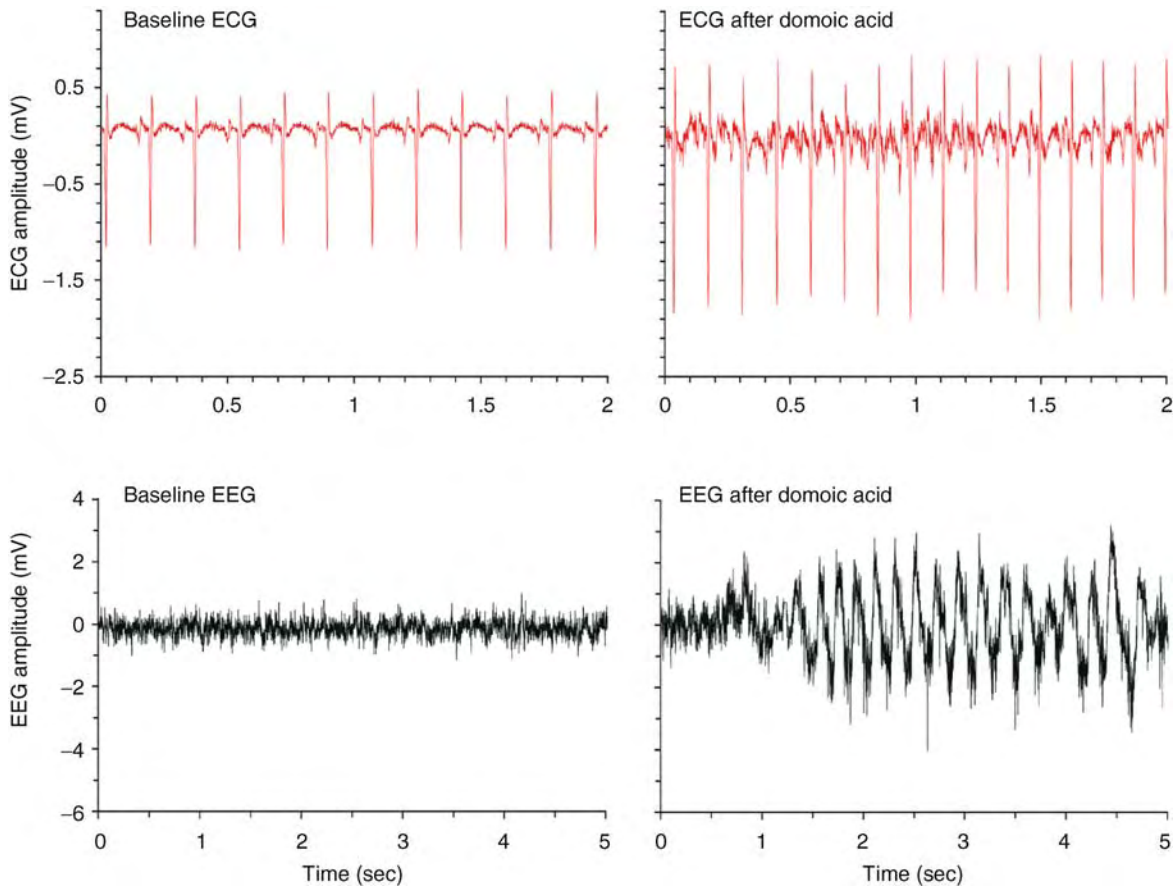
Because of its high affinity and potent agonist activity at KA and AMPA receptors, domoic acid readily produces seizure activity acutely and, at higher doses or following prolonged exposure, acts as a strong "excitotoxin" producing sustained ionotropic glutamate receptor activation, tonic dendritic depolarization, neuronal hyperexcitability, excessive $Ca^{2+}$ influx and ultimately, dendritic damage and neuronal loss. This excitotoxic cascade has been observed in a number of CNS regions, and is particularly pronounced in the mammalian hippocampus which is rich in AMPA and KA receptors. *In vitro* electrophysiological analyses in rat hippocampal slices have shown domoic acid to be 5–10 fold more potent than KA in the induction of epileptiform activity in region CA1, producing neuronal hyperexcitability within minutes of application and, with prolonged administration, a significant suppression of neuronal activity, presumably due to depolarization block of cell firing [8].

The hippocampus plays an important role in information processing, learning and memory and, in cases of animal or human epileptogenesis, is often a focus of limbic seizure activity. During a well-documented episode of domoic acid poisoning in Canada [3] a number of people suffered disorientation, seizures, convulsions, coma, and even death. Several people exhibited long-term anterograde amnesias consistent with excitotoxic lesions and neuronal loss from the hippocampus and associated limbic/median temporal structures. CAT, MRI and PET scans of individuals exhibiting severe amnesia, coupled with post-mortem tissue histopathology confirmed that significant neuronal degeneration had occurred in many of these brain regions [3]. In animals, behavioral indices of limbic seizures include "wet-dog shakes," hypermotility, stereotypical scratching, head nodding, loss of balance, and mild facial clonus at lower doses, followed by forelimb clonus, salivation and rearing (characteristic of *status epilepticus*) at higher doses. EEG analyses have yielded evidence of generalized bilateral seizures characterized by increased frequency and amplitude of electrographic spikes, a dominance of delta and theta activity, intermittent limbic paroxysmal burst discharges, and frontotemporal epileptiform activity in humans and animals suffering domoic acid poisoning. Of particular concern is the fact that acute seizure activity following domoic acid poisoning can lead to long-term epilepsy in humans, with onset delayed up to 1 year after the initial insult.

## Domoic Acid-Induced Cardiac Damage

During the 1987 case human domoic acid poisoning, hypertension and cardiac arrythmias were seen in affected patients. More recently, cardiotoxicity has been documented in sea lions and sea otters exposed to domoic acid [9]. Cardiac lesions included myocardial pallor, myocardial haemorrhage and fibrinous epicarditis. In addition, lymphocytic myocarditis, gross lesions consistent with dilated cardiomyopathy, and congestive heart failure characterized by pulmonary oedema were evident in many animals. Whether cardiac injury is a direct or indirect effect of domoic acid is currently a subject of debate. As noted, animals exhibit strong, sustained seizure activity following domoic acid and it is possible that cardiac injury arises secondary to *status epilepticus* or during prolonged excitation of CNS cardiac control centers. Ictal tachycardias and/or bradycardias often arise during seizures, and most likely relate to propagation of electrical activity via insular cortex, amygdala and central nuclei to cardioregulatory centers in the medulla. Furthermore, intracerebral kainate injection leads to myocardial necrosis in rats and intrahippocampal injection of picomole amounts of domoic acid produce sustained tachycardias (Sawant and Kerr, unpublished observations; Fig. 3).

However, while domoic acid-induced cardiac damage occurs downstream of autonomic "sympathetic storm," domoic acid can also exert *direct* effects on cardiomyocytes. A number of studies have identified gene transcripts and proteins for ionotropic glutamate subunits in rat heart and, although precise mechanisms underlying excitotoxic insult within the myocardium have yet to be established, GluRs within the atrial/septal conducting fibres, ganglia cells, nerve fibers, intercalated discs and blood vessels may provide a means of modulating cardiac autonomicity, contractility and rhythmicity. Recent studies by our group indicate that treatment of isolated cardiac mitochondria with domoic acid results in a rapid uncoupling of mitochondrial respiration and specific damage to mitochondrial complex enzyme activity. We have also found that cultured H9c2 cardiomyocytes readily transport domoic acid into the intracellular compartment, and that mitochondrial respiratory activity



**Domoic Acid Neurotoxicity. Figure 3** Electrocardiograms (ECGs) and electroencephalograms (EEGs) from adult rat before (left panel; heart rate 330 bpm) and following intrahippocampal injection of 100 picomoles domoic acid (heart rate 450 bpm). (Sawant and Kerr, unpublished observations.)

is suppressed following *ex vivo* perfusion of intact hearts with domoic acid [10, and unpublished observations]. Interestingly, acute (20 min.) exposure to domoic acid does not alter Langendorff cardio-haemodynamics, suggesting that longer exposures, as occur naturally, may be required in the direct induction of cardiomyopathy. At this time it appears that cardiac damage involves direct actions of domoic acid on cardiac mitochondrial energetics in conjunction with indirect effects associated with excitation and/or damage to CNS autonomic control centers during domoic acid exposure. As such, seizure activity likely provokes or exacerbates gross and ultrastructural myocardial damage, consistent with pathology reported following domoic acid exposure.

## Dopamine

### Definition

The catecholamine dopamine was first proposed to be a novel brain synaptic transmitter by Arvid Carlsson in the mid-1950's and the subsequent body of evidence, confirming this hypothesis and its relevance to several important brain disorders including Parkinson's disease and schizophrenia, earned him a Nobel prize in 2000.

Dopamine is synthesized from L-tyrosine. Dopamine acts via five distinct G protein-coupled metabotropic receptors which are categorized into two separate classes based on activation (D1-D5) adenylyl cyclase or reduction (D2,D3,D4) of cyclic AMP. There are six separate neural pathways containing dopamine as the primary synaptic transmitter, and two have particular relevance to systems neuroscience and higher order brain function. The nigrostriatal projection from the substantia nigra to dorsal striatum plays a critical role in initiation of movement and damage to this pathway leads to Parkinson's disease. The mesocorticolimbic projection arises from dopaminergic neurons in the ventral tegmental area and projects to regions of the limbic system and the prefrontal cortex. This pathway is essential for incentive motivation and reward function and is implicated in substance abuse and other forms of addiction. Dopamine activity in the prefrontal cortex has been linked to working memory and other aspects of executive function involved in predicting the outcome of subsequent behavior. Enhanced and reduced dopaminergic activity in the prefrontal cortex are both proposed as biochemical correlates of psychotic behavior.

►Parkinson's Disease

## Dopamine Receptors

### Definition

Dopamine acts via five distinct G protein-coupled metabotropic receptors which are categorized into two separate classes based on activation (D1-D5) adenylyl cyclase or reduction (D2,D3,D4) of cyclic AMP.

►Dopamine

## Dopamine Transporter

### Definition

Dopamine Transporters (DAT) are present in dopamine nerve terminals and are critical for removing dopamine from the synapse. DA is then transported into vesicles by the monoamine transporter (VAT).

►Dopamine

## Dopamine-β-hydroxylase (DβH)

### Definition

Dopamine-β-hydroxylase (DβH) is the enzyme that converts dopamine to noradrenaline, in the pathway for catecholamine biosynthesis from the essential amino acids phenylalanine or tyrosine. DβH in postganglionic autonomic neurons is synthesized in the cell body, and transported to the terminal varicosities in membrane bound vesicles. These vesicles take up dopamine, DβH converts it to noradrenaline, and noradrenaline is stored in the vesicles prior to release (or, in amphibians, prior to its conversion to adrenaline).

►Adrenaline
►Dopamine
►Noradrenaline
►Postganglionic Neurotransmitter

## Dopaminergic Drugs

### Definition

Medications that either act as dopamine precursors (levodopa), dopamine mimickers (dopamine agonists), or dopamine level enhancers (monoamine oxidase-B inhibitors).

►Dopamine

## Dorsal Cap of the Inferior Olive (DC)

### Definition

A nucleus within the inferior olive that receives optokinetic information from the accessory optic system and eye movement-related information from the nucleus prepositus hypoglossi (NPH).

►Inferior Olivary Nucleus
►Vestibular Secondary Afferent Pathways

## Dorsal Cochlear Nucleus

### Definition

Major division of the cochlear nucleus.

►Cochlear Nucleus

## Dorsal Column

### Definition

The dorsal columns are composed of two bundles of afferent nerve fibers located on each side of the spinal cord behind the gray matter. They carry signals predominantly from mechanoreceptors in skin and deep tissues.

►Somatosensory Projections to the Central Nervous System

## Dorsal Column Ataxia

►Proprioception: Effect of Neurological Disease

## Dorsal Column Nuclei

### Definition

Nuclei that lie at the spinomedullary junction and receive projections from sensory afferent fibers carrying touch and position sense stimuli from the body. The medially lying nucleus gracilis carries this information from the lower limb and lower part of the trunk, and the laterally neighboring nucleus cuneatus carries this information from the upper part of the trunk, the upper limb, and the neck. The dorsal column nuclei project to multiple sites in the brainstem, the most prominent of which is a dorsal thalamic nucleus, the nucleus ventralis posterolateralis of mammals and its homologues in other vertebrates.

## Dorsal Horn

### Synonyms

Cornu posterius; Posterior horn of spinal cord; Posterior Horn

### Definition

Area of the spinal cord where sensory neurones relay information at a segmental level after entering the cord to other neurones.

## Dorsal Lateral Pontine Nuclei

### Definition

The dorsal lateral pontine nuclei relay smooth pursuit commands from the cerebrum to the cerebellar flocculus.

►Gaze Shift
►Smooth Pursuit Eye Movements

## Dorsal Lateral Thalamic Nucleus

### Synonyms
Nucl. lat. dors. thalami

### Definition
This thalamic nucleus of the lateral nuclear group is, like the anterior thalamic nucleus, reciprocally connected with the limbic cortex of the cingulate gyrus, retrosplenial area as well as the pre- and parasubiculum. Concomitantly, it receives afferents from the pretectal area and projects to the hippocampus, parietal lobe and retrosplenial cortex and is involved in somato-sensory-motor integration processes.

►Diencephalon

## Dorsal Longitudinal Fasciculus, (Schiitz)

### Synonyms
Fasciculus longitudinalis post; Posterior longitudinal fasciculus

### Definition
The dorsal longitudinal fasciculus is a central axis of the autonomic nervous system, coupling the hypothalamus to the nuclei of the brainstem, primarily the parasympathetic nuclear regions, cranial nerve nuclei of the vagus nerve (X), trigeminal nerve (V), hypoglossal nerve (XII) and facial nerve (VII). Ascending fibers come from the solitary nucleus and the reticular formation, conveying predominantly gustatory information to the hypothalamus.

►Diencephalon

## Dorsal Motor Nucleus of the Vagus (DMV)

### Definition
Located ventral to the nucleus tractus solitarii (NTS) in the medulla oblongata, contains pre-ganglionic motor neurons innervating the gastro-intestinal tract. DMV neurons have spontaneous pace-maker activity that is dampened by GABAergic NTS projections. More than 95% of DMV cells are cholinergic, the remaining neurons are catecholaminergic (mainly dopamine-containing) and nitrergic. Some portion of the DMV reside outside the blood brain barrier.

►Nucleus Tractus Solitarii

## Dorsal Nucleus of the Vagus Nerve

### Synonyms
Nucl post. n. vagi; Posterior nucleus of vagus nerve

### Definition
In this approximately 2 cm long nucleus, the preganglionic parasympathetic (GVE) fibers originate. The nucleus runs in the medulla somewhat parallel to the nucleus of the hypoglossal nerve, in the lower angle of the fourth ventricle (vagal trigone). Afferents are received by the nucleus from the solitary nucleus, dorsal tegmental nucleus and other structures.

The special visceromotor fibers in the vagus nerve originate in the nucleus ambiguus, as in the case of those from glossopharyngeal nerve (IX).

### Synonyms
Nucleus raphé dorsalis

►Raphé Nuclei

## Dorsal Respiratory Group

### Definition
A group of neurons in the ventrolateral portion of nucleus tractus solitarius that participates in generation of the respiratory rhythm, particularly inspiration.

►Motion Sickness

## Dorsal Root Ganglion (DRG)

### Definition
The dorsal root ganglion is situated on the spinal dorsal root and contains cell bodies of sensory afferent nerve fibers. Axons in the dorsal root convey somatosensory and viscerosensory information into the spinal cord and brain from the periphery.

## Dorsal Root of the Spinal Nerve

### Synonyms
N. spinalis, radix post; Posterior root of the spinal nerve

### Definition
Via the dorsal root, peripheral sensory nerve fibers enter the spinal cord. A distinction is made between various types of fibers (A, C fibers etc.)

►Medulla Spinalis

## Dorsal Root Potential (DRP)

### Definition
A prolonged negative potential recorded from the central stump of a cut dorsal root filament. These potentials are produced by electrotonic conduction of intraspinal depolarization of primary afferent fibers (primary afferent dpolarization: PAD).

►Presynaptic Inhibition

## Dorsal Root Reflex (DRR)

### Definition
An action potential back-propagated into the axon when primary afferent terminals reach firing threshold as a result of primary afferent depolarization (PAD).

►Presynaptic Inhibition

## Dorsal Telencephalic Area

►Evolution of the Pallium: In Fishes

## Dorsal Telencephalon

## Dorsal Ventricular Ridge (DVR)

### Definition
A structure in the lateral telencephalon.

►Evolution of the Brain: in Birds

## Dorsolateral Cortex

►Prefrontal Cortex

## Dorsolateral Fasciculus of Spinal Cord (Lissauer)

### Synonyms
Tractus posterolat. (Lissauer); Posterolateral tract (Lissauer)

### Definition
Like the fasciculus proprius, Lissauer's tract contains primarily fibers for the intrinsic and reflex apparatus of the spinal cord.

►Medulla Spinalis

## Dorsolateral Placodes

### Definition
A series of epidermal thickenings found in all vertebrate embryos. These patches of cells give rise to the receptors, ganglion cells, and the glial and supporting cells of the octavolateralis systems.

►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

## Dorsolateral Prefrontal Cortex

### Definition
A region in the prefrontal cortex that is thought to control working memory and attention.

►Attention
►Working Memory

## Dorsomedial Hypothalamic Nucleus

### Synonyms
Nucl dorsomed. hypothalami

### Definition
A diffusely organized hypothalamic nucleus implicated in eating behavior. Afferents from many subcortical areas. Efferents to the paraventricular nucleus, parvocellular part (influences neuorendocrine system). The motor nucleus of the vagus nerve (parasym. effect on endocrine pancreas => insulin production), circumventricular organs (control of humoral factors from the blood).

►Diencephalon

## Dorsomedial Thalamic Nucleus

### Definition
A large collection of cells within the thalamus, a part of the forebrain. It plays a variety of roles in the regulation of rhythms and sleep.

►Nocturnal/Diurnal
►Thalamus

## Double Bouquet Cell

### Definition

A type of inhibitory cortical neuron with characteristic spiny dendrites oriented vertically. There are multiple subtypes defined neurochemically, and commonly are visualized with an antibody to calbindin.

## Double Dissociation

### Definition

A dissociation occurs when one factor, A, affects process 1 but not process 2; or, when another factor, B, affects process 2 but not process 1. A double dissociation occurs when both of these are true: when one factor, A, (whether an experimental manipulation or neural damage) affects process 1 but not process 2 while another factor, B, affects process 2 but not process 1.

►Visual Illusions

## Double Innervation

### Definition

Generally, visceral organs of mammals are innervated by two kinds of nerves, sympathetic and parasympathetic nerves, and is defined as double innervation. For example, the heart, stomach, pupil etc, are innervated by sympathetic and parasympathetic nerves, but the sweat gland is not (only innervated by the sympathetic nerve).

If an organ is innervated by two kinds of nerves, it is defined as double innervation. For example, most of the visceral organs of the mammals are innervated by sympathetic and parasympathetic nerves, and muscles of the claw of the crab are innervated by facilitatory and inhibitory nerves.

## Double Saccade Task

### Definition

After fixating a central target, the subject (human or monkey) is shown two peripheral visual targets in succession. The offset of the central fixation target signals the subject to make saccades to the two peripheral targets, in the order in which they appear. Both targets, however, are extinguished shortly before saccade onset. The first saccade, of course, will change the position of the eyes so that the second saccade will not be directed to the same retinotopic location where the target had appeared.

►Saccade, Saccadic Eye Movement

## Double Visceral Innervation

### Definition

Generally visceral organs of mammals are innervated by two kinds of nerves, sympathetic and parasympathetic, and this is referred to as double innervation. For example, the heart, stomach, pupils etc. are innervated by sympathetic and parasympathetic nerves, but sweat glands are not (they are only innervated by sympathetic nerves). Most of the visceral organs of the mammals are innervated by sympathetic and parasympathetic nerves, and muscles of the claw of the crab are innervated by facilitatory and inhibitory nerves.

►Diplopia.

## Down Syndrome Cell Adhesion Molecule

Hung-Hsiang Yu, Tzumin Lee
Department of Neurobiology, University of Massachusetts Medical School, Worcester, MA, USA

### Synonyms

DSCAM/Dscam

## Definition

DSCAM/Dscam, an immunoglobulin superfamily member primarily expressed in the nervous system of both vertebrates and flies, is broadly required in the *Drosophila* for neuronal morphogenesis, especially the proper segregation of neuronal branches that derive from the same neuron.

## Characteristics

### Mammalian DSCAMs as Immunoglobulin-Containing Neuronal Proteins

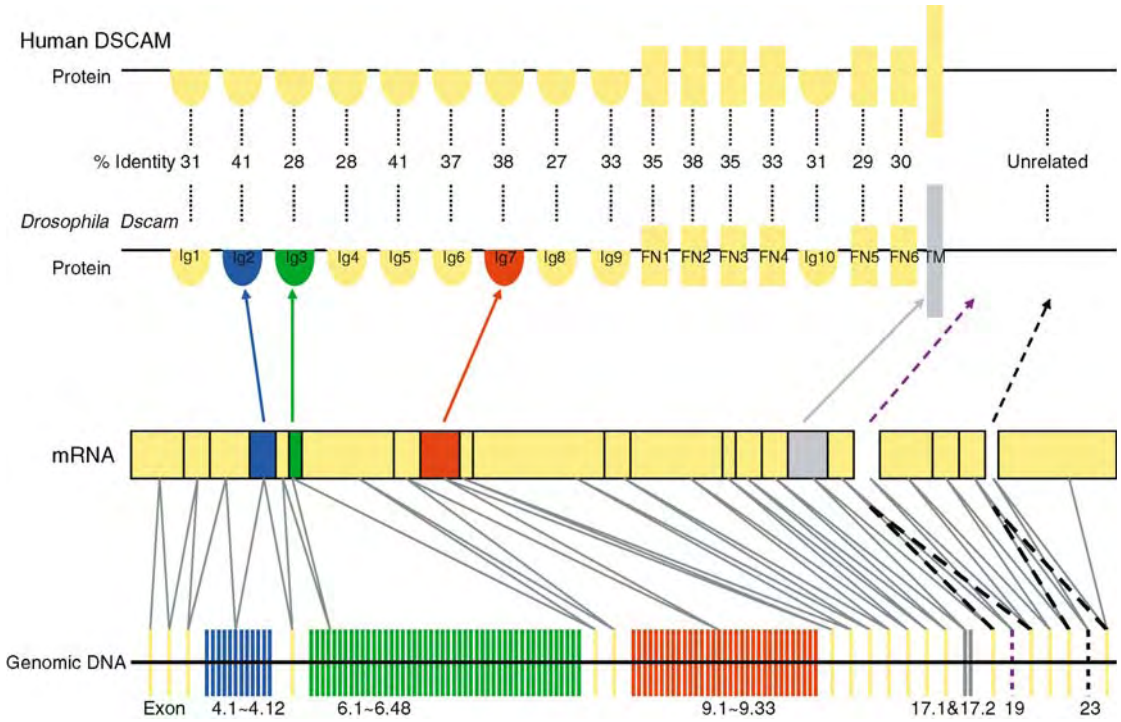
Down syndrome, the most common cause of genetic mental retardation, is strongly associated with trisomy of human chromosome 21, especially in the region of 21q22. One of the molecules located in this region is Down syndrome cell adhesion molecule (DSCAM). DSCAM and its paralog DSCAML1 are cell surface proteins with ten Immunoglobulin (Ig) domains and six fibronectin (FN) III domains on their extracellular region, a transmembrane domain and a cytoplasmic tail (Fig. 1) [1].

As revealed by in situ hybridization, both *DSCAM* and *DSCAML1* are dynamically expressed in the developing spinal cord and brain; and they are expressed in distinct and/or complimentary patterns [1]. However, the function of DSCAM in the mammalian nervous system and whether over-expression or extra copies of DSCAM would lead to Down syndrome have not been elucidated.

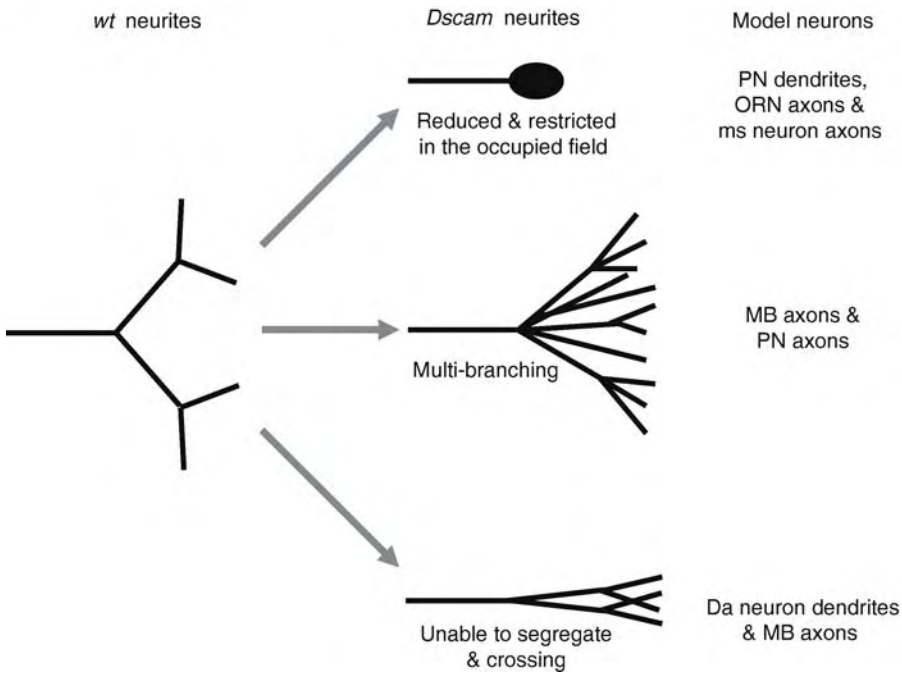
### The Function of Drosophila Dscam and Dscam2 in the Neural Development

Four Dscams (Dscam and Dscam 2–4) in the *Drosophila* genome are highly related to human DSCAM with the same number and organization of Ig and FNIII domains in their extracellular region, sharing about 30% sequence identity (Fig. 1) [2–4]. In contrast, the intracellular region of these *Drosophila* Dscams does not share similarity with their mammalian homologues. Dscam and Dscam2 are primarily expressed in the developing nervous system and, required for the formation of connections of various types of neurons during the development (Fig. 2) [2–4].

Dscam is important for assembling axon connectives and commissures of the embryonic central nervous system (CNS) and for correct axon projection of Bolwing's nerve (BN) [2]. BN is constituted by 12 photoreceptor neurons, whose axons navigate to their target in the brain at the embryonic and larval



**Down Syndrome Cell Adhesion Molecule. Figure 1** The domain structures of human DSCAM and *Drosophila* Dscam are compared. Percentage identities of the compared domains are indicated in numbers between dashed lines. A large number of *Dscam* isoforms are produced by alternative splicing on multiple alternative exon clusters (exons 4, 6, 9 and 17). These alternative splicing exons are responsible for generating the variable regions on Ig2, Ig3, Ig7 and transmembrane domains of Dscam isoforms [2,3]. Additional variants, existing in the Dscam cytoplasmic domain, are generated from skipping exons 19 and/or 23 [7].



**Down Syndrome Cell Adhesion Molecule. Figure 2** A schematic illustration of hypothetical neurites summarizes the phenotypes observed in the wild-type and *Dscam* mutation. Phenotypes of different model neurons are indicated. PN, projection neuron; ORN, olfactory receptor neuron; ms, mechanosensory; MB, mushroom body; da, dendritic arborization [3,5,6].

stages. BN axons were often mistargeted and bypassed their intermediate target neuron in *Dscam* mutant embryos [2].

Dscam is crucial for constructing olfactory neural circuits in the *Drosophila* brain. Olfactory receptor neurons (ORNs), residing in two adult appendages (antennae and maxillary palps), project their axons and make the connections with dendrites of second-order projection neurons (PNs; equivalent to the mammalian mitral/tufted cells) in glomeruli of the antennal lobe (equivalent to the mammalian olfactory bulb). PNs send their axons to higher-order neurons in the mushroom body (MB) and lateral horn where the olfactory information is processed. When *Dscam* is deficient, mistargeted ORN axons were observed in ectopic sites within and outside the antennal lobe [3]. Compared to well elaborated wild-type ORN axonal branches within glomeruli of the antennal lobe, *Dscam*-deficient ORN axons tended to be restricted to the entry site of glomeruli of the antennal lobe. Similarly, removing *Dscam* specifically from the PNs resulted in clumped dendrites and reduced the dendritic field in glomeruli of the antennal lobe [5]. In single cell analyses, a *Dscam*-deficient DL1 PN axon became multiple branches after projecting into the region of the lateral horn in contrast to a single major axonal tract in the wild-type DL1 PN [5]. Furthermore, Dscam is essential for establishing the correct axonal pattern during MB neuronal morphogenesis. Depleting *Dscam* from MB neurons led to an increase in axon branch number and/or a failure in segregation of sister branches [3].

Besides the functions in the CNS, Dscam is also required for generating proper axonal and dendritic patterns of *Drosophila* sensory neurons. Air flow- and touch-sensing mechanosensory (ms) neurons, innervating large bristles of the posterior thorax, have a remarkable stereotyped axonal branching pattern within the CNS. Axons of *Dscam*-deficient ms neurons frequently stalled near the CNS margin, resulting in a clumped axonal branch phenotype [3]. On the other hand, *Drosophila* dendritic arborization (da) neurons are peripheral sensory neurons with multiple dendritic projections, which spread their dendrites along the epidermis. Dendritic arbors within an individual single da neuron normally follow a "self-avoidance" rule to avoid contacting and crossing over each other. When *Dscam* was absent, dendrites of da neurons tended to bundle together and cross over each other [6].

In the *Drosophila* visual system, photoreceptor neurons from the ►compound eye specifically innervate the lamina and medulla in the brain. For example, R7-R8 photoreceptor neurons extend their axons into the developing medulla columns where they make synaptic connections with lamina neurons (L1-L5). Normally, neurites of L1-L5 neurons are confined to their column unit in the medulla. A recent study of *Drosophila Dscam2*

on two lamina neurons, L1 and L2, has just started to reveal its function in the development of the visual system. *Dscam2* is required for restricting arbors of the L1 neuron, but not for L2 neuronal arbors, to a single column of the medulla. When *Dscam2* was deficient, L1 neurons were no longer able to limit their terminal structures within single columns [4].

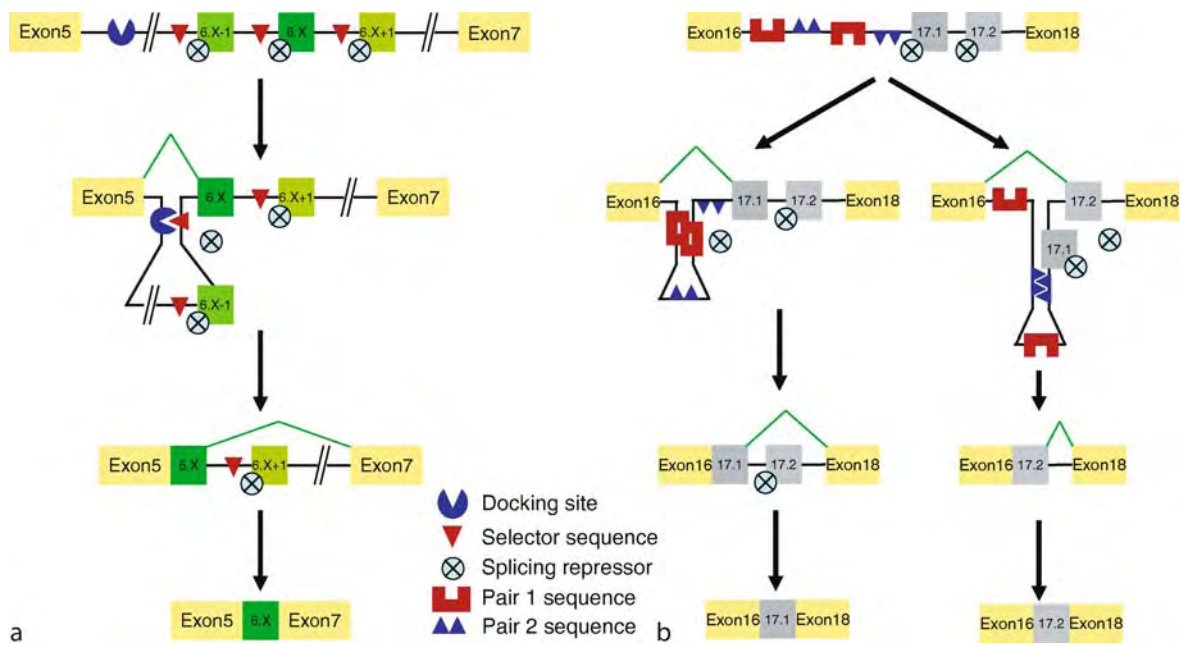
## Extraordinary Molecular Diversity of Drosophila Dscam

A striking feature of *Drosophila Dscam* is its ability to produce a huge number of different isoforms [2], while no extensive isoform diversity can be found in mammalian DSCAMs and *Drosophila* Dscam 2–4 [4]. This remarkable molecular diversity comes from the genomic organization of *Dscam*, which contains multiple cassettes of alternative splicing exons (Fig. 1). Mutually exclusive alternative splicing exon 4, 6, 9 and 17 clusters have 12, 48, 33 and 2 alternative exons, respectively, which correspond to the variable regions found in Ig2, Ig3, Ig7 and transmembrane domains of different Dscam isoforms [2]. Four additional variants, existing in the Dscam cytoplasmic domain, are generated from alternative splicing of exons 19 and 23 [7]. These alternative exons can potentially produce 152,064 Dscam isoforms.

The mechanism(s) underlying the mutually exclusive alternative splicing in the *Dscam* mRNAs is not entirely clear. Comparative sequence analysis of the *Dscam* gene of 16 insect species led to identification of some RNA sequence elements that may control the mutually exclusive alternative splicing in the *Dscam* exon 6 cluster [8]. Two classes of conserved elements were recognized: the ▶docking site, located in the intron downstream of constitutive exon 5, and the ▶selector sequences complementary to a portion of the docking site, located upstream of each exon 6 variant (Fig. 3a).

The mutually exclusive nature of interactions of the docking site and selector sequence ensures that only one exon 6 variant is included in each *Dscam* mRNA. Similarly, two pairs of complementary sequences found on the *Dscam* intron 16–17.1 can form competing stem structures for mutually exclusive selection of one of exons 17.1 and 17.2 (Fig. 3b).

Since tremendous cellular and molecular diversity exists in the nervous system and Dscam, respectively, one interesting question is whether only a single Dscam isoform is expressed in any given neuron, endowing each neuron with its own identity. To address this question, a quantitative real-time PCR in combination with a customized oligonucleotide microarray, which contains sequences of all alternative exons from exon 4, 6 and 9 clusters, were used to analyze the usage of *Dscam* isoforms in distinct isolated neurons, including R3/R4 and R7 photoreceptors, MB neurons and ms



**Down Syndrome Cell Adhesion Molecule. Figure 3** The mechanism of mutually exclusive alternative splicing is proposed for how to choose a single exon on exon 6 (a) and exon 17 (b). Only three exons of the alternative exon 6 cluster are shown in A (x can be 2–47). Hypothetically unidentified splicing repressors normally prevent the splicing event from occurring. When a selector binds to the docking site (exon6) or complementary sequences bind to each other (exon 17), the splicing repressors are removed from pre-mRNA of *Dscam* in order to go on the mutually exclusive alternative splicing event [8].

neurons [3,9]. Such analyses revealed that individual neurons express around 10–50 distinct mRNA molecules chosen from thousands of splicing variants of *Dscam* isoforms in a stochastic yet biased fashion.

This stochastic yet biased *Dscam* expression raises another intriguing question: whether distinct Dscam isoforms have different specific functions. Two lines of evidence indicated that some Dscam isoforms have distinct functions in different types or sub-cellular regions of neurons. First, two deficiency lines with the deletion of exon 4.2–4.6 versus exon 4.4–4.8 of *Dscam* were used to examine axonal patterns of ms neurons. Interestingly, qualitatively different phenotypes for the axonal patterns of ms neurons were observed in these two deficiency lines [3], though no phenotype was detected in MB neurons lacking various subsets of exon 4s [7]. These results suggested that distinct Dscam exon 4 isoforms might mediate different neuronal morphogenesis at least in ms neurons (Fig. 4a).

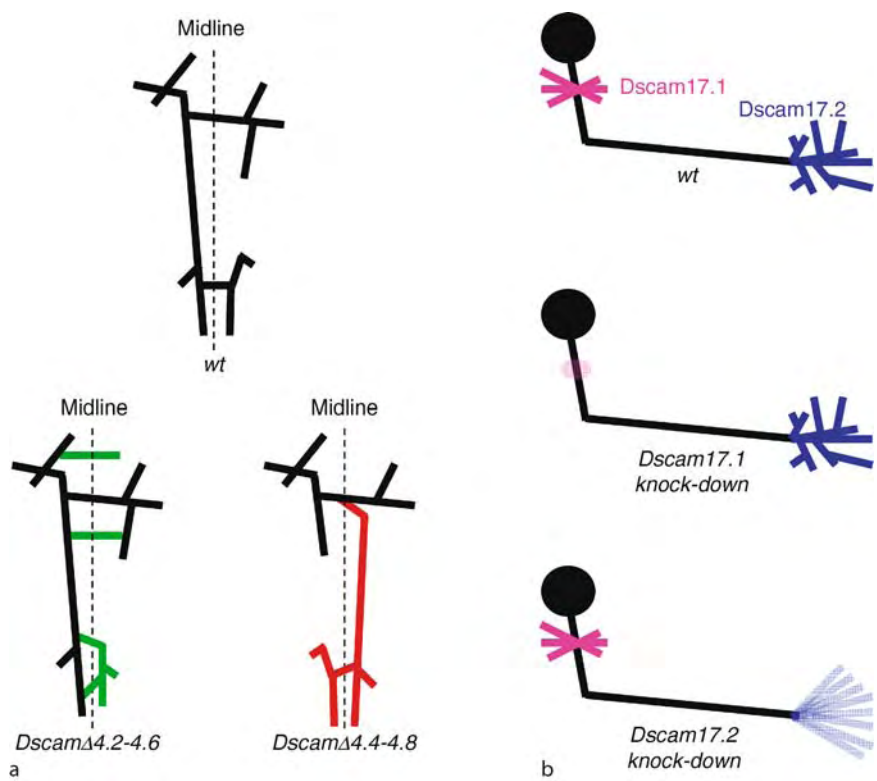
Second, it has been reported that Dscam with exon 17.1 versus exon 17.2 is preferentially targeted to dendrites versus axons (Fig. 4b) [7]. Consistent with this notion, depleting exon 17.1-containing Dscam selectively blocked PN dendritic morphogenesis while knocking down Dscam with exon 17.2 specifically disrupted axonal morphogenesis (Fig. 4b) [10].

## Homophilic Binding Resulting in Repulsion

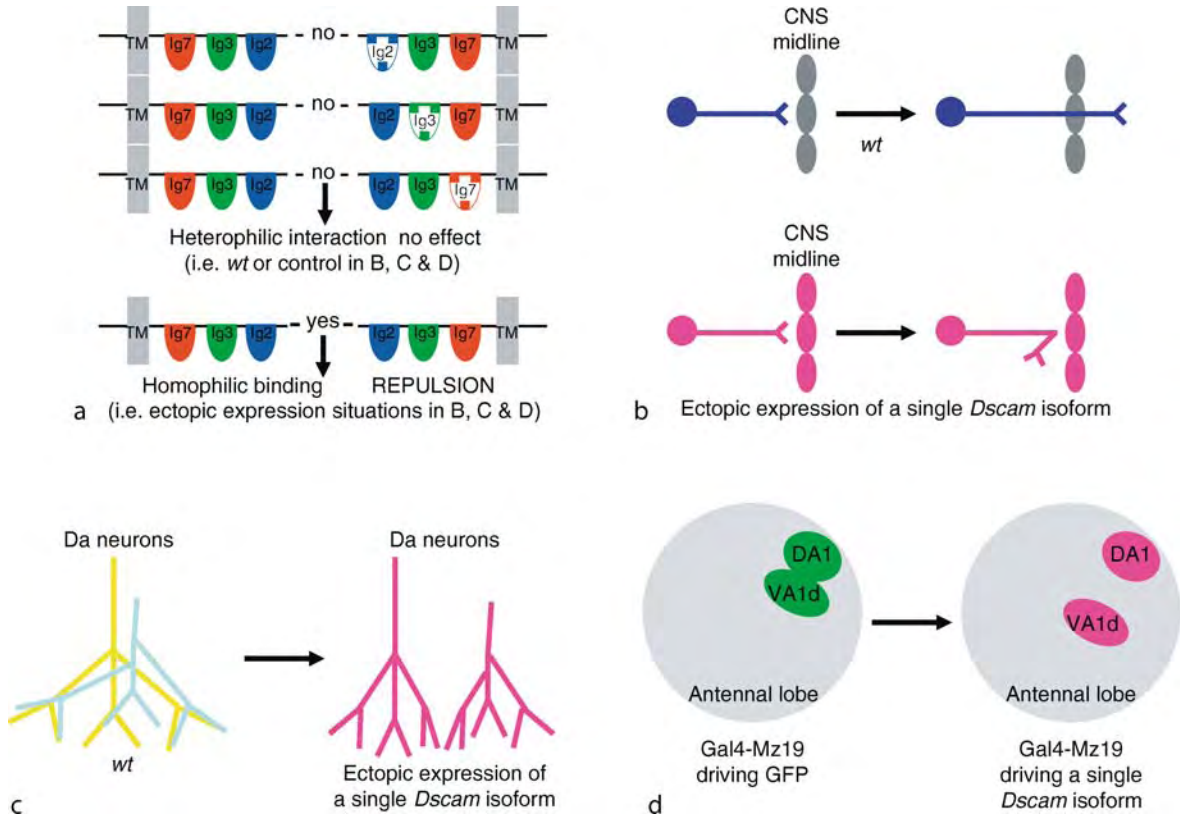
Like many Ig domain-containing proteins, mammalian DSCAMs and *Drosophila* Dscams are cell adhesion molecules which can promote aggregation between DSCAM/Dscam expressing cells [4]. Since *Drosophila Dscam* can produce a large number of isoforms that vary in the Ig domains, it is possible that different binding affinities may exist among distinct Dscam isoforms. A series of in vitro binding assays revealed that robust binding was restricted to identical Dscams, while no interaction was found in the heterophilic binding pairs (Fig. 5a) [3].

The homophilic binding region was further mapped to the variable Ig2, Ig3 and Ig7 domains. Varying the encoding exon for any of these three domains in Dscam drastically reduces the binding affinity among Dscams [3].

However, instead of mediating adhesion, three sets of experiments have shown that homophilic binding of



**Down Syndrome Cell Adhesion Molecule. Figure 4** Schematic illustrations depict phenotypes observed in ms neurons (a) and PNs (b) by removing subsets of *Dscam* exon 4 and exon 17 isoforms. Ectopic branches and misrouted contralateral projection were observed when exon 4.2–4.6 and exon 4.4–4.8, respectively, are deleted from the *Dscam* genomic region. Dscam exon 17.1 and exon 17.2 isoforms have preferential localization on dendrites and axons of PNs. Using a RNA interference technology to remove *Dscam* exon 17.1 and exon 17.2 isoforms from PNs results in distinct dendritic and axons phenotypes [3,7,10].



**Down Syndrome Cell Adhesion Molecule. Figure 5** Homophilic binding of identical Dscams leads to repulsion of neurites, while heterophilic interaction of different Dscams does not induce any biological effect. Neurites of embryonic interneurons (b), dendritic arborization neurons (c) and PNs (d) can trigger the repulsive responses when a single Dscam isoform is over-expressed (*shown in pink*) [3,5,6].

*Drosophila* Dscam results in repulsion during the formation of neuronal connections. First, some embryonic CNS interneurons normally extend axons across midline cells during embryogenesis. However, axons of these embryonic interneurons failed to cross the CNS midline when Dscam was ectopically expressed in both the interneurons and midline cells (Fig. 5b) [3]. Second, four different classes of da neurons normally overlap with each other in their dendritic fields. Over-expression of a single Dscam isoform in da neurons led to dendritic recognition and avoidance, resulting in non-overlapping dendritic fields (Fig. 5c) [6]. Third, the wild-type DA1 and VA1d PN dendrites normally form two overlapping dendritic arbors adjacent to each other at the anterior surface of the antennal lobe. Using Gal4-Mz19 to over-express a single Dscam isoform in DA1 and VA1d PNs, VA1d dendrites were observed to shift to a more ventral position on the anterior surface and to be separated from DA1 dendrites by another glomerulus (Fig. 5d) [5].

Loss of such Dscam-dependent contact-mediated repulsion may underlie some *Dscam* loss-of-function phenotypes. For instance, *Dscam* mutant MB sister branches often failed to extend away from each other [3]. In addition, aberrant bundling and crossing-over were frequently observed in *Dscam* mutant da neurons [6]. In both cases, removal of Dscam caused defects in self-avoidance, further supporting the model that homophilic binding of Dscam promotes repulsion of neuronal branches (Fig. 2).

## Down's Syndrome

### Synonyms
Trisomy 21 Syndrome

### Definition
Down's syndrome is due to an additional chromosome 21 or translocation of part thereof. Trisomy 21 is the only trisomy compatible with survival past infancy. Cardiac malformations (septal defects) may lead to early death, but some individuals live into old age and may reproduce. Brain weight is reduced and the ►cerebral cortex shows a simplified gyration. Mental retardation is common, older individuals often develop a premature ►Alzheimer's type of brain degeneration. Characteristic are eye and face changes, spots in the iris. The disease has a higher frequency of cataracts, periodontal disease, hyperextensibility of joints, and acute leukaemia.

## Downward Causation

### Definition
Exists if the system parts are to some degree constrained by the whole (which is a converse of the principle that the microstructure of a system determines the system properties and dispositions).

►Emergence

## Dracomorph Lizards

### Definition
Large-sized lizards, e.g. Varanidae, Teidae, Iguanidae, not a taxonomic term.

►Evolution of the Brain: At the Reptile-Bird Transition

## Dream Enactment

### Definition
In humans, dream enactment may involve complex and violent movements. In cats, lesions of the ventral ►locus coeruleus can produce ►REM sleep without the usually associated ►atonia.

►Rapid Eye Movement (REM) Sleep

## Dreaming

Tore A. Nielsen
Dream & Nightmare Laboratory, Sleep Research Center, Hopital du Sacré-Coeur, QC, Canada; Psychiatry Department, Université de Montréal, Montreal, QC, Canada

### Synonyms
Sleep mentation; Dream imagery; Hypnagogic imagery; Oniric mentation; Nightmare

### Definition
Dreaming (see ►*Dream*) is the simulation, during sleep, of both the process and the contents of ►waking state experience. Experiential processes are largely simulated quite accurately, giving the impression that one perceives,

acts, feels and thinks in a manner indistinguishable from wakefulness. Experiential content, on the other hand, is not reliably simulated. Episodic memories are only rarely present and many classes of common behaviors (e.g., reading, typing, calculating) are infrequent. Elements of episodic memories do, however, contribute to dreaming, as do elements of more general semantic memories. Dreaming can be remembered, with effort, during the waking state but is more typically forgotten. The most vivid and most copious dreaming is recalled after awakenings from ►REM sleep, but it is also recalled, albeit less frequently and with less vividness, after awakenings from ►NREM sleep.

## Characteristics

### Dreaming Simulation of Experiential Process

The process or flow of experience during dreaming is indistinguishable in many key respects from that of typical waking state experience. Emotional sequences in ►dreams, for example, are for the most part true to their waking state counterparts. When they are present in laboratory REM dreams (70% of reports), subjects judge them to be appropriate to the dreamed situation over 80% of the time. Dreamed thinking is also relatively lifelike, with high prevalences of volition, inference, reflection, self-reflection, self-consciousness, choice and internal commentary [1]. One notable exception to this is the ability to detect bizarre dream contents; over half of the time dreaming subjects do not notice when bizarreness is present.

Perceptual activity is also reliably simulated. The subjective self is present in 95% of dream reports, perceived to be oriented normally within 3D space, and to be viewing the dream scene from an egocentric (own-eyes) point of view much more often (89%) than from a third person (other's-eyes) point of view (11%). When present, the self is also felt to be participating in dreamed actions over 90% of the time. Fictive movements within a dream usually respect the mechanical forces dictated by the 1*g* earth gravity field. This means that when the self moves about within a dreamed environment (90% of reports), it experiences apparently normal self-initiated movements of the trunk, face and limbs as well as normal, externally-imposed, movements such as being driven in a car. Further, the self's interactions with a succession of settings, objects and other living beings in the dreamed environment are experienced to be normal most of the time [1]. Basic perceptual features of this flow of environmental features display a relative constancy, e.g., size and shape are only rarely (<13%) distorted relative to reality.

The eye movements of REM sleep have been proposed to reflect perceptual activity of the visual system during dreaming, in particular, the "scanning" of fictive visual events. Evoked potential analyses of eye movements during REM sleep do not support this proposition; however, new research reveals the existence of morphologically distinct types of eye movements, only some of which may reflect dream scanning.

In sum, phenomenological studies of dreaming suggest that rather remarkable simulations of the flow of waking state experience are achieved during sleep, reliably depicting the emotional, orientational and perceptual underpinnings of awareness. Such simulations are by no means perfect, however, and many of the exceptions contribute to dreaming's notoriety as a strange and surreal phenomenon. For example, a relatively familiar fallibility of orientation simulation is the suspension and distortion of gravity; illusions of falling, flying, floating and loss of balance are well-known. Such exceptions have been shown to occur more frequently when proprioception is disrupted during REM sleep either with external stimulation or because of vestibular disease. The induced bizarreness reveals the fragility of perceptual simulation in the absence of stable constant input from the multiplicity of external sense receptors active during wakefulness.

### Dreaming Simulation of Experiential Contents: Negative Findings

Despite the fidelity with which dreaming simulates experiential process, the specific contents of experience are not so reliably reproduced. First, dreams do not replay personal memories reliably and are thus not clearly a form of episodic narrative. In fact, only a small fraction (<2%) of dream reports describe complete episodic memories, in the sense that an ensemble of locations, objects, actions and characters specific to the memory are depicted. The episodic element most frequently absent from this ensemble is location; only 16% of dream reports contain locations that subjects confidently rate as reflecting an actual memory from wakefulness [2]. This dramatic absence of episodic replays stands in marked contrast to the replicative nightmares frequently reported by individuals with posttraumatic stress disorder; such nightmares replay, night after night, the individual's experience of a previously inflicted trauma.

Second, dreaming often fails to simulate many prominent waking state behaviors and objects. Research has found that about 90% of subjects "never" or "hardly ever" dream about reading, writing, typing and calculating even though they spend an average of 6 h per day engaged in these activities. Similarly, only 4% of subjects dream about using computers and only 7% of reading even though the prevalence of these activities during waking is significantly higher. We found surprisingly low percentages of first-year university students who had ever dreamed about the very common activities of seeing themselves in a mirror (16%) or

being at a movie (17%). Some common objects are also strangely missing from dreams; money, tools, food and drink all occur in <2% of reports [3]. Sensations of smell and touch are also much less prevalent during dreaming than would be expected from their importance to daytime experience. Findings from one study of 3,372 dream reports converge with those from several others in demonstrating that olfactory and gustatory experiences occur in 1% or less of all reports.

To summarize, while the experiential flow of waking awareness is largely preserved during dreaming, the contents of such experience are lacking in several important respects. Coherent episodic memories are virtually absent and many common behaviors and objects are underrepresented relative to their importance during wakefulness. Dreaming is clearly not a mirror that reflects waking existence in any simple fashion as the widely cited "continuity hypothesis" of dreaming would suggest. Rather, it is as if memory elements are selectively filtered for relevance before they are employed as contents during the dream formation process.

## Dreaming Simulation of Experiential Contents: Episodic Referencing

If dreaming does not typically simulate real episodic memories, it does draw heavily and consistently upon some components of such memories, and it does so in a rather disjunctive manner. This is amply demonstrated by studies that have presented subjects with distinctive stimuli, such as emotionally charged films or ego-threatening tasks, prior to sleep and then successfully tracked partial references to them in their subsequent dreams. The Fosse study cited above found that 65% of dream reports contain such partial references to previous episodic events – despite the overall low incidence of complete episodic narratives. One of the most common forms of episodic referencing seen by sleep researchers is the dreamed reoccurrence of laboratory features; they are observed in about a third of dreams on the first laboratory night. Such referencing of events from the prior day is but one example of the well-known "day residue" effect identified by Freud. A less well-known phenomenon is the referencing of events occurring approximately a week prior to the dream, the so-called "dream-lag effect." Even more generally, episodic referencing is apparent in the frequent dream appearances of an individual's friends, acquaintances and family members. Dreamed characters, excluding the self, are more often familiar than they are unfamiliar in both children's dreams (70% vs. 30% respectively) and adults' dreams (52% vs. 48%). Evidence also supports the presence of episodic referencing of waking state experiences such as social interactions and current concerns and everyday activities such as driving, watching TV and working.

Of course, dream contents do not consist only of rehashed episodic features. Dreaming draws also upon dissociated elements of more generalized knowledge, or semantic memories. Semantic memories concern meanings and general facts that are not connected to individual (episodic) experiences and are usually not temporally tagged. The occurrence of semantic knowledge during dreaming has not been systematically evaluated but the fact that thematic references to daytime experiences was the most frequent class of memory source of dreams (53%) in one study – even higher than that of objects (39%) or actions (41%) [2], indicates that such knowledge elements are prevalent indeed.

In sum, dreaming simulates the process or flow of experience quite dependably but it produces only inexact, partial simulations of the contents of such experience. The result is a sustained illusion of first-hand experience in which episodic elements such as people, places and objects are combined with semantic elements such as facts and other general knowledge in novel and unexpected ways. The dreamer's thoughts and feelings about these events remain largely as they would be during the waking state. It may be this juxtaposition of accurate experiential process and selective, reorganized episodic and semantic content that underlies the surreal quality of dreaming (as it is remembered and evaluated from the perspective of wakefulness) and that is very likely responsible for judgments about its "bizarre" or "distorted" nature.

## Neurophysiology

The neurophysiological basis of dreaming as a general mental state has been widely linked to the state of REM sleep but the occurrence of dreaming reports in NREM sleep has left this equation controversial (for review see [4]). Some purportedly formal qualities of dreaming, such as its visual- and auditory-hallucinatory aspects, its coherence, or its portrayal of distorted and bizarre contents, have also been tied hypothetically to sub-processes of REM sleep, such as rapid eye movements, gamma oscillations or ►PGO waves [5]. Some evidence supports the contention that dream emotions are associated with variations in autonomic activity during sleep. However, very little research has succeeded in directly linking specific features of dream content with underlying neurophysiological events.

Even with the achievement of brain imaging during REM and NREM sleep, links between specific dream elements and specific brain regions have not yet been identified. However, this has not prevented much speculation about possible neurophysiological bases for dreaming. Neuroimaging studies reveal a pattern of characteristic activation and deactivation throughout the brain during REM sleep. In the case of brain activation, significant increases have been found in the mesopontine tegmentum, thalamic nuclei,

limbic/paralimbic areas (amygdaloid complexes, hippocampal formation, anterior cingulate cortex) and posterior cortices (temporo-occipital areas) [6]. With respect to brain deactivation, a meta-analysis of 207 PET scans revealed significantly less activity bilaterally in the temporo-parietal region, inferior lobule of the parietal cortex (below the intra-parietal sulcus) and inferior frontal gyrus and middle frontal gyrus (but neither superior frontal gyrus nor medial prefrontal cortex) [7].

Maquet suggests that the marked redistributions of frontal and parietal cortical activity during REM sleep constrains cognition in a unique fashion, and shapes the phenomenological nature of dreaming. For example, the deactivation of specific prefrontal and parietal regions may account for a lack of episodic narratives and a diminished capacity to formulate clear behavioral goals [7].

## Function

The functions of dreaming remain unknown although much recent speculation concerns the evolution of reality simulation during dreaming as a basis for successful human adaptation (see review in [8]). Simulated threat scenarios during nightmares and bad dreams are thought to have evolved to serve the basic function of rehearsing adaptive responses for threats encountered during wakefulness. Similarly, simulations of social interactions during dreaming may have evolved to serve broader, more polyvalent, functions of attachment and social cohesion, cognitive development and the formation of fear extinction memories. Other emerging theories stipulate a role for dreaming in the consolidation of memories and in psychological (e.g., emotional) adaptation.

In general, empirical research supporting these various theories of dream function is meager. However, substantial indirect support for the theories can be found in a growing body of research on the functions of REM sleep. Recent animal studies support the fear extinction memory model of dream function in demonstrating that REM sleep disruption leads to inhibition of fear extinction learning. Similarly, several human studies indicate that REM sleep deprivation impairs consolidation of new memories.

## Pathology

Many types of disturbed dreaming have been identified, the most common of which are nightmares and bad dreams. Both types are characterized by excessively real simulations of dysphoric emotion – typically fear – and varying degrees of associated waking distress. They are differentiated by the fact that nightmares produce awakenings from sleep while bad dreams do not. Replicative nightmares are often reported by patients with PTSD and are distinguished from typical nightmares and bad dreams by the simulation of episodic narrative content, i.e., episodic replays of the individual's memory of a previously inflicted trauma.

The nature and frequency of dreaming may be altered dramatically by drugs and alcohol. Catecholaminergic agents (e.g., reserpine, thioridazine, levodopa), beta-blockers (e.g., betaxolol, metoprolol, propranolol), some barbiturates, non-benzodiazepine hypnotics (zolpidem), atypical antidepressants (bupropion), SSRIs (paroxetine, fluvoxamine), and tricyclic antidepressants all can induce nightmares and bizarre dreaming. The therapies most often associated with nightmares are sedative/hypnotics, beta-blockers, and amphetamines [9]. Alcoholic patients report vivid dreams and nightmares post-withdrawal, sometimes lasting for weeks, and can lead to resumed drinking. Withdrawal is associated with an increase in REM sleep "pressure" and predicts early relapse.

Dreaming may be disturbed in a variety of medical disorders (for review see [10]. At one extreme, primarily among neurological patients, there may occur a global cessation of dreaming. A related, but less severe disturbance, impoverished dreaming (reduced recall, vividness or complexity) is observed among alexithymic patients, PTSD and some brain syndromes. At the other extreme, there may occur excessive dreaming and a heightening of the experience simulation process to the point that dreaming is totally confused with reality. Some brain-damaged patients report increases in the frequency and vividness of dreaming or in the continuous occurrence of the same content throughout the night. Patients who spend prolonged periods of time in an intensive care unit (ICU) frequently experience "ICU dream delirium," or the occurrence of persistent horrific nightmares that combine the reality of the ICU with macabre dream content; these may have a lasting traumatic effect [10]. A total confusion of dreaming and reality may occur among actively psychotic or borderline psychotic individuals and may lead to violent acting out. Dream realism is also frequently disturbed in a variety of sleep disorders, such as narcolepsy, ►sleep paralysis and ►REM behavior disorder or after severe sleep fragmentation, as with new mothers. In such conditions, highly realistic, even pseudo-hallucinatory dreams are commonplace; frequently, a vivid sense of presence of another person or entity in the bedroom is experienced.

To summarize, dreaming is an altered state of awareness characterized by an accurate simulation of experiential flow, a selective simulation of experiential contents and an admixture of various types of episodic and semantic elements. The neurophysiological changes characteristic of REM sleep have been proposed to constrain and shape the nature and content of dreaming, but no specific replicable correlates of

dream content have yet been reported. Possible functions of dreaming have been tied to this simulation process, with the suggestion that simulation enhances adaptation to threat, social cohesion, cognitive development and fear extinction. A variety of disorders of dreaming, too, often implicate either a weakening or a strengthening of the oniric reality simulation process.

# Dreams

## Definition

Dream in the verb form refers to the involuntary process of simulating experience during sleep, as in "she dreams vividly." In the noun form, dream refers to the product that ultimately results from an episode of dreaming, as in "to recall a dream." A dream can be remembered, with some effort, during the waking state; however, for most individuals, the majority of their dreams are quickly and irretrievably forgotten. Dreams accurately simulate the flow of waking state experience in most respects but only selectively simulate the contents of such experience.

# Drinking Disorders and Osmoregulation

Dick F. Swaab[1], Paul J. Lucassen[2]
[1]Netherlands Institute for Neuroscience, Amsterdam, The Netherlands
[2]Centre for Neuroscience, Swammerdam Institute of Life Sciences, University of Amsterdam, The Netherlands

## Definition

Subjects that consistently drink too much or too little suffer from disturbances in endocrine or central components of osmoregulation.

## Characteristics

The cause of these disorders may be on the level of the osmoreceptors, vasopressin (= antidiuretic hormone) production, release from the neurohypophysis, the sensitivity of the kidney to vasopressin or due to deficits in the circulation (for reviews see [3] and [4]).

### Quantitative Description and Description of the Process

Plasma osmolality is accurately maintained within a remarkably narrow range of 282–298 milliosmol/kg, which is achieved by the close integration of the antidiuretic action of vasopressin and a feedback regulation through the sensation of thirst. Plasma osmolality is the most important physiological determinant of vasopressin secretion, but blood pressure is also involved. Small changes in osmolality are rapidly detected in the circumventricular organs, specific brain

regions, characterized by the presence of fenestrated capillaries and endothelial cells, from which the blood brain barrier is largely absent. Primary monitoring takes place through osmoreceptors in the hypothalamic supraoptic and paraventricular nuclei (SON and PVN). The osmotic threshold above which secretion of vasopressin is triggered is 284.3 milliosmol/kg. Water reabsorption in the kidney conserves water and subsequently decreases osmolality. During drinking and fluid ingestion there is an almost instantaneous suppression of vasopressin secretion, probably due to the activation of oropharyngeal stretch receptors, which send inhibitory feedback signals that protect against overhydration. The osmotic threshold for thirst is similar to that for vasopressin release.

Decreases in blood pressure and blood volume are additional, although less powerful stimuli for vasopressin secretion. These conditions activate stretch sensitive baroreceptors in the atria of the heart that signal the hypothalamus to secrete vasopressin and conserve fluid. Animal experiments have further revealed a number of other peptides that modulate drinking behavior, such as angiotensin II and orexin-A. Histamine, produced in the tuberomamillary nucleus (TMN), elicits drinking, increases the release of vasopressin and decreases urine output via H1 and H2 receptors.

The kidney concentrates or dilutes urine under the influence of vasopressin. In the absence of vasopressin, the collecting duct of the kidney is impermeable to water. When vasopressin acts on the cell, water pores of the aquaporin family are inserted in the apical membrane of the collecting duct, which makes it permeable and causes water to move out of the lumen by osmosis. The segmental permeabilities in the nephron correlate with the expression of different members of the aquaporin family, seven members of which have been identified in the kidney. Vasopressin dependent expression of aquaporin-2 is particularly found in the apical membrane of the principal cells of the collecting tubes.

Vasopressin is released from the neurohypophysis, which is characterized by its rich vascularity, nerve endings and their swellings – the Herring bodies – and pituicytes, which are specialized astrocytes that can modulate neurohormone release. The capillaries have fenestrated endothelial cells and extensive perivascular spaces. Clinically, pathology of the neurohypophysis may lead to diabetes insipidus or to inappropriate secretion of vasopressin (Schwartz–Bartter syndrome). Pathology of the neurohypophysis includes congenital malformations, lymphocytic foci, hemorrhages, necrosis, inflammation, fibrosis, cysts, craniopharyngiomas and other tumors, metastatic carcinomas and granulomas. Hypovolemic shock of the mother at the time of delivery may not only cause pituitary necrosis, but also affect the tuber cinereum, pituitary stalk, SON and PVN, i.e. Sheehan's syndrome. Pathological states of the neurohypophysis may be reflected in a disappearance of the MRI high intensity signal of the posterior pituitary, which is presumed to be caused by the neurosecretory granules containing vasopressin.

## Higher Processes

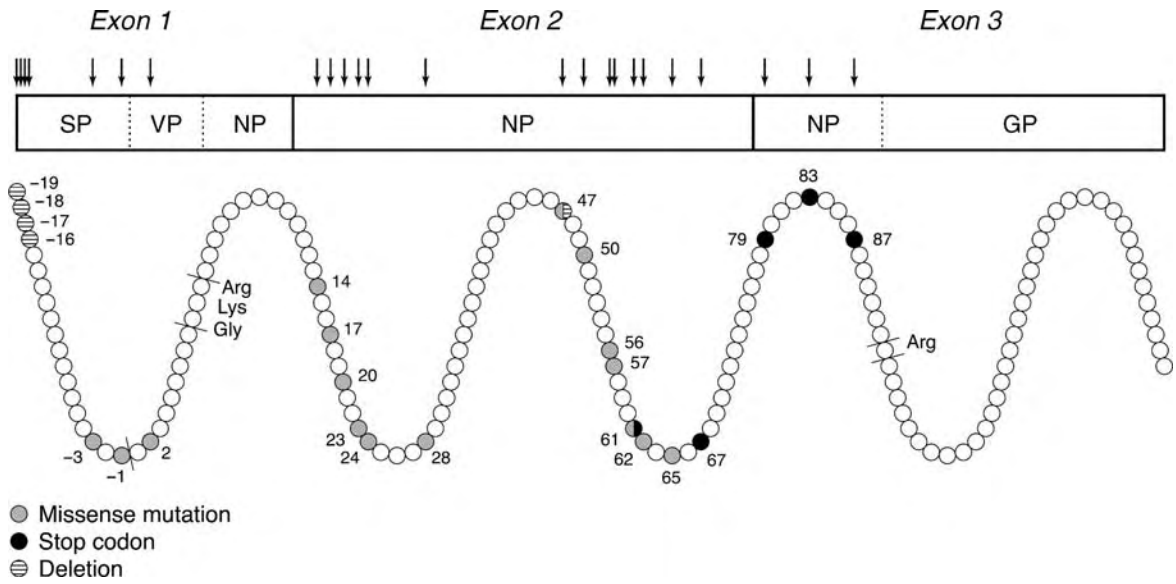
### *Diabetes Insipidus*

In diabetes insipidus, the mechanism that concentrates urine is inadequate or absent. Diabetes insipidus in familial cases may be due to a central vasopressin deficiency caused by a defect in the kidney receptors for vasopressin or to mutations in the vasopressin regulated water channel of the renal collecting duct aquaporin-2 in nephrogenic diabetes insipidus or to primary polydipsia. Inability to reabsorb water in the collecting ducts leads to excretion of large volumes of dilute urine. Consequently, thirst is the most prominent symptom of hypothalamic diabetes insipidus. The old treatment, pitressin in oil, given intramuscularly, was effective for 24 h, but the injection was often painful. Desmopressin (1-desamino-8-arginine vasopressin, DDAVP) however, does not have the pressor effect and is effective when given as a nasal spray twice daily. DDAVP is now also available in tablet form.

### *Familial Central Diabetes Insipidus*

Familial hypothalamic diabetes insipidus is a rare disease that accounts for about 5% of all cases of diabetes insipidus. It is transmitted as an autosomal dominant or X-linked recessive disorder. Affected individuals have low or undetectable levels of circulating vasopressin and suffer from polydipsia and polyuria. They respond to substitution therapy with exogenous vasopressin or analogues. Urine production may amount to some 20 l/day. Most mutations are presumed to impair the folding and intracellular trafficking of the preprohormone for vasopressin. Some 40 different mutations have now been found, including six mutations in the part that encodes the signal peptide. The rest are in different loci in the neurophysin II moiety, i.e. in exon 1 or 2, including two in vasopressin itself, five nonsense mutations (premature stop codons) in exon 2 or 3 and one trinucleotide deletion in exon 2. All the dominant mutations contrast with the recessive mutation in vasopressin itself. The mutated form of vasopressin is a weak agonist with an approximately 30-fold reduced binding to the vasopressin receptor (V2) (Fig. 1).

The few available histological observations in postmortem samples from families with hereditary hypothalamic diabetes insipidus point to severe neuronal death in the SON and PVN, associated with a loss of nerve fibers in the posterior pituitary. This suggests that the mutated product might be toxic to the neurosecretory cell. Slowly acting toxicity also explains why urine production is normal, often up to school age. Studies



**Drinking Disorders and Osmoregulation. Figure 1** Schematic diagram of the coding regions of the arginine vasopressin–neurophysin II (AVP-NPII) gene and the primary structure of the preprohormone, showing the location and type of mutations identified in familial hypothalamic diabetes insipidus [1]. (Fig. 1 with permission).

in which various other human mutant vasopressin precursors were expressed in cell lines also showed an accumulation of the mutated vasopressin precursor in the endoplasmic reticulum, a reduced viability of the cells and a reduced vasopressin expression. The protein did not seem to reach the trans-Golgi network, probably because mutant vasopressin precursors do not fold correctly. The mutated proteins subsequently also interfere with the expression of the normal allele by their accumulation in the endoplasmic reticulum, explaining the dominant nature of the disease.

### *Autoimmune Diabetes Insipidus*

Idiopathic diabetes insipidus is associated with autoimmunity in one third of the cases. It has not yet been established whether the autoantibodies observed in diabetes insipidus are indeed cytotoxic, nor whether they can destroy the vasopressin cell bodies, but ultimately their presence seems to go together with partial or complete diabetes insipidus. A dramatic improvement may take place following administration of corticosteroids. Patients with lymphocytic infundibuloneurohypophysitis presenting as diabetes insipidus may have autoantibodies to vasopressin and on MRI show a normal pituitary with focal nodular thickening of the infundibulum, stalk thickening and lack of a hyperintense signal from the neurohypophysis.

### *Pregnancy Induced Diabetes Insipidus*

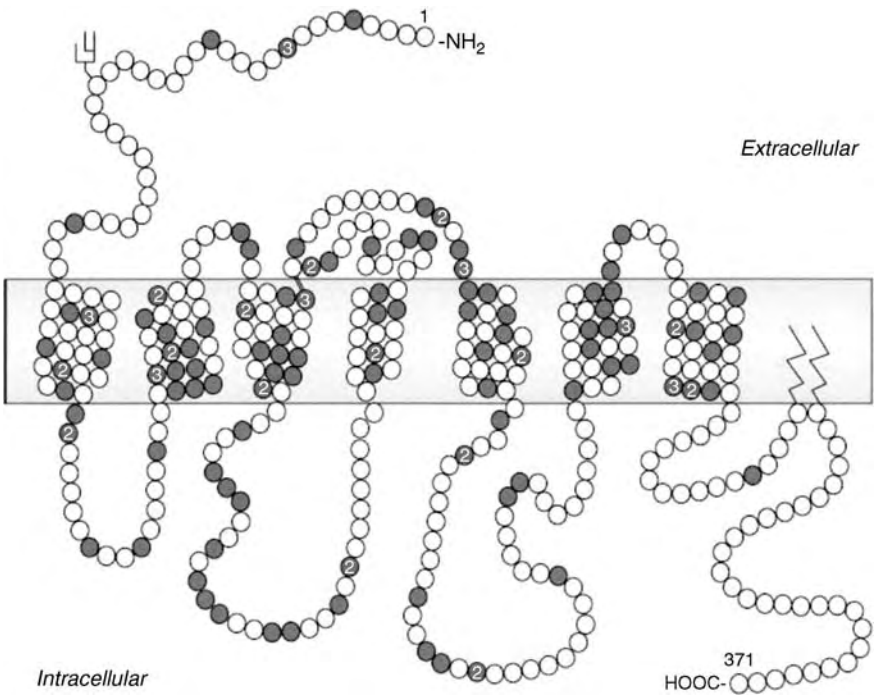
During pregnancy a transient form of diabetes insipidus sometimes occurs. The central form may respond to the analogue DDAVP but not to vasopressin itself, because the former is much less susceptible to degradation by placental vasopressinase, which is the same enzyme as the cystine aminopeptidase or oxytocinase that is responsible for the fourfold increase in metabolic clearance of vasopressin during pregnancy. In addition, during pregnancy, thirst increases and more water is consumed. The lowering of the thirst threshold is accompanied by a similar lowering of the osmotic threshold for the release of vasopressin. As a result, pregnant women drink more water, which may subsequently be retained.

### *Nephrogenic Diabetes Insipidus*

Nephrogenic diabetes insipidus is characterized by an inability to concentrate urine despite normal or elevated plasma vasopressin levels and insensitivity to exogenously administered vasopressin analogues. It may be partially controlled by thiazide diuretics, amiloride or indomethacin.

About 90–95% of patients with nephrogenic diabetes insipidus are males with the X-linked recessive form of the disease, who have mutations in the vasopressin receptor-2 gene, located on Xq28. The severe X-linked form is expressed in heterozygous boys, whereas heterozygous girls may have moderate expression to no symptoms at all. Over 155 mutations within the vasopressin receptor (V2) gene are known that may cause inherited nephrogenic diabetes insipidus (Fig. 2).

In less than 10% of the families, nephrogenic diabetes insipidus has an autosomal recessive or autosomal dominant mode of inheritance, caused by mutations on chromosome 12q13 in the gene of the water channel



**Drinking Disorders and Osmoregulation. Figure 2** Schematic representation of the Vasopressin (V2) receptor and identification of 155 putative disease causing AVPR2 mutations. A solid circle indicates the location of (or the closest codon to) a mutation; a number indicates more than one mutation in the same codon. There are 78 missense mutations, 42 frameshift mutations, 6 in frame deletions or insertions and 3 splice site mutations. Eight large deletions and one complex mutation are not shown [2]. (Fig. 7 with permission).

protein aquaporin-2. Nephrogenic diabetes insipidus generally manifests a few days after birth (Fig. 3).

### Primary Polydipsia

Primary polydipsia is characterized by thirst, excessive fluid intake and hypotonic polyuria, despite preservation of the ability to secrete appropriate amounts of vasopressin in response to osmotic stimuli. Primary polydipsia may be associated with psychiatric disorders and is then generally termed "psychogenic polydipsia" A physiological inhibition of vasopressin is present due to excessive drinking. Compulsive water drinking is sometimes also called dipsogenic diabetes insipidus. However, the term "dipsogenic polydipsia" is generally used for "somatic" patients who may e.g. suffer from damage to the hypothalamus after closed head trauma, neurosarcoidosis, infections, multiple sclerosis or medicines such as lithium or carbamazepine. Although the actual cause of the disorder is not yet established, it has been suggested that primary polydipsia is caused by abnormal function of the osmoreceptors that govern thirst.

### Adipsinogenic Disorders

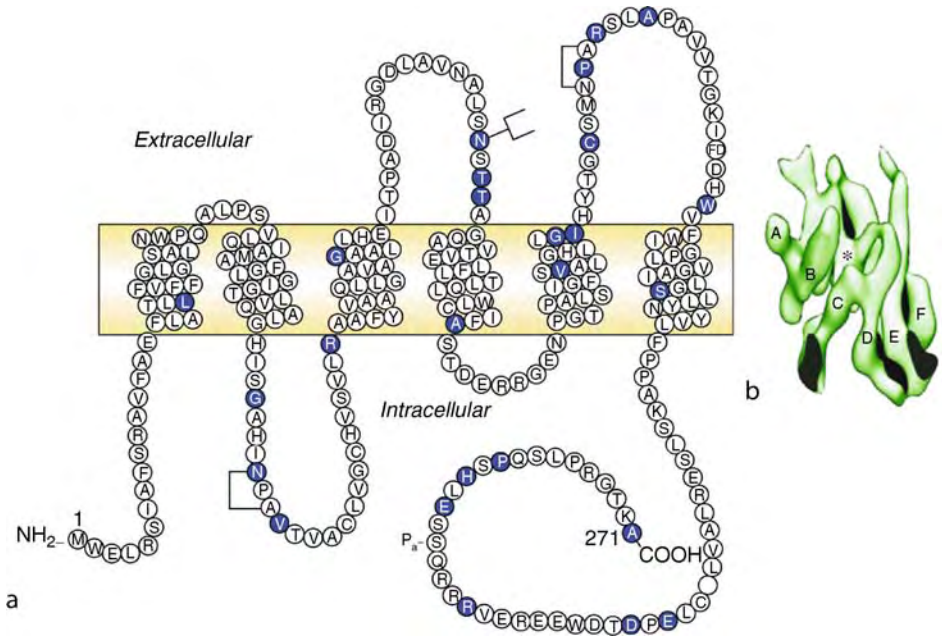
In the case of inappropriate lack of thirst, with consequent failure to drink in order to correct hyperosmolality, the patient denies thirst or does not drink spontaneously. The adipsogenic disorders are supposed to be based upon an osmoreceptor dysfunction and often associated with a defect in the osmoregulation of vasopressin secretion and diabetes insipidus.

### Vasopressin Hypersecretion in Diabetes Mellitus

Diabetes mellitus is associated with polyuria and polydipsia. In patients with diabetic ketoacidosis, plasma osmolality and vasopressin levels are increased, circulating volume is decreased and urinary excretion of the aquaporin-2 water channel is increased. Polyuria is classically said to be due to the osmotic diuresis caused by glucosuria. However, when hyperglycemia is improved by i.v. infusion of insulin and fluid, plasma vasopressin levels decrease promptly, i.e. within 6 h, although plasma osmolality remains high. This indicates that both osmotic and nonosmotic stimuli are involved in the hypersecretion of vasopressin.

### Syndrome of Inappropriate Secretion of Antidiuretic Hormone (Schwartz–Bartter Syndrome)

This syndrome is characterized by high vasopressin levels that can not be suppressed by acute water load. In addition there is renal sodium loss, hypotonic



**Drinking Disorders and Osmoregulation. Figure 3** (a). Schematic representation of the aquaporin-2 (AQP-2) protein and identification of 26 putative disease causing AQP2 mutations. A monomer with six transmembrane helices is represented. The location of the protein kinase A phosphorylation site ($P_a$) is indicated. This site is possibly involved in the arginine vasopressin induced trafficking of AQP2 from intracellular vesicles to the plasma membrane and in the subsequent stimulation of endocytosis. Solid circles indicate the locations of the mutations. (b) Representation of the six-helix barrel of the AQP1 protein viewed parallel to the bilayer [2].

hyponatremia and urine that is relatively or absolutely hyperosmolar to serum, i.e. greater than 300 milliosmol/kg. Plasma osmolality is below the osmotic threshold for thirst and drinking is minimal. The clinical features may include confusion, muscle cramps, seizures, fatigue, loss of appetite, nausea, vomiting, some clouding of consciousness and coma. Rapid correction of hyponatremia may lead to central pontine and extrapontine myelinolysis.

The syndrome was first described following exogenously administered pitressin and may be due to excessive vasopressin release from the posterior pituitary, despite hypo-osmolality. In cases of nonosmotic baroreceptor mediated stimulation of vasopressin release, as occurs in pulmonary hypertension due to heart failure or liver cirrhosis, there is a decrease in "effective" blood volume or arterial underfilling. Therefore the enhanced vasopressin release, lower plasma sodium levels and osmolity can in fact be considered as an appropriate reaction to a hemodynamic stimulus. The inappropriate vasopressin syndrome may also be due to ectopic production of vasopressin by extrahypophysial neoplasms, e.g. by a bronchus carcinoma. Other diseases which may be accompanied by increased vasopressin release include head injuries and central nervous system infections such as pneumonia, exacerbations of multiple sclerosis, brain infarction, hematoma, traumata, subarachnoid hemorrhage, subdural hematoma, stroke, polyneuritis, asthma, hepatorenal syndrome and meningitis, in which IL-6 may be the mediator through which vasopressin secretion is stimulated. The syndrome has also been found in patients using psychotropic drugs. The treatment of inappropriate vasopressin secretion consists of fluid restriction, urea, furosemide or administration of a mineralocorticoid.

### Synonyms
Drugs for movement disorders

### Definition
The term "motor disorders" encompasses a wide spectrum of disorders ranging from an inability to move normally to an inability to prevent unwanted involuntary movements. Parkinson's disease is the most common of such disorders. Its symptoms include ►bradykinesia, ►tremor and rigidity. Other disorders include Huntington's disease, which leads to motor symptoms including ►chorea, and disorders such as Tourette's syndrome in which motor tics occur. This is a very selective list and many other syndromes occur. Importantly, motor disorders may occur as a side-effect of drugs, especially those used in the treatment of psychosis. For example, ►dystonia may occur as a side effect of treatment with dopamine blocking drugs, and ►tardive dyskinesia may also develop after exposure to dopamine receptor blocking agents.

### Characteristics
A diverse range of causes may lead to motor disorders, including genetic causes (as in Huntington's disease or ►Wilson's disease), drug side-effects (as in tardive dyskinesia or dystonia), and idopathic causes (as in Parkinson's disease). The pathophysiology of motor disorders often involves the basal ganglia, and in particular is often associated with abnormal dopamine function in the striatum (caudate-putamen). Thus, dopamine agonists and antagonists feature prominently among the drugs for motor disorders. However, there are many non-dopaminergic neurotransmitters in the basal ganglia, and there is therefore great interest in the contribution of these other neurotransmitter systems to the pathophysiology of motor disorders, and their potential importance as novel targets for drug treatments.

Parkinson's disease is the most common of such disorders and will be used to illustrate many of the important circuits and neurotransmitters involved in movement. We review the motor functions of the basal ganglia, the circuitry and neurotransmitters of the basal ganglia, and then consider the clinical features of Parkinson's disease. Using this disease as a model, we consider the major classes of drugs used to treat motor disorders.

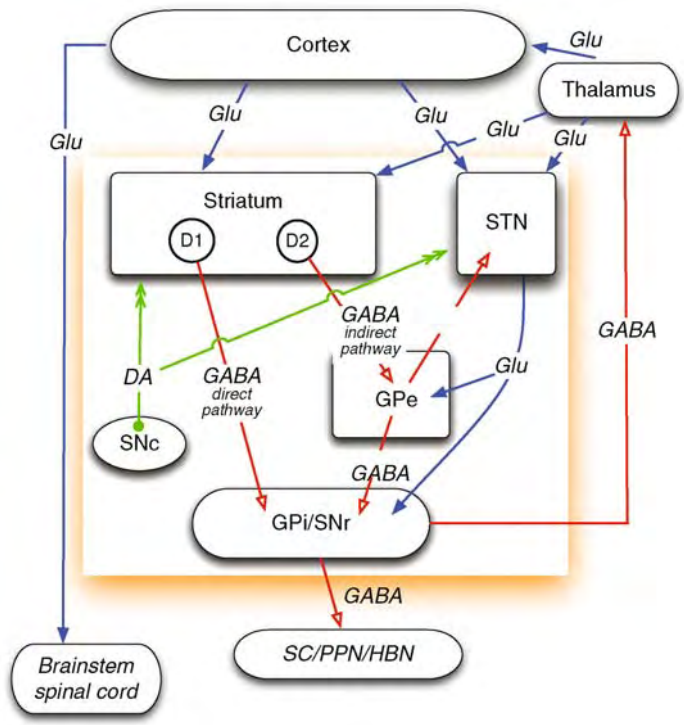
## Motor Functions of the Basal Ganglia

The basal ganglia are a group of subcortical structures comprising several interconnected nuclei: the striatum, the globus pallidus external segment (GPe), the globus pallidus internal segment (GPi), the substantia nigra pars reticulata (SNr), the substantia nigra pars conpacta (SNc), and the subthalamic nucleus (STN). The anatomical connections of the basal ganglia mainly link it to elements of the motor apparatus of the brain, and the electrical activities of many basal ganglia neurons correlate with movements. In addition, dysfunction of the basal ganglia underlies the symptoms of Parkinson's disease, Huntington's disease, and several other motor neurological disorders. Thus, the major function of the basal ganglia is the control of movement. In addition to motor functions, the basal ganglia participate in some nonmotor aspects of behavior, such as cognition and reward processing. Current views based on experimental studies have indicated that the basal ganglia play a crucial part in the planning, initiation, and termination of movements with a complex cognitive dimension and motivational significance.

## Basal Ganglia Connections and Neurotransmitters

An overview of the anatomical structures and general circuitry making up the basal ganglia is provided (Fig. 1).

The striatum is the main input structure of the basal ganglia, receiving excitatory glutamatergic inputs from cerebral cortex and thalamus [1]. The STN also receives excitatory input from outside the basal ganglia. On the other hand, the outputs from basal ganglia arises from GPi and SNr, and their major targets are the thalamus and the midbrain and brainstem, which influence movement via direct or indirect connections with motor areas. These outputs are inhibitory GABAergic, and an increase in basal ganglia output leads to a reduction in the activity of its targets. The microcircuitry of the striatum was recently reviewed [1]. In addition to glutamatergic inputs from outside of the basal ganglia, the striatum and STN receive dopaminergic inputs from SNc. In the striatum, the great majority of neurons are GABAergic spiny projection neurons. These projection neurons can be divided into two, roughly equal groups, with little overlap: those that express dopamine D1 receptors and



**Drugs for Motor Disorders. Figure 1** Simplified diagram of basal ganglia circuitry. The nuclei of the basal ganglia are included in the orange box. Excitatory (glutamatergic, Glu) and inhibitory (GABAergic) connections are indicated by blue and red, respectively. Dopaminergic projections are indicated by green. *GPe* globus pallidus external segments, *GPi* globus pallidus internal segments, *HBN* lateral havenula, *PPN* pedunculopontine nucleus, *SC* superior colliculus, *SNc* substantia nigra pars compacta, *SNr* substantia nigra pars reticulata *STN* subthalamic nucleus. D1 and D2 indicate dopamine D1 receptor- and dopamine D2 receptor-expressing striatal projection neurons, respectively.

project to the GPi and SNr (*direct pathway*); and those that express D2 receptors and project to the GPe (*indirect pathway*). The GPe gives rise to GABAergic axons to the STN, and then the STN projects excitatory (glutamatergic) outputs to the GPi and SNr. Thus, the output nuclei of the basal ganglia (GPi and SNr) receive striatal information not only directly (direct pathway) but also indirectly via GPe and STN (indirect pathway). Elucidation of these pathways over the past few decades has led to improved understanding of how to treat disorders of these structures, though much remains to be understood.

## Clinical Features of Parkinson's Disease

Parkinson's disease (PD) is the most common progressive neurodegenerative disorder after Alzheimer's disease with a mean age at onset of 55, and the incidence increases markedly with age. Patients with PD experience a number of motor symptoms including constant tremor at rest, muscle and limb rigidity, poverty of voluntary movement (akinesia), and slowness in performing voluntary movement (bradykinesia). Abnormalities of affect and cognition also accompany the motor symptoms frequently. Depression is common, and dementia is significantly more frequent in PD, especially in older patients.

In neuropathological terms, PD is characterized by the presence of intracytoplasmic inclusions from protein aggregates called Lewy bodies and the depletion of pigmented DA-containing neurons in the SNc. Approximately 60% of dopaminergic neurons in SN are already irreversibly destroyed when the first symptoms of PD become significantly visible. This degeneration of dopamine neurons in SNc with an accompanying loss of dopamine and its metabolism in the striatum cause the major motor symptoms in PD [2].

## Drugs for Treatment of Parkinson's Disease and Their Mechanisms

The motor symptoms of PD can be managed with several drugs in the initial years, but the disorder slowly progresses, eventually resulting in significant disability. Strategies for delaying onset or slowing progression of PD are important considerations in overall treatment approaches. The current management of PD is based on dopaminergic therapy aimed at reversing the effects of striatal dopamine depletion induced by the degeneration of dopaminergic neurons in SNc. L-DOPA, acting as a precursor of dopamine, and dopamine agonist drugs are the most effective drugs for the control of motor symptoms of PD [3]. However, long-term L-DOPA treatment causes a high level of motor complications including fluctuations of motor responses ('on-off' phenomena, 'off' means periods of return of PD symptoms when the medications' effects wears off), and ►dyskinesia (drug-induced involuntary movements including chorea and dystonia). To delay onset of motor complications of L-DOPA, most patients begin treatment with a dopamine receptor agonist (e.g., bromocriptine, pergolide, pramipexole), but they need to add L-DOPA within a few years. The mechanisms of induction of the motor complications of L-DOPA treatments are still unclear, although several hypotheses have been proposed [4].

Catechol-O-methyltransferase (COMT) inhibitors (entacapone, tolcapone) are used mainly in combination with L-DOPA in order to increase the half-life of L-DOPA and reduce off time. COMT is one of the key enzymes that metabolizes catecholamines such as dopamine, and therefore, COMT inhibitors act to block endogenous dopamine degeneration and then enhance dopamine content in the synaptic cleft.

Amantadine, an antiviral agent, has been shown to have a mild efficacy against the motor symptoms of PD and also reduce dyskinesias. Amantadine is thought to have anti-dyskinesia actions by acting as an antagonist of glutamate receptors [5].

Monoamine oxidase (MAO)-B serves to break down dopamine, and MAO-B inhibitors (selegiline, rasagiline) act to increase striatal dopamine contents. MAO-B inhibitors improve motor features in early and late PD. In addition, MAO-B is involved in the oxidative pathway on dopaminergic neuronal degeneration. Antioxidants acting via MAO-B inhibition could delay progression of PD.

As indicated above, dopamine-replacement therapies with L-dopa and dopamine-related drugs are highly efficient for symptomatic management of PD, however, these treatments are associated with a series of long-term, treatment-related motor complications that increase in severity with disease progression. Novel non-dopaminergic approaches for management of PD are becoming available, that are designed to improve motor function of PD without inducing motor complications nor losing efficacy with disease progression. The adenosine $A_{2A}$ receptor antagonist (istradefylline) is one of the leading candidates for non-dopaminergic treatments of PD [6]. Istradefylline provides modest symptomatic improvements without increasing troublesome dyskinesias. $A_{2A}$ receptors selectively localise on the striatopallidal projection neurons, and serve to modulate the striatopallidal neuron via GABAergic modulation in the striatum and GP. Istradefylline can ameliorate the excessive activity of the striatopallidal pathway, which is caused by dopamine depletion in PD, then resulting in improving motor symptoms of PD.

## Other Movement Disorders

The list of other movement disorders is extensive and cannot be covered in this brief essay. However, it is reasonable to consider these disorders as arising from dysfunction in one or more of the various neurotransmitter systems in the basal ganglia. Among

the better understood neurotransmitter systems are acetylcholine, which is released by the large aspiny interneurons of the striatum, and gamma-aminobutyric acid (GABA), which is released by projection neurons and interneurons.

Centrally acting anticholinergic drugs have been used to treat dystonia, which may occur in a small number of syndromes in which the pathology is understood, idiopathically, or as a side effect of treatment with dopamine blocking drugs. Dystonia may also be treated with botulinum toxin [7]. GABA receptor agonist drugs, on the other hand, have been used to treat tardive dyskinesia. This is a movement disorder that may also develop after exposure to dopamine receptor blocking agents. Tardive dyskinesia may persist after discontinuing the drugs that triggered it. Several different tardive dystonia syndromes have been described, which have different pathophysiologies and treatments [8]. These drugs may act on the spiny projection neurons of the striatum or any of several types of GABA interneuron [9].

## Dualism (Property Dualism, Substance dualism)

E. J. Lowe
University of Durham, Durham, United Kingdom

### Definition

►Property dualism is the doctrine that mental properties are distinct from and irreducible to physical properties, even if properties of both kinds may be possessed by the same thing, such as the human brain. ►Substance dualism is the doctrine that the things that possess mental properties are distinct from and irreducible to the things that possess physical properties – for example, that the

human mind or soul is distinct from and irreducible to the human body or any part of it, such as the brain.

## Description of the Theory

The most famous proponent of substance dualism was the French philosopher and scientist René Descartes (1591–1650), who maintained that there is a "real distinction" between the human mind or soul and the human body [1]. According to Descartes, the mind and the body are distinct and separable substances. (By a "substance" in this context, Descartes means an individual thing or object which possesses properties.) Descartes held that the mind and the body each have just one essential attribute – thought or consciousness in the case of the mind and ►spatial extension in the case of the body – and that all of the properties of each of these substances are modes of its essential attribute. Thus the body, he believed, has properties such as shape, size and spatial location but no mental properties, whereas the mind has properties such as belief, desire and volition but no physical properties. In support of his view, Descartes advanced two principal arguments – an argument from the conceivability of disembodiment, and an argument from the indivisibility of the mind or soul.

The ►conceivability argument may be reconstructed as follows. (i) It is clearly and distinctly conceivable that I (that is, my mind or soul) should exist without a body. (ii) What is clearly and distinctly conceivable is possible, because at least God can bring it about. (iii) Hence, it is possible that I should exist without a body. (iv) If it is possible that I should exist without a body, then I must be distinct and separable from my body. (v) Therefore, I am distinct and separable from my body. However, both of the premises (i) and (ii) are evidently open to challenge and for this reason the argument has generally been regarded as unpersuasive.

The ►divisibility argument may be reconstructed as follows. (i) My mind or soul contains no parts into which it is divisible. (ii) My body, being spatially extended, is necessarily divisible into parts. (iii) Hence, my mind or soul must be distinct from my body and cannot be spatially extended. Again, however, premise (i) is open to challenge and the argument has consequently failed to persuade philosophers who are not already sympathetic to substance dualism.

Even if Descartes's arguments are unpersuasive, his position (Cartesian dualism) has considerable intuitive appeal and is in accord with the religious beliefs of many people. But it is widely regarded as being incompatible with our advancing scientific understanding of the workings of the human brain and nervous system. In particular, Cartesian dualism is thought to be faced with an insuperable problem regarding ►psychophysical causation, that is, the causal interaction between mind and brain. Descartes believed that this interaction was centered on the pineal gland, where the mind or soul was able to affect the motion of "animal spirits" and in turn be affected by such motion. ("Animal spirits" were thought to be subtle fluids flowing through nerve fibers.) However, this theory is apparently incompatible with physical conservation laws, notably the law of the conservation of momentum, as even some of Descartes's own contemporaries perceived. As a consequence, interactionist substance dualism of the Cartesian variety fell out of favor, to be replaced by parallelist and epiphenomenalist versions, which deny that there is any causal action of the mind upon the body (the former also denying that there is any causal action of the body upon the mind). However, these versions of substance dualism are extremely counterintuitive, since we all have a strong conviction that our mental choices or decisions can have an effect upon our bodily behavior.

Substance dualism is a stronger theory than property dualism, in the sense that the former entails, but is not entailed by, the latter. Monistic property dualism is the view that substance dualism is false but that property dualism is true. One of the earliest versions of this view was advanced by Descartes's contemporary, Baruch Spinoza (1632–1677), at least according to some interpretations of his position [2]. Spinoza denied that the mind and the body are distinct substances. Indeed, he denied that they are substances at all, holding that God or Nature – that is, the entire universe as a whole – is the only real substance, or fully independent thing. But he agreed with Descartes in distinguishing between the attributes of thought and extension, the modes of these attributes being mental and physical properties respectively. Where he differed from Descartes was in believing that the same substance or thing can possess both mental and physical properties. Most present-day versions of dualism are likewise versions of monistic property dualism [3,4], typically maintaining that the human brain possesses both mental and physical properties but that these properties are distinct and mutually irreducible.

Perhaps the most compelling case for monistic property dualism may be made by appeal to the apparently irreducible character of the properties of phenomenal consciousness, or so-called qualia, as revealed to us by introspection. It is hard to see how mental qualities such as the perceived redness of a rose or bitterness of a lemon could simply be physical properties of the brain or nervous system, such as complex patterns of neuronal activity. There seems to be an unbridgeable "explanatory gap" between such sensory qualia and the neurophysiological activity that seems to be correlated with them, which prevents us from either simply identifying the former with the latter or even somehow "reducing" the former to the latter [5]. The most that we seem to be able to say is that there is, as a matter of empirically confirmed fact, a causal correlation

between such mental properties and certain physical properties of the brain – but one which it seems impossible for us to explain.

However, physicalist philosophers of mind – those who are hostile to any form of dualism – protest that monistic property dualism suffers from at least some of the difficulties that are seen to beset substance dualism, in particular the problem of psychophysical causation. Such critics tend to appeal to the principle of the causal closure of the physical domain in advancing their objections [6]. This principle has a number of variants, but one popular one states that if we trace the causes of any physical effect backwards in time, we shall never encounter a chain of causation that takes us out of the domain of purely physical events. For example, if we trace back the causal antecedents of a certain bodily movement, such as a movement of my hand, we shall only ever encounter other physical events, such as neural events in my brain and nervous system. It seems most improbable to suppose that, at some point in such a causal chain, we shall find a physical event that has no other physical event as its immediate cause – in short, a point at which we might locate a purely mental event as its immediate cause, such as my experiencing the taste of a lemon or a twinge of pain. Consequently, such physicalists maintain, we must either regard such experiences as being merely epiphenomenal – that is, as having no effect upon the physical domain – or else maintain that, if indeed they really exist at all, they are in fact identical with, or somehow reducible to, physical occurrences of some kind, even if we cannot presently (and indeed may never) understand how. Against epiphenomenalism, however, they would argue that it leaves us with a mystery as to why mental properties should exist at all, given that they can have no effect upon the physical domain. In reply, some epiphenomenalists advance a panpsychist version of their theory, which maintains that it is a fundamental metaphysical fact about our universe that every physical occurrence is accompanied by a corresponding mental occurrence, as a matter of necessity. (In fact, Spinoza is often seen as any early proponent of this view.) To their opponents, however, this appears to be a wild speculation which is by its very nature incapable of being either confirmed or falsified empirically.

At present, physicalism is the dominant view in the philosophy of mind, with dualists of all kinds being very much in the minority and interactionist substance dualists [7,8] especially rare. However, physicalism has its difficulties too, as a consequence of which dualism is currently undergoing something of a revival. The main difficulty for physicalism is the "explanatory gap" mentioned earlier. We simply cannot see how mental properties might just be, or be reducible to, physical properties. Some physicalists urge that this is merely because our access to our own mental properties is different from our access to the physical properties of other things, being via introspection rather than via our sensory organs, so that these properties appear to be different to us, when in fact they could be the same [9]. (This so-called "dual aspect" theory is sometimes attributed to Spinoza, as a rival to the interpretation of him as being a property dualist.) However, the idea that we can distinguish between "appearance" and "reality" in the case of mental properties such as pain is problematic, and this fact has been appealed to in support of dualism in recent times, notably by Saul Kripke [10].

Kripke invites us to consider the hypothesis that pain just is (that is, is identical with) a certain kind of physical activity, such as the firing of C-fibers, by analogy with the hypothesis – now accepted as true on empirical grounds – that heat just is the kinetic activity of molecules. Kripke argues that if such an identity obtains, then it does so necessarily, not just contingently. So, for example, given that heat is the kinetic activity of molecules, it could not have been anything else. He readily acknowledges that we seem to be able to imagine that it might have been something else, explaining this by the fact that there could have been a different kind of physical activity which had the same appearance as heat, that is, which gave rise to the same phenomenal experience as the kinetic activity of molecules gives rise to in us. But this is where the intended analogy inevitably breaks down, according to Kripke. For if pain just is the firing of C-fibers, say, then again this identity will have to be necessary rather than contingent, but we should likewise seem to be able to imagine that pain might have been something else. However, that would require the possibility of there being a kind of physical activity which had the appearance of pain without being pain, just as there could have been a kind of physical activity which had the appearance of heat without being heat. And it seems evident that there can be no such possibility, because whatever seems like pain is pain, even if not everything that seems like heat is heat.

Naturally, the debate, being a philosophical one, does not end there. What is fundamentally at issue in this debate is something that Descartes himself was intimately concerned with in his own defense of dualism, namely, the relation between what is possible and what is conceivable. Some present-day philosophers believe, like Descartes, that conceivability is a reliable guide to possibility and exploit this to argue in favor of property dualism, on the grounds that we can conceive of beings ("zombies") who are physically just like us but lack properties of phenomenal consciousness [3]. Unsurprisingly, others dispute this. However, it is crucial to bear in mind that dualism and physicalism are rival metaphysical theories, not simply scientific theories amenable to empirical confirmation or refutation. As such, they are concerned with what is

necessarily the case and with what is merely possibly the case, rather than just with what is actually the case. Empirical evidence on its own, however, can at best only reveal to us what is actually the case. To go further than this, as metaphysics does, requires other sources of evidence or kinds of reasoning than those deployed by the empirical sciences. Unfortunately, metaphysicians themselves disagree, as scientists tend not to, about the methods of inquiry proper to their own discipline, with the result that their disputes are more intractable – but none the less interesting or important on that account.

# Duchenne Muscular Dystrophy

Kati E. Draper, Qiong Wang, Brian O. Williams, Robert W. Grange
Department of Human Nutrition, Foods and Exercise, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

## Synonyms

DMD

## Definition

►Muscular dystrophy describes a group of ~40 inherited heterogeneous disorders that result in progressive muscle weakness and muscle wasting [1,2]. The most common and fatal disorder is ►Duchenne muscular dystrophy (DMD), first recognized in the mid 1800s and named for a French physician [3]. DMD is characterized by childhood onset, prevalence in boys, progressive muscle weakness, and abundant ►fibrosis and adipose tissue at later stages of the disease [3]. The genes associated with many but not all muscular dystrophies have been identified [1]. The ►genetic defects associated with DMD include deletions or nonsense mutations in the dystrophin gene, which result in the absence of the membrane-associated protein, dystrophin [4]. Although the genetic basis of the disease has been known for over ~20 years, the onset mechanism(s) of the disease is/are not yet clearly defined.

## Characteristics

### Quantitative Description

Gene: The gene for the protein dystrophin is ~2.4 million bases and is located on chromosome X at locus p21. It has 79 coding exons and 7 tissue-specific promoters for 7 protein isoforms. Three promoters produce "full-length" transcripts whose 427 kDa proteins only differ in their amino-terminal sequences. These isoforms are brain (B), muscle (M), which is expressed in skeletal and cardiac muscle, and Purkinje (P), which is expressed in both cerebellar Purkinje cells and skeletal muscle [5].

Protein: Dystrophin is expressed in both invertebrates and vertebrates. Vertebrate dystrophin is located at the cytoplasmic membrane of skeletal, cardiac and smooth muscle and at synapses in the central nervous system. The 427 kDa cytoskeletal isoform has 3,685 amino acids [6] and is a member of the β-spectrin/α-actinin protein family [7]. Dystrophin has four separate domains: (1) an amino-terminal actin-binding domain; (2) a central rod domain; (3) a cysteine-rich domain; and (4) a carboxyl-terminal domain [5]. Dystrophin represents about 5% of sarcolemma proteins [6].

Incidence: Today, DMD is recognized as a severe X-linked muscle-wasting disease (►X-linked disease) that affects 1 in 3,500 boys [3]. One third of all DMD cases arise from a sporadic mutation in the dystrophin gene, most likely a result of its large size [4].

### Higher Level Structures

#### *Dystrophin, Dystrophin Glycoprotein Complex, Costameres and Basal Lamina*

The skeletal muscle isoform of dystrophin is considered a key structural element in the muscle fiber. It is a rod-like cytoskeletal protein localized to the inner surface of the skeletal muscle membrane, or sarcolemma. It forms part of the ►dystrophin glycoprotein complex (►DGC) that links the cytoskeleton and the basal lamina [2]. The DGC, along with additional proteins, form rib-like lattices on the cytoplasmic face of the

sarcolemma known as costameres, which facilitate force transmission between active and non-active fibers [8]. This complex of proteins also likely acts as a signaling conduit between the outside and inside of the fiber [1].

## Lower Level Components

The dystrophin glycoprotein complex is made up of several subcomplexes, including the dystroglycan complex, the sarcoglycan:sarcospan complex, and the peripheral proteins of the cytoplasmic dystrophin-containing domain. The amino or N-terminal of dystrophin binds cytoskeletal F-actin, and its carboxy or C-terminal region binds the dystroglycan complex, which is composed of α- and β-dystroglycans. β-dystroglycan, an integral membrane protein, interacts with dystrophin in the cytosol and with α-dystroglycan in the extracellular matrix, which in turn binds to laminin-2 in the basal lamina (Fig. 1). The sarcoglycan:sarcospan complex, composed of α, β, γ, and δ sarcoglycans and sarcospan, stabilizes the dystroglycan complex in the sarcolemma [2,5,7]. Additional proteins include α-dystrobrevin and the syntrophins [1,7] (Fig. 1).

## Structural Regulation

Absence of expressed dystrophin in DMD leads to the complete loss of the DGC [2].

## Higher Level Processes

### *Effects of Dystrophin Deficiency*

Mutations in the dystrophin gene result in premature stop codons that yield a truncated non-functioning protein. In the absence of dystrophin, the components of the DGC are also absent from the membrane. Loss of the DGC is considered to render the sarcolemma membrane more fragile and to disrupt signaling [1,7].

## Process Regulation

### *Mechanisms of Muscle Degeneration*

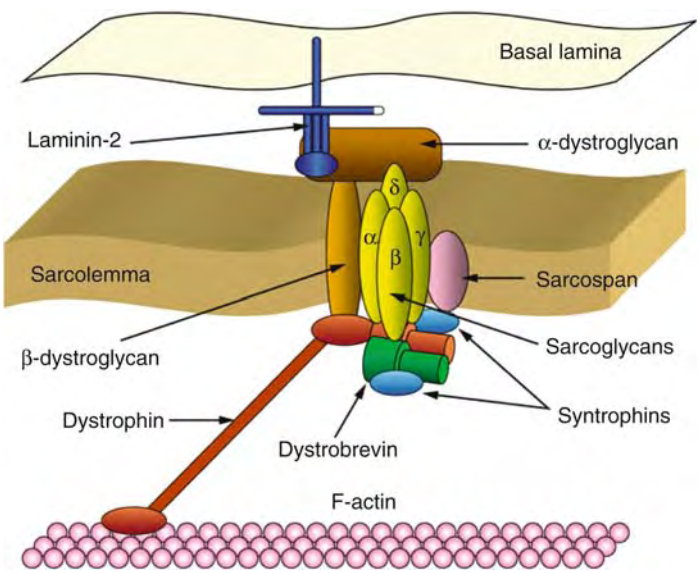
The mechanism, or mechanisms, of onset of DMD are not yet clearly defined.

One possibility is abnormal intracellular calcium regulation. The calcium hypothesis states the absence of dystrophin results in an influx of calcium through the sarcolemma, due to either abnormally functioning mechano-sensitive channels or cation-leak channels. The increased calcium entry would cause a rise in cytosolic free calcium, activate calcium-dependent ►proteases, and eventually lead to muscle fiber necrosis, including further degradation of the sarcolemma [9].

## Function

### *Structure and Signaling*

The precise role(s) of dystrophin and the DGC at the membrane are incompletely understood at present, but they may play both structural and signaling roles [7]; it is therefore difficult to determine what processes are lost and/or changed when they are absent. Structural roles likely include maintaining the integrity of the membrane to ensure proper intracellular $Ca^{2+}$ regulation, and stabilizing the sarcolemma from shear stresses imposed during eccentric muscle contractions [7,8]. However, in the absence of dystrophin and the DGC, skeletal muscles of older dystrophic animals are susceptible to ►contraction-induced injury, while skeletal muscles of maturing dystrophic mice are less



**Duchenne Muscular Dystrophy. Figure 1** Schematic of DGC with currently understood relationship of the components. (Roberts [7]).

susceptible [10]. Thus, the absence of dystrophin and the DGC in dystrophic membrane stability may change with maturation. There is increasing evidence that the DGC plays an important signaling role, such as the interaction between neuronal nitric oxide synthase (nNOS) and α-syntrophin [1]. The nature of the signals that may be disrupted when the DGC is absent is still unclear.

### Pathology

#### *Characteristics of Muscle Pathophysiology*

The two main features of DMD pathophysiology are: (i) progressive degeneration of muscle tissue, and (ii) progressive muscle weakness [2]. DMD muscles demonstrate grouped degenerating and necrotic fibers even before muscle weakness is clinically observed [5]. Necrotic fibers are infiltrated by inflammatory cells such as macrophages and CD4+ lymphocytes, while regenerating fibers are characterized by centralized nuclei. Eventually, regenerative capacity is lost and muscle fibers are replaced by adipose and fibrous connective tissue, giving rise to initial ►pseudohypertrophy, followed by atrophy [3]. Dystrophin-deficient muscle is characterized by increased permeability to endogenous macromolecules flowing in and out of the cell. Muscle fibers stain positively for endogenous extracellular proteins such as serum albumin (in to cell), and increased serum concentrations of cytosolic proteins such as creatine kinase are observed (out of cell) [5].

*Clinical Signs* Onset of DMD occurs at age ∼3–5 years, with evident delays in speech and motor development. In the early stages, calf muscles are enlarged, some of which is due to adipose and connective tissue deposition (i.e. pseudohypertrophy). The muscle involvement is bilateral and symmetrical, first affecting the lower limbs. The proximal muscles are more affected than the distal muscles. Additional features are a waddling gait due to weakness in hip abductors, lumbar lordosis because of weak gluteal muscles, and the Gower's maneuver, which is difficulty rising from the floor or a chair, owing to weakened knee and hip extensors. One third of DMD patients also show intellectual impairment. By age 12, 95% of patients are confined to a wheelchair. Contractures occur at the elbows, knees, and hips and a severe kyphoscoliosis can develop. There is steady deterioration of pulmonary function. By age 20, 90% of DMD patients die, most from cardiac failure and respiratory insufficiency [3].

### Therapy

*Treatment* Specific treatments to significantly increase the lifespan of DMD patients are currently being developed including pharmacological and genetic therapies [6].

## Dummy Treatment

►Placebo Analgesic Response

## Dura Mater of Brain

### Synonyms

Dura mater cranialis; Cranial dura mater

### Definition

Pachymeninx. One of the three meninges. In the dura mater of brain it is closely connected with the periosteum of the calvaria, lined with the arachnoid on the inside. Consists of two layers which spread out

along the longitudinal fissure of cerebrum the falx cerebri (falx = sickle), and between cerebrum and cerebellum the tentorium cerebelli. Also forms blood sinuses such as the superior sagittal sinus and inferior sagittal sinus.

## DW-MRI, Diffusion Weighted Magnetic Resonance Imaging

### Definition

A modified magnetic resonance imaging technique that produces images for which the MR image signal intensity is sensitized to local differences in the diffusional movement of water.

►Magnetic Resonance Imaging

## Dyad

### Definition

Ribbon synapse made by bipolar axons in the inner plexiform layer onto two postsynaptic profiles.

►Retinal Bipolar Cells
►Retinal Ribbon Synapses

## Dynamic Clamp

►Computer-Neural Hybrids

## Dynamic Range

### Definition

Difference (in dB) between the threshold of audibility and the threshold of discomfort.

►Hearing Aids

## Dynamic Range in Acoustics

### Definition

Difference (in dB) between the threshold of audibility and the threshold of discomfort.

►Hearing Aids

## Dynamic Range of Neurons

### Definition

Range of intensity or amplitude of a stimulus that is encoded by a given property of a neural response. The neural code can for example be the rate of action potentials (spike rate) produced by a neuron.

## Dynamic Stiffness

### Definition

The proportionality constant for a linear dynamical system that relates the force (or torque) produced in response to an imposed displacement.

►Impedance Control

## Dynamical System

### Definition

A means of describing how one state develops into another state over the course of time. In engineering and mathematics, a dynamical system is a deterministic process in which a function's value changes over time according to a rule that is defined in terms of the function's current value. Simple nonlinear dynamical systems and even piecewise linear systems can exhibit a completely unpredictable behavior, which might seem

to be random. This unpredictable behavior has been called chaos.

►Emergence

## Dynein

### Definition

A class of motor proteins in cells that move proteins along microtubules, usually from the distal part of the cell towards its centre (i.e. in the direction of the minus end of the microtubule). This form of transport is known as retrograde transport.

►Microtubules
►Retrograde Transport

## Dysarthria

### Definition

Articulatory speech deficit, usually due to cerebellar or brainstem disease.

►Central Vestibular Disorders

## Dyscalculia

### Definition

Inability to perform mathematical operations.

## Dysdiadokokinesis

### Definition

A neurological sign in which the patient is unable to perform rapidly alternating movements of the extremities. Classically, this sign results from pathology in the cerebellum.

►Cerebellar Functions

## Dysesthesia

### Definition

When an innocuous sensory stimulus is perceived as unpleasant or painful.

►Central Pain
►Proprioception: Effect of Neurological Disease

## Dysgeusia

### Definition

Dysgeusia is a term referring to any distortion in the sense of taste. Dysgeusia can occur as a distortion in the perception of a tastant that is actually presented (e.g., a usually pleasant tastant is perceived as unpleasant) or as the perception of a taste in the absence of a tastant (e.g., persistent metallic taste). Dysgeusia may or may not be associated with loss of taste sensitivity and is usually caused by many of the same conditions that result in a pure reduction or loss of taste (see Ageusia for further details). Some authors refer to dysgeusia as a general term, encompassing all taste disturbances, both quantitative and qualitative. Thus, the term parageusia may be used to refer to distortions to the sense of taste, as described above.

►Ageusia
►Gustation
►Taste

## Dysgraphia

### Definition

Writing disability, despite maintained sensory and motor functions of the arm.

## Dyskinesia

### Definition

Literally means abnormal movement. However, the term has evolved to refer to abnormal drug-induced

involuntary movements, usually choreatic, dystonic, or a combination of both. Dyskinesia in patients with Parkinson disease results from the long-term complications of levodopa therapy. Tardive dyskinesia refers to choreo-dystonic movements secondary to long-term use of neuroleptic (antipsychotic) or anti-emetic medications, which have dopamine antagonist activity.

►Drugs for Motor Disorders
►Parkinson's Disease
►Tardive Dyskinesia

## Dysmetria

### Definition

A neurological deficit characterized by the inability to coordinate properly the extent and direction of goal-directed movements. Impaired trajectory movement of a limb towards an intended target, by undershooting or overshooting the target most commonly detected during the finger-nosefinger test in the upper limb, or the heel to shin test in the lower limb. Dysmetria is typically seen in disorders of cerebellar function and is part of the overall cerebellar ataxia syndrome.

►Cerebellar Functions

## Dysmetric Saccades

### Definition

Saccades that are not accurate. The term dysmetria is more often used to describe hypermetric saccades, i.e., saccades that overshoot the target, than hypometric saccades.

►Central Vestibular Disorders
►Saccade, Saccadic Eye Movement

## Dysosmia

►Smell Disorders

## Dysphagia

### Definition

►Disturbance in swallowing.

## Dysphasia

### Definition

►Aphasia.

## Dysphonia

### Definition

►Disturbance in vocalization due to weakness or incoordination of muscles controlling the vocal apparatus.

## Dysplasia

### Definition

Dysplasia (Greek dys- a combining term meaning difficult, painful, or abnormal, and plasia, a combining term meaning formation). Thus displasia is an abnormality of development.

## Dyssynergia

### Definition

A neurological sign characterized by the decomposition of movement reflecting the inadequate coordination of complex, multi-joint movements of the extremities.

►Cerebellar Functions

## Dystonia

### Definition

Abnormal sustained muscle contraction causing twisting or turning around one or multiple joints. It may affect the neck (cervical dystonia/torticollis), eyelids (blepharospasm), limbs (e.g. writer's cramp), trunk (segmental), or vocal cords (spasmodic dysphonia). Dystonia can be focal, segmental, or generalized. Generalized or multifocal dystonia affects multiple body parts.

►Complex Regional Pain Syndromes: Pathophysiological Mechanisms
►Drugs for Motor Disorders
►Proprioception: Effect of Neurological Disease

## Dystrophin Glycoprotein Complex (DGC)

### Definition

The complex of proteins associated with dystrophin that forms a link between the cytoskeleton of a muscle cell and the basal lamina outside the cell. It likely plays both structural and signaling roles for the cell. This complex is absent in Duchenne muscular dystrophy, and therefore structural and signaling functions are lost.

►Duchenne Muscular Dystrophy

## E2

►Long Loop Reflexes

## E Box

**Definition**
DNA motif with the consensus sequence 5'-CACGTG-3' that constitutes a binding site for Clock (or NPas2) and Bmal1.

►Clock-Controlled Genes

## Early Selection

**Definition**
A model, first proposed for attention, assuming that unattended signals are eliminated already on an early cortical level.

►Sensory Plasticity and Perceptual Learning

## Early Sensory Cortices

**Definition**
Those parts of the cerebral cortex that receive direct input from sense organs, usually via the thalamus, i.e., the primary (and secondary) sensory cortices.

►Sensory Plasticity and Perceptual Learning

## Earmold

**Definition**
A molded silicone, acrylic or vinyl mold worn in the ear.

►Hearing Aids

## Earth's Magnetic Field

►Geomagnetic Field

## Earth's Structure

**Definition**
The planet Earth is layered. The subdivisions are crust (average thickness of continental crust: 35 km; oceanic average 6 km), mantle (35 – 2900 km depth), outer core (2900–5150 km depth), and inner core (5150 – 6371 km depth). The crust and mantle consist of solid rock, while the core is metallic. The inner core is solid, the outer core liquid.

►Geomagnetic Field

## Eating

**Definition**
Eating is the process of taking food into the mouth, masticating the food and swallowing it.

## E-box

**Definition**
Sequence of nucleotides that serves as DNA binding site for proteins involved in transcription. The consensus sequence is CANNTG and is found in the promoters of clock and clock-controlled genes.

►Clock Genes

## E-C Coupling

►Excitation-Contraction Coupling

## Eccentric Contraction

**Definition**
A period of muscle activity during which the length of the muscle fibers increases.

►Energy/Energetics

## Echolocation

**Definition**
A sensory system in bats, and toothed whales, in which usually high-frequency sounds are emitted and their echoes interpreted to determine the direction, and distance and shape of objects.

►Evolution of the Auditory System in Mammals

## Ecphory

**Definition**
This term was originally introduced by German biologist Richard Semon, who used it in the sense of "activation of a latent engram." Subsequently, Canadian psychologist Endel Tulving used it to denote "the process by which the relevant information in the retrieval environment interacts with the information stored in a specific memory trace to produce conscious memory of certain aspects of the original event."

►Episodic Memory

## Ectopia/Dystopia

**Definition**
Congenital aberrant or inappropriate location of organs (such as the pituitary) or organ systems.

►Endocrine Disorders of Development and Growth

## Ectotherm

**Definition**
An animal that relies on the surrounding temperature to regulate its body temperature. Animals in this group include fish, amphibians, and reptiles.

►Evolution of the Hypothalamus in Amniotes

## Edge Detectors

**Definition**
►Visual Cortical and Subcortical Receptive Fields

## Edge Enhancement

►Contrast Enhancement

## Edinger-Westphal Nucleus

### Synonyms

Nuclei viscerates (Edinger-Westphal); Visceral nuclei (Edinger-Westphal); Accessory Nucleus of Oculomotor Nerve

## EDSS (Kurtzke Expanded Disability Status Score)

### Definition

The EDSS is a measure of neurologic impairment. It relies heavily on the ambulatory status of the patient and can provide a measurement of clinical status over time. The scale ranges from 0.0 (normal) to 10.0 (death due to multiple sclerosis, MS). Most patients with a score of <3.5 have RRMS and walk normally whereas patients with EDSS >5.5 need assistance to walk and may have progressive forms of MS.

►Multiple Sclerosis

## EEG

### Definition

Electroencephalogram, recording of brain wave activity.

►EEG in Sleep States

## EEG Delta Power

### Definition

The electrophysiological hallmark of non-REM (NREM) sleep. Electroencephalogram (EEG) slow waves (slow-wave activity, SWA) have a frequency within the delta frequency range between 1.0–4.0 and 0.75–4.5Hz. The prevalence and amplitude of slow or delta waves can be quantified by spectral analysis algorithms such as the Fourier transform. Because the delta frequency band is well defined (while the term slow-waves is more ambivalent) and because the units of the Fourier output are power, the term EEG delta power is more precise although SWA is more widely used. EEG delta power is a measure of the depth of NREM sleep and its level is high when the duration of prior wakefulness was long and decreases over the course of a sleep episode.

►Electroencephalography
►Fourier Transform(ation)
►Non-REM Sleep
►Sleep Homeostasis

## EEG in Sleep States

Kenneth P. Wright Jr.
Sleep and Chronobiology Laboratory, Department of Integrative Physiology, University of Colorado at Boulder, Boulder, CO, USA

### Synonyms

Sleep electroencephalograpy (EEG); Sleep brain wave activity

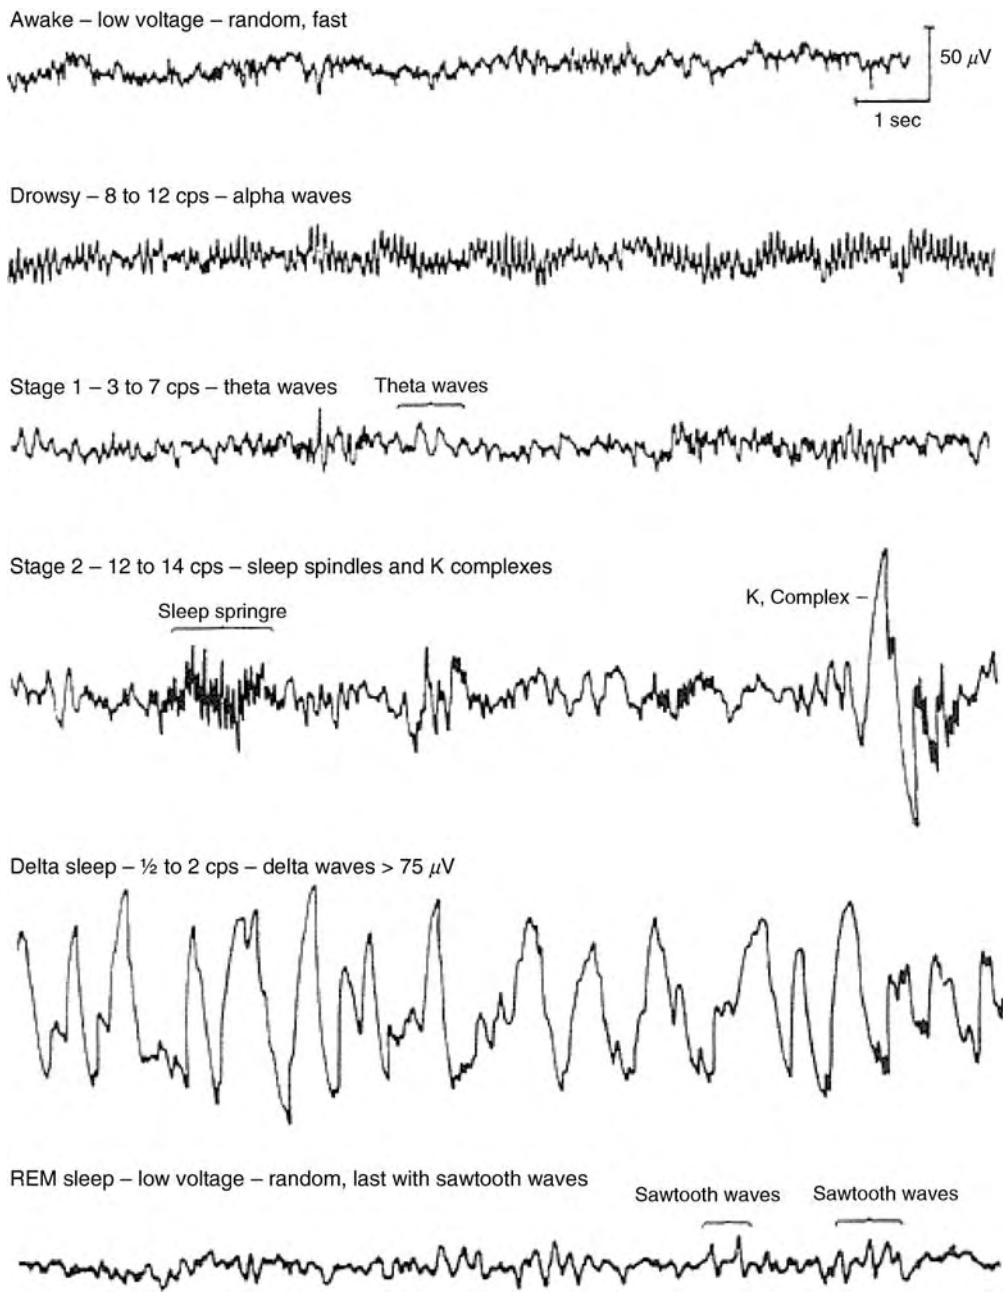
### Definition

Recordings of the electrical activity of the brain during sleep.

### Characteristics

Sleep EEG activity can be recorded by placing sensors directly into brain tissue or onto the surface of the scalp. Brain wave activity can be recorded from individual cells, from populations of cells and from the surface of the brain and scalp. The EEG has been used in both research and clinical settings. Hans Berger was the first to report performing an EEG recording on a human subject in 1929. Loomis and colleagues were the first to report recordings of the human sleep EEG [1–3]. In humans, electrodes are typically placed on the scalp according to the international 10–20 system [4]. Brain wave activity recorded at the scalp generally represents cortical activity [5]. However, synchronization between cortical and sub-cortical structures influences the sleep EEG recorded at the scalp [6]. The features most commonly used to describe EEG waveforms are frequency, amplitude and morphology. Frequency is a measure of the number of cycles per second or Hertz (Hz). Amplitude is a measure of the height of the EEG waveform, commonly reported in micro volts (μV) when measured on the scalp. Morphology is a description of the shape of the EEG waveform.

The EEG is commonly divided into bandwidths based on the assumption that the EEG within those bandwidths share common activity; the latter assumption may not always be accurate and thus some researchers examine EEG activity in single Hz [7]. The four primary EEG bandwidths include delta, theta, alpha and beta [7,8]. Different definitions of these bandwidths are found in the scientific and clinical literature; however, the following can be used as a general guide. The delta band is commonly defined as the EEG rhythms between ~0.5 and 3 Hz with amplitude of ~20–200 μV. To be defined as delta sleep, the amplitude of the waveform must exceed 75 μV [9]. Delta EEG activity is most common during synchronous slow wave sleep [8,9], also referred to as Delta or stage N3 sleep (Fig. 1), and is of highest



**EEG in Sleep States. Figure 1** EEG activity during wakefulness and sleep note due to nomenclature changes, stages 1, 2 and delta sleep are now referred to as stages N1, N2 and N3 sleep. Figure from http://www.sleephomepages.org/sleepsyllabus/a.html © Copyright 1997 Sleep Syllabus. Basics of Sleep Behavior. WebSciences International and Sleep Research Society (United States).

amplitude over the frontal cortex. The theta band is commonly defined as the EEG rhythms between ~4 and 7 Hz and with amplitude of ~20–200 μV [7–8]. Theta EEG activity is most commonly observed during the ►transition from wakefulness to sleep [7] and during sleep stages N1, N2 and REM [8]. Theta activity tends to be of highest amplitude over the central cortex. Theta EEG activity is also commonly recorded in non-humans in the hippocampus during REM sleep and wakefulness [10]. The alpha band is commonly defined as the EEG rhythms between ~8 and 12 Hz with amplitude of ~20–100 μV [7,8]. Alpha EEG activity is most commonly observed during quiet wakefulness, drowsiness, and the transition from wakefulness to sleep [7]. Alpha activity tends to be of highest amplitude over the occipital (visual) cortex of the brain, especially when eyes are closed [7]. The beta band is commonly defined as the EEG rhythms between ~15 and 25 Hz with amplitude of ~2–20 μV. Beta EEG activity is most commonly observed during active wakefulness. The 40 Hz rhythm associated with the gamma bandwidth is an EEG waveform reported to be associated with cognition.

Common EEG waveforms defined by their morphology include K-complexes, sleep spindles, vertex sharp waves, sawtooth waves, mu rhythm, and spike and sharp waves. The presence of K-complexes and sleep spindles define stage N2 sleep [9]. The K-complex is an EEG waveform having a well-delineated negative deflection immediately followed by a positive deflection with duration of ~0.5 s (Fig. 1). The ►sleep spindle is an EEG waveform in the shape of a spindle with duration of ~0.5 s (Fig. 1) [2]. Sleep spindles have frequencies between ~12 and 14 Hz with highest amplitudes over the central cortex. Vertex sharp waves are EEG potentials occurring during the transition to sleep over the vertex of the central cortex. Sawtooth waves are a form of theta waves observed during REM sleep (Fig. 1). Saw-tooth theta waves have a shape like the blade of a saw [2]. The Mu rhythm is observed over the somatosensory cortex during wakefulness, with a frequency in the alpha bandwidth. Mu activity is morphologically different from alpha activity in that it has an arch-like shape like the letter m. Synchronous spike and sharp EEG waveforms maybe associated with epilepsy during sleep.

# EEG Sleep Stages

## Definition

Distinct electroencephalogram (EEG) patterns recorded from the sleeping human subject during different periods (stages) of his/ her sleep. There are four main sleep stages: 1st stage –drowsiness; 2nd stage – light sleep; 3rd and 4th stages –deep sleep. The resting alpha rhythm gradually attenuates during falling asleep and disappears in the 2nd stage. Sleep spindles (bursts of beta rhythm) and K complexes (slow waves associated with the spindles) characterize the 2nd stage. Slow-wave (delta) activity dominates during the 3rd stage and becomes more intensive in the 4th stage. After deep sleep, either the 2nd stage returns or rapid-eye-movement (REM) sleep may occur, associated with dreaming. The REM sleep apparently fills a rather specific place among the sleep stages and plays an important role for brain functioning.

## Synonyms

Alcoholic brain damage

## Definition

Alcohol misuse leads to cognitive, physiological, and structural changes in several cortical and sub-cortical structures. Neuroactive drugs such as ethanol influence neurotransmission to alter mood. Long-term alcohol use can lead to addiction, the compulsion to take the drug and loss of control over intake, or dependence, the need for continued drug exposure to avoid withdrawal. Tolerance, where a reduced effect follows repeated exposure to a constant dose, or an increased dose is needed maintain the same effect, is also common (see ►Tolerance and Dependence). While research in this area is ongoing, the current understanding about the cellular and molecular mechanisms that bring about the multitude of changes is discussed in this essay.

## Characteristics

### Introduction

The present era has seen a tremendous upsurge in the misuse of psychoactive substances around the world. Despite the public attention lavished on illicit drugs, one of the greatest impacts on human health and societal well-being is exerted by a licit drug, alcohol. Alcohol causes 3.2% of total world-wide deaths, and a loss of 4% of all disability-adjusted life years (a standardised estimate of disease burden) [1]. Close to 40% of the alcohol-related disease load is caused by neuropsychiatric conditions [1]. Figures are higher for men and markedly higher in special populations. Alcohol consumption has declined slowly in recent years in developed countries, but is growing steadily in developing countries. Although the prevalence of hazardous/harmful drinking varies from country to country, drinking behavior and alcohol-related problems show many common features. Major commonalities amongst all chronic alcohol abusers are patterns of hazardous drinking that exacerbate the harmful effects of alcohol on the brain. Understanding the mechanisms that constitute this harm is a major research priority.

### Acute Effects: Molecular Targets

Alcohol has diverse short-term effects on the brain, ranging from intoxication to sedation, analgesia and anesthesia. The dose of alcohol required to induce intoxication in humans is 10–20 mM, whereas the dose to produce anesthesia in experimental animals is 100–200 mM. Since a high concentration of alcohol is required to induce an effect, alcohol was thought to have a non-specific mechanism of action. However, in recent years, specific protein targets mediating the action of alcohol have been identified; many of these proteins have a role in neurotransmission. Specific binding sites for alcohol have been identified on a number of ionotropic (ligand-gated ion channel) neurotransmitter receptors [2,3]. In experimental animals, physiologically relevant concentrations of alcohol affect G-protein regulated inward-rectifier potassium channels (GIRKs), neurotransmitter transporters (DAT), anion channels gated by GABA and glycine ($GABA_A$ and Gly receptors; see ►Anxiolytics and Hypnotics), and cation channels gated by glutamate (►NMDA receptors), serotonin ($5HT_3$ receptors), nicotinic acetylcholine (nACh receptors) and ATP (P2X receptors). The action

of alcohol at each of these protein targets is thought to underlie the many behavioral effects of alcohol. For example, GIRK channels have been shown to mediate the analgesic effects of alcohol. Further research aims to identify the specific protein targets that underlie craving, reward, tolerance and dependence.

## The Path to Long-Term Effects: Gene and Protein Expression

Chronic exposure to alcohol has wide-ranging effects on gene expression in the brain leading to long-term changes in function. Microarray assays of mRNA transcripts, together with proteomic studies, have shown changes in the expression of numerous genes in the animal and human brain. Affected genes are involved in metabolism, the immune response, cell survival, cell communication, signal transduction and energy production [4]. In the human prefrontal cortex, genes encoding DNA-binding proteins, transcription factors and repair proteins are responsive to alcohol, and there is an overall down-regulation of genes encoding mitochondrial proteins. Genes involved in myelination and cell-adhesion are also affected; the majority are down-regulated [4]. These observations suggest that myelin formation and cell adhesion, both important processes in the development and plasticity of the CNS, could be severely impaired in the alcoholic brain. This proposition is supported by evidence of a change in cell-cell adhesion in an in vitro model. These broad-spectrum approaches highlight the large number of genes affected by long-term alcohol exposure that may lead to a generalized impairment of metabolism in affected cells.

In addition to the acute, short-term effects of alcohol on neurotransmitter receptor functions discussed above, long-term alcohol exposure affects the expression and composition of these receptors. Examples include NMDA receptors (NMDAR) and $GABA_A$ sites [2,3]. NMDARs are hetero-multimeric complexes consisting of NR1 and NR2 polypeptide subunits. Variations in the properties of NMDARs are generated through the incorporation of alternate versions of the NR1 and NR2 subunits. The NR1 subunit is encoded by a single gene that is expressed in eight alternate splice variants. NR2 subunits are encoded by four distinct genes giving rise to four alternate subunits, NR2A–D. NMDARs are reviewed in detail in [2].

Prolonged exposure to alcohol leads to an overall up-regulation of NMDARs in the rat brain, presumably to compensate for the reduction in ion flow caused by the action of ethanol on the receptor. In the same animal model, the level of NMDAR NR1 subunit mRNA expression was not significantly affected, although NR2B mRNA was significantly increased. In contrast, in the human autopsy brain we find that, although NR1 mRNA did not vary significantly, NR2B mRNA was unchanged in alcoholics without comorbid disease but was decreased in cirrhotic alcoholics.

$GABA_A$ sites are also significantly affected by chronic alcohol exposure. These are hetero-multimeric complexes consisting of five subunits permutated from several classes (α, β, γ, δ, ρ and ε), each of which has several isoforms. As with NMDARs, the level and subunit composition of $GABA_A$ sites are altered after prolonged alcohol exposure in an adaptive process. In an in vivo animal model the levels of α1, α2 and α4 subunit mRNA are significantly increased, and there are concurrent increases in the concentrations of the corresponding subunit proteins. In the human autopsy brain, significant regional differences in the expression of the α3 and α1 subunit transcripts and proteins were seen. The overall trend was toward an increase in α1 and a decrease in α3 in the alcoholic cases. $GABA_A$ sites are reviewed in detail in [3; see also ►Anxiolytics and Hypnotics].

It can be seen from this evidence that alcohol has a significant long-term influence on the expression and composition of, and in consequence the function of, NMDARs and $GABA_A$ sites. This influence is complex, and it is species-, region-, and comorbidity-dependent. However, the overall trend is for the tissue to adapt to higher levels of alcohol so as to compensate for its effects. This adaptation does appear to be reversible after time, but the altered levels and function of these receptors are thought to be primarily responsible for the neurological effects seen during withdrawal.

## Long-Term Effects: Neuropathology

Changes in gene and protein expression due to chronic alcohol misuse and dependence leads to significant brain damage (see ►Tolerance and Dependence). This is manifest clinically in characteristic neuropsychological behaviors, including impairment to executive functions, visuospatial abilities, judgment, insight, problem solving, motivation, and learning [5,6]. Alcoholism induces several types of brain damage that are confined to specific brain regions. Chronic alcohol misuse results in brain shrinkage, particularly of the frontal lobes, which is largely due to a reduction in volume of the cerebral ►white matter [7]. In contrast, ►grey matter is affected differentially. The evidence suggests that neurons in specific regions of the brain, such as cerebellar ►Purkinje cells and ►superior prefrontal gyrus pyramidal neurons, are selectively damaged [7]. The frontal cortex is important in judgement, decision-making and other executive functions; thus, the alterations in this area are in line with known changes in cognitive function, and correlate with findings of a retraction of dendrites and a reduction in synaptic density through ethanol toxicity.

Several other cortical regions, such as the motor or occipital cortices, do not show neuronal loss, but do show reduced dendritic arborisation [8]. Local differences in neuronal susceptibility may be a consequence of their possession of specific protein profiles [9]. The pathological changes may result from the direct neurotoxic actions of ethanol itself, or of one of its metabolites [5].

Alcoholics differ markedly in their neuropathological presentation, ranging from little or no damage to severe frontal lobe and/or cerebellar atrophy. The extent of atrophy can be correlated with estimates of lifetime alcohol consumption and is more severe in alcoholics who have comorbid diseases such as cirrhosis of the liver or the ►Wernicke–Korsakoff Syndrome [5]. These diseases are more prevalent with high rates of alcohol consumption so it appears that the pathology worsens with increasing disease severity.

Imaging studies utilizing computer-aided tomography (CAT), magnetic resonance imaging (MRI) and positron emission tomography (PET) have been instrumental in identifying the abstinence-induced reversibility of some types of alcoholic brain damage. Longitudinal studies have shown that even short term abstinence ameliorates neuropathological changes. Grey matter volume increases with one month's sobriety; longer-term abstinence is required for an increase of white matter and the partial recovery of ventricular size [6]. The recovery of certain parts of the brain suggests that the damage seen in chronic alcoholic misuse may be the result of a combination of irreversible axonal degeneration and neuronal death, and reversible changes in myelination. In is not clear from these analyses whether all brain damage associated with chronic alcoholism is reversible, or if there is a point of no return after which brain damage becomes permanent.

## Long-Term Effects: Mechanisms of Alcoholic Brain Damage

The cellular and molecular mechanisms behind alcohol-induced brain damage are poorly understood. As men tioned above, ligand-gated ion channels such as $GABA_A$ (inhibitory) and NMDA (excitatory) receptors mediate acute drug intoxication, but their roles in the long-term effects are still under investigation. Glutamate operates 67–73% of cortical synapses in the human brain and is the major excitatory transmitter: the influx of cations it mediates depolarizes post-synaptic cells, which have a negative internal polarity in the resting state. In contrast, the influx of anions mediated by GABA (and glycine) hyperpolarises the post-synaptic cell; GABA is used at 16–25% of cortical synapses, where it is the major inhibitor. Excitation-inhibition balance is a key determinant of neuronal viability: when tilted toward excessive excitation it is termed ►excitotoxicity (see ►Neurotoxicity).

In experimental studies, such a shift may be elicited in several ways. What is not clear is whether such mechanisms occur in the human brain in vivo, and how the localisation of pathology comes about. Plausible options include locally overactive NMDA or underactive ►$GABA_A$ receptors, and a diminished clearance of glutamate from the synaptic cleft [10]. Receptor and transporter pharmacology are determined by the expression of many genes; if some are switched off, and others switched on, profound changes in receptor function or transport capacity are brought about. It is thus of interest that the alcoholism risk is differentially associated with alleles of several transmission-related genes. The products of these genes (receptors, transporters) are targets for several drugs used to treat alcoholism. Genotype-phenotype interaction is a very active area in alcohol-misuse research.

## Efference Copy

### Definition

A negative copy of a motor command; defined by von Holst and Mittelstaedt in 1950 for the opto-motor response in flies. It is part of the Reafference Principle that describes how a sensory system can cope with self-induced (i.e., "re-afferent") sensory input, such as image motions on the retina during eye-movements. If efference copy and re-afferent signal are of equal magnitude, the subtraction of the efference copy from the re-afference will cancel the sensory input signal. The same principle was simultaneously and independently discovered by Roger Sperry and termed "corollary discharge."

## Efferent

### Definition

The term efferent (from Latin "ex" = out of and "ferre" = carry) refers to axons that relay information away from the central nervous system. The somatic motor system consists of efferent nerves that have muscles as targets and whose cell bodies are contained within the central nervous system. The autonomic motor system differs from the somatic in that the motor neurons are contained in ganglia outside the central nervous system. Efferent nerves from the autonomic motor system innervate diverse targets including sweat glands, cardiac muscle, and smooth muscle.

## Efficiency

### Definition

Ratio of the free energy increase in the driven process to the decrease in the driving process.

►Energy/Energetics

## Efficient Coding Hypothesis

### Definition

The efficient coding hypothesis was proposed by Horace Barlow in 1961 as a theoretical model of sensory coding in the brain. It posits that the spikes in the sensory system form a neural code for efficiently representing sensory information and that the number of spikes needed to transmit a given signal is minimized.

## Electric Communication and Electrolocation

Bernd Kramer
University of Regensburg, Institute of Zoology, Regensburg, Germany

### Synonyms
Electrocommunication

## Definition

*Electric Communication:* Via their electric organ discharges, which are under brain control, certain fish broadcast biologically relevant information into their environment. The information may include species, age, sex, or individual identity, and motivational state.

*Electrolocation:* The detection of usually weak electric fields of abiotic or biotic origin for orientation or object location, thanks to the electric sense that is present in all classes of lower aquatic vertebrates and monotreme mammals (platypus, echidna). Electrolocation is passive for ambient, extraneous electric fields. It is active when a weakly electric fish locates nearby objects that distort the fish's electric field.

## Characteristics

### Function

#### *Electrocommunication*

Electrocommunication differs greatly between the different taxa of electric fish [reviews 1–3].

##### *Batidoidimorpha (Rays)*

*Torpedinidae (Electric Rays):* The exclusively marine electric rays, such as *Torpedo* or *Narcine* species, discharge their strong electric organs for prey capture or defense (see entry "Electric organ discharge"). As with all strong-electric fish, a communication function of the electric organ discharge cannot be excluded, but evidence for such a hypothesis is lacking.

*Rajidae (Skates):* The predominantly marine weakly electric skates carry electric organs in their tail filament, the only known function of which is communication. *Raja* skates discharge only rarely, not even when swimming; however, in social encounters, such as when lying on top of each other, discharge sequences were recorded quite often. Depending on the species, electric organ discharges of 70–217 ms pulse duration were recorded in trains of less than 100, at less than 8 Hz. Although a correlation between electric organ discharges and overt behavior has been observed, much remains to be studied in skates.

##### *Mormyriformes*

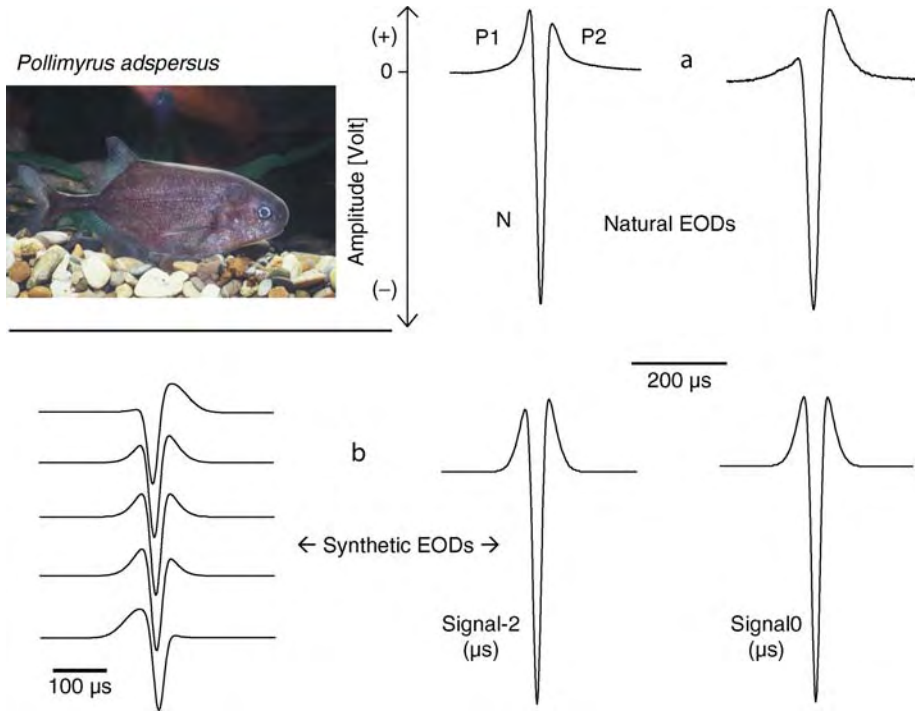
Only Found in African Freshwater Bodies: (i) Gymnarchidae: The only living representative of the Gymnarchidae, *Gymnarchus niloticus*, is a large, piscivorous predator with a constant-frequency wave discharge. Its social behavior in relation with electrocommunication is virtually unexplored. However, it displays a Jamming Avoidance Response (JAR), or frequency shift, to an electric A.C. wave stimulus (if sufficiently close to its electric organ discharge frequency), which resembles the JAR in the South American gymnotiform *Eigenmannia virescens* (with similar discharge). (ii) Mormyridae (snoutfish): All snoutfish (about 200 species) studied to date generate electric organ discharges of the pulse type, waveform and duration of which are species-specific. Fish are active at night, when their electric organ discharge serves in group cohesion, at least in certain species [1].

Species and individual signature by electric organ discharge waveform. Electric organ discharge pulse waveforms that differ between syntopic sibling species point to their significance in communication, and aid in systematic research [4]. Despite an electric organ discharge duration far below 1 ms, trained, food-rewarded *Pollimyrus adspersus* discriminated between playback electric-organ discharge waveforms pre-recorded from another species, and even between different conspecific individuals. The intraspecific waveform variability is much greater than the fish's discrimination threshold, suggesting the electric organ discharge waveform is an individual signature (Fig. 1). The discrimination between electric organ discharge waveforms, as present in *P. adspersus*, relies on a purely temporal (and not spectral frequency) analysis, as demonstrated by using synthetic electric organ discharges of different waveforms but identical amplitude spectra [5].

Electric organ discharge waveform and sex. Although the electric organ discharge waveform in individual mormyrids varies within a species-specific range that may be quite wide for certain species, it is highly stable for an individual fish. In the males of certain species, the electric organ discharge waveform broadens with adolescence, or readiness for reproduction. A seasonal sexual dimorphism in electric organ discharge waveform is present in *Marcusenius altisambesi* (Upper Zambezi River), with a tenfold longer electric organ discharge duration in mature males than females; but in many other species, such as *P. adspersus* or *Petrocephalus catostoma* (Upper Zambezi form), only a statistically significant difference between the sexes with wide overlap is found. There is no difference at all between the sexes in still other species (Fig. 2).

The detection of such electric organ discharge waveform variation has been shown to be instrumental for one or more of the following functions: (i) recognition of mate identity during the many hours of a spawning night, with its hundreds of short female visits and retreats; (ii) female choice regarding male quality (that is, intersexual selection); and (iii) intrasexual selection among males competing for resources to gain access to gravid females. Runaway selection for still longer male *M. altisambesi* electric organ discharges is blocked by catfish predators, who detect male electric organ discharges the longer the better, with their low-frequency electroreceptor organs (during the famous "catfish runs" in the Okavango) [6] (Fig. 3). For evolutionary theory, particularly in South American setting, see [3].

Sequence of Inter-Discharge Intervals: The sequence of discharge intervals (SDI) fluctuates with the state

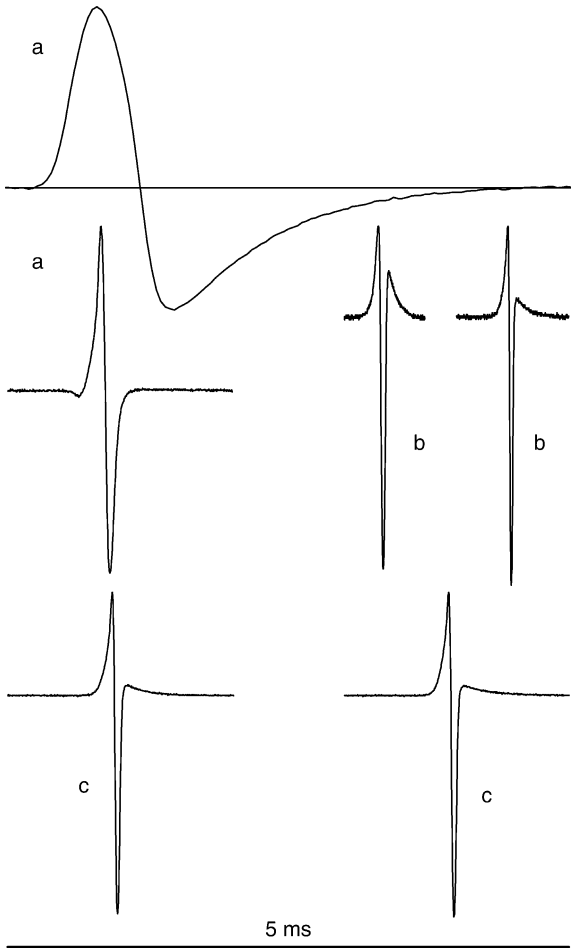


**Electric Communication and Electrolocation. Figure 1** (a) Electric organ discharge as an individual signature for two *Pollimyrus adspersus* snoutfish. Note difference in amplitude ratio of *P1* and *P2* phases; *N* head-negative phase. (b) A family of computer-generated stimulus pulses were used to determine the discrimination threshold for an N phase shift. The fish still discriminated the symmetrical Signal0 from Signal-2 with its N phase advanced by 2 µs. Discharges normalized to the same amplitude (peak-to-peak) [5].

of excitation in a mormyrid fish. Therefore, the SDI appears suitable for signaling motivational state, potentially in addition to all the information the electric organ discharge waveform is already transmitting [7]. The signaling of species identity by SDI was demonstrated in *Petrocephalus bovei*, when it showed spontaneous preference for conspecific playback SDIs over those from two other species (*Pollimyrus adspersus* and *Brienomyrus niger*, with electric organ discharge waveform excluded as a factor). Similar results were obtained with *Campylomormyrus rhynchophorus*, which "preferred" conspecific SDIs to those recorded from immature *C. tamandua*; the reverse experiment, however, was inconclusive (difference not statistically significant). The result shows that SDIs may indeed encode species identity, and perhaps sex or age; however, between sibling species, electric organ discharge waveform prevails [2].

*Agonistic Signaling:* An especially clear correlation of characteristic SDIs with overt behavior has been established for aggression and escape (agonistic behavior) in several species [2]. Overt attack is announced by a transient, short-lived, sharp increase in discharge rate that may be followed by a decrease (SID). The correlation of overt behavior with electric signaling is so strict in *Gnathonemus petersii* and *P. adspersus* that the SID may be considered an integral part of the motor behavior attack, the two components apparently never occurring in isolation. In *G. petersii, P. adspersus*, and *Marcusenius pongolensis*, an attacking fish's SID is often not followed by a decrease, but by a short period of a very high and stable discharge rate (SI-HD). This steady-state, high discharge rate component (HD) may last up to 4 s in *G. petersii*. During this period, *G. petersii* may either display a long sequence of the shortest possible interval for the species (ca. 8 ms), or an interval about twice its duration, or the two intervals may alternate in a sustained double pulse pattern. Any combination of these patterns may occur in a single SI-HD. An aggressive fish's butt or bite of its opponent usually occurs at the end of the SID component, and the ensuing HD component is accompanied by a lateral (often antiparallel) display in close contact with the attacked fish. Compared to the discharge rate at the moment of physical contact, the HD component is usually twice that rate (up to 150 Hz). Multiple SI-HDs are observed in pairs of fish fighting about territorial dominance, with the HD component usually disappearing when one of the two opponents gives up.

In *G. petersii*, the loser of a fight usually increases its discharge rate during the moment of greatest danger

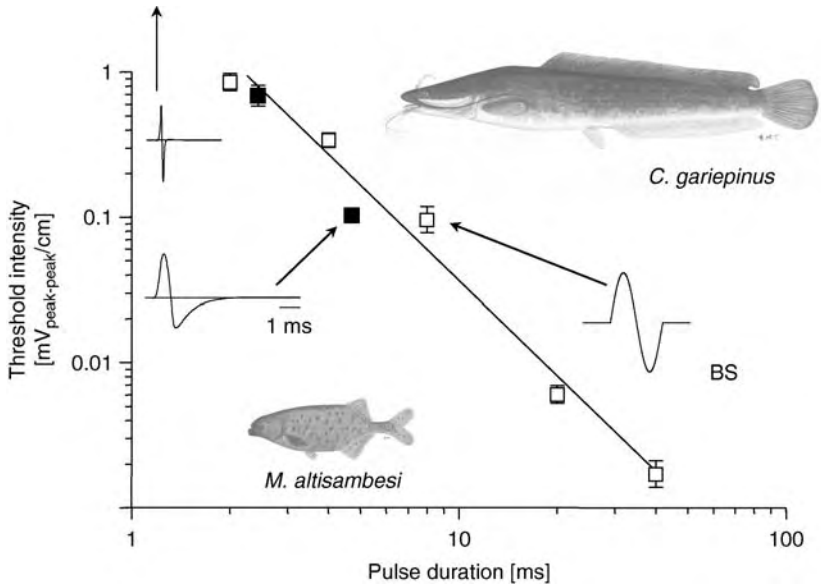


**Electric Communication and Electrolocation.**
**Figure 2** Electric organ discharge waveform and sex, in three snoutfish species of southern Africa. All electric organ discharges represented as voltage over time, recorded in the field immediately after capture. Same time bar for all. (a) Sexual dimorphism in *Marcusenius altisambesi* with two distinct waveforms. (b) Sex difference of only a statistical nature in *Petrocephalus catostoma* (Upper Zambezi form) with, in most males, a stronger second positive phase than in females, such as shown here. (c) *Petrocephalus wesselsi* (Sabie River, South Africa) with no difference between the sexes. *P. wesselsi* was recognized as distinct from *P. catostoma* only recently.

of being bitten by a dominant, attacking fish. In contrast to the aggressor, the subordinate fish's discharge rate remains well below the highest possible level. The increases given by a fish when actively escaping are preceded by a short electric organ discharge cessation of up to 1 s, contrasting strongly with the sequence of subsequent, short inter-discharge intervals (IDIs) of constant duration (at up to 55 Hz). As observed repeatedly in certain pairs of fish, these displays deter some aggressors' attacks. Therefore, they are thought to represent threat displays, resulting from a conflict between aggression and escape tendencies.

Playback experiments contrasting "resting" electric organ discharge patterns with "aggression" electric organ discharge patterns (as pre-recorded from fish showing the appropriate behavior), established that the "aggression" pattern was more effective in evoking activity from the resident fish. The "aggression" pattern evoked full-fledged electric and motor behavior of aggression, including butts, bites, and lateral displays with correct orientation towards the dipole model, and with correlated SI-HDs of the highest intensity [2]. This shows that a simple, immobile electrical decoy bearing no physical resemblance with a real fish (except in electric field geometry) is sufficient to evoke the most complex, coordinated social behavior in this animal, as observed in territorial defense and reproduction (*M. pongolensis*). Agonistic signaling is clearly a function of the IDI code of communication in mormyrid fish, and has been confirmed in similar form in other mormyrid species.

*Signaling in Courtship and Spawning:* The nocturnal reproductive behavior was first observed in captive *P. adspersus* from West Africa. In addition to elaborate electrocommunication and motor behavior, the male produces complex songs at night ("advertisement calls"). A male with a territory and a nest attracts gravid females from a distance. An intensely singing male attacks a visiting female while also displaying attack-correlated SI-HDs. The female quickly escapes, but keeps repeating her short visits at about 2–3 per minute, and the male's aggression and singing slowly wane. Without discharging, the female briefly advances onto the bottom in the male's territory or right inside his hiding place, and rapid antiparallel circling at surprisingly low electric organ discharge rates follows until the female's quick retreat. This provokes courtship attacks and again intense singing from the male. After several repeats, eventually the female allows the male to move into a parallel position from behind, when both fish mechanically link their anal fins. Thus united, the pair performs a full, slow rotation (3–4 s), head-over-tail or tail-over-head both occur, accompanied by a low-rate electric signaling (medium uniform rate). For about 2–5 h on a spawning night, the pair carry on this courtship behavior while the male's singing slowly wanes; he is completely silent during the later stages of courtship and also during spawning. The behavior preliminary to a spawning bout is an abridged version of a courtship bout. On the female's arrival at the spawning site, the male immediately positions himself alongside, stimulating her anal fin region with a quivering motion of his anal fin, followed by oviposition (a few eggs per visit), fertilizing the eggs, and transporting the eggs to the nest. Head-to-tail circling and the elaborate rotation part are omitted. The female marks the end of



**Electric Communication and Electrolocation. Figure 3** Electrosensory thresholds of a snoutfish predator, the catfish *Clarias gariepinus* (*ordinate*), as a function of stimulus pulse duration (ms) *(abscissa)*. Food-rewarded catfish detected stimulus pulses the longer the better. □ bipolar, single-cycle sine wave stimulus, ■ electric organ discharge of two male *Marcusenius altisambesi* with electric organ discharges of long duration (compared to females). Note that the thresholds for the two male electric organ discharges agree well with those for bipolar sine wave pulses of similar duration, whereas the brief female discharge was ineffective as a stimulus, and threshold was not reached [6] (Fish pictures from P. H. Skelton).

spawning by abruptly switching from a low and constant electric organ discharge rate to a pulse pattern that regularly alternates (at 2/s) between a low and a high electric organ discharge rate (that contrasts with all other patterns). The male's aggression returns immediately and is again accompanied by intense singing [2].

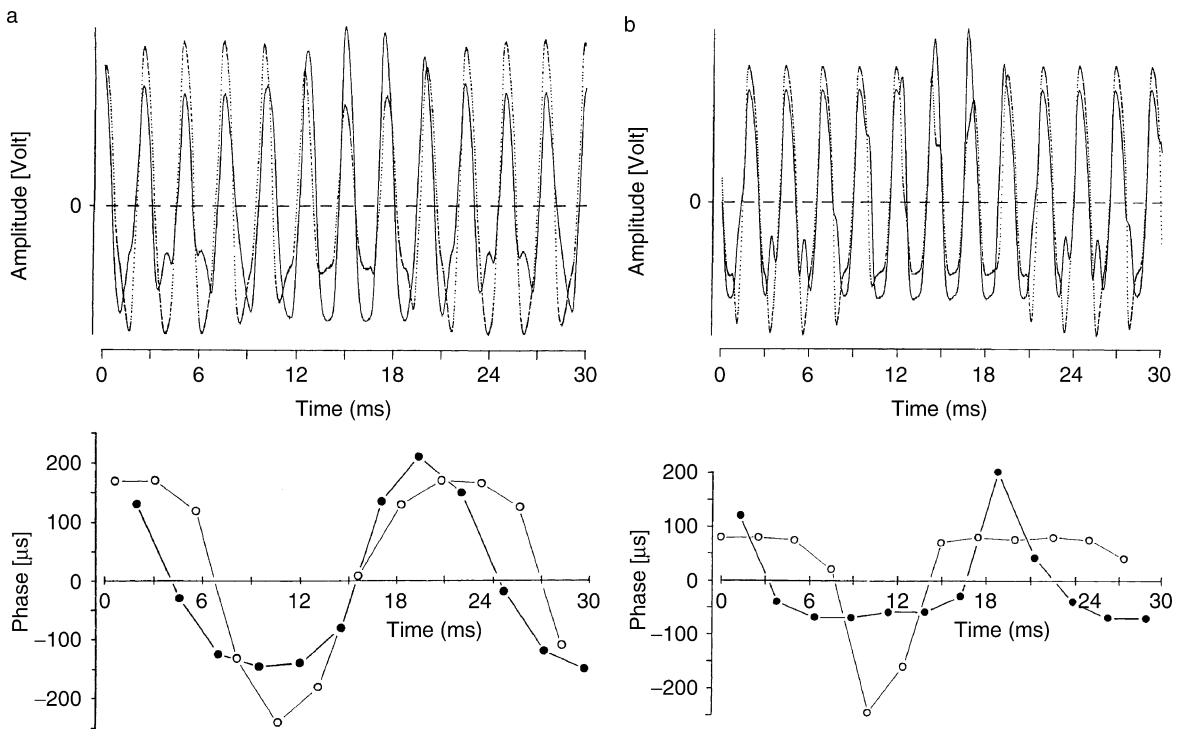
#### *Siluriformes (Catfish)*

Worldwide Occurring Freshwater Fish (Only a Few Marine): The African strong-electric catfish, *Malapterurus electricus*, stuns its prey and deters predators with its powerful discharges, and intraspecific electrocommunication is unknown in this fish (see the entry Electric Organ Discharge). Reports about weak electric potentials recorded from other African catfish (Mochokidae, squeakers, and the sharptooth catfish, *Clarias gariepinus*), suggestive of electric organs and electrocommunication, await confirmation or extension.

#### *Gymnotiformes (Electric Knifefishes)*

Only Found in South American Freshwater Bodies: The electric knifefish comprise perhaps 150 species, all of which seem to be nocturnal. All species known so far are weakly electric, except the electric eel, which is both strong and weakly electric (see entry Electric Organ Discharge). (i) *Pulse type knifefish:* Compared to the more erratically-discharging Mormyridae, pulse type knifefish generate electric organ discharges at either fairly constant (e.g. *Gymnotus carapo*, 35–55 Hz at rest) or even highly constant pulse rates (e.g. *Steatogenys elegans*, ~60 Hz). The former will respond to most kinds of disturbances by electric organ discharge rate changes, and give SIDs during agonistic behavior and attack on prey. Social messages and/or changes of excitation are thus encoded as pulse rate modulations, similar to (if less varied and less specific than) mormyrids. Some species feature sex differences in electric organ discharge waveform [3]. The latter species will change their electric organ discharge rates exclusively to specific electrical stimuli, as occurring in social context. Effective pulse stimuli are of nearly (or exactly) the same rate, especially at specific phase relationships relative to the receiver's discharge cycle. (ii) *Wave type knifefish:* Wave knifefish are probably the most stable biological signal sources. The Sternopygidae (at least 24 species) discharge at about 15–800 Hz, the Apteronotidae (at least 45 species) at about 500–1,800 Hz; a circadian rhythm does not seem to be present (unlike some pulse knifefish). Wave knifefish may signal to conspecifics by electric organ discharge waveform, by frequency modulations, by brief pauses that, especially when repeated, form a social signal, and by phase-locking to another fish's electric organ discharge cycle of identical frequency. As in pulse knifefish, much of the social behavior has yet to be explored. In *Eigenmannia virescens*, age and sex are encoded in electric organ

discharge waveform; the fish even detect a difference in waveform in artificial wave stimuli when spectral amplitude cues are lacking, a feat the human ear cannot repeat for acoustic signals [8]. A wave fish such as *E. virescens* (individual A), detects another wave fish's electric organ discharges (individual B) of slightly different frequency, when B's electric organ discharges rhythmically modulate A's own electric organ discharges in amplitude and phase, that is, when B's electric organ discharges beat against A's electric organ discharges. Fish A analyses such a beat pattern for (i) the frequency difference, including its sign, (ii) the intensity of the spectral component, or harmonic, closest to its own electric organ discharge fundamental, and (iii) waveform of B. If (i) is small in absolute terms, fish A may give a Jamming Avoidance Response, or frequency change, usually increasing the difference from B, in order to improve the resolution or speed of its signal analysis. The strength of JAR increases with (ii), and strongly depends on motivation (age, sex, habituation, hunger, etc.). A trained, food-rewarded fish A is incapable of discriminating between two different stimulus waveforms of its own frequency, B and B', when an electronic frequency clamp is used that is designed to "frustrate" A's attempts of a JAR, by dynamically maintaining frequency identity of the stimulus with A's electric organ discharge. No sooner is the frequency clamp disabled than A (now successfully) performs a JAR and discriminates again. Stimulation experiments with a frequency clamp that, in addition to frequency identity of B with A, also controlled for a dynamically constant phase relationship of the B stimulus to the electric organ discharge cycle of A, showed that beat analysis is a purely temporal sensory mechanism, suggesting the involvement of only one kind of tuberous electroreceptor organs, the T units (Fig. 4).



**Electric Communication and Electrolocation. Figure 4** Stimulus waveform detection by left-right comparison of beats (for the left and right body sides) in a wave gymnotiform, as mediated by its polarity-sensitive T electroreceptor units. (a) female *Eigenmannia virescens'* electric organ discharge (400 Hz) is superimposed by that of a close-by female in A, male in (b) (of both 30% amplitude and 450 Hz). *Top panels* additive superposition of signals (shown as *lines*) for one body side facing, say, the near pole of the stimulus source, subtractive ones facing the other pole (by curved field lines), *dotted* (representing the adequate stimuli for local T electroreceptor organs of the receiving fish's right and left body sides, respectively). One full beat cycle (20 ms) is shown centered. *Bottom panels* time disparities between the zero-crossings of the two curves (of *top panels*) as a function of time. Whether positive- (●) or negative-going (o) zero-crossings are chosen is irrelevant, as the time disparities between both represent the waveforms of the superimposing electric organ discharges in the same way and at greatly reduced speed (similar to using a stroboscope). The only difference is a 180° phase shift relative to the beat cycle. At such a high beat frequency as chosen here for illustration (50 Hz), the waveform reconstruction is rather crude; a more realistic beat frequency of 10 Hz (that is, a beat cycle of 100 ms) yields a fivefold better resolution [8].

The fish's threshold was lowest when the phase-locked stimulus evoked strong phase changes in a fish's electric organ discharge (measured as zero-crossings time shifts, detected by T units) but little amplitude change, and highest when amplitude change was strong (that is, optimal for the more "sloppy" amplitude-coding P units) but phase change minimal. Furthermore, with a free-running, not phase-locked, stimulus the JAR may already be evoked at stimulus detection threshold (that is determined by the sensitive T units), when the relatively insensitive P units are not responding.

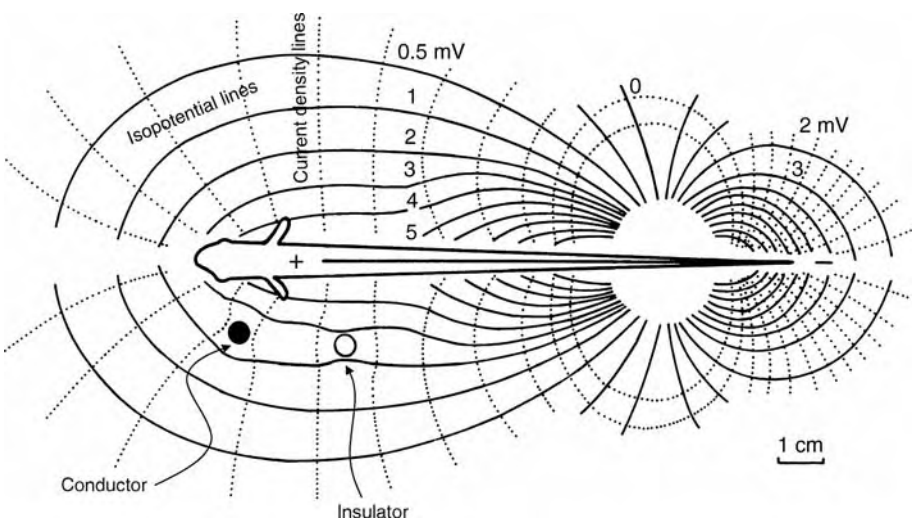
## Electrolocation

### Passive Electrolocation

Ampullary electroreceptor organs detect weak electric fields of extraneous origin in the passive mode. This is true for both the common, primitive (or original) receptor organ type and its secondarily evolved replica that is found in certain teleosts, such as catfish ("small pit organs") and weakly electric fish. Geochemical and electromagnetic fields of sufficient strength to stimulate these receptor organs are found in natural waters; this is also true for the bioelectric fields that emanate from live organism, including prey. The spectral frequency content of these fields is usually low (or even D.C.), corresponding to the properties of ampullary receptor organs (both kinds). Famous examples are sharks that detect the electric fields generated by their prey, such as flatfish buried under sand, using their ampullary electroreceptor organs, the ampullae of Lorenzini. The observed threshold sensitivities and attack distances were 5 nV/cm and 40 cm in marine sharks, and 5 μV/cm at 5 cm distance in freshwater teleosts [9]. Electric fields may also be used for orientation. In the ocean, electric fields are generated by the flow of water through the vertical component of the earth's magnetic field, while in freshwater bodies fields of electrochemical, rather than electromagnetic origin prevail. These environmental fields are potential orientational cues, as indicated by the behavior of trained animals. In the sea, motional-electric fields of up to 500 nV/cm have been measured; they may inform elasmobranch fish about their drift with the water, or provide them with orientational cues during their movements in familiar territory. Captive freshwater fish (catfish and weakly electric fish) have been successfully trained to orient at field strengths of 1 μV/cm.

### Active Electrolocation

Active object detection is an evolutionary feat only present in the Mormyriformes and Gymnotiformes. It is based on a complex sensorimotor system comprising: (i) the generation of a test signal that is broadcast into the environment, the electric organ discharge; (ii) tuberous electroreceptor organs that are co-adapted



**Electric Communication and Electrolocation. Figure 5** Active electrolocation in a weakly electric fish. Horizontal section through the electric field generated by a fish's organ (indicated by *central line* in the fish's body and tail). The dipole field is shown as *lines of equal current density*, or lines of force (*dotted*), which are normal to the *isopotential lines* (solid, with *mV* figures). Note that an insulator (*white circle)* and a conductor (*black circle*) distort the fish's field in opposite ways. The fish "feels" the presence of an object as an increase or a decrease of current intensity that is stimulating its electroreceptor organs next to the object. (The current is, of course, generated by the electric organ discharge.) A conductor pushes away the isopotential lines, increasing their density (or voltage gradient) next to the skin. This causes an increase of current flowing across the skin that is detected by tuberous electroreceptor organs. An insulator does the opposite; it decreases the isopotential line density and therefore current intensity (modified from H. Scheich).

to the spectral properties of the electric organ discharge (usually of much higher frequencies than present in ambient electric fields); and (iii) huge brains with specialized areas and somatotopic maps for complex computations on the sensory feedback (reafference) received from autostimulation. In its function and complexity, this system is comparable to the echolocation, or SONAR, system of many bats; however, the reach of this active electric system is severely limited by physical constraints.

A weakly electric fish detects the presence of an object when it distorts the geometry of the electric dipole field the fish generates with each electric organ discharge (Fig. 5).

Nonconducting objects, such as stones, force the electric current to pass around, whereas conducting objects (such as live organisms) attract the electric current. Therefore, a local decrease of resistivity (relative to the tropical freshwater of high resistivity) causes the current passing through the fish's skin next to the object to increase (for conductors), whereas a local increase in resistivity causes a decrease (for nonconducting objects). The tuberous receptor organs embedded in the skin faithfully reflect these changes in the strength of reafference from autostimulation. Receptor organ position on the fish's body and receptor response pattern are mapped to the brain. In mormyrids, active electrolocation is mediated by tuberous receptor organs termed mormyromasts rather than Knollenorgan, in gymnotiforms, it is probably both types of tuberous electroreceptor organs that are involved (B and M units for pulse fish, T and P units for wave fish). In addition to the resistive impedance properties of an object, an electric fish may also detect its capacitive impedance (if present). As long as they are alive, all organisms have considerable capacitive properties that filter the discharge in phase, waveform and spectral properties, making it thus detectable for the fish [10].

## Synonyms

Electrogenic fish

## Definition

Some fishes possess electric organs who's only known function is the generation of electricity outside their bodies. Strong organs are for defense and stunning prey, weak organs for active electrolocation and electrocommunication in nocturnal species.

## Characteristics

For more detailed reviews, see [1–3]. Any living tissue generates an electric field in its environment. The field is associated with the regulation of the tissue's ionic balance. These fields are D.C. or of low frequency, and, in animals, usually modulated by superimposed field potentials arising from normal nerve and muscle

cell activity. Relative to a distant electrode, potentials measured are up to 0.5 mV in marine species, and a few Millivolt in freshwater teleosts (see entry "►electric communication and electrolocation").

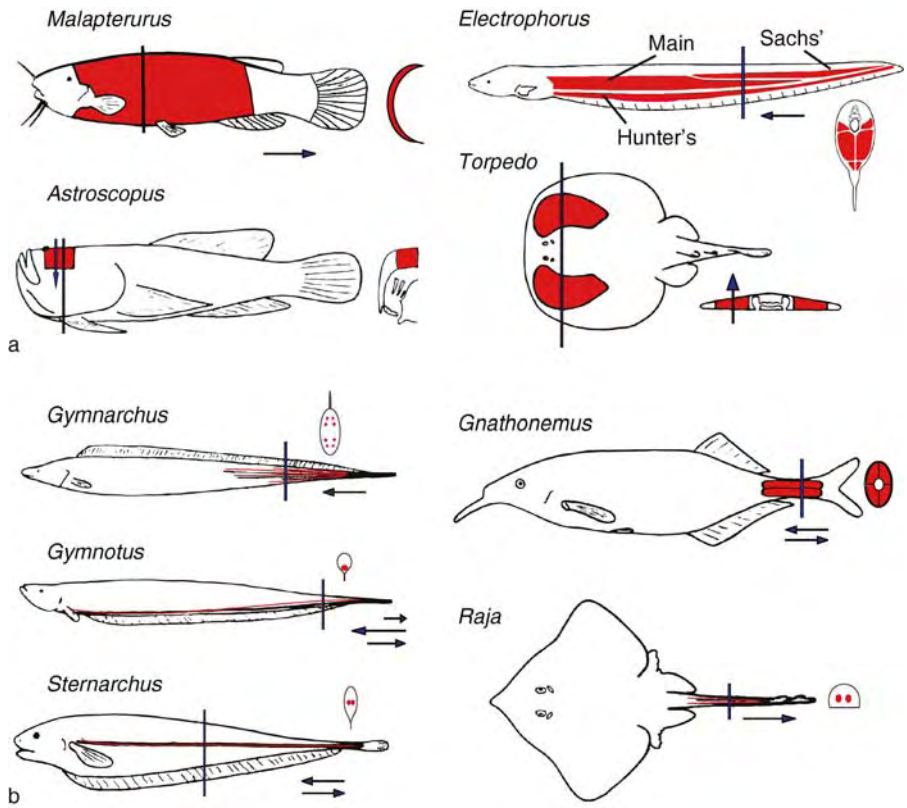
In electric fishes, however, the generation of electricity is of another dimension, both in amplitude and regularity. These fishes' electric organs are anatomically and physiologically specialized to generate electric organ discharges [4]. Electric organ discharges are precisely controlled in waveform, amplitude and frequency; electric organ discharges are species-characteristic and have even been used to tackle systematic and taxonomy problems. The electric organs are under the exclusive control of the brain [4]. The electric fields generated range from very weak (similar to the magnitude of incidental stray fields) to very strong (greater than 500 V).

All electrogenic species, except the stargazers, are also electroreceptive, and carry electroreceptor organs of at least one kind [5].

## Phylogeny

In the whole animal kingdom, it is only among two classes of jawed aquatic vertebrates (Pisces) that we find electrogenic members: the cartilaginous and the bony fishes (Chondrichthyes and Osteichthyes, respectively; Fig. 1).

Within the cartilaginous fishes, only some rays (Batidoidimorpha) have electric organs; these include the weakly electric skates (190 species of Rajidae) and the exclusively marine, strongly electric rays (38 species of Torpedinidae). Among the bony fishes, it is only in four among the many orders and suborders of teleosts that we find electrogenic members. All of these are tropical freshwater fish, with the exception of the marine stargazers (3 species among the perches or Perciformes that are rather "weak" strong electric fish). The electrogenic tropical freshwater fish include the Mormyriformes, the African weakly electric snoutfishes (about 200 species; Fig. 2); the Gymnotiformes,



**Electric Fish. Figure 1** Schematically represented electric fish and their organs. (a) Strongly electric, (b) weakly electric. All are shown from the side except *Torpedo* and *Raja*, which are shown from the top. Electric organs shown by *color*. Cross-sectional plane as indicated by *line*. The *arrows* indicate the direction and sequence of current flows through the organs; the length of these arrows is proportional to the amplitude of the successive phases (if there is more than one). *Raja* and *Torpedo* species are cartilaginous fishes, all other fishes are bony fishes (subdivision teleosts). *Astroscopus,* several species of stargazers, are perches; *Malapterurus electricus*, the electric catfish; *Gnathonemus sp*., a snoutfish, and *Gymnarchus niloticus* are Mormyriforms; *Electrophorus electricus*, the electric eel, *Gymnotus sp.* and *Sternarchus sp.* are all gymnotiforms, or knifefish [modified from [4]; Srivastava, Szabo (1973); Libouban, Szabo, Ellis (1981)].

the South American knifefishes that are all weakly electric except the electric eel with its powerful discharge (perhaps 150 species; Fig. 3); and the Siluriformes or catfishes, only very few, exclusively African members of which are electrogenic (including both strong and – less well confirmed – weak electric representatives).

Electric organs have evolved at least six times independently of each other: two times among the rays, and four times among the teleosts.

By independent evolution, electric organs are a derived group character for both Mormyriformes and Gymnotiformes, that is, present in all members of their group, but not in their respective sister groups (a synapomorphy). Perhaps a similar situation applies for the skates and the electric rays. This is in contrast to the large taxa catfish and perches, only very few members of which are known to posses electric organs. For a taxonomy of Mormyriformes, see [6]; Gymnotiformes, [7]; constantly up-dated is The Catalog of

## Phenotypes

The terms strongly and weakly electric fish delineate alternative adaptations and behavioral strategies, or phenotypes, but do not correspond to phylogenetic categories; there is even one species, the South American electric eel, *Electrophorus electricus*, which is both strongly and weakly electric. "Strong" electric organs are discharged in pulse volleys for brief periods of time only, while attacking prey or during defense; these discharge volleys cause discomfort or pain to a human handling a fish [4]. A particularly strong discharge is that of an attacking or disturbed electric eel which is, according to historical notes from South American natives, capable of "knocking a man down" in its natural environment.

Weak electric organs operate continuously throughout life, and field intensities are usually below detection threshold for non-electroreceptive organisms. Weak electric organs form part of an information system, communication and active electrolocation (see entry "►electric communication and electrolocation"). There are a few intermediate cases, such as the stargazers, whose predatory attack is accompanied by discharge volleys, even though the discharges are much weaker than usual in strongly electric fish; on the other hand, the discharges of *Mormyrus hasselquistii* are unusually strong for a snoutfish, all weakly electric, and can also cause mild discomfort to a human handling this fish.

Among weakly electric, teleost freshwater fish, the Mormyriformes and Gymnotiformes, there are two phenotypes of EOD, wave and pulse, both of which encode social signals as discharge rate modulations.

The pulse EODs of very few species resemble the monopolar time course or waveform of strong discharges; in most weakly electric pulse fish, EOD waveform is bipolar with two or more phases (reducing energy in the low-frequency range of the amplitude spectrum). The wave EODs of wave species are relatively broad pulses that are repeated at such a high and regular rate that they merge into a continuous A.C. wave. While a pulse fish, although discharging continuously, is silent most of the time (because the duration of an EOD is short compared to the inter-EOD interval), a wave fish's signal is always "on" (except on rare occasions, a brief "off" being a display of social significance).

While in Africa the wave discharge type is represented by a single species, *Gymnarchus niloticus*, the only living member of the Gymnarchidae (which is the sister family of the Mormyridae), there are two families of wave fishes in South America, the Sternopygidae, and the still larger family of Apteronotidae (with their neurogenic electric organs). In contrast to Africa, in South America wave species are far more numerous than pulse species.

We are still unable to identify the selection pressures that shaped the ancestors of certain Mormyriformes and Gymnotiformes to discharge their organs either in pulse or in waveform, with only one living species known to date that may represent a transitional state (Fig. 3.18 in [3]). Wave and pulse fishes are found on both continents that are home to the Mormyriformes in Africa, and the Gymnotiformes in South America. The intricate pattern of speciation in the tropics, leading to the highest degree of biodiversity on earth, is a subject of prime interest for which weakly electric fish have proven to be particularly amenable (e.g. [8]).

In contrast to the monopolar EODs of strong-electric fish, the EODs of many weakly electric pulse and (as far as we know) all wave species lack energy in the D.C. and low-frequency range. This seems to be an adaptation to electroreceptive catfish, some of which are voracious, piscivorous predators (see entry "►electric communication and electrolocation"). Catfish are sensitive to low-frequency electric fields by their small pit organs (that are functionally equivalent to ampullary electroreceptor organs and often referred to by that name).

## Embryology of Electric Organs

Electric organs usually form from modified muscle cells, or electrocytes, which are unable to contract but are still capable of generating action potentials that are often unusually large [9]. In different species, electric organs are derived from the most diverse muscles and thus can be found almost anywhere in a fish's body. For example, in the mainly marine skates, the organs are located in a slender tail filament, while the strong electric organs of rays form part of the head region of their flattened, disc-shaped bodies ("pectoral" position; Fig. 1).

In the snoutfishes (Mormyriformes), two possible locations of electric organs are found: (i) a rather long and massive electric organ located posteriorly in the body trunk that arises from several columns of axial muscle (up to a third of a fish's length). This has been established in larval specimens for a few species of the family Mormyridae, and such a larval organ grows into the adult organ in the only representative of the Gymnarchidae, *Gymnarchus niloticus*. (ii) In the mormyrid species studied so far, the larval organ starts to degenerate when about 50 days old; while a compact adult organ starts to operate (simultaneous operation of the two organs for a short transition period). The adult organ is located more posteriorly in the caudal peduncle of the tail fin [10].

In the strongly electric catfish *Malapterurus electricus* from African freshwater bodies (the best-known among several, only recently discovered, new species), the electric organ forms from peripheral muscle cells (apparently pectoral), enclosing the body as a tight jacket. In a few members of small catfish, the squeakers (Mochokidae), an organ located dorsal to the swim bladder that may have formed from sonic muscles has been reported to generate very weak and irregular electricity.

In most South American knifefishes (Gymnotiformes), the electric organ forms from several columns of axial muscle. The organ is very long, running from the tip of the tail to near the pectoral fins. Many gymnotiforms have accessory electric organs, the function of which is unclear. In one gymnotiform family, the Apteronotidae, the electric organ forms from presynaptic endings of spinal motor nerves, even though larvae form a temporary organ of myogenic origin that degenerates early in life.

The dipole fields generated by electric organs are usually horizontally orientated, in a fish's long axis; so is the orientation of the electric organ. In a few cases, however, the field vector (that is, current flow) is vertically orientated; the same holds true for these fishes' electric organs. In the strongly electric rays and the stargazers, this is in agreement with these fishes' vertically directed prey capture behavior.

## Impedance Matching

Electric organs consist of closely packed, orderly arranged groups of cells, electrocytes, with each electrocyte innervated separately by a spinal electromotor neuron. As the whole organ is enclosed by a tight jacket of connective tissue, there are only little shunt currents, and the voltage differences generated by the individual electrocytes add up (like in a serial arrangement of batteries). The electric current generated by the organ is channeled such that it must leave the body in order to

return to the opposite pole of the source. This is important in freshwater fish with water conductivity far below the conductivity of body fluids (usually below 100 µS/cm for tropical freshwaters vs. 5,000 µS/cm for body fluids, or, in resistivity terms, 10 kOhm × cm vs. 200 Ohm × cm, respectively) [4].

In strongly electric fish, impedance matching to the surrounding water is especially obvious, both on a gross morphological level and also regarding membrane physiology. In freshwater fish, such as the South American strongly electric eel, there are only about 70 columns arranged in parallel, consisting of about 6,000 electrocytes each. Therefore, in this fish, it is the voltage that is maximized (500 V or more). In a marine environment, this would not be possible; here, it is the current that should be maximized. Accordingly, in the strong electric rays, such as the *Torpedo* species, there are many relatively short columns arranged in parallel, yielding a low-voltage strong-current output. The number of columns is 500–1,000, the number of electrocytes per column about 1,000. The discharge amplitude is only 50 V in air, corresponding to a massive power output of greater than 1 kW at the peak of the pulse. For an unknown reason, marine electric fish generate (unusually large) postsynaptic potentials (PSPs) rather than muscle action potentials.

# Electric Organ

## Definition

So far only electric fishes are known to possess electric organs. In most cases myogenic organs generate electric fields. Some fishes, like the electric eel, use strong fields for prey catching or to ward off predators, while others use weak fields for electrolocation and communication.

Specialized organs in electrosensitive fishes – mostly derived from muscle tissue – that give off electrical discharges, both pulse-like and sinusoidal, under the control of the nervous system.

# Electric Organ Discharge

Bernd Kramer
University of Regensburg, Institute of Zoology, Regensburg, Germany

## Synonyms

EOD; organ discharge

## Definition

Certain fish possess an electric organ that, on brain command, generates a three-dimensional electric dipole field around their bodies. Compared to incidental stray fields as measured close to any organism [1], an electric organ discharge (EOD) is characterized by a stronger amplitude, higher temporal and spatial stability, and a

species-specific orientation that is adapted to its function.

## Characteristics

### Quantitative Description

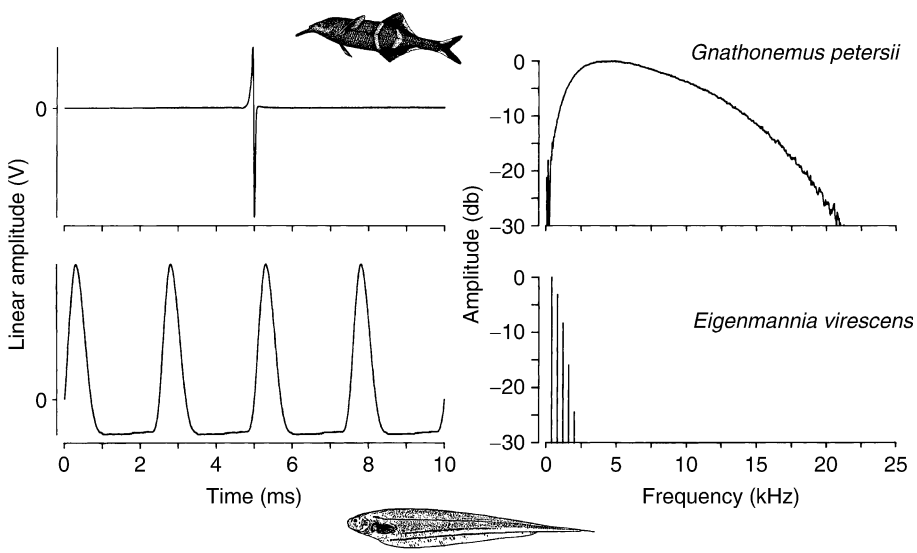
Strongly electric fish all generate monopolar (D.C.) pulses. They are head-positive or head-negative in horizontally attacking fish, and dorsal-negative or dorsal-positive in vertically attacking fish. The time course of an individual EOD pulse is that of a muscle action potential, or of a postsynaptic potential (PSP) in the marine skates, rays, and stargazers (skates possess only weak organs). For the human touching a fish, perceived amplitudes range from mild discomfort associated with the EODs of the weakest strong-electric fish, the marine stargazers (up to 5 V with its dorsal surface in air), to intense pain caused by, for example, the electric catfish's (►*Malapterurus electricus*) or the electric eel's EODs (►*Electrophorus electricus*; several hundred Volts).

There are two phenotypes of weakly electric freshwater fish (Mormyriformes, Gymnotiformes), pulse and wave species (Fig. 1).

Played through a loudspeaker, wave EODs sound tonal and are termed "hummers," whereas pulse species are sometimes termed "buzzers." In wave EODs, pulse duration and the inter-pulse interval are of about the same length, and merge into a constant-frequency wave. Frequencies range from about 50 to about 1,800 Hz. The amplitude spectrum of a wave EOD, such as that of ►*Eigenmannia virescens,* shows a few discrete frequency lines only where all the energy is concentrated. These frequencies are the fundamental frequency (which is the repetition frequency of the discharge "pulse," or of a single signal period), and the higher harmonics which are integer multiples of the fundamental.

Pulse EODs are single-cycle clicks repeated at rates from below 1 to about 65 Hz at rest. Pulse discharges are separated by pauses that are long (and often variable) compared to the duration of an EOD. The amplitude spectrum of a single pulse shows energy over a broad and continuous frequency range with a flat peak region; that is, the signal is broadband. Frequencies of peak amplitude are usually below 10 kHz (but may be as high as 25 kHz). For intraspecific and interspecific waveform or frequency differences see the entry "electric communication and electrolocation."

Wave EODs represent a continuous drain of energy for the sender; there are no strong-electric wave fish. Compared with most wave EODs, pulse EODs are of lower repetition rate and stronger amplitude. Pulse EODs may be detected over a greater distance because of their usually stronger amplitude. This would be an advantage for both communication and active electrolocation. However, wave EODs compensate for being weak by strongly contrasting from background noise by their harmonic structure. There is no or little D.C. component to the EOD of wave fishes (only a few studied), unlike that of many pulse species, making them less prone to detection by certain predators [2,3,4].



**Electric Organ Discharge. Figure 1** Pulse and wave discharges. *Left* Oscillograms of EODs (head-positivity is upwards); *right* amplitude spectra with the amplitudes expressed as dB attenuation relative to the strongest spectral component. Same time and frequency axes. Pulse EODs, such as that of the African snoutfish *Gnathonemus petersii*, are short and broad-band; they are repeated at highly variable rates. The wave EOD of the South American knifefish *Eigenmannia virescens* is of constant frequency and harmonically structured.

## Higher Level Structures

As two spike-generating membranes arranged in series with each other tend to desynchronize each other's activity, each electrocyte must be innervated separately to receive the central command synchronously [2]. The electric catfish probably has the simplest command system for controlling its electric organ. It consists of only two giant electromotoneurons (>100 µm diameter) in the first spinal segment, one on either side. Both cells are closely coupled electrotonically by presynaptic fibres, and behave functionally as a unit. Each giant cell innervates the millions of electrocytes on its side of the body.

In gymnotiforms, the command system has four levels from peripheral to central: spinal electromotoneurons, medullary relay cells, medullary pacemaker cells, and mesencephalic prepacemaker cells. Pacemaker and relay cells either form two separate, but closely adjacent, midline nuclei (for example, in a ►*Hypopomus* pulse fish species), or are intermingled in a single nucleus, as in an *Eigenmannia* wave species [5].

Depending on the species, there are some 30–200 pacemaker cells activating about 50 large relay cells in gymnotiforms, and they project to hundreds or thousands of spinal electromotoneurons. In all gymnotiforms, except apteronotids, electromotoneurons innervate a number of electrocytes. In apteronotids, the electromotoneurons themselves generate the discharge. The connection of the command system to electroreceptive afferences is by the nucleus electrosensorius rostral from and connecting to the prepacemaker nucleus, which have been shown to modulate the pacemaker firing frequency.

At each level of the gymnotiform command system a single spike occurs for each organ discharge. However, in wave gymnotiforms the electromotor neurons have been observed continuing to firing at a similar frequency after completely cutting their input from relay cells by spinal section. Ringing seems to be an intrinsic property of all parts of the command system in these fish (and has even been observed in electroreceptor organs), and may somehow be necessary for generating the most stable biological rhythm, the wave discharge.

In mormyrids, the electromotoneurons that innervate the electrocytes of the organ form a nucleus in the caudal spinal cord [2,6]. They are driven by the cells of a medullary relay nucleus, a single midline structure, by chemical synapses. Electromotoneurons and relay neurons are coupled together electrically amongst each other. The medullary relay cells fire in "doublets" that evoke a triplet of spikes in the electromotoneurons. The three spikes are propagated out to the electrocyte stalk, where the first spike causes a small PSP, the second spike a greatly facilitated PSP, and the third spike reaches threshold. Thus, each volley of three spikes (about 1 ms apart) evokes only a single discharge. The triplet can be recorded externally.

The pacemaker nucleus is a midline structure of 16–20 relatively small neurons located just ventrally to the medullary relay nucleus. The cells are functionally coupled by gap junctions. In contrast to the cells of the relay nucleus, their dendrites extend far beyond the confines of the nucleus, into the surrounding reticular formation and longitudinally running fibre tracts, where they are presumably contacted by the most diverse sources. It is probably these afferent inputs that mediate the effect of virtually any kind of sensory input on a mormyrid's discharge rate.

Command-associated corollary discharges "inform" afferent brain areas, such as the ELL (electrosensory lateral line lobe), of a reafference to be expected from the fish's own electroreceptor organs that is evoked by the fish's own EOD [7]. The corollary discharges greatly facilitate the task of separating reafferences from exafferences, by blanking "unwanted" sensory input. Reafferences to a fish's own EODs are the adequate response from mormyromast electroreceptor organs (in active electrolocation), and exafferences are the adequate response from the Knollenorgan, to another fish's EODs (in communication). Therefore, mormyromast afferences are facilitated when coincident with a corollary discharge, but blanked when not. For sensory feedback from Knollenorgans, the reversed situation holds: reafferences are blanked, and exafferences are facilitated.

## Lower Level Components

Electric organs are derived from muscle tissue (nerve terminals in Apteronotidae), although different muscle groups are involved in different taxa. These muscle cells are unusual in that they do not twitch when neurally excited by transmitter substance (acetylcholine); various anomalies have been found in different groups that may explain why in electric organs the electromechanical coupling does not work.

Often these muscle cells, or electrocytes, form short cylinders and are stacked in series, an arrangement that increases the voltage. Several such columns in parallel increase the current, and are enclosed by a tight jacket of connective tissue. There is also connective tissue inside the columns, as well as blood vessels and nerve fibres. In general, the columns are orientated rostro-caudally, as is the potential difference and the direction of internal current flow. In the bottom-dwelling stargazers and the electric rays, the columns are orientated vertically (dorso-ventrally), in accordance with their upwards directed attacks on prey fish [review 4].

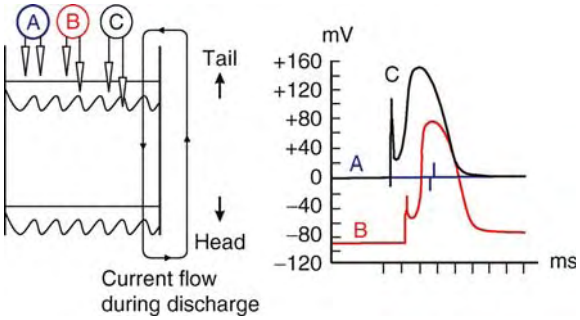
In contrast to all other electric fish, the apteronotids (Gymnotiformes) have neurogenic electric organs; their presynaptic nerve fibres have lost their contact with muscle cells and form the organ (larval apteronotids

have a temporary organ of myogenic origin; [8]). Apteronotids are outstanding for their very high discharge frequencies, up to 1,800 Hz in certain species. No ordinary nerve or muscle tissue comes close to even half that rate (at least not in sustained activity), and the explanation may reside, in part, in a command pathway with exclusively electrotonic synapses, and the specialized anatomy and physiology of the electric organ.

The ionic mechanisms of electrocyte membranes differ widely among species; these differences are the main source of the wide variation of organ discharge waveforms and frequencies among species [2,5]. The mechanism of the electric eel's discharge was the first to be elucidated (Fig. 2).

The electrocytes are innervated on their posterior face by spinal nerves that contact the cell primarily on short stalks. The anterior faces are uninnervated and have an increased surface area by a large number of papilli. The innervated face responds to depolarization by an overshooting spike of unusual amplitude (150 mV). The uninnervated face of very low resistance is unexcitable (0.2 $\Omega \cdot cm^2$ as compared with 19 $\Omega \cdot cm^2$ for the innervated face, and about 3000 $\Omega \cdot cm^2$ for frog twitch muscle). The two faces of the electrocyte are thus fairly matched in impedance, still more so when the innervated face becomes excited (and its resistance declines). This is clearly an organ adapted to maximum power output, because the circuit for all the $Na^+$ inward current of a cell is completed by the external environment, and not by local opposing currents [2].

In contrast to freshwater fish, marine strong-electric fish, including the stargazer, generate exceptionally large PSPs (of up to 90 mV amplitude) instead of spikes. Their membranes can only be excited neurochemically, not by depolarisation. The advantage of a PSP- over a spike-generating membrane in the marine environment is unknown.



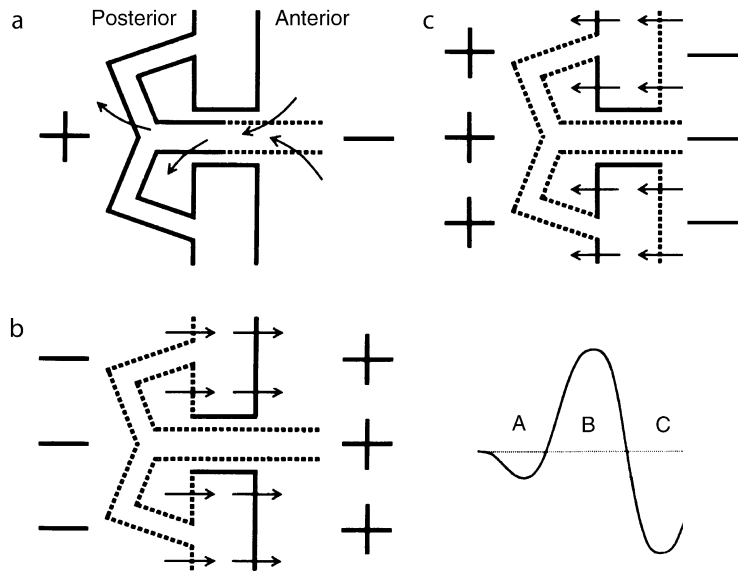
**Electric Organ Discharge. Figure 2** The mechanism of the electric eel's discharge. (A) A pair of recording electrodes external to the innervated face of an electrocyte records no response to a brief stimulus (*blue*; note a small, diphasic stimulus artifact). (B) One electrode is advanced into the cell. The inside negative resting potential of about 90 mV and an overshooting action potential of about 140 mV are recorded (*red*). (C) When the exploring electrode is advanced to outside the uninnervated face, the resting potential disappears, but the spike is essentially unchanged [after Keynes & Martins-Ferreira 1953, modified B. Markowski].

Most weakly electric freshwater fishes tend to have little or no D.C. associated with their discharges, which allows them to have a more effectively dual electrosensory system: one for low-frequency voltages of primarily external origin, and another for monitoring the higher-frequency organ discharges. The wave fish ►*Gymnarchus niloticus* (perhaps also *Eigenmannia* species) achieves an organ discharge free from D.C. by modification of one electrocyte face (the uninnervated one) to pass current only capacitatively. This face has a large capacitance and a high resistance and is unexcitable [2]. Essentially, diphasic pulse fish, such as some *Hypopomus* species, *Gymnotus carapo*, and most mormyrids, have the opposed faces of their electrocytes act in sequence to achieve a similar effect. The uninnervated face is electrically excited to generate a spike that is slightly delayed compared to the spike of the innervated face. The net result is a diphasic potential, because the currents flow in opposite directions (with some cancellation in the shorter discharges).

In contrast to mormyrids, many gymnotiforms (excepting the sternopygids) have more than one organ, which are either anatomically distinct (as in the eel, and certain hypopomids and apteronotids that carry rostral accessory organs), or functionally heterogeneous (as in *G. carapo* where the dorsal portion of the organ is fired ½ ms early; in addition with reversed polarity because of its reversed pattern of innervation). This complexity is reflected in additional phases or inflexions to the basically diphasic discharge waveform, and additional deviations from the geometry of a dipole source at close range, making them species- or even individually specific signatures.

Mormyrids have more or less elaborate stalks of the innervated face of the electrocytes. The simplest (probably primitive) stage is that of ►*Mormyrus rume*, with multiple innervations on fine and numerous stalks. In species with shorter discharges, the number of innervation sites is reduced to the final limit of one, suggesting that more precise synchronization can be achieved with fewer innervation sites. Synchronization is especially important in these bi- or triphasic discharges, because slight out-of-phase firing would lead to cancellation. The stalks may, in certain species, penetrate the electrocyte and find their nerve on the "wrong", usually the anterior, side of the cell, and this shows up in the overall organ discharge by an initial, weak head-negative potential in addition to the diphasic "main" discharge (Fig. 3).

In a few species, the stalks penetrate the cell twice so they contact their nerve on the "correct" side of the cell



**Electric Organ Discharge. Figure 3** Schematic explanation of a diphasic electric organ discharge (EOD) of a mormyrid, which in certain species is preceded by a smaller prepotential (*A* in EOD diagram, *lower right*). *Arrows* show direction of current flow; active membranes are indicated by *dotted outlines* in order to show which stage in the excitation sequence (a, b, c) corresponds to which phase in the EOD waveform. A head-negative prepotential (*A*) is present when electrocyte stalks (formed by the posterior face) penetrate the electrocyte to contact the motor nerve from the "wrong" anterior face (such as here). The stalk potential invades the caudal face of the electrocyte, giving rise to the head-positive main phase of an EOD (*B*). The associated current flow through the electrocyte (b) triggers an action potential of the opposite, uninnervated cell face (c), giving rise to the head-negative main phase of an EOD (*C*). Evolving a bipolar EOD reduces the D.C. component detectable to catfish predators. The cost of a bipolar EOD is a loss of amplitude, especially in the many species that terminate the *B* phase early by fast triggering of C [2].

(usually the posterior one, just like in species with non-penetrating stalks). Some species have a combination of penetrating with non-penetrating stalks [2,3,9].

In some species such as *Pollimyrus adspersus* and *P. isidori*, the relatively long-lasting head-positive potential generated by the posterior face is split into two by an overriding, strong and brief spike of opposite polarity generated by the anterior face. Microsecond-timing of the second potential relative to the first is critical for the overall waveform within a relatively wide intraspecific variability (see "electric communication and electrolocation").

## Structural Regulation

Impedance matching is clearly seen in marine and freshwater strongly electric fish, with both adapted to most efficient shocking in their respective environments. The marine species have flattened organs with many columns in parallel (500–1,000 columns, each with about 1,000 cells in series in ▶*Torpedo* rays; 150–200 in the stargazer). Their organs generate a low-voltage strong-current output as is adequate for their conductive medium; for marine rays, 50 V measured in air, but >1 kW at the peak of a 5-ms pulse. In contrast, electric organs of freshwater species (teleosts) are often long, generating a high-voltage, low-current field (>500 V), as indeed they must in a medium of high resistivity. The eel has about 6,000 electrocytes in series, and dorsoventrally about 35 (bilaterally) in parallel [2,3,9].

## Higher Level Processes

For the ionic mechanisms of firing rate in a pacemaker nucleus, see [5]. In wave gymnotiforms, androgen hormones affected the discharge frequency [5].

## Lower Level Processes

There are clear effects of androgen hormones on EOD waveform when administered to mormyrids, especially females that usually respond by increasing their pulse duration [3,9,10].

## Process Regulation

A sudden, strong decrease of water conductivity may cause complete or partial loss of a mormyrid's head-negative EOD main phase (that is electrically evoked). The waveform is restored after a period of about two days, supposedly by the synthesis of additional ion channels [4,5].

## Function

*Electric communication and Electrolocation*: see the special entry on these topics.

*Prey capture and defence*. Strong-electric fish discharge for prey capture, defence, or related functions. Volleys of monopolar pulses lead to more effective shocking, irrespective of polarity. There is little or no evidence for an intraspecific communication or active electrolocation function in these fish; however, the negative evidence is compelling only in the non-electroreceptive stargazers.

*Torpedo marmorata* (electric ray). A ray is an ambush predator with a flattened, disc-shaped body with short tail that is usually buried under sand, with only its eyes and spiracles visible. A ray will start its predatory attack, accompanied by its deadly discharge volley, whenever a fish comes sufficiently close to the front rim of its body. Within half a second, the ray lifts itself up on its pectoral fins, jumping up and forward, landing on top of its prey in a successful attack. By rocking movements involving its tail, the ray tries to seize the head of its prey with its mouth and to swallow it; this takes from 7–24 s.

The electric organ is fired 80 ms after the onset of a ray's jumping attack. The duration of the discharge volley varies between 0.1 s (when the prey escaped) to 24 s, corresponding to 20–340 EODs. The discharge rate is high and stable up to the moment of landing (140–290 Hz); afterwards, when the ray tries to seize the prey with its mouth, the pulse rate is low and unstable (<10 Hz after 3 s of discharging).

The effect of a ray's electric discharge is quite devastating. Fish were partially immobilised, slowly turned black on one or both body sides, or had a broken spinal cord. Fish that closely managed to escape died one or a few days after. This is astonishing since the current density, as measured in seawater, was not particularly high (30 mA/cm$^2$, at 15 V). Stimuli that effectively evoked an attack were touch and water current or pressure waves from objects passing by, at a distance not greater than ½ the diameter of a ray's disc.

*Malapterurus electricus* (electric catfish).This species of electric catfish is a large, strong-electric predator of up to 1.2 m (there are several new members of the genus in African freshwaters). Its head-negative EOD of 1.3 ms duration at 28°C is evoked by mechanical and gustatory stimuli. In an attack on prey, a feeding volley may be up to 562 EODs at 300 Hz; still longer volleys of still higher frequency were observed when defending itself against a superior predator (such as a conspecific or a *Clarias* catfish of bigger size). A surgically denervated catfish unable to discharge had a drastically lowered success rate in prey capture.

*Electrophorus electricus* (electric eel). The electric eel is the only South American knifefish having both a weak and a strong discharge. There is evidence that the eel may prey largely on other gymnotiforms; unlike the electric catfish, the eel possesses, in addition, the high-frequency electroreceptor organs required for detecting many species' EODs. When roaming around its territory at night, it discharges its weak Sachs' organ at a very low rate (around 1/s or even below). The weak discharge may aid the fish in detecting obstacles etc. by active electrolocation, and warn other eels at a distance. Upon mechanical disturbance of any kind, including surface water waves when sufficiently close, or else a fellow gymnotiform's EOD, the eel strikes at the object with its wide and strong mouth. Concomitantly with an overt attack, the eel turns on its strong discharge (generated by the main organ, assisted by two weaker organs) at a very high rate (500 Hz or more) [2,3,4].

## Pathology

Very rarely, certain mormyrid specimens showed EOD waveforms that appeared totally deviant compared with all other specimens ever seen before or thereafter (e.g., *Brienomyrus niger*). An ontogenetic anomaly, or an imperfect regeneration after a predator's attack, are possible reasons for this malfunction. Electroreceptive predators of weakly electric fish are common in both South America (e.g., the electric eel and certain apteronotids) and Africa (several species of non-electrogenic catfish, such as *Clarias gariepinus;* the mormyriform *Gymnarchus niloticus;* the electric catfish). Especially in certain gymnotiforms, specimens sampled from their habitat quite commonly had regenerated or malformed tails.

Immediately after transfer into water of very low conductivity (such as 10 µS/cm, as found in certain tropical forest streams), very rarely certain mormyrid specimens tended to display EOD triplets, rather than one single strong discharge, per command (e.g., *G. petersii*). A propensity for EOD triplets has also been observed in one *Marcusenius macrolepidotus* individual even without conductivity stress.

## Definition

The Australian platypus, *Ornithorhynchus anatinus*, and the two species of spine covered echidnas, *Tachyglossus aculeatus* and *Zaglossus brujnii*, are the only surviving species of ►monotremes. Among the three tribes of extant mammals, monotreme, marsupial and placental mammals, monotremes are the most primitive and limited to Eastern Australia, Tasmania, and New Guinea.

Since little is known about the role and function of the electric sense in echidnas this article focuses mainly on the platypus. The nocturnally diving platypus subsists entirely on live food caught during nightly dives in lakes and streams. With eyes, nostrils, and ear canals closed underwater, its ability to locate and catch mobile prey like crayfish, shrimp, and small fish is unlikely to depend exclusively on the remaining tactile sense of the bill which has long been known to be covered with mechanoreceptor organs. Behavioral experiments have shown that the platypus can detect weak electric fields. It locates small living objects and avoids large obstacles provided they generate such fields. The legendary sixth sense of the platypus was shown to be electrical. Several lines of evidence suggest that electroreception in monotremes has evolved independently from the corresponding senses in fishes and amphibians.

## Characteristics

The platypus with a body length of about 45 cm is characterized by short legs, a flat tail, a dense fur with remnants of reptile scales, a duck-like bill of 15 cm length, small eyes, and a lack of pinnae. The male is slightly larger than the female. Aspects of its scull as well as its brain are reminiscent of those of reptiles. Its broad paws have five toes with sharp claws. A single poisonous hollow spur is exposed on the hind feet of the male. The urinal and genital tracts and rectum have a common opening (cloaca). Another unusual reptile-like characteristic of monotremes is that the platypus lays 2–3 eggs of about 2 cm. Embryos of 2.5 cm length hatch after a week, and are blind and nude. Their teeth are replaced by horn plates at a later stage of development. The platypus as well as the echidna are not endangered species, as their only natural enemies are snakes, crocodiles, marsupial foxes, and probably in former times the Tasmanian wolf.

The platypus lives in a self-made burrow, always near fresh water, which may be extremely long (10–20 m) and has its openings slightly above water level. It has adapted to catch small animals in water and roams about creeks and rivers in Eastern Australia and Tasmania. At dawn the animal swims and dives and then may stay under water for 5 min. It uses skin folds to close its eyes, ears, and nostrils, and relies totally on its somatosensory and electrical senses to feed on live prey, including several species of grubs, worms, decapod crustaceans, frogs, and small fishes. Typically the animal shows reflex-like head jerks when encountering transient electric fields in the millivolt range which may be generated by its prey.

## Quantitative Description

### *Description of Structures, Processes, and Conditions*

As recently as 1986 a German–Australian team of biologists from the Universities of Darmstadt and Canberra discovered that the large bill of the platypus is not only a

mechanoreceptive feeding device, but also a highly sensitive electroreceptive organ [1]. The animal makes use of direct (d.c.) and alternating (a.c.) current fields in object location and avoidance. In a manner comparable to that of electro-sensitive fishes and amphibians, the platypus may use electric fields generated by live animals to find its food. The tail flicks of a local freshwater shrimp (*Macrobrachium australiense*), were found to be associated with compound muscle potentials that amount to 0.2–1 mV/cm at a distance of 5 cm. These potentials are well above the behavioral threshold of the platypus. Since a tail flick yields only a few centimeters of escape distance, the potentials are meaningful stimuli to guide prey catching. These myogenic alternating currents can lead the animal while it is probing blindly in the mud or among stones. The animal catches prey amounting to half its body weight during one day. When diving, a platypus usually performs 2–3 undulatory sweeps per second with its bill in parallel to the bottom. This "patrol phase" changes into a "search phase" when the bill contacts interesting objects or detects traces of food smell in the water (presumably mediated by the large ►vomero-nasal organ) and weak electric dipole fields. The search phase consists of erratic movements of the bill allowing the animal to home-in on a prey object. The sequence may be completed by an "attack phase" in which the object of interest is seized with rapid snaps of the bill.

The first evidence for an electrical sense in the platypus was the observation of a change from the patrol to the search phase of a diving platypus when in the vicinity of a small battery placed on the bottom of a pool [1]. Subsequently, animals could be easily trained to actively search for batteries baited with dead freshwater shrimp (Fig. 1).

More evidence came when electric fields generated by electrodes in the water were switched on, which elicited reflex movements of the heads and tails of the animals. Threshold values, when the animals were approximately in the centre of a homogeneous field, could be as low as 50 μV/cm (equivalent to 4 nA/cm²). Animals learned to avoid invisible plastic plates that had carbon electrodes attached at their ends. They made a detour around the plates at distances corresponding to a d.c. field gradient of <200 μV/cm, but regularly bumped into the plate when the field was switched off. There is still an unexplained discrepancy between these extremely low behavioral sensitivities and the threshold of individual ►electroreceptors, which is around 1 mV/cm [2].

The electrical sense in the echidna, or spiny anteater (*Tachyglossus aculeatus*), which together with the platypus belongs to the monotreme group, is the first and only example of electroreception in a purely terrestrial animal. Responses of dissected filaments of the trigeminal nerve to focal, low-voltage stimuli applied to the moist skin surface showed that the echidna has electroreceptors, and that receptive fields are restricted to small spots at the tip of the snout [2]. The skin is covered with large mucus-secreting glands similar to the ones in platypus. Trained animals discriminated between water-filled troughs with weak electric fields across them down to field strengths of 1.8 mV/cm, corresponding to the electro-physiological thresholds of the most sensitive receptors. A continuous nasal secretion always keeps the tip of the snout wet and may provide a low electrical resistance even under dry conditions. However, the behavioral significance of the electric sense in the echidna in its normal habitat remains largely speculative.

### Higher-Level Structures, Processes, and Conditions

Evoked cortical potentials in a platypus obtained with electrical stimulation of the bill had a threshold below 100 μV/cm [1]. They revealed an electrosensory cortical field representing the contralateral bill about 5 mm ventral to the auditory cortical field [3]. Besides electric potentials mechanical waves traveling through the water from moving prey are detected by the bill which is densely covered with mechanoreceptors. Information from electroreceptors and mechanoreceptors probably converges in the same cortical field, as all electroreceptive neurons seem to receive mechanoreceptive input as well [4]. Behavioral and physiological experiments support the hypothesis that the platypus may be able to determine its distance from a target, by the difference in arrival times of electrical signals and mechanical waves produced by the prey [5]. It has been proposed that this is achieved by interfacing mechanosensory and electrosensory inputs in a type of cortical organization of alternating columns resembling the ocular ►dominance columns of primates [6]. A columnar organization was already demonstrated by means of cortical mapping of electrical stimuli applied dorsoventrally across the left side of the bill in a ►2-deoxy-glucose (2DG) experiment [7]. The experiment revealed a large cortical map with the strongest contralateral stripe-like labeling having an extension of about 6–8 mm with inter-columnar distances of 1–2 mm (Fig. 2).

These columns actually do resemble the ocular dominance columns of some visual cortices. The strongly labeled contralateral columns are separated by gaps which spatially seem to fit into most of the weakly labeled columns in the ipsilateral hemisphere. Thus adjacent columns may integrate information from corresponding areas of the two sides of the bill. This would be compatible with the hypothesis that information about the distance from a source is available from the pattern of field decay across the bill [8]. The field decay should be identical for both sides of the bill when the electrical source is located directly ahead, a situation comparable to binocular processing. As cortical neurons were found to be bimodal [4], electroreceptive and mechanoreceptive input should be localized in the same cortical columns.

The dominance columns representing the spatial disparities of receptors across the surface bill together with the bimodal input within columns may indeed be the powerful tool used by the platypus to localize its underwater prey in three dimensions. The electroreceptors on the bill are organized as a directional antenna which is suitable for determining the azimuth and elevation of an electrical field source and enables the animal to generate accurate head saccades toward the prey [9].

### Lower Level Components

Already before the discovery of its electrosensory function the bill of the platypus was known to be covered with dense arrays of unusual receptor organs dissimilar to its numerous mechanoreceptors [10]. In electron microscope studies they were described as gland duct receptors of unknown function. These receptors are unique to the platypus but do also occur in echidnas in simpler form. Two kinds of gland duct receptors may be recognized from their morphology as potential electroreceptors because the association of skin pores with serous and mucous glands enables electric current to reach the trigeminal nerve endings. The approximately 40,000 mucous gland type electroreceptors of the platypus are arrayed in parasagittal rows on the surface of its bill, but also on the inner surfaces of its mandibles [5].

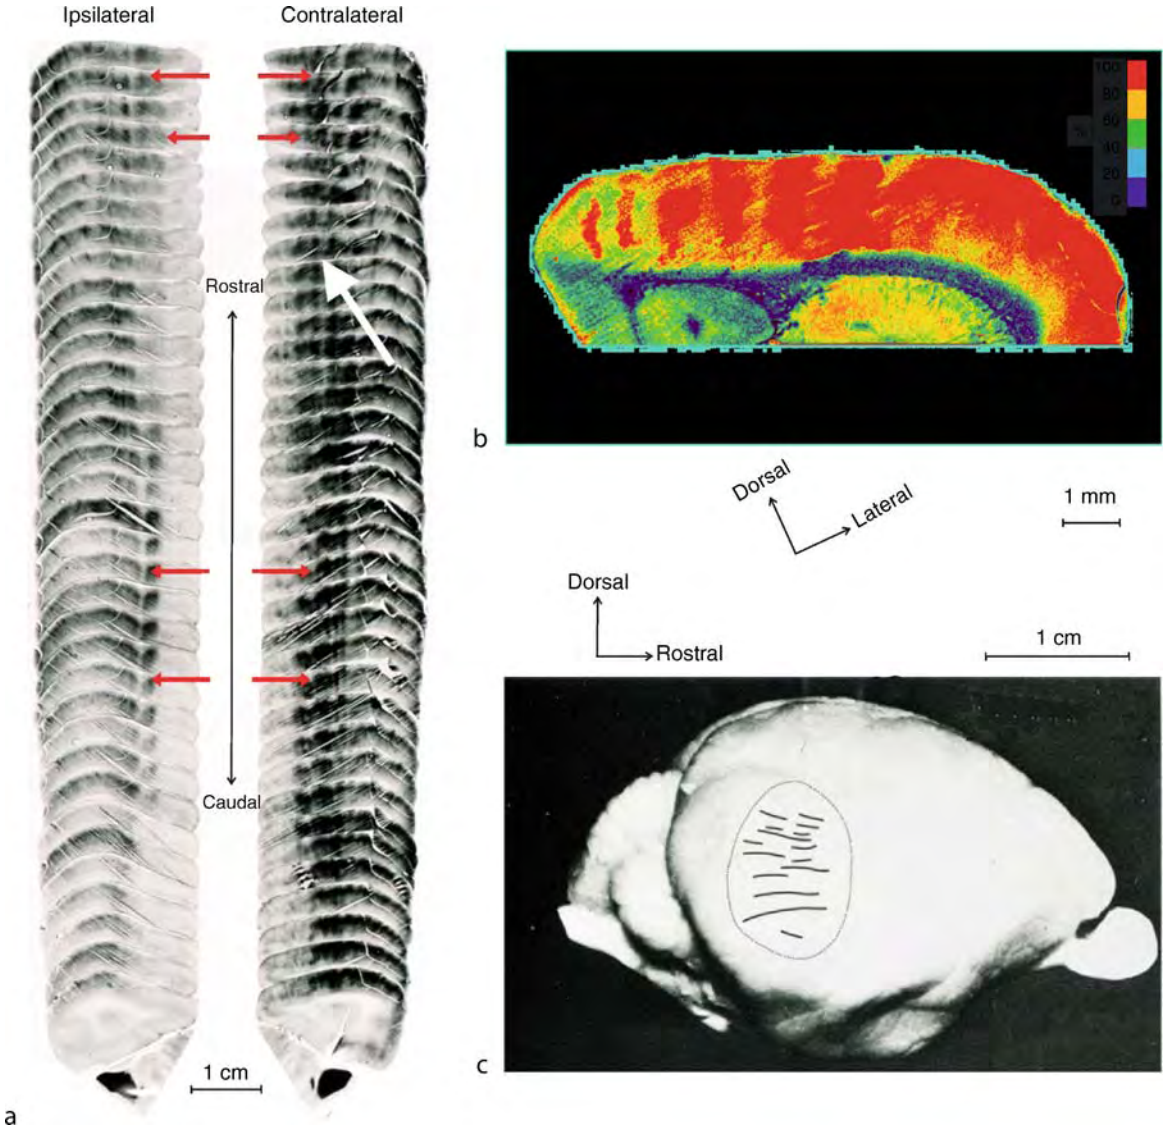
The epidermal ducts of the mucous glands are innervated by myelinated axons of trigeminal neurones with morphologically distinct axon terminals. The electroreceptors consist of small protoplasmatic protrusions from these axons which form filamentous processes extending into the ducts of the skin glands [10]. This arrangement is ideal for electroreception in a semi-aquatic animal. Because the epidermis of the bill dries out when the animal leaves the water, the glands help to preserve conductivity and to prevent damage to the electroreceptors by desiccation.

Electroreceptors which are sensitive enough to detect electrical signals generated by internal electrochemical processes of prey animals are well known in phylogenetically old fishes and some amphibians. In African mormyriform and South American gymnotiform fishes this sense has evolved to an additional active system using an ►electric organ as a source for a.c. impedance measurement of the environment and for communication. All electroreceptors found in fishes and amphibians that do not have electric organs are of the ampullary receptor type and probably form part of the acoustico-lateralis system. In contrast, the electroreceptors in platypus belong to the trigeminal system. Their sensitivity to d.c. as well as to high-frequency pulses [2] contrasts with the mostly d.c. or low-frequency responsiveness of ampullary receptors, which are less well-adapted to detect rapid muscle action potentials.

The presence of ampullary-like electroreceptors of a unique structure connected to the trigeminal nerve indicates that electroreception has evolved independently in monotremes. This in turn emphasizes that monotremes are a highly evolved group which split off from the main mammalian stem a long time ago.

## Function

Since the discovery of the electric sense of the platypus in 1986 [1] an extensive series of behavioral



**Electric Senses in Monotremes: Electroreception and Electrolocation in the Platypus and the Echidna.**
**Figure 2** [$^{14}$C]2-deoxyglucose labeling of platypus cortex after 6-s stimulation with electrical pulses applied dorsoventrally across the right side of the bill through wet cotton (1 ms square pulses, 1 mV/cm). (a) Serial reconstruction of transverse sections, separate for left and right side, in the area of strongest contralateral labeling. Note the columnar arrangement with weakly labeled patches on the ipsilateral (*left side*) roughly corresponding to the gaps between the strongly labeled patches on the contralateral side (*right side*). *Red arrows* mark these spatial correspondences for some patches and gaps. (b) Color-coded labeling (indicated by the color scale) of patches in cortex layers 3–4 of one section in the area indicated in (a) by a *white arrow*. (c) Reconstruction of labeled columns from (a) superimposed on a platypus brain.

experiments has clarified how the animal uses electroreception together with mechanoreception, to locate aquatic prey in three-dimensional space [5,6]. The results showed that the platypus can detect weak electric dipoles and that it is able to locate moving prey by the electrical activity associated with its muscle contractions. All receptive fields mapped in the trigeminal nerve are located along the lateral border of the upper bill and are characterized by a single spot of maximum sensitivity on the bill surface. Rapidly changing pulses are most effective in exciting receptors, indicating that the animal is adapted to detect moving prey by the electrical activity associated with muscle contraction. The skin of the bill also contains different kinds of mechanoreceptors that are highly sensitive to water waves. After 20 years of intensive behavioral,

physiological, and anatomical studies the conclusion has been reached that the platypus bill is indeed a mechano-electro-sensitive antenna [8].

►Reafferent Control in Electric Communication

# Electrical Coupling

## Definition

Electrical coupling refers to the coupling of membrane potentials of two cells. Usually electrically coupling is mediated by electrical synapses, which are formed by gap junctions. In less common cases, electrical coupling of cells can occur through ephaptic transmission, a process by which electrical activity in one cell affects the membrane potential of a neighboring cell through direct electrical field effects without the intervention of a synapse.

►Electrical Synapses
►Ephaptic Interaction

# Electrical Excitability

## Definition

Excitability refers to the capacity of nerves and other tissues to generate and sometimes propagate action potentials, i.e., signals that serve to control intracellular processes, such as muscle contraction, synaptic transmitter release or hormone secretion. Examples of excitable cells and tissues include neurons and glia, muscle and endocrine tissues. Examples of non-excitable cells and tissues include blood cells, most epithelia and connective tissues.

►Action Potential
►Action Potential Propagation
►Intrinsic Properties of Auditory Neurons

# Electrical Stimulation

## Definition

Electrical pulses may be used to activate cells. Currents must be large enough to elicit an action potential, but small enough to not damage the cells. Electrical stimulation is used, for example, in Parkinson patients to counter the akinesis.

# Electrical Synapses

## Synonyms

Electrotonic synapse

## Definition

An electrical synapse is an electrically conductive junction between two cells formed by arrays of gap junction channels. Neighboring cells joined by such a junction are said to be electrically coupled because membrane potential changes can be directly transmitted between the partners without intervention of extracellular messenger molecules such as neurotransmitters.

## Characteristics of Electrical Synapses

### Structural and Functional

►Gap junctions are structures consisting of one or more channel forming intercellular junctions between eukaryotic cells. The cytosolic bridges formed by gap junction channels allow direct cell-to-cell exchange of ions and small molecules up to a molecular mass of approximately 1 kDa such as second messengers and other intracellular metabolites, i.e. gap junctions allow cells to be both electrically and metabolically coupled." Each gap junction channel is made from two mirror-image "half-channels," traditionally called connexons or hemichannels (one provided by each of the partner cells) that align themselves in areas where the plasmamembrane of the partner cells closely appose each other (see Fig. 1).

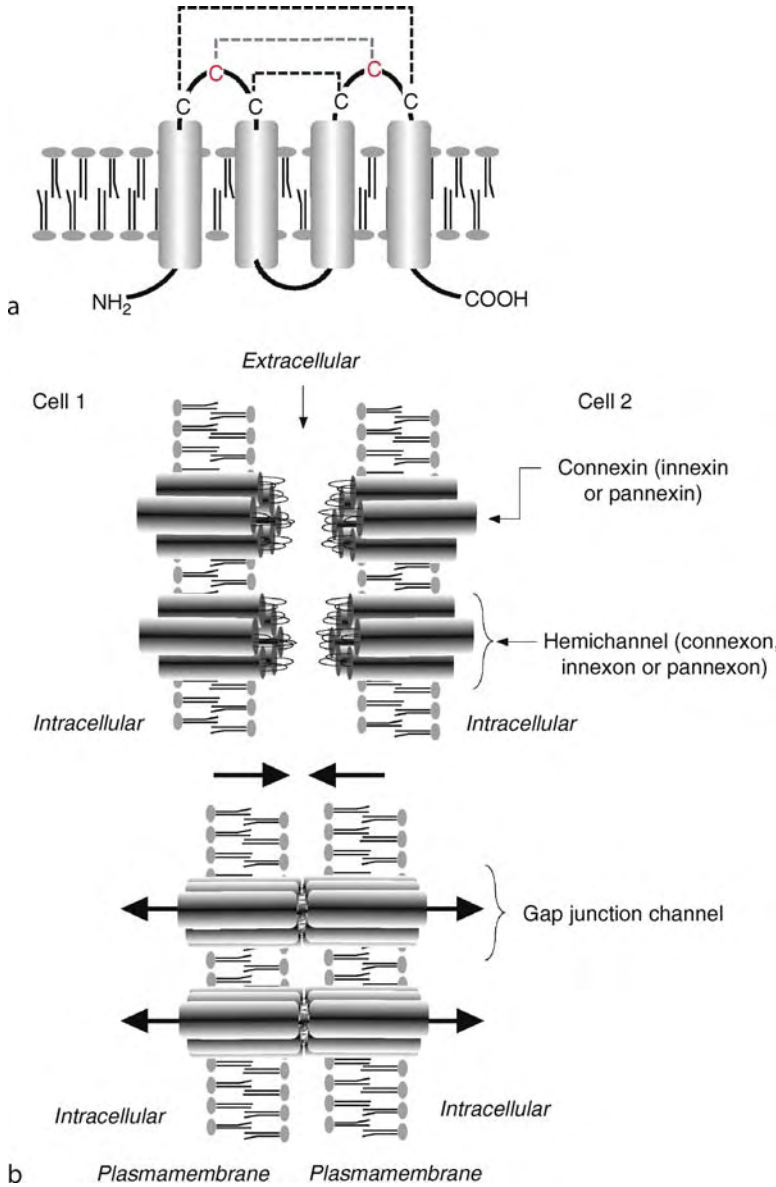
Each of the hemichannels is composed of six homologous tetra-span integral membrane proteins that are called connexins (but see section on phylogenetic considerations). Each connexin molecule contains four membrane-spanning α-helices connected by two extracellular loops, one cytoplasmic loop, and intracellular C and N termini [1]. The two extracellular loops contain several conserved cysteine residues that are thought to be essential in alignment and docking of contralateral hemichannel pairs [1,2]. The mammalian genome encodes over 20 connexin family members that may assemble in various homomeric and heteromeric combinations and instill gap junction channels with various physiological and pharmacological properties [3].

### Phylogenetic Considerations

Gap junctions are found throughout the animal kingdom and support very similar functions in representatives of all major animal taxonomic groups. Until quite recently it was thought that only members of the connexin family formed gap junctions. However, it is now evident that at least two, not directly related gene families, the connexins and the innexins, have evolved to fulfill the fundamental roles of gap junctions. Although the proteins encoded by members of these gene families have very different primary sequences, they nonetheless share many structural and functional features [1,2]. Both share the basic tetraspan transmembrane topology outlined above and both retain several positionally conserved cysteine residues in their extracellular loops and form functional gap junction channels [1,2]. All available genomic data indicates that the connexin family is confined to chordate lineages while the innexin family proper appears to be restricted to invertebrates. However, this dichotomy may be less absolutely than originally thought since distant innexin homologs, called pannexins, have been identified in the genomes of rat, mice, humans and other vertebrates [2]. This finding led to the proposal to reclassify innexins as members of a larger and phylogenetically broadly distributed family of pannexins [1]. Both the connexins and innexins/pannexins are members of large multigene families. Over 20 connexin genes were discovered in mammals in addition to three pannexins The fruitfly *Drosophila melanogaster* genome codes for 8 innexin homologs, whereas the nematode *C. elegans* has 20 different innexin homologs supporting a variety of biological processes [1,2]. Dealing with these matters in more detail is beyond the scope of this introductory assay. For the current purpose, it suffices to conclude that despite their genetic diversity, gap junctions formed by connexins, innexins and pannexins share similar molecular organization and transmembrane topologies and, in neurophysiological terms, appear to instil very similar functions into electrically coupled cells.

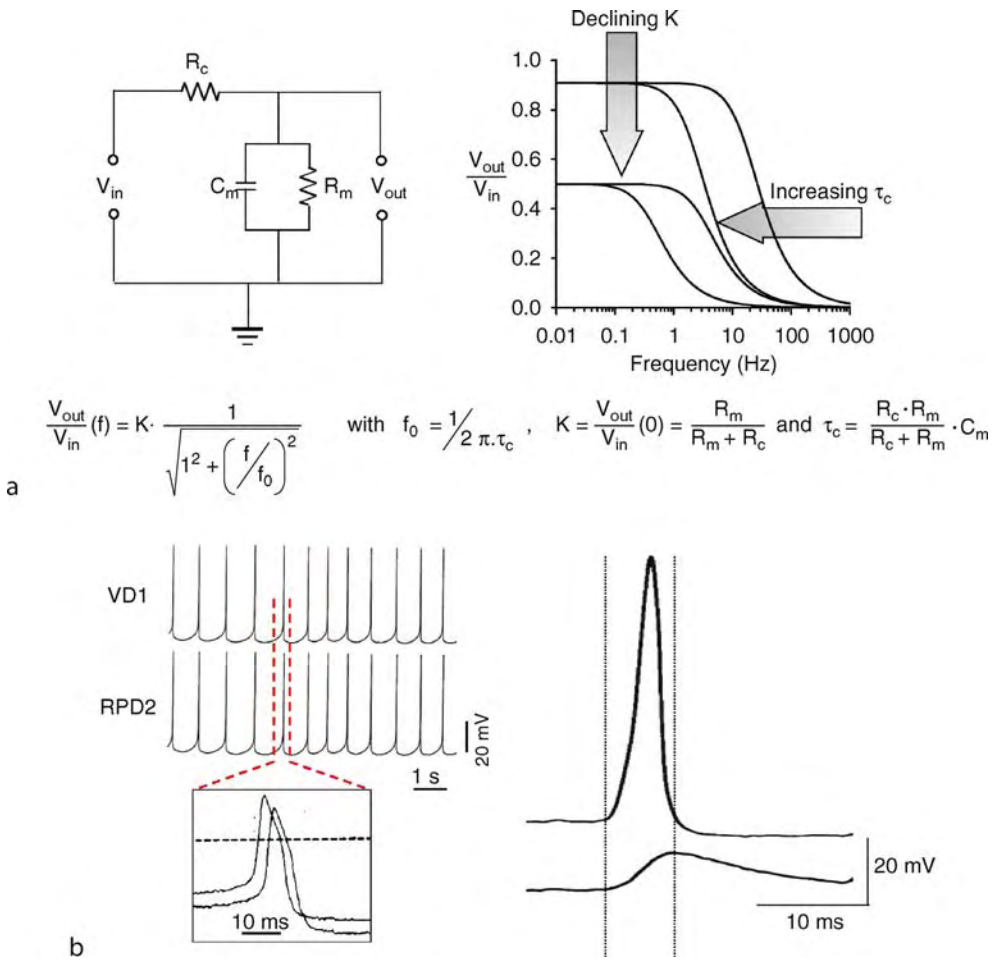
### Fundamental Electrophysiological Characteristics of Electrical Synapses

Ionic current flow across an electrical synapse is fundamentally a function of the voltage difference applied across the synapse (i.e., the transjunctional potential) and the number, unitary conductance, permeability and gating characteristics of the gap junction channels constituting the synapse. In principle, the cytosolic bridges provided by gap junctions allow exchange of molecular signals in both directions. In keeping with this bidirectionality, many gap junctions conduct ionic currents equally well in both directions. Moreover, the amount of junctional current flow is in many cases a linear function of the transjunctional potential, i.e., the synapse obeys Ohm's current-voltage law. This kind of ►electrical synapses is called ►non-rectifying gap junctions to distinguish them from their



**Electrical Synapses. Figure 1** Generic structure of gap junctions and their protein components. (a) Gap junctions are homo- or heteromeric assemblies of members of the connexin, innexin or pannexin families. All three families of gap junction proteins have the same basic topology: four plasmamembrane spanning a-helices coupled by two extracellular loops and one intracellular loop in addition to intracellular N and C-terminal amino acid chains. Connexins are further characterized by three conserved cysteine residues in each of their extracellular loops. Pannexins and innexins have two of these cysteine residues in each of their extracellular loops. Disulfide bridges between the extracellular cysteine residues of connexins as well as pannexins/innexins are thought to be essential in creating the extracellular topology that allow gap junction hemichannels of opposing cells to dock and align with each other. (b) Gap junction channels are formed when two hemichannels, one of each provided by the two apposing cells align themselves and dock with each other forming a continuous cytosolic bridge between the two cells. Depending on their phylogeny gap junction hemichannels are also known as connexons, innexons or pannexons. Each hemichannel is build from six tetraspan protein subunits known as connexins, innexins or pannexins (see (a)).

►rectifying gap junctions brethren. Rectifying electrical synapses conduct ionic currents better in one direction than the other, i.e., their conductive properties are a non-linear function of the transjunctional potential. The rectification properties are a function of voltage-sensitive elements in some connexin family members and arise from asymmetries in hemichannel composition.



**Electrical Synapses. Figure 2** Fundamental electrical properties of electrical synapses. (a) Equivalent resistance/capacitance circuit modeling the passive membrane properties of two electrically coupled cells and its sinusoid voltage-transfer characteristics. In this simple circuit, electrical conductive properties of the electrical synapse are represented by an ohmic resistance ($R_c$) standing in series with a parallel capacitance ($C_m$)/resistance ($R_m$) circuit. The latter two variables represent the membrane capacitance ($C_m$) and membrane resistance ($R_m$) of the postsynaptic cell. For the current purpose the presynaptic cell is considered an ideal voltage source ($V_{in}$). Although this model ignores intricacies arising from the usually much more complex cable-like structure of neurons, it does adequately illustrate the basic principles underlying the transmission characteristics of electrical synapses. The voltage transfer function ($V_{out}/V_{in}$) is the product of the steady state coupling ratio (K) and a frequency ($f/f_0$) dependent term. K is a function of the resistive values $R_m$ and $R_c$ only. An increase in $R_c$ or a decrease in $R_m$ will lead to a decline in K. A decrease in $R_c$ or an increase in $R_m$ will lead to higher values of K. Because of the presence of $C_m$, electrical synapses act as low-pass frequency filters attenuating higher frequencies stronger than lower frequencies. The coupling time constant $\tau_c$ relates this frequency dependent behavior to passive membrane properties of the coupled cells. The cutoff frequency $f_0$ is inversely proportional to $\tau_c$. Hence, an increase in $\tau_c$, which may arise as a consequence of an increase in $R_c$, $R_m$ or $C_m$, will lower the coupling's cutoff frequency and make the coupling more restrictive. Lower values of $\tau_c$ are associated with higher values of $f_0$ and less restrictive high-frequency filtering. To illustrate the effects on the transmission characteristics of an electrical synapse, the plot in the *top right* panel shows four examples of voltage transfer functions with progressively smaller K (top to bottom) and larger $\tau_c$ (right to left). (b) Electrical synapses are often involved in the synchronization of electrical activity in groups of neurons. This figure shows synchronized action potential activity in two peptidergic neurons in the pond snail *Lymnaea stagnalis*. The cell named visceral dorsal 1 (VD1) is an intrinsic pacemaker. VD1 is coupled through an electrical synapse to the second cell called right parietal dorsal 2 (RPD2). The presence of an electrical synapse allows VD1 to drive RPD2's spiking rhythm in close synchrony (see *inset*). In the right panel RPD2 was hyperpolarized to reveal the postsynaptic potential (the smaller lower trace of the two) generated by an action potential in VD1 (the larger upper trace of the two). Note that in its transfer across the electrical synapses the action potential is attenuated and slowed down appreciable. This phenomenon arises from the fact that most of the action potentials power spectrum lies substantially above the cutoff frequency ($f_0$) of this synapse.

Electrical synapses act as ►low-pass frequency filters, a feature arising from the fact that current flowing through the junction feeds into both the membrane capacitance and membrane resistance of the postsynaptic cell (for further explanation see equivalent RC circuit of electrically coupled cells in Fig. 2, see also [4]). The transmission characteristics of an electrical synapse and the influence of various junctional and non-junctional membrane properties thereon are easiest appreciated by considering a simplified equivalent RC-circuit (Fig. 2).

Since current flowing through the gap junction ($R_c$ in Fig. 2) feeds into both membrane capacitance ($C_m$ in Fig. 2) and resistance ($R_m$ in Fig. 2) of the postsynaptic cell, the synapse behaves like a low-pass frequency filters with passband attenuation. That is, when the frequency of the input signals ($V_{in}$) approaches 0, i.e., when a steady state has been accomplished, the transmission efficacy of the synapse ($V_{out}/V_{in}$) will reach its maximum. This so-called steady state coupling ratio (K in Fig. 2) is a function of the resistive components of the coupled cells only ($R_m$ and $R_c$ in the equivalent circuit of Fig. 2; see also [4]). The extent to which non-steady state input signals (i.e., AC signals) are attenuated depends on their frequency relative to the so-called cutoff frequency of the synapse ($f_0$ in Fig. 2). In simple situations resembling the equivalent RC-circuit shown in Fig. 2, $f_0$ is a function of the passive membrane properties of the postsynaptic cell (i.e., $R_m$ and $C_m$) and the electrical resistance of the junction ($R_c$) which collectively determined the coupling time constant ($\tau_c$ in Fig. 2). Thus, although the strength of an electrical synapse is traditionally expressed in terms of ►coupling coefficient, this value only expresses the transmission efficacy for signals substantially slower that the synapse's cutoff frequency (i.e., $\leq 5 \times f_0$). Clearly, few electrically coupled neurons have an electrotonic architecture simple enough to be accurately represented by a one compartment RC-network like the equivalent circuit shown in Fig. 2. However, the model does provide valuable insights in the operational constraints of electrical synapses. For example, an increase in $R_m$ will increase the steady state coupling coefficient, but restrict the AC response of the synapse. An increase in $R_c$ will attenuate both steady state and AC response characteristics of the synapse. Larger cell size, through increased larger membrane capacitance $C_m$, correlates with increasingly restrictive low pass filter characteristics. Thus, in order to obtain high steady state coupling ratio $R_c << R_m$. In addition, to obtain the fastest possible synaptic transmission through electrical synapses, $C_m$ should be as low as possible.

Much of the attention on electrical synapses has focused on their role in fast synaptic transmission of impulse-like potentials such as action potentials. However, as outlined above electrical synapses act as low-pass frequency filters. Most action potential waveforms are dominated by components substantially faster than a few Hz. However, many types of synaptic potentials, pacemaker potentials and other subthreshold membrane potentials have a substantial representation in this frequency range. Therefore, electrical synapses, particularly those combining a high steady state coupling ratio with low a cutoff frequency may have substantial impact on synaptic integration, rhythmogenesis and other integrative properties of coupled neurons while transmitting little of actual action potentials [5,6].

## Modulation of Electrical Synapses

The permeability characteristics of gap junctions and therefore the conductance characteristics of electrical synapses depend on various factors. For example, insertion or removal of gap junction channels from the membrane will affect overall conductance of the synapse. Also, depending on their subunit composition gap junction permeability, gating, electrical conductivity and selectivity characteristics may differ [4]. Furthermore, the conductance of many gap junction channels is modulated by intracellular signaling factors, including intracellular free $Ca^{2+}$, pH, cAMP, and in other cases, the transjunctional voltage [4]. In addition, since the electrical synapse's coupling coefficient is a function of both junctional and non-junctional membrane resistance, the strength of coupling can be altered by changing the gap junctional conductance itself as well as by changing the conductance of adjacent non-junctional membranes through for example chemical synaptic activity.

## Electrical Synapses and Gap Junctions in the Invertebrate Nervous System

Since their original description by Furshpan and Potter in crayfish in 1957, it has become abundantly clear that electrical synapses are not only quite common but also play various critical roles in the invertebrate brain. For example, due to their relative transmission speed and insensitivity to temperature, electrical synapses are frequently found in circuits controlling critical behavioral functions that require quick responses such as escape and defensive behaviors such as the crayfish tailflip escape response. A more general purpose of electrical synapses is to synchronize electrical activity among populations of neurons. For example, electrical synapses contribute to the synchronization of electrical activity of various populations of hormone secreting neurons in various invertebrates thereby facilitating a burst of hormone secretion into the circulation. Interestingly, electrical synapses serve similar roles in the synchronized release of neurohormones by several groups of mammalian hypothalamic and pituitary neurons.

### Electrical Synapses and Gap Junctions in the Vertebrate Nervous System

The significance of electrical and ►metabolic coupling mediated by gap junctions in development, morphogenesis and circuit formation in the mammalian brain has long been recognized. However, although the existence of electrical synapses in various areas of the mature mammalian brain has been known or suspected for quite a while, ►electrical coupling was until quite recently not considered of great importance in adult brain function [3]. Since the biochemical steps involved in chemical synaptic transmission proceed at a faster rate at the higher body temperatures, electrical synapses have less of a speed advantage over their chemical counterparts in homeotherms. This led to the idea that the contribution of gap junctions to processes requiring high-speed synaptic transmission was probably of lesser importance in warm-blooded mammals than in cold-blooded animals. Interestingly, consistent with this contention electrical synapses are a critical factor in the response characteristics of the Mauthner cell system, the neural circuit subserving the tail flick escape response of, obviously cold-blooded, teleost fish.

Recently, the significance of gap junctions in information processing in the adult mammalian brain is undergoing a substantial reappraisal. For example, a growing body of evidence indicate that gap junction coupling is a crucial factor in the temporal coordination of neuronal activity and the generation of endogenous neuronal ►network oscillations in various areas of the mammalian brain including the olfactory bulb, the ►olivocerebellar complex, thalamus, hippocampus and neocortex (reviewed by [3,4,8]). In addition, although the significance of electrical coupling in retinal signal processing has been known for a long time, transgenic model systems have been instrumental in confirming existing ideas and uncovering new insights in the significance of gap junctions in various aspects of retinal signal processing, including photoreceptor signal-to-noise characteristics, sensitivity, spatial resolution, determination of receptive field size (reviewed by [3]). Consistent with their new found functional importance, gap junctions are also increasingly implicated in various neurological disorders of the mature mammalian nervous system, including the progression of epileptic seizures, post ischemic damage and demyelinating diseases [8–10].

Non-neuronal roles of gap junctions in the nervous system – This essay focuses on the role of gap junctions in forming electrical synapses between neuron al cell populations. However, most macroglial cell types of the mammalian nervous system express specific sets of connexins and are extensively coupled through gap junctions organizing many of these cell types in distinct functional syncytiums [9,10]. Gap junctions support long-range metabolic coupling within several glial cell populations and is implicated in the brain's osmolarity and global excitability regulation. Treatment of these topics is beyond the scope of this essay. However several good reviews are available [9,10].

## Electrochemical Gradient

### Definition

The free energy difference for an ion in the extracellular versus the intracellular aqueous solution of a cell, i.e. the transmembrane free energy difference. The direction of this electrochemical gradient will determine whether the ion will flow into or out of the cell through a transmembrane pathway such as a $Na^+$ channel; the gradient magnitude is a major factor affecting the rate of this ion flux (hence it is sometimes called "the driving force" for an ion). The electrochemical gradient for an ion has both electrical (i.e. transmembrane voltage) and chemical components (i.e. the transmembrane concentration difference for the ion).

## Definition

Electroencephalography (►EEG) is a technique for recording brain electrical activity from the human (or animal) scalp for research and diagnostic purposes. The term "electroencephalogram" means the sample of the scalp record.

## Purpose

Electroencephalography is applied in a broad field of noninvasive studies of brain activity. Having as well as magnetoencephalography the highest time resolution among the brain imaging techniques, the EEG recordings are the most effective for tracking the rapid changes of the brain functional states. Such an important field of brain science as the study of the cortical connectivity is most usefully served by the analysis of ►EEG synchrony. ►Sleep stages (fast and slow sleep) are revealed and described by means of overnight EEG monitoring. EEG can reveal the impairment of the brain's workings, in terms of both its functional and organic nature. Therefore, clinical electroencephalography is a widely used technique for diagnostics, particularly in neurology and psychiatry. EEG is especially efficient in the diagnosis of epilepsy, as EEG signs in this disease are rather specific (►sharp waves/spikes and ►slow wave complexes). Information about EEG changes in various brain pathologies can be obtained from special clinical EEG Handbooks [1,2]. EEG can also be used for external devices control, particularly in Brain-compute Interface.

## Principles

### Physiological Basis of the EEG

The electrical brain potentials recorded by EEG are the primary effects of neural activity. The neuronal ►action potentials are the real "language" of neuronal communication. However, scalp-recorded EEG does not directly reflect the action potentials as the intervening tissues sharply attenuate their fields. Instead, the slower ►postsynaptic excitatory and ►inhibitory potentials generated predominantly in the dendrites of pyramidal cells make the main contribution to the EEG [3]. The reason is that the pyramidal neurons possess a well-developed dendritic system and that these dendrites constitute masses of equally oriented fibers. When, during the generation of postsynaptic potentials, dendritic currents flow inside these fibers, they acquire the properties of electric current dipoles. In the case of synchronous activity of masses of pyramidal cells, the co-oriented dendritic dipoles produce fairly large electrical potentials on the surface of the head. In contrast, the dendrites of smaller neurons display a random orientation and are not able to contribute significantly to the superficially measured EEG. Still, they can influence the EEG indirectly by modulating the discharge patterns of the pyramidal cells. ►Volume conduction due to intervening dura, skull, and soft tissue acts as a spatial ►low-pass filter and smears the electric potentials over rather large brain areas. Thus, the scalp-recorded EEG may be attributed to the activity of underlying neuroanatomical structures over about a 1 cm range. Despite these restrictions, the contemporary methods of EEG analysis provide valuable accounts about the brain's workings. The analysis of EEG rhythms is indeed a key point for understanding the informational processing in the brain.

### EEG Rhythms

In 1929, the founder of the method, Hans Berger, discovered that the EEG consists of rhythms. There are two reasons why EEG acquires rhythmical properties. Firstly, some ►pacemaker neurons possess an intrinsic capability for rhythmic discharges. On the other hand, neuronal groups can synchronize their activity through excitatory and inhibitory connections in such a manner that they constitute networks with oscillatory properties. Such networks are called ►neuronal oscillators.

The whole frequency range of EEG rhythms has traditionally been divided into several bands: delta (1–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), and gamma (>30 Hz). Moreover, the alpha band is often divided into the lower alpha (8–11 Hz) and the upper alpha (11–13 Hz).

The most prominent EEG rhythm is the alpha rhythm of rest (Berger's rhythm), with a frequency of about 10 Hz. This rhythm is observed in about 85% of normal adults, and is mostly expressed in occipital and parietal recording sites with eyes closed. The alpha rhythm reduces when the subject perceives a visual signal or makes a mental effort, e.g., performs arithmetic calculations. This rhythm results from an interplay of thalamic and cortical ►neuronal networks.

Other rhythms of alpha frequency are also distinguished. The 10 Hz ►mu-rhythm (Rolandic rhythm) can be observed at central electrodes above the motor and supplementary motor cortices. It has a specific 'spiky' waveform and is blocked by movements or preparation for movements. The 10 Hz tau-rhythm is recorded under temporal electrodes (above the auditory ►cortex) and is attenuated by sounds.

The slow-wave ►delta rhythm appears in deep sleep, both natural and narcotic, and also in coma. Delta

E

activity in the awake condition in adults was formerly considered as a sign of brain pathology, but new data indicates that in frontal site delta wave can also appear in some mental load.

The ►theta rhythm is normal in children and is replaced with ►alpha rhythm at the age of about ten. The midline frontal theta rhythm in adults may accompany a short-term ►memory load and cognitive effort, and is supposed to be related to the activity of the ►hippocampus.

The beta rhythm is of a merely cortical origin and is believed to underlie cognitive processing.

The gamma rhythm probably reflects the retaining and processing of elementary informational patterns in local cortical structures, such as the coding of visual features in primary visual cortex. Most probably, the integrating role of gamma rhythms goes beyond mere sensory processing.

The amplitude of the EEG rhythms usually ranges from 0.5 μV (gamma rhythm) to as large as 100 μV (alpha rhythm at rest in some subjects and delta waves).

Recent studies have shown that the spatial and frequency distribution of EEG rhythms under cognitive loads form stable patterns that are specific for an individual and a task type. These patterns are preserved in time and constitute a 'rhythmical portrait' of a person.

The contemporary view of the functional role of the brain rhythms could be briefly sketched as follows. The brain rhythms may perform a threefold function (i) Gating, i.e., transforming the informational processes into discrete representations in the time domain. (ii) Retention of elementary parts of information in brain microstructures for a time necessary to associate informational elements with each other. This is achieved by reverberating the signal in inter-neuronal loops with excitatory and inhibitory connections. (iii) Synthesis of informational elements into an integrative whole. This is achieved by synchronizing rhythms in the appropriate brain loci.

As mentioned before, a mixture of electrical potentials produced by various cortical neuronal oscillators forms the superficially measured EEG. Oscillators may work independently (at different frequencies) or synchronously. The synchronization may be of two types: mass or selective. The mass synchronization, in which all oscillators of a macroscopic brain area work synchronously, results in an increased amplitude of the rhythm measured above this area and is considered as a sign of the area's idleness. Under informational load, however, the oscillators in the area begin to work at different frequencies (desynchronize), which leads to a decrease in the wave amplitude. Thus, the desynchronization of a formerly massively synchronized brain area is a sign of the area's activation (e.g., mu-rhythm blockade during the preparation to a movement). By contrast, the phenomenon of selective synchronization implies that neither all oscillators work at the same frequency (as in the idling condition), nor do they all work independently. Instead, certain cortical oscillators are selectively and distantly synchronized. In particular, those oscillators that carry parts of the information to be associated with each other are synchronized, i.e., integrated into a whole. Thus, the selective synchronization underlies the informational link in the brain. Mikhail Livanov [4] was the first to experimentally prove this idea. In his experiments, the correlation coefficient between EEG signals recorded in the visual and the motor cortices of the rabbit were monitored. It appeared that the animal responded to a light flash with a paw movement only when this coefficient was sufficiently large. This approach is the major one in the study of cortical connectivity.

The framework of ►nonlinear dynamics, which in recent years has been widely applied to EEG studies, extends the frequency-specific synchrony approach. It is supposed that the neuronal interactions may be both linear and nonlinear, with phase interdependences among brain areas across and between a wide range of frequencies. The resulting spatio-temporal patterns are labile and short-lived. To adapt to fast environmental changes, the patterns are created, destroyed and again recreated. In EEG dynamics, they may be seen as a rapid alternation (intermittency) of synchronized and desynchronized episodes. Therefore, the balance between synchronization and desynchronization is considered to be an important point for understanding the mechanism of adaptive cognitive functions.

## EEG Recording

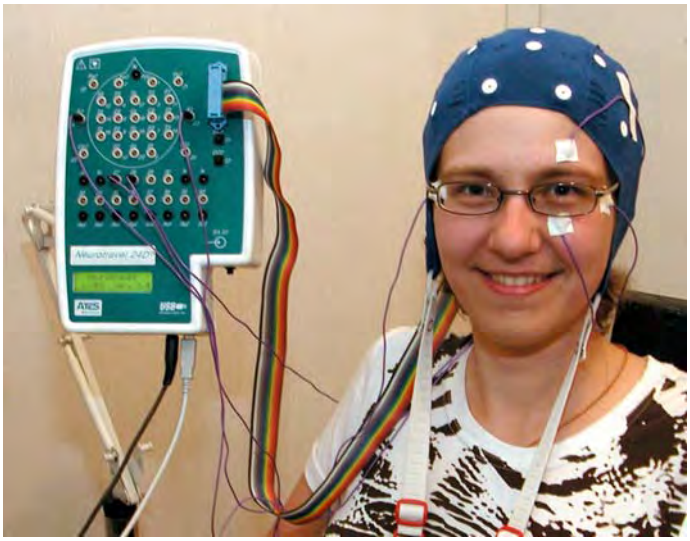
An EEG acquisition system typically consists of electrodes, amplifier (electroencephalograph), ►analog-to-digital converter, and a computer for storage, analysis and display of the obtained data.

EEG recording usually includes the following steps:

1. A subject is comfortably seated in a sound-, light-, and electromagnetic fields-proof room
2. Electrodes are placed according to a certain scheme
3. The reference electrodes are chosen
4. Parameters of the EEG acquisition system are set
5. To establish the exact amplitude of the EEG signal and to evaluate the amplifier noise, the acquisition system is calibrated
6. Non-biological artifacts (e.g., due to bad electrode placement or external electromagnetic sources) are detected and removed as far as possible
7. EEG is recorded (Figs. 1, 2)

## Recording Place

Modern EEG systems have been designed to provide clear recordings in almost any environment. Wireless (telemetric), portable electroencephalographs enables long-term EEG monitoring even at a subject's location.



**Electroencephalography. Figure 1** The procedure of the EEG recording. The subject is sitting in a comfortable chair with an electrode cap on her head in a sound- and light-proof cabin, which is also shielded from electromagnetic fields. The electrodes for monitoring of possible artifacts from blinks and eye movements are placed above and below the left eye and on the outer canti of both eyes. The 32-channel EEG amplifier is situated on the *left side*. Smiling is not recommended because of possible muscle artifacts.

However, the removal of nearby electric devices is a usual requirement for the EEG recording place.

### Electrodes and Electrode Placement Schemes

Typical EEG electrodes are made from metal (gold, silver, or tin). A gel or salt solution is used to improve the conduction between skin and electrode surface. The acceptable scalp-electrode impedance depends on the type of amplifier used and ranges from 3 to 40 kOhms. Except for a specific goal, any electrode placement scheme is aimed to sample evenly the head surface. The traditional 10–20 system uses topographical markers for electrode position (such as inion, nasion, pre-auricular points), and is well situated for single-electrode

built-in electrodes makes topographical measurement for each electrode unnecessary. The caps allow the quick and accurate application of any number of electrodes (up to 256).

### Reference Electrode

As EEG measures the voltage, e.g., the difference in potential between an active and a reference site, the choice of the reference electrode is crucial. The reference electrode should be placed in the most 'inactive' site that is maximally distant from the brain sources of interest. For example, averaged signals from both earlobes are the most popular reference. Alternatively, the reference may be derived analytically after recording. The widespread solution is an average reference that is a mean of all electrodes. A 'reference-free' signal may be obtained using surface Laplacian derivation, which is computed as the second derivative of the potential field at each electrode.

### Parameters for EEG Acquisition and Storage

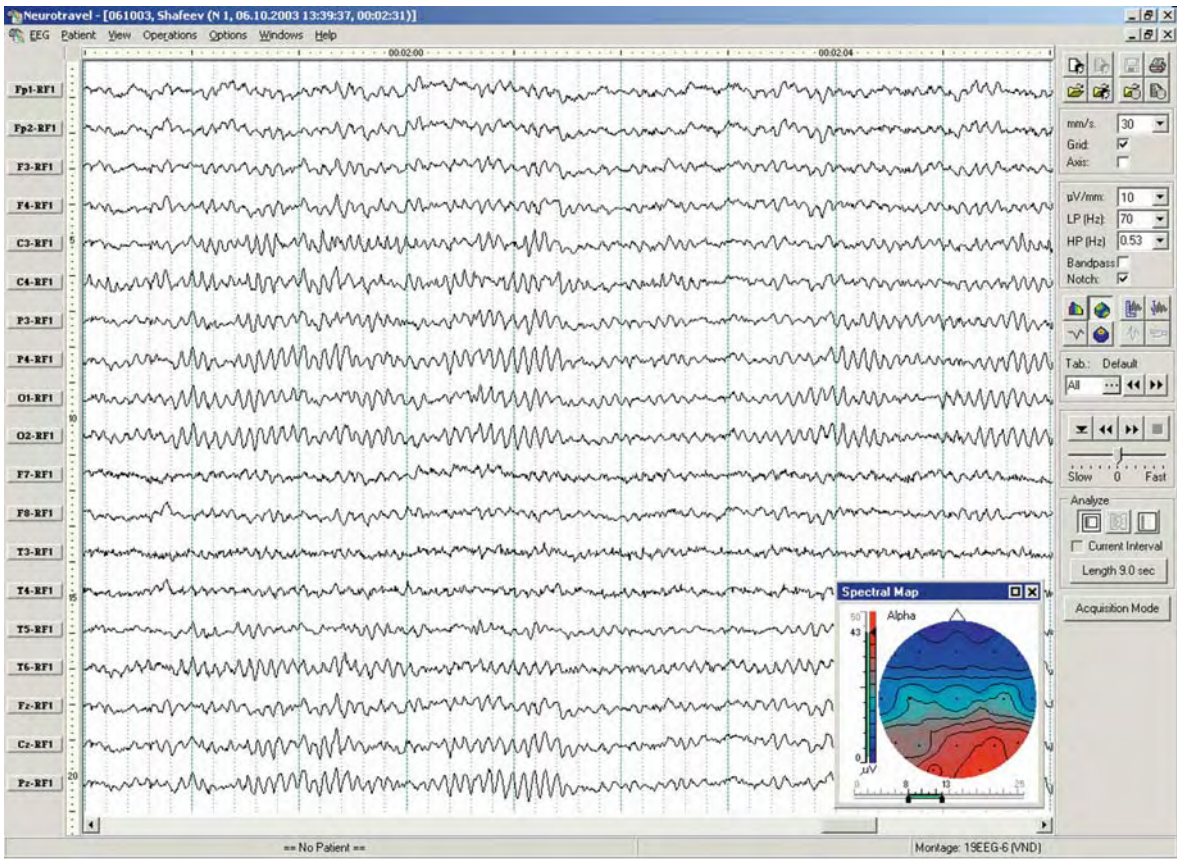
To catch the frequencies of the main EEG rhythms (up to 100 Hz), the minimum ►sampling rate of the analog-to-digital conversion (ADC) has to be at least 200 samples/second. ADC should be done at a resolution of at least 12 bits in order to resolve the EEG signal down to 0.5 μV. The low-pass filter should be set to 0.16 Hz or less to acquire slow wave activity. A 50–60 Hz ►notch filter should be available, but not routinely used, especially in studies of EEG rhythms in the gamma band [5].

### EEG Signal Analysis

(See [6] for details)

### Spectral Analysis

►Spectral analysis is used to reveal frequency components of an EEG signal. Each frequency presumably reflects the activity of a particular oscillating neuronal group. The transformation of a signal from the time domain into the frequency domain may be done by means of the ►Fourier transform (FT). It is based on the mathematical fact that any signal defined in a given time interval can be decomposed into a sum of sine waves of different frequencies, phases and amplitudes. The result of FT gives the information about the amplitude and the phase of the signal at each frequency for the whole



**Electroencephalography. Figure 2** Electroencephalogram and spectral map in the alpha band as they are seen on the monitor screen. Each line corresponds to one of 19 EEG channels (*marked on the left*) referenced to the common electrode RF1 (placed on the left earlap). On the right, in the menu table, the experimenter can choose the scale of the EEG visualization (i.e., it is set at 10 μV/mm, 30 mm/s etc.). The menu for other types of EEG data analysis and presentation is also available. In the posterior channels, the synchronized bursts of alpha waves, of the amplitude of approximately 50–60 μV, are visible. On the power spectral map in the right bottom corner, this activity may be localized with maximum in the occipital regions.

studied period of time. The frequency resolution of FT is the inverse of the width of the analyzed time window: $\Delta f = 1/T$. To estimate the time course of EEG spectra, the windowed FT is applied. In this method, the FT is calculated in a window of constant duration that moves along the EEG record. The discrete fast Fourier transform (FFT) is an algorithm, which is mostly used to efficiently compute the FT on a discrete grid of time points. To know the power of different frequency components, the power spectrum is used. It is the squared absolute value of the FT, and no longer contains the phase information. It is also possible to calculate the relation of power in different bands, spatial asymmetry of band power, peak frequencies, and peak asymmetries.

The ►wavelet transform (WT), like FT, enables the estimation of the amplitude and the phase for a set of frequency components of the EEG, but, in addition to traditional FT, it enables the tracing of the development of each frequency component in time. In the WT, the template signal ("mother wavelet") and its compressed or dilated copies are convolved with the EEG signal with successive time shifts, resulting in the time-frequency representation of the signal. The WT's time resolution is inverse to the frequency – it is better for high frequencies than for low frequencies. This property makes WT especially useful for the analysis of high-frequency (gamma) EEG bands.

## EEG Long-Range Synchrony

►Coherence analysis provides a measure of the phase consistency of two signals, independently of these signals' amplitudes. This measure is important, since a constant phase lag between oscillating EEG signals at different recording sites may be an index of these sites' neural connection. The method is based on the calculation of the cross-spectrum of two EEG signals. This function contains information about the phase lag between the signals for each frequency component.

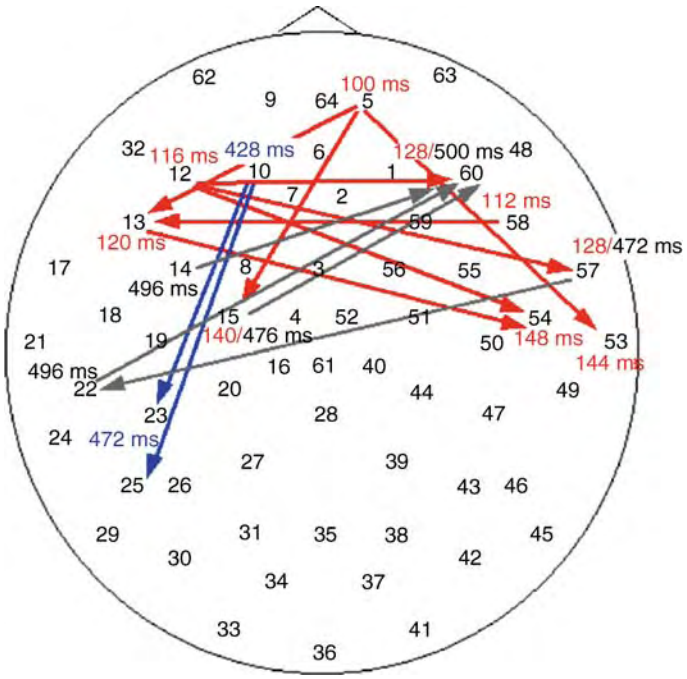
Obtaining the coherence measure is essentially an accumulative procedure. Accumulation is achieved by averaging the cross spectra of many EEG trials. If for some frequency component there is a consistency in phase difference between the two signals over many trials, the cross-spectrum value for this frequency will be high. To obtain the coherence function, the accumulated cross-spectrum is normalized to the product of the signals' power spectra, resulting in the coherence values lying in the range from 0 (randomly changing phase difference) to 1 (constant phase difference).

One drawback of the coherence analysis is the reverse side of its advantage: the coherence is strongly influenced by phase-shift changes between two interacting oscillators during the analysis epoch. However, one may propose that phase lag may change during the analysis epoch as it can determine both the neural connection mode (active vs. silent) and its direction.

To overcome this difficulty, a technique called ►Intracortical interaction mapping has been developed. This method is based on the same idea that the EEG spectral components reflect the activity of the main cortical oscillators, and that the coincidence in their frequency properties reports on communication between cortical areas. It is proposed that this technique reveals the cortical connections that are invariant to transient phase shifts between the interacting cortical oscillators. After FT (or WT), the major spectral peaks are selected and the peaks coinciding in their frequency are determined. The coincidence of the frequency peaks in two or more brain areas can indicate that these areas are potentially connected. To verify whether the connection is significant, the usual procedure of the comparison of two experimental conditions (e.g., before and during some mental task) is performed (Fig. 3).

## Event-Related Synchronization and Desynchronization

Event-related desynchronization (ERD) is a short-lasting, topographically localized attenuation of rhythms within the alpha and lower beta band. It is considered as a sign of activation of cortical areas, while synchronization is characteristic for the relative rest. For quantitative estimation of ERD, the following formula has been proposed: ERD% = 100%*(R-A)/R, where R is the average power of the band-filtered reference EEG trials,



**Electroencephalography. Figure 3** Additional cortical connections in the search-for-word association task (i.e., "pen – write") in comparison to the simple reading task. The connections were found by a version of the intracortical interaction mapping – calculation of the correlation coefficients between wavelet curves within consecutive time windows of 100 ms duration. Connections on the early, intermediate and late stages of the task solving were observed at 12–16, 17–19 and 21–24 Hz, correspondingly and presented with lines of different colors. The color digits indicate the time of the peaks in wavelet curves after the noun presentation on the monitor screen. The supposed direction of information transmission is indicated by *arrows*. Electrode numbers are in *black*. The frontal areas are in the *upper part* of the figure, and the occipital areas in the *lower part* of the figure.

and A is the same kind of average for the investigated trials. This approach efficiently reveals the activated cortical areas in numerous motor and cognitive tasks.

### Dipole Source Localization

As stated earlier, the electric currents generated by neural cells' dendrites are the principal physical sources of the EEG. Each of the active dendrites can be viewed as a microscopic electromotive force of dipolar nature. Any potential distribution instantaneously measured over a set of scalp electrodes is thus a sum of potentials produced by elementary dipole current sources. The goal of the inverse problem of electroencephalography is to find the distribution of dipoles in the brain that provides the potential distribution over the scalp as close as possible to the measured one. Due to its mathematical essentiality, the inverse problem of EEG has neither a unique, nor a precise solution. Instead, approximate solutions are searched for under certain assumptions and constrains.

The usefulness of the method is supported be several considerations. Firstly, in certain physiological conditions, neurons in a very local brain area may fire highly synchronously, thus surpassing the activity of all other neurons. An example is provided by ►epileptiform discharge. In this case, the one-dipole model is quite appropriate. On the other hand, it is obvious that in normal conditions, a great number of dipoles are simultaneously active. Nevertheless, in many situations, the measured potential can be well approximated by the influence of a few dipoles; these dipoles are then named the equivalent dipoles. Although the equivalent dipoles surely do not coincide with actual dipoles, the method may provide a robust, but useful, approximation of the activation sequence of brain areas, especially under some a priory assumptions on the expected active areas. A variety of complicated mathematical methods have now been elaborated to accomplish this task. The approach is effective both in research and in the localization of brain pathology.

### EEG Mapping

►EEG mapping is a presentation of EEG parameters on a schematic head surface, obtained by interpolating the data recorded at each single electrode site into inter-electrode space. This provides the researcher with a visual image presenting multi-channel ►EEG in the most integrative and illustrative form. In the clinic, the mapping helps reveal the exact site of pathological activity, for example, slow waves or epileptic spikes. The map can be an instant representation of the EEG signal amplitude, or its spectral value for the chosen period of time (Fig. 2). A valuable version of the EEG map is the connectivity map, when the coupled electrode sites are joined with lines (Fig. 3).

## Advantages and Disadvantages

Modern methods of studying brain functions, such as ►positron emission tomography (PET), ►functional magnetic resonance imaging (fMRI) and ►magnetoencephalography (MEG), have become very popular among neuroscientists. However, the EEG remains a widespread tool for research and diagnostic purposes because of its cheapness, simplicity in use, mobility (can be applied while the subject performs behavioral tasks, i.e., during professional activity and out of the laboratory as far as in space flight) and the possibility of long-term monitoring (e.g., during sleep). The current biofeedback studies show that the EEG signal can be used for the direct control of some devices, i.e., a cursor on the monitor screen or even a wheelchair.

The main advantage of EEG over PET and fMRI is based on the fact that electrical potentials are the primary effects of neural excitation, while metabolic changes in the brain tissue measured by PET/fMRI are secondary effects. Therefore, the EEG has a much higher temporal resolution and can reveal a most important parameter of neural activity – its rhythmic property. One might say that EEG shows not only "where" but also "how" information is processed in the brain. The main disadvantage of the EEG is its low spatial resolution, which, however, can be partly overcome by using dense arrays of electrodes and dipole modeling. Moreover, the combination of EEG and fMRI recording seems very promising.

The main difference of EEG compared to magnetoencephalography (MEG) is that the latter cannot record the radially oriented dipoles and deep sources of activity due to the property of magnetic fields. MEG is also much more expensive, bulky and complicated in use.

## Electrogenic Fish

►Electric Fish

## Electrolocation

### Definition

Detection of remote objects by sensation of the distortions in a self-generated electric field created by the object.

►Electric Communication and Electrolocation
►Evolution of Mechanosensory and Electrosensory Lateral Line Systems
►Magnetic and Electric Senses

## Electrolocation – Active

### Definition

Certain nocturnal teleost fishes of Africa (Mormyriforms) and South America (Gymnotiforms) generate "weak" electric organ discharges to test the impedance properties of the surrounding water body. Any close-by object representing an impedance inhomogeneity relative to the water is detected by these fishes' specialized electroreceptor system of the tuberous type. The adequate stimulus is an increase or a decrease of the strength of autostimulation that is associated with the presence of the object. Both an object's resistive and capacitive properties are detected in the species studied.

►Electroreceptor Organs

## Electrolocation – Passive

### Definition

An electroreceptive fish detects an extraneous current source, provided the electric field is above threshold and within the frequency range of its receptor organs. Examples are flatfish buried in sand that, like any live organism, generate strong DC fields that are associated with the regulation of the ionic balance of its tissues, and low-frequency field potentials from muscle and nerve activity. These fields are detected by the ampullary electroreceptor system (ampullae of Lorenzini) of sharks swimming over the sea floor. Another example are weakly electric fish, such as mormyrids or gymnotiforms, who generate electric organ discharges that can be located "passively" by conspecifics (usually with their tuberous electroreceptor organs), as well as by electroreceptive predators (ampullary or tuberous system, depending on the species).

►Electroreceptor Organs

## Electromagnetic Induction

### Definition

According to Faraday, charges crossing a stationary magnetic field experience a deflecting force perpendicular to the motion, and, if there is a conducting path (such as a wire) in this direction, a current is induced. A shark heading east or west in the ocean crosses the horizontal component of the earth's magnetic field, leading to dorso-ventral potential differences of a magnitude detectable by the shark's ampullary electroreceptor organs. By swimming and probing in different directions, the shark may thus derive magnetic compass orientation through its electroreceptive system.

►Electroreceptor Organs

## Electromotor Neuron/Cells

### Definition

In fishes that possess electric organs, electromotor neurons are the last neurons in the brain's command chain that triggers a discharge. The cell bodies of these neurons are located in the spinal cord, and each one sends its axon to a different modified muscle cell, called electrocyte, many of which form an electric organ. In certain fishes, the ensemble of electromotor nerves themselves constitutes the electric organ by their terminal swellings (Apteronotidae). The electric catfish (Malapterurus species) has only two giant electromotor neurons in the first spinal segment.

# Electromotor System

## Definition

A system of electric organs and control circuits that creates an electrostatic field surrounding the possessing organism. Generally used in communication and electrolocation.

►Electrolocation
►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

# Electromyogram

## Definition

EMG; A recording of the electrical activity of muscle obtained using electrodes that may be on skin over a muscle (e.g., in human recordings) or placed into the muscle.Because the electrical activity arises from action potentials in the muscle fibers, EMG activity can be a rough measure of the rate of activation of the muscle and of muscle force.

# Electromyography

Madeleine Lowery
Rehabilitation Institute of Chicago, Department of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL, USA

## Synonyms

EMG

## Definition

Electromyography (EMG) is the study of the electrical activity of muscle.

## Characteristics

### Quantitative Description

The electromyogram, or EMG signal, is the electrical signal generated by contracting muscle fibers. It can be detected with electrodes placed on the skin surface above the muscle of interest, or with indwelling intramuscular or subcutaneous electrodes. When a muscle fiber is stimulated, an action potential propagates along the fiber membrane in both directions away from the neuromuscular junction. The flow of current across the membrane produces an electric field that can be detected as a change in the electric potential or voltage at an electrode located in the surrounding tissue. As the action potentials propagate along the muscle fiber, the potential at the electrode varies, giving rise to a characteristic muscle fiber action potential waveform. Additional components, known as start-up and end-effects, due to the generation and extinction of the ►transmembrane action potential, may also be observed. The shape of the ►single fiber action potential depends on the fiber membrane properties, the electrical properties and geometry of the surrounding tissues, and on the electrode location and configuration. In general, the greater the distance between the muscle fiber and electrode, the lower the amplitude and frequency content of the propagating part of the action potential that will be detected. As the distance between the fiber and electrode is increased, high frequency components are attenuated and the action potential becomes increasingly low-pass filtered [1]. This phenomenon, known as spatial filtering, is not due to properties of the conducting tissues, but rather to the propagating nature of the action potential source. When the muscle fiber lies far from the electrode, the variation in potential as the action potential propagates along the muscle fiber is small, yielding a slowly varying, low frequency signal. For fibers located close to the electrode, there is a much sharper increase in potential as the action potential propagates beneath the electrode, yielding a high-frequency action potential. The stationary start-up and end-effect components are not subject to spatial filtering and, therefore, decay more slowly than the propagating part of the waveform, becoming more pronounced at large distances from the muscle fiber [2].

Under normal conditions muscle fibers do not contract individually, rather all fibers belonging to a single motor unit are simultaneously stimulated. The waveform detected when the fibers in a single motor unit are stimulated is termed the ►motor unit action potential (MUAP). Small delays between individual fiber action potentials occur due to differences in the locations of the neuromuscular junctions, the lengths and conduction velocities of terminal nerve branches and random variations in the excitation times of each fiber, known as jitter. The EMG signal detected during voluntary or electrically elicited contractions is comprised of the linear summation of MUAPs from all active motor units lying within the electrode pick-up volume.

## Surface EMG

Surface EMG is a non-invasive, easy-to-use method of measuring the electrical activity of a muscle. Due to the relatively large pick-up volume of the surface electrodes, surface EMG is suited to applications where information about the activity of the entire muscle is required, where activation timing is sought, or where EMG is used as a control signal, for example, in myoelectric prosthesis or biofeedback (Fig. 1a).

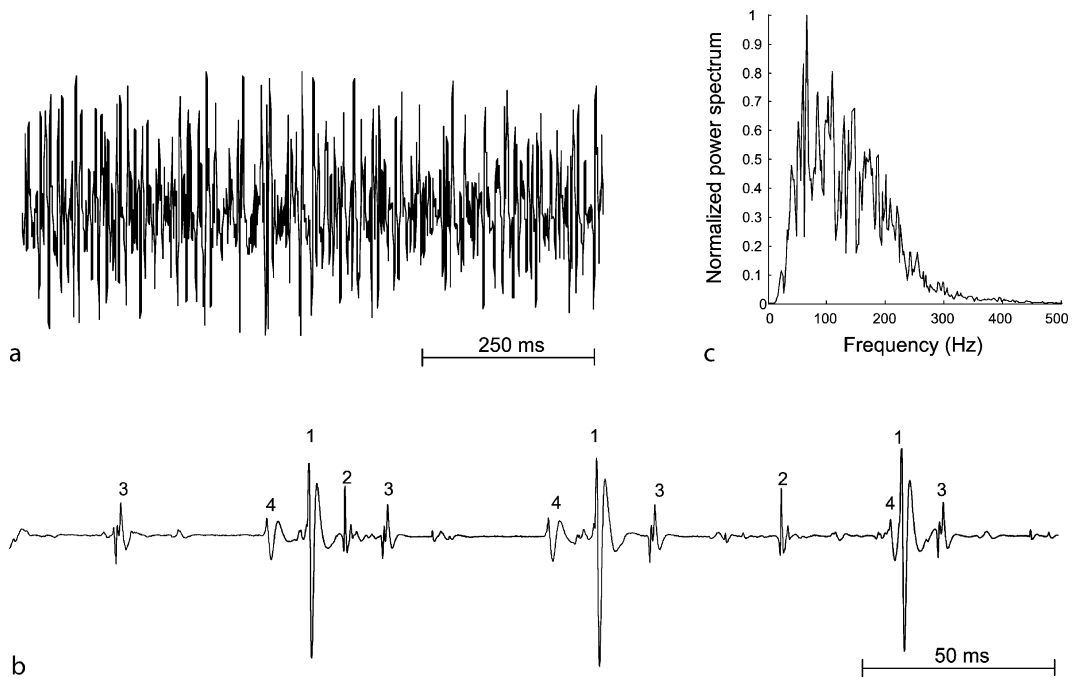
The main disadvantage of surface electrodes is that they can only be used to detect signals from muscles lying close to the skin surface, are not suited to recording from small muscles and may become contaminated with signals from neighboring muscles that are simultaneously active [3].

## Intramuscular EMG

Indwelling fine-wire or needle electrodes enable EMG signals to be recorded from a much smaller area than with surface EMG, facilitating the study of action potentials from single motor units (Fig. 1b), particularly during low-level contractions. Needle electrodes may be used in monopolar or bipolar configurations, with electrode surfaces mounted on the side of the needle or on wires placed inside the cannula. It is possible to adjust the position of the electrode using needle electrodes to get close to a particular muscle fiber. Fine-wire electrodes are inserted into the muscle using a needle that is then withdrawn, leaving the wires resting within the muscle. The tips of the insulated wires are first exposed to form the recording surfaces of the electrodes. Fine-wire electrodes may also be inserted subcutaneously, at the interface of the muscle and the fat tissue. Intramuscular fine-wire electrodes may be implanted and withdrawn with relative ease and with less discomfort than needle electrodes. However, they have a tendency to migrate within the tissue as the muscle contracts [3].

### *Electrode Configuration*

EMG signals are usually recorded using a bipolar electrode configuration, whereby signals detected at two adjacent electrodes are differentially amplified. Signals from far away sources appear similar at both electrodes and are therefore attenuated, while those originating from fibers close to the electrodes are amplified. In the standard bipolar electrode configuration, the electrodes are generally aligned parallel to the muscle fiber direction to optimize selectivity, and are positioned mid-way between the muscle end-plate zone and the tendon to minimize the contribution of start-up and end-effects. More selective recordings can be obtained by further differentially amplifying the EMG signal, for example, using a double-differential configuration. With highly selective two-dimensional electrode arrays it is possible to obtain further selectivity and to examine single motor unit behavior [4], while linear arrays, comprised of a series of bar electrodes



**Electromyography. Figure 1** (a) Sample bipolar surface EMG signal recorded from the first dorsal interosseous muscle. (b) Sample fine-wire EMG signal recorded from the brachioradialis muscle, indicating MUAPs from four different motor units. (c) Power spectral density of the surface EMG signal in A.

orientated perpendicular to the muscle fiber direction, can be used to estimate ►muscle fiber conduction velocity and the locations of the tendon and end-plate zone [5].

### Amplitude Parameters

The amplitude of the surface EMG signal is the most commonly investigated surface EMG parameter. It is generally quantified in terms of the average rectified (AR) value or the root mean square (RMS) value of the signal. At high levels of muscle activation, the surface EMG signal may be approximated as a band-limited Gaussian signal, for which the RMS value and AR value are directly proportional to one another. However, when the number of action potentials detected is low, there is no longer a simple relationship between the two parameters. For zero mean signals, the RMS value approximates the square root of the signal variance. If the firing times of individual motor units are uncorrelated, the variance of the EMG signal will be equal to the sum of the variances of the constituent MUAP trains. Under these conditions the RMS value, unlike the AR value, is not affected by the superposition or cancellation of MUAPs and is, therefore, considered a more reliable method of quantifying surface EMG amplitude.

The amplitude of the EMG signal is generally interpreted as an indication of the level of activity of the underlying muscle. The recruitment of additional motor units or increases in the firing rates of active units will cause the surface EMG amplitude signal to increase. The magnitude of this increase will vary depending on the location of the motor unit with respect to the electrodes. Short-term synchronization of motor units can also cause EMG amplitude to increase, while changes in muscle length, fatigue, the electrode-skin contact and temperature may further alter the amplitude of the EMG signal. The relationship between EMG amplitude and muscle force has been widely examined, with both linear and non-linear relationships observed [6]. While EMG amplitude reflects the level of activation of the motor unit pool, the complexity of the relationships between the motor unit activity, muscle force output and the surface EMG has precluded the establishment of a simple relationship between EMG amplitude and muscle force.

### Frequency Parameters

Due to the phenomenon of spatial filtering, the frequency content of the surface EMG signal lies below 300–500 Hz (Fig. 1c), whereas the intramuscular EMG signal may contain power up to several kilohertz. The shape of the power spectrum of the EMG signal is primarily determined by the spectra of the constituent MUAPs [1], but is also influenced by the motor unit firing statistics and synchronization between motor unit firings. The most commonly employed EMG spectral parameters are the power spectrum median and mean frequency [7]. To obtain a more complete picture of the behavior of the EMG spectrum a range of characteristic frequencies throughout the spectrum should be examined. EMG frequency parameters are commonly used to track the progressive shift of the EMG spectrum towards lower frequencies that occur during muscle fatigue. The frequency content of the EMG signal has also been proposed as a means of detecting the recruitment of higher threshold motor units through their higher conduction velocities, however, this effect tends to be masked by other factors including motor unit location. To apply conventional spectral analysis methods, the EMG signal must be assumed to be stationary (statistically invariant over time). This may generally be assumed for EMG signals of 0.5–1 s duration during isometric contraction [7].

### Cross-Talk

EMG cross-talk, the detection of unwanted signals from muscles other than the muscle of interest, is one of the most significant limiting factors associated with surface EMG. Cross-talk increases with subcutaneous fat tissue thickness, due to the increased distance between the electrode and the active fibers [8]. Problems with EMG cross-talk can also arise when recording from small muscles, or concurrently active neighboring muscles. There is currently no reliable means of distinguishing between cross-talk signals and EMG signals originating in the muscle beneath the electrode. Previously suggested frequency-based methods such as high pass filtering of the EMG have been shown to be unsuitable when the signal is dominated by high-frequency ►muscle fiber end-effects. The most effective means to reduce cross-talk remains the use of selective electrode recording configurations, such as a double differential or Laplacian electrode configuration [9].

### EMG during Muscle Fatigue

Changes in both the amplitude and frequency spectrum of the surface EMG signal are consistently observed during sustained fatiguing contraction. During sustained maximal voluntary contractions, a decrease in EMG amplitude is generally observed. In contrast, at submaximal force levels EMG amplitude is observed to increase. This increase is commonly attributed to the recruitment of additional motor units or an increase in motor unit firing rates to maintain force output, while the decrease in EMG amplitude at maximal force levels is associated with derecruitment and a reduction in mean firing rates. During sustained contraction, a progressive reduction in muscle fiber conduction velocity also occurs, causing the frequency content of the surface EMG signal to decrease and EMG amplitude to increase with increasing duration of the

extracellular action potentials [1]. The relationship between characteristic frequencies of the surface EMG spectrum and muscle fiber conduction velocity is approximately linear, but is also influenced by changes in motor unit firing rates and synchronization between motor units.

### *EMG during Dynamic Contraction*

When interpreting EMG signals recorded during dynamic contraction, several additional factors should be considered. As the length of the muscle fiber changes, the location of the electrodes with respect to the underlying fibers will also vary. Variations in the EMG signal may not necessarily reflect different levels of muscle activity, but rather changes in muscle fiber length and in the location of the fibers with respect to the electrodes. Furthermore, the condition of stationarity generally assumed during isometric contraction no longer holds, precluding the application of classical spectral analysis techniques. To overcome this limitation, time-frequency techniques can be applied. These are becoming increasingly popular methods of estimating EMG frequency parameters during dynamic contraction [10].

►Nystagmus
►Vestibular Tests: Caloric Test
►Vestibular Tests: Galvanic Test

# Electrooculogram (EOG)

## Definition

This is an older method for measuring the movements of the eyes that is still used with human subjects because of its ease of use. Electrodes for measuring horizontal movements are typically placed bi-temporally near the canthus of each eye, and those for measuring vertical movements are placed over the bone above and below one eye. The method thereby depends on conjugacy of the two eyes, although other electrode placements can measure the movement of

one eye with less accuracy. The electrical signal recorded by the EOG is produced by an electrostatic dipole moment in each eye, which is in turn produced by the dark current in the retinal photoreceptors. The EOG signal is therefore greatest and most stable with the subjects adapted to very low light levels, while other conditions result in considerable drift and other changes in accuracy. With care and frequent calibration, eye movements can be measured with a resolution of about 1°.

►Photoreceptors

## Electroporation

### Definition

A gene transfer technique that uses electrical pulses to drive DNA, RNA or morpholino oligonucleotides into cells. This approach is commonly used in mouse, chick, zebrafish and Xenopus to assess the function of a gene in a developmental process.

## Electroreception

### Definition

A sense that detects the weak electric fields generated by an animal itself or other animals. Present in all taxa of lower aquatic vertebrates, including newts and salamanders, by common descent. Also present in the egg-laying monotreme mammals of Australia and New Guinea (such as the duckbill, or platypus) by independent evolution. The ancestors of a few subtaxa of lower aquatic vertebrates, such as the Teleostei, have lost electroreception, but some of these have re-evolved electroreception. Electroreception is based on the possession of specialized electroreceptor organs that form part of the octavo-lateralis system (excepting the monotreme mammals), and sensory afferents connecting to specialized brain areas, and only works in water.

### Definition

►Electroreceptor organs are sensory organs adapted to detect electrical potential differences in aquatic environments. They are found in the skin of some species of fishes and amphibians, and on the bill of monotremata such as the platypus. In fishes and amphibians, they represent specializations of the ►octavolateralis system. Unlike the mechanosensitive specializations of the octavolateralis system – such as the sense of hearing, the sense of equilibrium, and the sense of rotation that respond to mechanical stimuli – they respond to electrical environmental stimuli. The lower detection level of the electroreceptive system approaches 10 nV/cm in media with a conductivity of 0.05 S/cm. Electroreceptor organs behave as band filters within the range of 0.1–10,000 Hz, the specific bandwidth depending on the type of organ. They give the organism access to electrical worlds, just as photoreceptor organs give the organism access to visual worlds. Electroreceptor organs were recognized as parts

of an electrosensory system in the middle of the twentieth century. Before then they were well known from morphological studies, but considered mechanosensory organs, or even glands.

## Characteristics

### Qualitative Description

Electroreceptor organs are, just like the mechanosensitive lateral line components, found in or immediately under the skin. There is a conspicuous dichotomy in appearance, related to the conductivity of the environment. All marine electrosensitive fishes have ampullae of Lorenzini, i.e. centimeters long, jelly-filled channels ending in innervated capsules (Figs. 1–3), whereas the freshwater fishes have microampullary organs (Figs. 4, 5) or tuberous organs (Fig. 6) within the skin.

Typical electroreceptor organs consist of open or closed invaginations of the skin. At the bottom of the invagination or cavity, receptor cells make contact with lateral line fibers. Open organs are called ampullary, closed organs tuberous. The recently discovered electroreceptor organs in Monotremata deviate from this general design in that they lack ►secondary receptor cells. The sensitive structures here are specializations of the afferent trigeminal nerve endings. The nerve ending itself consists of highly convoluted plasma membranes inside a myelin capsule. From those capsules, unmyelinated axonal spines protrude in the direction of the lumen of the gland. Such receptor organs are found on the bill of the platypus, *Ornithorhynchus anatinus*, and the snout of the echidna, *Tachyglossus aculeatus*, and the long-nosed echidna *Zaglossus bruijnii*.

The majority of electroreceptor organs belong to either the ampullary or tuberous organs.

Of the ampullary organs, the ampullae of Lorenzini in marine fishes are jelly-filled subcutaneous canals of less than 1 mm diameter and a length of several cm. The canals form a salt bridge between the receptor cells and the seawater. Thousands of receptor cells are clustered in capsules where they contact the endings of afferent lateral line nerves. Ampullae of Lorenzini occur in elasmobranch fishes like the dogfish *Scyliorhinus canicula*, the marine teleost catfish *Plotosus lineata*, and the living coelacanth *Latimeria chalumnae*. The other type of ampullary organ is the microampullary organ, found in freshwater fishes and amphibians. These are microscopically small invaginations of the skin that do not extend beyond the dermis. One lateral line nerve fiber innervates some tens of secondary electroreceptor cells at the bottom of the ampulla. Microampullae are found in a variety of electrosensitive freshwater species like the catfish *Ameiurus nebulosus*, the lamprey *Petromyzon marinus*, the sturgeon *Acipenser* sp., and also in urodeles like for instance *Siren* sp.

The tuberous organs in freshwater fishes can be described as microampullary organs where a plug of cells closes the ampulla lumen. The receptor cells do not connect to the outer world directly. The receptor organs have the appearance of skin-deep cavities. There are various subtypes, usually innervated by several types of

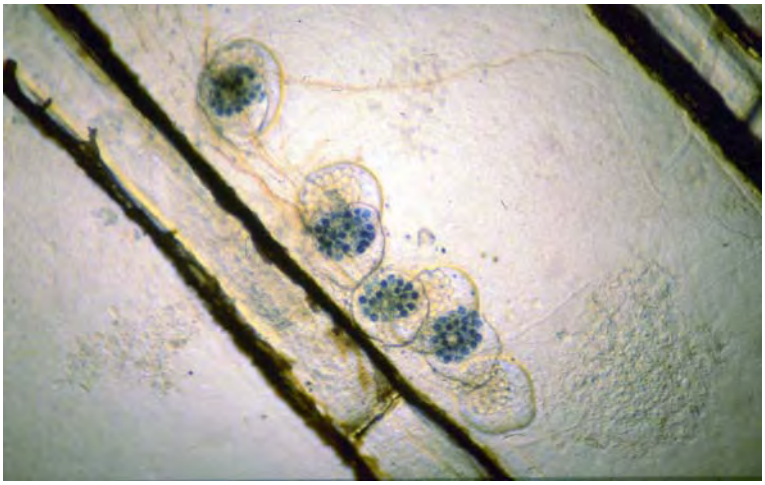
lateral line fibers. Tuberous organs occur in Mormyridae like *Gnathonemus petersii*, in Gymnarchidae like *Gymnarchus niloticus*, and in Gymnotiformes like *Eigenmannia virescens*. In the Mormyridae there are two subtypes, the Knollenorgans and the mormyromasts. They are tuned to discharges emitted by electric organs of the fish itself, respectively by conspecifics and other species with electric organs. Knollenorgans are also called rapid timing units, because they respond with a single spike to a single ►electric organ discharge. Mormyromasts are amplitude-modulated units, because they code the amplitude of the electric organ discharge in a spike train. In other Osteoglossiformes and Gymnotiformes, similar types of receptor organs exist. One type is involved in encoding timing, whereas another is involved in encoding strength.

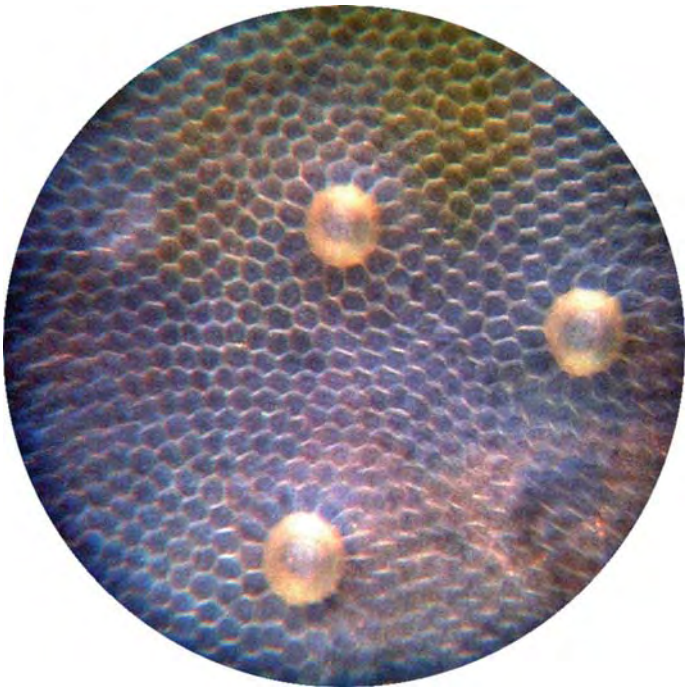
Electroreceptor organs are found in the following subdivisions of the animal kingdom: Osteoglossiformes, Siluriformes, Gymnotiformes, Myxiniformes, Petromyzontiformes, Chimaeriformes, Squaliformes, Rajiformes, Coelacanthiformes, Lepidosireniformes, Polypteriformes, Acipenseriformes, Semionotiformes, some Amphibia, and Monotremata.

## Higher Level Structures

Electroreceptor organs are innervated by lateral line nerves in all electrosensory species except for monotremes, where the trigeminal nerve is involved. The lateral line nerves in aquatic vertebrates are a well-developed set of cranial nerves, not found among the cranial nerves in terrestrial vertebrates. The lateral line nerves end in a specialized region of the rhombencephalon named the octavolateralis area. The ventral part of the octavolateralis area is involved in the processing of octavus information, the dorsal part in lateralis information. In teleosts, the medial zone of the dorsal (lateralis) part is mechanosensory, the lateral zone electroreceptive. The electroreceptive zone is called the Electrosensory Lateral Line Lobe (ELLL). From the ELLL, fibers run bilaterally to the pre-eminential nucleus, mainly contralateral, and to the torus semicircularis. Back projections have been demonstrated from the torus via the pre-eminential nucleus to the ELLL, and also directly to the inferior olive and caudal cerebellar lobe. A limited number of electrophysiological studies were performed in elasmobranch brains and in passive electrosensitive teleost brains. Two active electric teleost species have been investigated



**Electroreceptor Organs. Figure 5** Overview of a set of ampullary electroreceptor organs in the anal fin of the freshwater catfish *Kryptopterus bicirrhis* after exposure of one side to a 1% methylene blue solution. The electroreceptor cells of this side of the anal fin stand out as dark dots, whereas the cells at the other side of the fin are unstained. The large rod-like structures are fin rays. The thin wires between the ampullae are nerve fibers. Diameter of an ampulla about 0.1 mm.



**Electroreceptor Organs. Figure 6** Photograph of a part of the skin of the electric freshwater fish *Gnathonemus petersii* with hexagonal epithelial cells and some tuberous organs. The tuberous organs stand out as white pearls against a dark background. The diameter of a tuberous organ is in the order of 0.2 mm.

extensively: (i) The ELLL of the Mormyrid representative *Gnathonemus petersii*, where separate processing of electrosensory information by the ampullary system, the Knollenorgan system and the mormyromast system takes place, and (ii) The ELLL of the gymnotiform representative *Eigenmannia virescens*, where the neurophysiology of the ►Jamming Avoidance Response was unraveled. Up to the ELLL there is a large degree of somatotopy. ELLLs excitatory and inhibitory electroreceptive units are found in both gymnotiforms and

Mormyrids involved in contrast enhancement via lateral inhibition mechanisms. Other examples of signal processing by the central nervous system are the suppression of respiratory common mode signals, the convergence-related sensitivity increase in second order neurons, and the existence of frequency and directionality maps.

## Lower Level Components

All electroreceptor organs, apart from monotreme organs, have secondary receptor cells that synapse to afferent fibers of the lateral line nerves. There is morphological and pharmacological evidence that the synapses are chemical and glutamatergic. Sensitivity of the synapse to the glutamate agonists kainate, quisqualate, AMPA, and NMDA has been demonstrated. Electrophysiological data do not exclude an electrical contact between receptor cell and nerve fiber.

The apical faces of the receptor cells bear microvilli or kinocilia. It is assumed that surface enlargement lowers the electrical resistance from environment to the basal face of the receptor cell, thus providing a low resistance path to the electrosensitive structures. In ampullary electroreceptor cells, which are more exposed to the outer world than the cells of tuberous organs, electron-dense inclusions are found consisting of paracrystalline substances.

## Lower Level Processes

The process understood best is probably the functioning of the chemical synapse. The synapse behaves as other glutamatergic synapses of the vertebrate brain. The synapses mediate in the generation of spontaneous activity and stimulus-evoked activity in the primary afferents. The spontaneous activity is more dependent on metabolic processes than is the stimulus-evoked response. The other lower-level processes in electroreceptor organs are less well understood. There are, however, strong experimental indications that the electroreceptor cell is under severe electrochemical stress. The apical face of the electroreceptor cell is exposed to the outer world, usually freshwater or seawater, the basal face to the body fluids. The apical face bears either kinocilia or villi, which are usually associated with surface enlargement and ion transport. Further, the electroreceptor cells provide a low-resistance path to external stimuli. Somehow the electroreceptor cells must cope with all these challenges of its homeostasis. Functional adaptations to the electrochemical stress might be high activity of membrane ATP-ases to maintain electrochemical homeostasis, and a well-developed intracellular detoxification process. Evidence for the latter is given by the presence of electron-dense bodies in the electroreceptor cell. Dense bodies are large paracrystalline inclusions that contain metal ions like Fe- and Cd-ions. Other adaptations are perhaps the mucus containing invaginations that separate the electroreceptor cells from the outer world and may act as an electrochemical buffer. The temperature dependence of the action potential patterns reveals that an energy-consuming process in particular sustains the spontaneous activity.

## Process Regulation

Data of process regulation are scanty. The general presented view in textbooks and research articles is that electroreceptor organs are open loop systems that convert an electric stimulus into an action potential pattern. The stimulus transport process can, however, be modulated by the ion composition of the surrounding water. The glutamatergic synapse, with NMDA and AMPA receptors, can be modulated by glycine and serotonin. The transmission process is temperature dependent. Turnover of receptor cells is most likely, as in related mechanosensitive octavolateralis organs. It is inferred that the electrochemical homeostasis of the receptor cells is narrowly linked to the stimulus transduction process. How these two features are coupled was never investigated.

## Function

Electroreceptor organs serve to detect electrical fields in the aquatic environment. Different types serve different purposes. The tuberous organs are tuned to the detection of the Electric Organ Discharges (EOD). EODs are discharges generated by electric organs, which are under the control of motor neurons. EODs can be pulses of less than 1 ms duration and several volts of amplitude as in many mormyrids, or continuous sinusoidal discharges with frequencies ranging from 15 to 1,800 Hz as in many gymnotiforms. The ampullary organs are tuned stimuli other than EODs, i.e. electrical stimuli with frequencies from 1 to 100 Hz.

Of the tuberous organs of the Mormyridae, the Knollenorgans are specialized to detect the EODs of conspecifics. The mormyromasts in Mormyridae are used for measuring the distortions (deformations) of EODs by foreign bodies in the vicinity. These distortions represent objects with conductivities different from water, and thus allow object location. The ampullary organs are used for the detection of low-frequency electric fields representing respiratory potentials and standing dc potentials of aquatic organisms, and electrical fields related to redox processes in the bottom, or electromagnetic induction phenomena. The complete set of electroreceptor organs is used for prey detection, prey recognition, spatial orientation, navigation, intraspecific and interspecific communication.

In gymnotiform wave fishes, a similar specialization of electroreceptor organs exists. Tuberous T-organs are involved in the detection of the timing of the sinusoidal EODs, whereas the tuberous P-organs are involved

in the detection of the EOD strength. The ampullary organs serve the same purpose as those of the Mormyridae. Gymnotid fishes with EODs of almost equal frequencies would disturb each other's perception. To avoid unwanted interference of the EODs, the fish show a Jamming Avoidance Response (JAR), i.e. both fishes shift the frequency of the EODs slightly in opposite directions. The neural mechanisms behind the JAR response have been extensively studied.

Not all electrosensitive fishes have electric organs to give off electric discharges. Fishes *with* electric organs are said to use electroreception in the active mode, whereas fish without electric organs use electroreception in the passive mode. Fishes without electric organs use, as a rule, only ampullary systems to detect low-frequency electric fields emanating from prey or other aquatic organisms, and electrical fields related to geochemical features of the environment and water motion in the earth magnetic field.

Behavioral experiments have demonstrated unequivocally that the electric sense is a real sensory system that is used for everyday survival by making use of electrical cues from the environment. Electroreception is used for the detection and recognition of food, for spatial orientation and navigation, and for social interactions. Apart from being sensitive to electrical stimuli, the electroreceptor organs also respond to chemical, thermal, and magnetic stimuli. Stingrays have been conditioned to orientate with respect to the natural magnetic field of the earth. The ampullae of Lorenzini are assumed to be the magnetic detectors involved. Further, both the spontaneous activity and the stimulus-evoked responses of the electroreceptor organs in freshwater fishes respond to slight, naturally occurring, variations of the water ion composition. Electroreceptors also respond to temperature changes. Until now, however, no behavioral experiments support a thermoreceptive or a chemoreceptive function.

### Pathology

Electroreceptor organ pathology is only known from dysfunction due to the administration of drugs like cisplatina, vincristine and cytochalasine in pharmacological studies, or acriflavine and trypaflavine in the fight against fin rot. Electroreceptor cells have been used as model systems for mechanosensitive hair cells of the vertebrate sense of hearing. The susceptibility of the electric sense as a whole to water pollution has been studied in order to develop early warning systems to monitor the quality of surface water.

## Electrosensory Systems

### Definition

A system of cutaneous receptors which respond to voltage changes across the skin with changes in neural

activity. Electrosensory systems have evolved multiple times within vertebrates.

►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

## Electrotonic Spread

### Definition

A change in membrane potential (e.g. a receptor potential or synaptic potential) originating in one region of a cell ($\Delta V_0$) is associated with local transmembrane currents that distribute and flow intra- and extracellularly to adjacent membrane regions (at distance d), where they in turn cause changes in membrane potential ($\Delta V(d)$). However, the underlying currents get progressively smaller with distance because fractions of them are diverted through transmembrane ion leak channels. Thereby, the elicited adjacent membrane potential changes ($\Delta V(d)$) are reduced in size and altered in shape (electrotonic decrement). In a cylindrical nerve or muscle fiber, the amplitude of the potential changes falls off exponentially with distance from the region where they have originated: $\Delta V(d) = \Delta V_0.\exp(-d\lambda)$, where the length (space) constant $\lambda$ is $\sqrt{(R_m/R_i)}$, defining the distance at which the original voltage change ($\Delta V_0$) drops to a fraction of $1/e \approx 0.37$, $R_m$ is the membrane resistance and $R_i$ the longitudinal intra-fiber resistance. Two important conclusions are that (i) the passive or electrotonic spread of local potentials across a cell membrane is no means for transmitting information over long distances; and (ii) a process of encoding is necessary to transform the local potential from a continuous graded potential to a discharge of action potentials which are able to propagate over longer distances.

## Embodied Neural Systems

►Computer-Neural Hybrids

## Emboliform Nucleus

### Synonyms

Nucl. interpositus ant; Anterior interpositus nucleus

### Definition

The emboliform nucleus and globose nucleus are collectively known as the interpositus nucleus, since both receive their afferents from Purkinje cells of the cerebellar hemisphere, intermediate part and from collateral spino- and rubrocerebellar projections. Their efferents pass via the fiber bundle of the superior cerebellar peduncle primarily to the small-celled red nucleus, but with fewer going to the ventral lateral thalamic nucleus.

►Cerebellum

## Embryonic Stem (ES) Cells

### Definition

Embryonic stem cells are pluripotent cells derived from the epiblast tissue of the inner cell mass (ICM) of a blastocyst. A blastocyst is an early stage embryo – approximately 3–5 days old mammals – consisting of about 50–150 cells. ES cells possess two unique characteristics: pluripotency (see after) and an indefinite self-renewal capacity, remaining genetically stable even after 140 cycles of division. Improvements regarding the ES culturing protocols to generate largescale numbers of transplantable ES have recently been described. Feeder-independent growth of human ES cells (e.g., using protein components solely derived from recombinant sources or purified from human material) can be achieved as well as the in vitro propagation (through continuous asymmetric cell division) of ES cell-derived neural stem cells without accompanying differentiation. However, protocols for avoiding in vivo teratocarcinoma formation after ES (or ES-derived cells) cell transplantation are still lacking.

Transplantation of both ES cells and ES cell-derived neural (neuronal, glial) progenitors efficiently promotes CNS regeneration in preclinical models of stroke, myelin deficiency, acute spinal cord injury (SCI), and Parkinson's disease (PD). Because of their unique combined abilities of unlimited expansion and pluripotency, ES cells are a potential source for regenerative medicine and tissue replacement after injury or disease. To date, no approved clinical medical treatments have been derived from embryonic stem cell research.

## Emergence

Achim Stephan
Institute of Cognitive Science, University of Osnabrück, Lower Saxony, Germany

### Definition

In ordinary language, the notions "to emerge" and "emergence" still bear the meaning of their Latin ancestor *se emergere*; they stand for "to appear" or "to show up," and "appearance," respectively. In scientific discourse, the term "emergent" is used to characterize

certain properties and structures, sometimes also laws. Three types of "emergence," which are of different strength should be distinguished: *Strong* (*synchronic*) *emergence* refers to irreducible properties, *diachronic emergence* points to unpredictable structures and properties, and *weak* (*synchronic*) *emergence* refers to properties that are instantiated only on the systemic level, but are reducible in principle.

## Description of Theory

During the last two decades the concept of emergence has seen a strong revival in ►cognitive science and the philosophy of mind (see, e.g., [1,2]; for a historical survey cf. [3]). People associate with it the hope to both adequately classify philosophical problems such as the "►hard problem of consciousness" and to adequately characterize behaviors of artificial systems that are not programmed explicitly, but arise from self-organizing processes. A closer look, however, reveals that no unique notion of emergence is available that is apt for both issues: The classification of mental phenomena that resist reductive explanations necessitates a strong notion of emergence, which is significant for metaphysical issues in the philosophy of mind, but of low interest to the other areas of cognitive science (and to the natural sciences in general [4]). These disciplines focus on behaviors of complex ►dynamical systems that exhibit unprogrammed or unexpected patterns and regularities without being resistant to reductive explanations. They need notions of emergence that go without irreducibility. Hence, there is a need for specifying different notions of emergence.

### Varieties of Emergence

The more ambitious versions of emergentism are all based on a common weak theory from which they can be developed by adding further theses. The weak (synchronic) theory of emergence specifies the minimal criteria for emergent properties. Its three basic features – the thesis of *physical monism*, the thesis of *systemic* (or *collective*) *properties*, and the thesis of *synchronic determination* – are jointly compatible with current reductionist approaches.

The thesis of *physical monism* is about the nature of systems that have emergent properties or structures. It claims that the bearers of emergent features consist of physical entities only: All entities existing or coming into being in the universe consist solely of physical components; likewise, properties, behaviors, or structures classified as emergent are instantiated by systems consisting exclusively of physical entities. Thus, all substance-dualistic positions are rejected; for they base properties such as being alive or having cognitive states on supernatural bearers such as an ►entelechy or a ►res cogitans, respectively.

According to the second thesis, only *systemic* (or collective) *properties* are candidates for emergent properties. These are properties of a *general* type, which are instantiated by the system as such, but by no subsystem or component of it. It is uncontroversial that many systems exhibit systemic properties. Otherwise, one would have to maintain that *all* system properties are already instantiated by system parts.

The thesis of *synchronic determination* specifies the type of relationship that holds between the systemic properties of a system and its microstructure (*i.e.*, the specific arrangement of the system's parts together with their properties): Systemic properties and dispositions depend nomologically on the microstructure of their bearers. There can be no difference in a system's systemic properties without some difference in the properties or arrangement of its parts. Anyone who denies the thesis of *synchronic determination* either has to admit properties that are not bound to the microstructure of its bearer, or she has to suppose that some additional factors, e.g., non-natural entities, are responsible for differing dispositions of physically identical systems.

*Weak* emergentism is compatible with contemporary reductionist approaches without further ado. Particularly for this reason, philosopher of science Bunge [5] is emphatic on it, but also cognitive scientists, e.g., Varela, Thompson, and Rosch [6] adopt this position.

The essential claims of the two more ambitious theories of emergence are those of *irreducibility* (synchronic emergentism) and of *unpredictability* (diachronic emergentism). These are closely connected. Irreducible systemic properties are *eo ipso* unpredictable before their first appearance. Hence, synchronically emergent properties are also diachronically emergent, but not conversely. All diachronic theories of emergence are based on a thesis about the occurrence of *novelties* in evolution. According to this thesis, in the course of evolution exemplifications of genuine novelties occur again and again. Existing entities combine to new configurations and structures that constitute new entities with new properties and behaviors. However, the thesis of novelty does not by itself turn a weak theory of emergence into a strong one, since reductive physicalism remains compatible with it. Only the addition of the thesis of *unpredictability*, in principle, will lead to stronger forms of *diachronic* emergentism.

The structure of an arising new system can be unpredictable, in principle, for two reasons: Its arrangement may be a result of indeterministic processes, or it may be the result of deterministic, but chaotic processes. Within emergentism, only the second option is discussed. It is captured by the thesis of *structure unpredictability*, which claims that the rise of a novel structure is unpredictable, in principle, if its formation is governed by laws of deterministic chaos. Likewise, any property that is instantiated by such a novel structure is unpredictable, in principle.

Emergence as *structure unpredictability* has a great deal in common with an approach Clark has called emergence as *uncompressible unfolding* [7]. This expression refers to those macrostates of a system that can only be derived by *complete* simulations of all interactions at the component's level and the external influences on the system [8]. Such complete simulations of the underlying microdynamics would be necessary for long-term predictions of structure formation governed by deterministic chaos. Since these simulations are not available – information compressing short cuts are not adequate for longer intervals –, structure unpredictability as introduced above is unpredictability, in principle.

Strong (synchronic) emergence has its roots in Broad's theory of emergence [9]. It involves irreducibility, *i.e.*, the principled failure of explaining reductively a systemic property. for a reductive explanation to be successful, several conditions must be met: the property to be reduced must be functionally construable (or reconstruable); it must be shown that the specified ►functional role is filled by the system's parts and their mutual interactions; and the behavior of the system's parts must follow from the behavior they show in isolation or in simpler systems than the system in question. If all these conditions are met, the behavior of the system's parts in other contexts reveals what systemic properties the actual system has.

Since these three conditions are independent of each other, there are three different ways in which systemic properties may be irreducible and thus: strongly emergent. A systemic property is irreducible: if it is not functionally construable (or reconstruable); if it cannot be shown that the interactions between the system's parts fill the systemic property's construed or reconstrued functional role; or if the specific behavior of the system's components, over which the systemic property supervenes (►Supervenience), does not follow from the component's behavior in isolation or in simpler arrangements (for further details, see [4]).

Hence, we have to distinguish three different types of strong synchronic emergence. Their consequences are also different. If a system property is irreducible due to the fact that the components' behavior is not reducible to the behavior they show in simpler systems given their current arrangement, then the system itself or its specific structure seems to exert some "downward causal influence" on its parts. However, such "►downward causation" would not violate the principle of the ►causal closure of the physical domain. We would just have to accept additional types of causal influences within the physical domain besides the known types of mutual interactions.

On the other hand, if the behavior of the system's parts cannot fill the functional role adequately attributed to the corresponding systemic property this systemic property itself would have causal powers different from those of the system's microstructure. If in addition, the systemic property were a nonphysical (mental) property with a causal influence on the physical world, we would have to admit a violation of the principle of the causal closure of the physical realm.

In contrast, the occurrence of properties that are not functionally construable does not imply any kind of downward causation. Systems with properties that admit of no functional analysis need not be constituted in such a way that their components' behavior is irreducible. Nor is it implied that the system's structure has a downward causal influence on the system's parts. Thus there is no reason to assume that properties that cannot be functionally analyzed have any causal influence on its bearer's parts. Rather, the question is how such properties might have any causal role at all.

## Applications

The debate about phenomenal ►qualia and consciousness shows that within the philosophy of mind there is need for a strong notion of emergence. Even if we would know everything about the neural correlates of consciousness, even if we could say how each single neuron and how each single synapse behave, we might not be able to reductively explain all mental properties correlated with these neural processes. In fact, such a failure would not be based on a lack of insight on the side of the neurosciences; rather it would come along with the conceptual impossibility to adequately reconstruct phenomenal qualities via their functional role.

In contrast, the notion of strong emergence has no application to cognitive science, except this discipline itself were concerned with phenomenal qualities, e.g., with the question whether or not an artificial system might have a ►first-person perspective and conscious experiences. In all other branches, strong emergentism has no relevance for cognitive science: Connectionist networks (►Connectionism), Artificial-Life colonies (►Artificial Life) and robots exhibit behaviors and properties (e.g., pattern recognition, flocking behavior, collecting cans, respectively) that are specified via their functional role. All of these are only *weakly* emergent, they are reductively explainable without residue [10]. However, it is not informative to learn that most properties of connectionist networks, robots, and *A-life*-creatures are weakly emergent, for there exist just too many properties which are instantiated at the system level only, and not at the level of the system's parts.

Rather, emergence as *structure unpredictability* or *uncompressible unfolding* is an alternative that cuts the *world of artifacts* in cognitive science at some interesting joints. Bedau has demonstrated the fruitfulness of this approach for *A-Life* research and the ►Game of Life [8]. In robotics and artificial intelligence, this approach to emergence might help particularly to characterize evolutionary and ►hybrid

architectures: quite often they develop in a way that is unpredictable, in principle.

# Emergency Response

The concept was first put forward by Walter B. Cannon who described that in a certain situation, such as under threat or in danger, the sympathetic-adrenal system is activated together as a whole, producing an increase in blood pressure, heart rate, cardiac contraction, hair erection (in hairy animals), salivary secretion, pupil dilation, and epinephrine secretion. In dogs and cats the response brings a picture of an angry animal. However, the sympathetic system is not always activated as a whole; in many other situations differential activation of the sympathetic nerves innervating various organs occurs.

## Synonyms

Affect

## Definition

Physiological and behavioral responses to an important environmental object or event, typically mediated by the autonomic nervous system and ►subcortical brain structures. These responses are combined with cortically-mediated modulation and interpretation. One's interpretation of emotional responses is often called a "feeling," and is typically considered separately from those responses.

## Characteristics

### Historical Perspective

Emotion has often been connected with ►motivation. Charles Darwin argued that emotions have the adaptive

value of communicating motivational states to other members of one's species or social group. ►William James also linked emotion to motivation, suggesting that emotions are a means of maintaining motivation in the absence of direct environmental input that would initiate and sustain it. The James-Lange theory of emotion, which combined James' ideas with those of Carl Lange, proposes that one's perception of an event or object stimulates physiological reactions and behavioral responses, the occurrence of which are interpreted by the brain as a feeling. To use James' famous example, we see a bear, become aroused, and then interpret that arousal as a feeling of fear.

Empirical investigations found problems with the James-Lange theory. For example, people whose brains cannot receive arousal cues from the ►autonomic nervous system because of spinal cord transection feel emotions nonetheless. Also, different emotional states produce identical behavioral and physiological arousal profiles, leaving it mysterious as to how the brain makes the appropriate interpretation. Consequently, the James-Lange theory was modified and extended by physiologists Walter Cannon and Phillip Bard, who proposed that one's perception of the arousing object or event simultaneously stimulates both subcortical mechanisms of physiological arousal and cortically-mediated feelings.

This perspective is echoed in Antonio Damasio's more contemporary somatic-marker hypothesis [1]. Damasio proposes that an individual contemplating a potential response to an emotionally significant event, or even to thoughts or memories of such events, experiences a bodily reaction to the perceived consequences of that response option. This bodily, or somatic, reaction marks the contemplated action with a positive or negative valence, and this marker goes on to influence one's choice of that response option; negative somatic markers devalue the associated response option, and positive somatic markers enhance it. Somatic markers then interact with one's (cortically-controlled) cognitive evaluation of one's options, leading to response selection and production.

## Neural Mechanisms of Emotional Responses: ►Pavlovian Fear Conditioning

Functional neuroanatomical investigations have given us valuable insight into the neural mechanisms of emotion. Subcortically, important structures include the ►thalamus, which receives sensory input, the ►amygdala, which coordinates the behavioral and physiological responses to the input, as well as relaying information to the cortex for interpretation, and the ►hypothalamus, which controls many of the autonomic and ►neuroendocrine (hormonal) responses to emotionally-relevant stimuli. Our understanding of the subcortical mechanisms that mediate linkages between sensory input and emotional responding has been greatly advanced by the work of LeDoux's research group on the neural mechanisms of fear conditioning in the rat [e.g. 2]. Although most of our knowledge about subcortical mechanisms of emotion has been gained from studying fear, there is ample evidence that the same processes and neural systems govern positive emotions as well [e.g. 3].

Fear conditioning is a specific case of Pavlovian or ►classical conditioning in which a stimulus that initially provokes no noticeable response (the conditioned stimulus or CS) is paired with a stimulus that provokes a fear response automatically (the unconditioned stimulus or US). In fear conditioning, the CS is typically a tone and the US is a slight electric shock to the rat's footpad. Sensory information about both of these is relayed by the thalamus and the sensory cortices to the basal and lateral nuclei of the amygdala. At the start of the conditioning experience, thalamic and cortical inputs that carry information about the tone do not induce any substantial response by the amygdala, while inputs carrying information about the footshock do induce a response. The basal and lateral amygdala respond to footshock input by activating connections with the central and medial nuclei of the amygdala. These nuclei in turn stimulate a constellation of behavioral and physiological reactions that we call a fear response. For example, the central and medial amygdala have connections with nuclei of the hypothalamus that initiate a series of reactions culminating in the release of adrenalin and ►corticosteroid ("stress") hormones from the adrenal glands. Outputs of the central and medial amygdala to other ►brainstem structures coordinate activation of the peripheral nervous system, and stimulate behavioral reactions such as freezing and other defensive responses.

During fear conditioning, the tone CS is repeatedly presented with the footshock US, until, after several such training trials, the tone presented by itself provokes the same constellations of reactions provoked initially only by the footshock. This change in response to the CS is a result of ►synaptic plasticity in the neural connections between the thalamus and the basal and lateral amygdala. The connections between neurons of the thalamus that processed the tone input and neurons of the basal and lateral amygdala were initially weak at the start of the conditioning experience, too weak to provoke the amygdala-mediated responses provoked by the US. However, activating those weak inputs simultaneous with the strong inputs carrying footshock information led to strengthening of the initially weak connections, such that they could provoke the same response in the basal and lateral amygdala that was provoked by the strong footshock inputs.

## The Adaptive Value of Emotional Reactions

Such mechanisms offer a neurobiological explanation of the valuable – although sometimes maladaptive – capacity of all animals to learn to have emotional

reactions to objects, events, or others that initially provoked no such response. In particular, reminiscent of James' ideas, animals can learn which environmental cues predict impending danger or reward and respond appropriately, even if the danger or reward is not immediately present.

In people, social concerns can also become associated with basic emotional responses, e.g. shame, guilt, and pride might all be seen as learned emotional reactions to sociocultural punishments or rewards. Also, given the reciprocal connections among the amygdala and the ►hippocampus, a structure critical to processing memories of episodes in one's past, one can respond emotionally to the *memories* of emotional events (see ►Emotional Learning and Memory).

## Cortical Mechanisms of Emotion

As Cannon and Bard pointed out, cortical structures are also involved in emotion. Cortical areas have been implicated in one's subjective interpretation of the subcortical arousals and reactions associated with an emotion (this interpretation is often called "feeling"), the capacity to perceive, comprehend, communicate, and recall emotional information accurately, and the ability to modulate emotional reactions.

Of the four major lobes of the cortex, the frontal lobe has been most closely linked to emotion. Its development is important to one's abilities to recognize and project emotion, to regulate emotion, and to coordinate emotional response with social and cultural expectations. For example, people suffering ►frontal cortex damage typically do not show autonomic arousal to pictures that most people judge as disturbing, while neurologically intact people show strong autonomic arousal to such images. (Based on such findings, some have speculated that sociopathy might derive from frontal cortex hypoactivity.) Other cortical areas have been associated with emotion. For example, people with ►temporal lobe epilepsy often report deeper, more intense feelings during seizures. Also, ►visual cortex in occipital and temporal lobe and ►somatosensory cortex in parietal lobe are relevant to recognizing emotional facial expressions, while auditory cortex in temporal lobe is relevant to recognizing emotional tone of voice. But most attention has focused on the role of frontal lobe areas in emotional information processing.

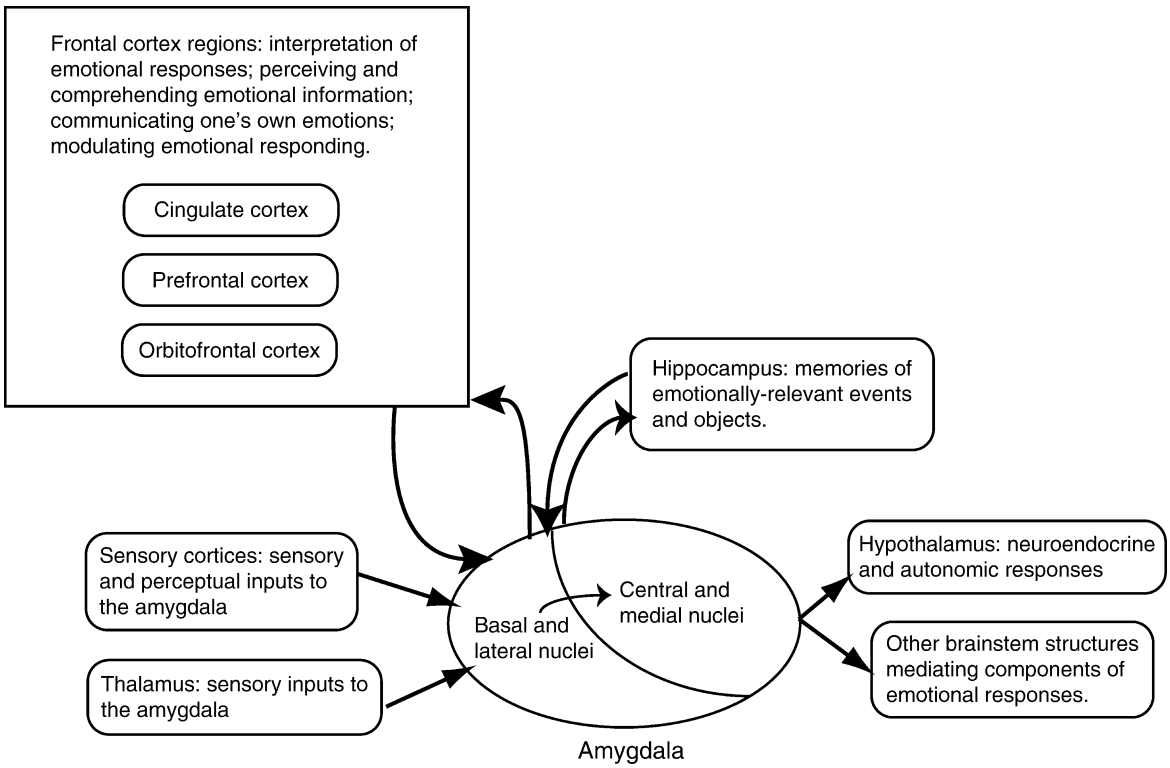
Data emerging from both human brain imaging studies and animal research suggest that ►prefrontal cortex, ►orbitofrontal cortex, and ►cingulate cortex are particularly implicated in emotional function. Both prefrontal and orbitofrontal cortex seem necessary to one's ability to recognize and discriminate among emotional facial expressions and vocal tones [4]. Medial prefrontal cortex is activated when an individual re-valuates how negative a negative event really was, and its activation inhibits the amygdala, presumably degrading the degree to which the individual reacts to the event [5]. Prefrontal, orbitofrontal, and cingulate cortex all influence subcortical structures such as the amygdala, and are all invoked to modulate emotional reaction based on expectations and beliefs about impending dangers or rewards. For example, these systems seem to play a role in the fact that normally non-painful stimuli are perceived as painful if one is told to expect pain, and that anticipation of a reward can enhance that reward's subjective value [6]. There even seems to be a dorsoventral (top to bottom) differentiation of function within these areas: more ventral (lower) frontal cortex areas may be involved in emotionally evaluating an object or event based on its context, and in guiding response selection based on that evaluation. On the other hand, dorsal (upper) areas may be important to purposive regulation of emotional reactions [6,7], such as an individual's decision not to react to an insult with physical violence.

## Cortical and Subcortical Interactions

Cortex and subcortical structures such as the amygdala do not act independently. Rather, they interact to govern several aspects of emotion. For example, communication from the amygdala to sensory cortex can sharpen cortical cell responses to certain sensory inputs associated with emotionally-significant events. Amygdala input also appears to inform cortical activity involved in directing one's attention to potentially salient environmental events. The amygdala also seems to mediate hormonal activity that affects the consolidation of emotional memories within the hippocampus [see 8 for a more detailed discussion of these interactions]. Thus, emotion is a combination of subcortically- and autonomically-governed behavioral and physiological reactions to environmental events together with the cortical interpretation and modulation of such reactions.

## Lateralization and Asymmetry

The cortex is somewhat lateralized in its emotional function. That is, structures in the left brain hemisphere may process emotional information differently than do structures in the right hemisphere. People with right hemisphere damage are often unable to interpret others' emotional facial expressions or tones of voice, or to project their own emotions in their own expressions and intonations. Left hemisphere damage is more likely to affect one's ability to understand the emotional content of writing or speech or to correctly process information about emotions. For example, such damage might impair empathy or one's "theory of mind," i.e. the ability to understand what another person might be feeling.



**Emotion. Figure 1** Schematic summary of major cortical and subcortical brain areas and their respective roles in emotion.

Similar ▶asymmetry may obtain in the amygdala. Right amygdala may perceive and respond relatively quickly to more gross-grained, immediately identifiable information coming from the surrounding environment, and mediate broad or global emotional reactions. On the other hand, left amygdala may be involved in the relatively slow perception of and response to details of emotional stimuli, orchestrating more specific responses to particular features of the environmental event or object [9]. Although most human brain imaging studies suggest that the left amygdala responds more strongly to emotional information than does the right, this asymmetry may be an artifact of the time resolution of current brain imaging technology: Faster right amygdala responses might not always be as observable as slower left amygdala responses [10].

## Summary

The roles and interactions of several brain areas that are important to emotion are summarized in Fig. 1.

Emotional responses begin with the sensation and perception of relevant environmental objects, events, or others. Sensory and perceptual information is relayed to the amygdala, either immediately from thalamic nuclei or following processing in sensory cortex. Amygdalar nuclei interact with the hypothalamus and other brainstem structures to coordinate the constellation of autonomic, behavioral, neuroendocrine, and other reactions that constitute the emotional response. Plasticity in synaptic inputs to and within the amygdala confers the ability to learn to respond emotionally to previously neutral environmental cues associated with emotional objects or events. Reciprocal connections between the amygdala and the hippocampus help mediate memory for emotional events, and allow the individual to respond emotionally to memories. Reciprocal connections between the amygdala and cortical areas, especially regions of the frontal cortex, mediate conscious, subjective interpretations of emotional arousal and also allow the individual to modulate emotional responding depending on the environmental context.

## Synonyms

Pain unpleasantness; Pain distress

## Definition

1. The immediate unpleasantness ascribed to a painful sensation that motivates behaviors of escape and avoidance to minimize injury
2. Cognitively-mediated emotional and affective disturbances such as depression, anger, anxiety, and despair that can be associated with having pain; pain distress

## Characteristics

Pain sensation varies in intensity, location, quality and duration. In addition, the experience of pain contains a salient disagreeable aspect that powerfully motivates behaviors to eliminate or reduce this disagreeable aspect. This dual sensory/motivational nature of pain, combined with its functional role of avoiding or minimizing injury, forms the basis for the formal definition of pain provided by the leading international pain organization, the International Association for the Study of Pain (IASP), "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."

Pain affect contains at least two distinct components. The first component can be described as immediate unpleasantness. This disagreeable component is readily demonstrated in both animals and man. It motivates behaviors of escape and avoidance, as well as recuperation; it serves as an immediate "alarm of harm" that commands attention and action to minimize injury. In contrast, the second component is implicit in the terms "emotional/affective," which imply a range of factors including anger, depression, hopelessness, anxiety, despair, and distress. These emotional and affective disturbances derive from cognitive evaluations of the meanings and consequences associated with having pain, especially if the pain is prolonged or chronic.

The immediate, unpleasantness component of pain shares many features with other sensory modalities such as temperature. Temperature sensations can be accompanied by unpleasant feelings that motivate behaviors (e.g., seeking warm or cool environments). The term "pain unpleasantness" is derived directly from human psychophysical studies of sensations such as taste and temperature that can be both intense and either pleasant or unpleasant. The study of human judgments of pleasantness and unpleasantness is termed "►hedonic psychophysics" and the use of the term "unpleasantness" in pain emphasizes the immediate nature of the disagreeable component in contrast to the more cognitively-mediated ►pain emotions and pain-generated affect.

The separation of the pain experience into sensory, and unpleasant and/or affective, dimensions has a long history that has been formalized more recently in both influential reviews [1] and pain measurement instruments. The most widely used instrument is the McGill Pain Questionnaire (MPQ) published in 1975 [2]. Based on a study of pain language [3], the MPQ and its subsequent short form divides the pain experience into a number of sensory qualities, and into additional non-sensory "affective" dimensions and an "evaluative" dimension. The adjectives in these scales can be construed as describing degrees of unpleasantness (e.g., annoying, troublesome, unbearable, agonizing) or emotional reactions directly (e.g., sickening, fearful, exhausting) or indirectly by personifying the pain (e.g., vicious, cruel).

The MPQ distinguishes between differences in the quality of pain sensation and in dimensions that can be aligned with the unpleasantness of these sensations and the emotional reactions to them. Figure 1 shows an alternative approach that measures the intensity of pain

**Emotional/Affective Aspects of Pain. Figure 1** The Gracely Box Scale measures pain intensity and unpleasantness directly by presenting adjectives that are scaled along these separate dimensions of pain. Respondents are instructed to focus on the words to determine their level of pain intensity or unpleasantness and then select the number that corresponds to this level.

sensations and unpleasantness directly by adjectives that are scaled along these dimensions. Other approaches use a pair of visual analog scales in which the dimensions are differentiated by instructions and by the labels used to describe the ends of the scale [4].

The outcomes of sensory and unpleasantness scales are often correlated, leading to questions of whether specific scales discriminate between dimensions or about the basic validity of the multidimensional approach. However, these dimensions can be both correlated and independent [5]. In this view, the amount of unpleasantness is determined by the intensity of the pain sensation and by another factor that can be thought of as an affective amplifier of sensory input with an affective gain control. This system is symbolized by an amplifier and the gain by a knob. From this figure, it is clear that the outputs of pain intensity and ►pain unpleasantness would be correlated. Pain unpleasantness can be altered by changes in the input signal related to the intensity of the pain sensation. However, the position of the knob on the affective amplifier, affective gain, is under central control and independent of sensory intensity. Manipulations that increase pain affect, such as anxiety, would do so by increasing the affective gain, resulting in more unpleasantness for a given pain sensation. Manipulations that decrease pain unpleasantness would likewise do so by decreasing the gain. In practice, pain intensity and unpleasantness can be measured by calculating the amount of unpleasantness for a given sensory intensity (e.g., ratio of unpleasantness to intensity responses). This calculated gain, which can be termed "►relative unpleasantness," together with the ratings of pain intensity, provides independent measures of both dimensions.

This system also depicts a second affective amplifier that receives input from cognitions associated with

the pain experience. It underlies the development of pain-related distress. A third affective amplifier receives input from cognitions unrelated to pain, for example, knowledge of a life-threatening disease. Feedback loops connect all of these systems to all gain controls (not shown). Thus, the overall emotional experience and suffering associated with human pain may reflect input from all three affective sources.

Several models of nociception have been developed to measure these affective reactions in animals. It is important to note that these assays differ from the more commonly used reflex measures that provide information only related to the sensory processing of noxious stimuli (intensity, location, duration). Furthermore, unlike most affective reactions, reflexive responses such as paw withdrawal and paw-licking do not require cerebral processing.

Animal models of pain affect can be divided into two types: those that directly measure unlearned or innate affective reactions to noxious stimulation (e.g., vocalizations) and those that indirectly measure pain affect by assessing learned responses of escape or avoidance. The audible vocalizations or cries emitted by rats *following* exposure to a noxious stimulus (►vocalization after discharges (VADs), ►Noxious stimulus evoked vocalizations) are considered a direct index of the unpleasantness associated with painful sensations [6]. Support for VADs as a valid rodent model of pain affect is derived from reports that VADs are suppressed by damage of or drug treatments into brain areas (anterior cingulate cortex, amygdala, hypothalamus, medial thalamus) implicated in the generation of pain unpleasantness in humans. These findings are consistent with serial transection studies indicating that the essential neural circuitry mediating the generation of VADs is organized at the level of the rhinencephalon ("smell-brain," also included in the limbic system)-diencephalon. Drug treatments that preferentially suppress the disagreeable feelings of human pain also preferentially suppress VAD production in rats, and more importantly, elicitation of VADs is necessary for noxious stimulation to support fear conditioning.

In contrast to VADs, audible vocalizations of the rat that occur *during* noxious stimulation are not considered an index of pain unpleasantness. These vocal responses are organized within the brainstem and exhibit different spectrographic characteristics compared to VADs. Rodents also emit ultrasonic vocalizations that have been suggested to reflect negative hedonic states in general and pain unpleasantness in particular during a noxious event. However, the validity and usefulness of measuring ultrasonic vocalizations in studies of pain is debatable.

Indirect measures of pain affect evaluate learned responses related to the emotive attributes of a noxious stimulus. In ►conditional place avoidance (CPA) paradigms, rats learn to avoid a compartment that was previously paired with a noxious stimulus. This avoidance behavior is indicative of a conditional response that stems from the association of the contextual cues of the compartment with the immediate unpleasantness of the ►noxious stimulus that was experienced within that compartment. Recent evidence from studies using CPA suggests that the rostral extent of the anterior cingulate cortex (rACC) may be a critical region for encoding the unpleasantness component of a noxious stimulus. Johansen et al. [7] demonstrated that inactivation of the rACC impaired the acquisition of pain-induced CPA, but failed to attenuate both the production of acute pain behaviors and avoidance conditioning to an aversive, but non-nociceptive, stimulus. More recently, these investigators showed that chemical activation of rACC produces CPA in the absence of noxious stimulation.

Operant tests also are indirect measures of pain affect. In these assays, animals perform learned (motivated) responses to escape from or avoid noxious stimulation (see for example [8]). In one type of escape paradigm, noxious simulation is delivered in either one of two sides of a testing chamber. To escape, animals must move from the noxious side of the chamber to the other, non-noxious side. In another operant approach, animals learn to perform behaviors (e.g., bar pressing) to avoid noxious stimulation. Lastly, in tests of motivational choice, animals can choose to voluntarily expose themselves to a noxious stimulus to receive a reward such as food. Thus, the motivational drive to acquire a desired reward must be evaluated against the motivational drive to avoid the unpleasantness of noxious stimulation.

Increasing evidence from clinical and preclinical (animal) studies using electrophysiological, neurosurgical, and functional imaging methods strongly suggests a neuroanatomical basis for independent sensory and unpleasantness processing (reviewed in [9,10]). The sensory attributes of pain appear to be encoded in a lateral pain system projecting through specific lateral thalamic nuclei to the primary and secondary somatosensory cortices. In contrast, pain unpleasantness may be determined within a medial pain system that projects through the reticular formation to terminate in medial/intralaminar thalamic nuclei. The medial thalamus in turn projects (often reciprocally) to limbic and forebrain regions that process emotional stimuli and unpleasantness in other sensory systems such as the amygdala, insula and anterior cingulate cortex. Processing of nociceptive input within this limbic-forebrain circuit is thought to contribute to the generation of innate

affective and autonomic reactions, the coordination of pain-related motor activity, and the development of fear conditioning.

## Synonyms

Emotional arousal-influenced learning and memory

## Definition

Memories of emotionally arousing experiences are generally well retained. The term "emotional learning/memory" refers to the phenomenon that remembrance of emotionally arousing experiences is typically more enduring and more vivid than that of emotionally neutral experiences. Studies investigating the neurobiological mechanisms underlying this phenomenon indicate that emotionally significant experiences activate hormonal and brain systems that regulate the formation of the memory of such experiences. Arousal-activated modulatory systems not only influence neurobiological processes underlying the consolidation of new information; they also affect other mnemonic processes, including ►memory retrieval and ►working memory.

## Characteristics

### Description of the Process

#### *Stress Hormone Effects on Learning and Memory*

This essay describes how acutely released stress hormones mediate ►emotional arousal (Emotion) effects on cognition. In recent years significant advances have been made in understanding the neurobiological processes underlying the strengthening of such memory traces. Emotionally arousing experiences induce the release of ►epinephrine from the adrenal medulla and ►cortisol (►corticosterone in rodents) from the adrenal cortex (Stress response). These stress hormones serve a large number of physiological functions, including influences on brain activity in modulating learning and memory. Chronic stress or sustained elevated levels of stress hormones also affect learning and memory processes. These effects, which are predominantly memory impairing, are due to either direct actions of the hormones on mnemonic processes or on brain organization or atrophy. In contrast, research on the effects of acutely administered or released stress hormones indicates that they have different effects on distinct components or phases of memory.

1. *Memory consolidation:* Adrenal hormones released by emotionally arousing experiences influence long-term memory by modulating ►memory consolidation processes [1]. Systemic injections of epinephrine administered, to laboratory animals, within minutes after training produce dose-dependent effects on subsequent long-term retention. Low doses enhance retention, whereas high doses impair retention. Administration of low doses of corticosterone or synthetic ligands immediately after training also enhances long-term retention. The memory-enhancing effects of glucocorticoids are mediated via an activation of the low-affinity glucocorticoid receptor. As the administration of these hormones several hours after training does not enhance later retention, such evidence indicates that they influence time-dependent processes underlying memory consolidation. Epinephrine and glucocorticoids, as well as stressful conditions that stimulate their release, also enhance memory consolidation in human subjects when administered shortly before or after learning. Adrenal stress hormones do not enhance memory consolidation of all kinds of training, but interact with training-associated endogenous emotional arousal to preferentially modulate memory consolidation of emotionally arousing experiences. Hormones from the hypothalamus or pituitary, such as corticotropin-releasing factor, adrenocorticotropin, enkephalins, vasopressin and oxytocin, as well as gonadal hormones (testosterone and estrogens) are also released during emotionally arousing experiences and either modulate memory consolidation directly or interact with other stress hormones in influencing the consolidation of memory of emotionally arousing experiences.
2. *Memory retrieval and working memory:* In contrast to the enhancing effects on memory consolidation, stressful experiences or the administration of glucocorticoids generally impair short-term memory in laboratory animals and humans. Further, when administered shortly before retention testing, glucocorticoids also impair retrieval of long-term memory [2]. Similarly, high circulating levels of glucocorticoids impair working memory in both rodents and humans. As with memory consolidation, these effects are mediated via an activation of glucocorticoid receptors but, in contrast to consolidation, the emotional arousal-induced impairments in memory retrieval and working memory are temporary and subside when the hormone levels return to baseline. Memory retrieval is also influenced by systemic administration of drugs affecting several other modulatory systems, including epinephrine, adrenocorticotropin, β-endorphin and vasopressin.
3. *Memory acquisition and encoding:* Some findings suggest that glucocorticoids can facilitate sensory and information processing during memory acquisition and encoding [3]. These effects appear to depend on an activation of the mineralocorticoid receptor, an adrenal steroid receptor subtype with a high affinity for corticosterone and cortisol. It is currently unknown whether other hormones also influence memory acquisition and encoding.

## Higher Level Processes

### *Involvement of the Basolateral Amygdala*

The modulating effects of stress hormones and emotional arousal on learning and memory are integrated through influences involving the amygdala [4] (►Amygdala). The ►basolateral amygdala (BLA) is the region of the amygdala that is critical for such integration. Permanent lesions or reversible inactivation of this brain region prevent the memory-modulating effects of administered stress hormones. Further, agonists for adrenoceptors or glucocorticoid receptors infused into the BLA enhance memory consolidation, whereas antagonists for these receptors impair memory when administered shortly after training. Drugs affecting other stress-activated neurotransmitter systems, including vasopressin, dopamine and corticotropin-releasing factor, also enhance memory consolidation when administered into the BLA, whereas the administration of opiates, gamma-aminobutyric acid (GABA) receptor agonists or benzodiazepines impair memory consolidation. There is also considerable evidence from human studies consistent with those of animal studies indicating that the enhancing influence of emotional arousal on memory consolidation involves activation of the amygdala [5]. In human studies, however, the experiments have not as yet investigated the possible selective involvement of the BLA. In human subjects with amygdala damage, unlike subjects with an intact amygdala, emotionally arousing stimulation does not enhance long-term memory. The involvement of amygdala activation in emotionally influenced memory has also been shown in healthy humans with studies using positron emission tomography (PET) (Positron emission tomography) and functional magnetic resonance imaging (fMRI). These studies indicated that activity of the amygdala assessed during the presentation of emotionally arousing stimuli correlates highly with memory of the stimuli tested weeks later. Further, the relationship between amygdala activity during encoding and subsequent long-term memory is greatest for the most emotionally arousing stimuli and does not depend on the emotional valence (i.e., positive or negative) of the stimuli.

### Role of Norepinephrine in the Basolateral Amygdala

As epinephrine passes the blood-brain barrier poorly, it does not directly affect amygdala activity in influencing memory consolidation. Epinephrine effects on memory consolidation are mediated by stimulation of peripheral β-adrenoceptors located on the ascending vagus nerve that innervates brain stem noradrenergic cell groups in the nucleus of the solitary tract and locus coeruleus (Noradrenergic drugs). Noradrenergic projections originating in these brain nuclei innervate brain regions involved in memory consolidation, including the BLA. Extensive evidence indicates that the memory-enhancing effects of peripheral epinephrine involve the release of norepinephrine and activation of postsynaptic β- and $\alpha_1$-adrenoceptors in the BLA [4]. Blockade of noradrenergic transmission in the BLA with infusions of adrenoceptor antagonists prevents the memory-enhancing effects of peripherally administered epinephrine. Norepinephrine-induced activation of adrenoceptors in the BLA results in the activation of the cAMP/protein kinase A intracellular signal transduction pathway. Blockade of this pathway also prevents the memory-enhancing effects of either epinephrine or norepinephrine. Studies using in vivo microdialysis techniques to assess norepinephrine levels in the amygdala provide additional evidence that noradrenergic activation within the amygdala is importantly involved in influencing memory consolidation. In rats, footshock stimulation of the kind typically used in fear-based training induces the release of norepinephrine in the amygdala and the amount of norepinephrine released varies directly with the footshock intensity. Further, the magnitude of training-induced increases in amygdala norepinephrine levels assessed shortly after training correlates very highly with the rats' subsequent long-term retention performance. Studies of human subjects indicate that the administration of β-adrenoceptor antagonists blocks the increase in amygdala activity and enhanced retention induced by emotional stimuli.

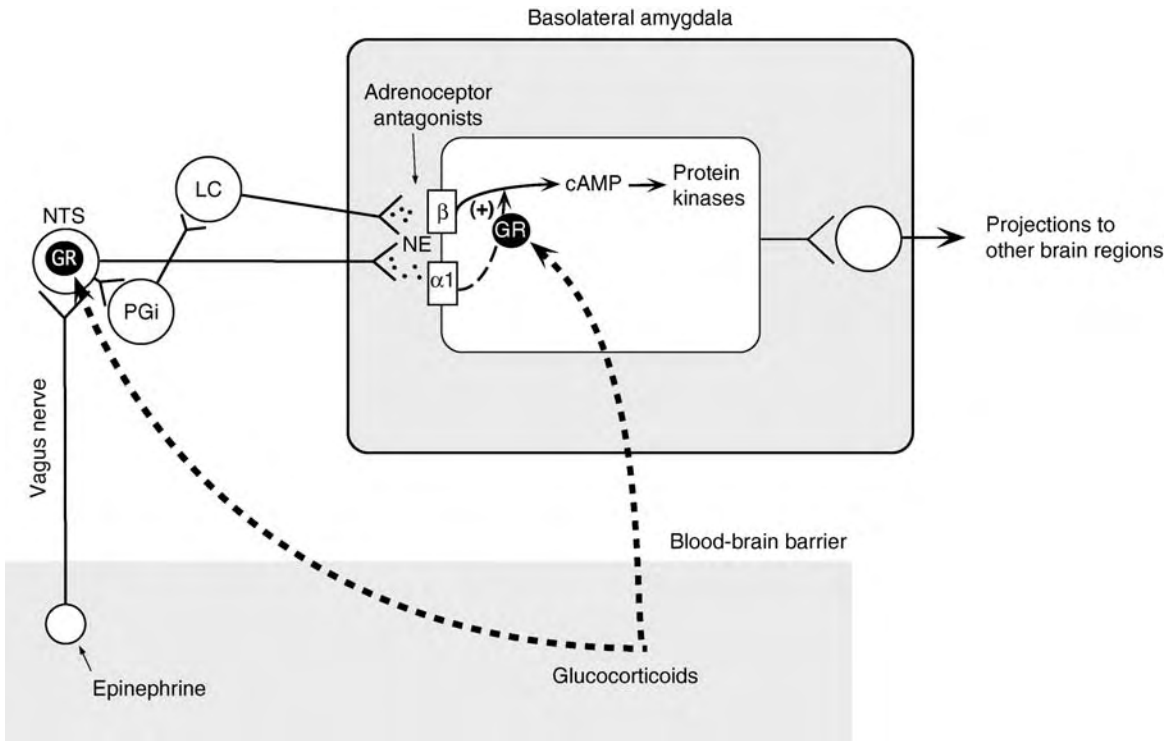
Noradrenergic activation of the BLA is also essential in enabling glucocorticoid ►modulation of memory consolidation [6]. Although glucocorticoids are lipophilic and, thus, can bind directly to intracellular receptors in brain to induce gene transcription and protein synthesis, such genomic actions alone are insufficient to enhance memory consolidation. Glucocorticoid-induced memory enhancement also requires interactions with arousal-activated noradrenergic mechanisms within the BLA. New findings suggest that glucocorticoids can bind to membrane-bound glucocorticoid receptors to activate the noradrenergic signaling cascade via G-protein mediated mechanisms. Such conditional effects of glucocorticoids on memory consolidation via interactions with arousal-associated noradrenergic activation fit well with evidence from studies of both animal and human subjects indicating that glucocorticoid enhancement of memory consolidation may be limited to emotionally arousing conditions that induce the release of norepinephrine [6]. Several other neuromodulatory influences on memory consolidation are also mediated through converging influences on noradrenergic transmission within the BLA. The interaction of epinephrine and glucocorticoids with noradrenergic influences in the BLA is summarized in Fig. 1.

The impairing effects of glucocorticoids on memory retrieval and working memory, like those obtained in studies of memory consolidation, depend critically on an interaction with noradrenergic mechanisms. Blockade of noradrenergic neurotransmission with systemic administration of a β-adrenoceptor antagonist prevents the impairment of memory retrieval and working memory induced by concurrent injections of corticosterone. Furthermore, inactivation of the BLA with either permanent lesions or infusion of a β-adrenoceptor antagonist prevents glucocorticoid-induced impairment of these memory functions. Such evidence is consistent with that from studies on memory retrieval in humans indicating that glucocorticoids or psychosocial stress impair only the retrieval of emotionally arousing information or during emotionally arousing test conditions. Further, the glucocorticoid-induced impairment of memory retrieval in humans, as well as rats, is blocked by concurrent administration of a β-adrenoceptor antagonist.

### Basolateral Amygdala Interactions with Other Brain Regions in Modulating Emotional Learning and Memory

Extensive evidence suggests that a region of the BLA, the lateral nucleus, may be a locus of neural changes underlying ►fear-based memories [7]. However, although the BLA is a critical brain site for integrating adrenergic, glucocorticoid and other stress-activated influences on memory consolidation, the BLA is not the locus of the long-term memory processes modulated by stress hormones. There is abundant evidence that the BLA is involved not only in modulating memory of aversively motivated training, such as footshock training used in inhibitory avoidance and Pavlovian ►fear conditioning, but also modulates the consolidation of memory for many other kinds of training experiences. And, as these different training experiences are known to engage different brain systems both during training and during the consolidation occurring after training, the BLA-induced modulation no doubt involves influences on processing occurring in these other brain regions [4]. The findings of many

E

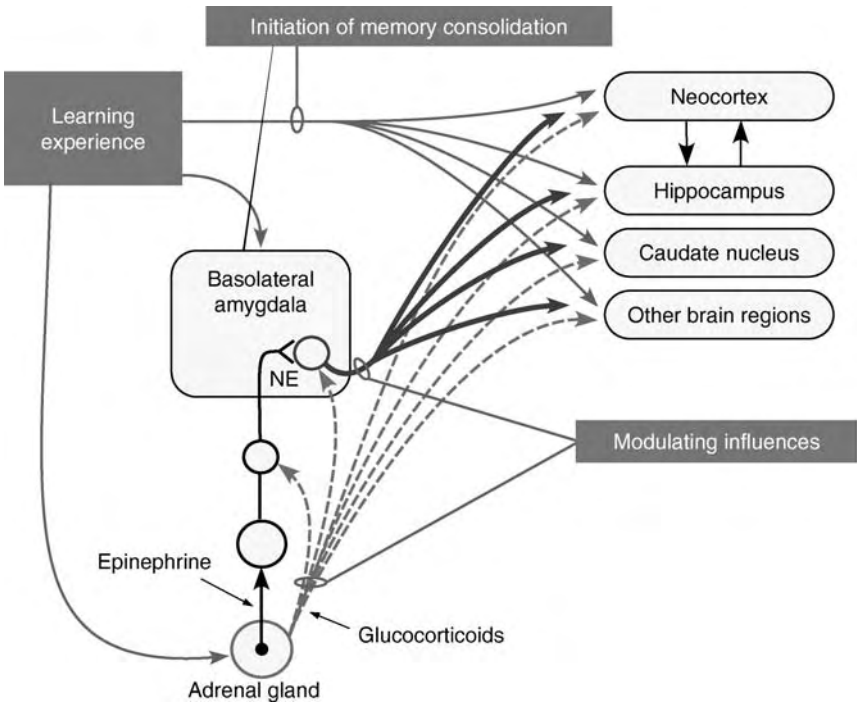


**Emotional Learning/Memory. Figure 1** Interactions of adrenal stress hormones with the noradrenergic system in the BLA in modulating memory consolidation. Epinephrine, which does not cross the blood-brain barrier, induces the release of norepinephrine (NE) in the BLA by activating vagal afferents to the nucleus of the solitary tract (NTS). Noradrenergic neurons in the NTS project directly to the BLA, and indirectly via the locus coeruleus (LC). Norepinephrine binds to both β-adrenoceptors and $\alpha_1$-adrenoceptors at postsynaptic sites and activates cAMP formation. Glucocorticoids freely enter the brain and bind to glucocorticoid receptors (GRs) in brainstem noradrenergic neurons to potentiate norepinephrine release in the BLA, as well as postsynaptically in BLA neurons to facilitate the norepinephrine signaling cascade. Glucocorticoids may influence the β-adrenoceptor-cAMP system via a coupling with $\alpha_1$-adrenoceptors. $\alpha_1$ = $\alpha_1$-adrenoceptor; β = β-adrenoceptor; cAMP = adenosine 3′,5′-cyclic monophosphate; PGi, nucleus paragigantocellularis. Reprinted with permission from Roozendaal B (2000) Psychoneuroendocrinology 25:213–238.

experiments provide strong evidence that BLA activation enhances memories of different types of experiences via interactions with a wide variety of brain regions. In rats, noradrenergic activation of the BLA enhances memory of training in many kinds of tasks, including water-maze spatial and cued tasks, inhibitory avoidance, contextual and cued fear conditioning, conditioned taste aversion and object recognition. These tasks are known to involve functioning of different brain regions. Conversely, inactivation of noradrenergic transmission in the BLA blocks the memory-modulating influences of drugs administered into the hippocampus (Hippocampal formation) or several cortical regions. Further, manipulation of BLA neuronal activity influences memory-associated changes in electrophysiological and molecular correlates of synaptic plasticity in a variety of efferent brain regions [8]. Other evidence suggests that synchronized oscillatory activity within the BLA may facilitate cortical processes involved in memory consolidation [9]. An intact and functioning BLA is also required for regulating emotional arousal effects on the impairment of memory retrieval and working memory involving other brain regions [10]. Figure 2 summarizes the roles of adrenal stress hormones and BLA activation in modulating memory consolidation in other brain regions.

## Regulation of the Process

The effects of emotional stimulation on learning and memory are modulated by several factors, including age and gender. For example, stressful stimulation in female rats can, depending of the menstrual period, have opposite effects on eye-blink conditioning that it has in male rats. Females also appear to be less sensitive to the impairing effects of glucocorticoids on memory retrieval. In general, these differences tend to become smaller or disappear after menopause and, therefore, are thought to be mediated via modulating influences of



**Emotional Learning/Memory. Figure 2** Emotional arousal-induced modulation of memory consolidation. Experiences initiate memory storage in many brain regions involved in the forms of memory represented. Emotionally arousing experiences also release adrenal epinephrine and glucocorticoids and activate the release of norepinephrine in the BLA. The BLA modulates memory consolidation by influencing neuroplasticity in other brain regions. Reprinted with permission from McGaugh JL (2000) Science 287:248–251.

circulating estrogens. However, there are also permanent differences in brain organization between males and females in the processing of emotionally arousing information. A striking example is that exposure to emotionally arousing stimuli induces activation of the right amygdala in men, but of the left amygdala in women. Although the basis or consequences of such a hemispheric differentiation are not well understood, it has been proposed that gender-specific processing of either the details or gist of emotionally arousing information may play a crucial role.

## Function

It is, of course, essential for our adaptation and survival that we record and retain lasting memories of our significant experiences. The facilitating effects of emotional arousal and stress hormones on memory consolidation directly subserve this function. However, as indicated, emotional arousal also impairs memory retrieval and working memory. Such impairments may seem to be more difficult to reconcile with an adaptive function. Why do we have a modulatory system that makes us forget to remember during emotionally arousing test conditions such as stressful examinations or job interviews? One hypothesis suggests that a temporary impairment of these memory functions may actually aid to an accurate consolidation of new information [10]. By impairing the retrieval of old information, this information is unable to interfere with the consolidation of new information, allowing this information to be stored without distortion. Thus, according to this hypothesis, the emotional arousal-induced impairment in memory retrieval and working memory also serves an adaptive function. But, stress hormones can also strengthen memories more than is necessary and create traumatic memories and post-traumatic stress disorder. Several lines of investigation indicate that understanding the neurobiological processes underlying emotional arousal effects on learning and memory may be useful in the development of new and efficacious therapies for stress-related memory disorders.

## Emotional Motor System

### Definition

In 1991, Gert Holstege suggested that three motor systems may be discerned in the central nervous sytem (CNS), the first, comprised by brainstem and spinal premotor interneurons, directly drives the cranial and spinal motoneurons responsible for muscle activation. The second (somatic) motor system acts mainly on the premotor neurons of "first motor system" to control the muscles of the head, neck, trunk, and limbs, with only limited direct synapses on motoneurons. Holstege's third system or the "emotional motor system" targets diffuse projecting networks such as the locus coeruleus, raphe nuclei, and medial ventral tegmentum of the caudal pons which in turn increase motoneuron excitability and also modulate sensory afferents. Specific somatic and autonomic motor patterns are also elicited by the emotional motor system via projections to periaqueductal gray, and to the lateral tegmental fields of the caudal pons and medulla.

These include emotionally elicited movements of the head and eyes, emotional vocalizations, emotional modulation of respiratory and cardiovascular output, as well as emotional aspects of behaviors such as vomiting, swallowing, licking and chewing. Notably, the second and emotional motor systems have little direct anatomical interconnections at higher levels of the neural axis (with the possible exception of axons targeting locus coeruleus and the raphe nuclei), and have topographically separate pathways to the premotor networks of the brainstem and spinal cord. These alternate projection corridors provide a rationale for the clinical observations of neural pathology that, for example, can preclude voluntary activation of facial muscles while leaving emotional activation of the same muscles intact (as with smiling or laughter). As a contrary example, in Parkinson's disease emotional facial expression may be severely compromised (masklike facial expression), while voluntary activation of facial muscles may be demonstrated.

►Extended Amygdala

## Empty Sella

### Definition

Absence or strong atrophy of the pituitary gland.

►Endocrine Disorders of Development and Growth

## En bloc Preparations

### Definition

In vitro preparation of the brainstem and spinal cord containing brainstem respiratory-rhythmic neurons, spinal tracts and spinal nerve roots that innervate muscles of respiration.

►Respiratory Network Analysis
►Isolated Respiratory Center Functions

## En Passant Synapses

### Definition

An "en passant" (French for in passing) synapse is a non-terminal synaptic contact on another neuron made before the "passant" axon continues to its terminal synapse. (See bouton en passant above.)

## Enantiomers

### Definition
Compounds of identical molecular composition that differ only in the three-dimentional arrangement of their atomic groupings.

## Ena/VASP

### Definition
A family of proteins involved in actin filament nucleation and elongation. Ena/VASP proteins are substrates for the kinase PKA which is activated following neurotrophin binding. Ena/VASP enhances actin filament elongation by recruiting actin complexes to sites of active actin remodeling such as the tips of lamellipodia.

►Neurotrophic Factors in Nerve Regeneration

## Encephalitis

### Definition
An inflammation of the brain caused by infections. Cerebral edema accumulates, causing destruction of nerve cells, bleeding (intra-cerebral hemorrhage) and brain damage. Tight junction: an intercellular junction, which tightly occludes the intercellular space in order to limit or eliminate intercellular passage of molecules.

►Neuronal Cell Death and Inflammation

## Encephalization

### Definition
Those increases in brain size that cannot be accounted for by scaling to body size alone.

►Evolution of the Brain: in Birds

## Encephalomalacia

### Definition
A process of tissue softening within the brain. It can result from an old injury, due to degenerative process or after stroke.

►Gliomas
►Stroke

## Encephalomyelitis

### Definition
An inflammation of the brain and spinal cord due to infectious or immune-related causes. The most common types of encephalomyelitis are acute disseminated encephalomyelitis (ADEM) – a demyelinating disease that most often affects children following a viral infection or vaccination; and viral encephalomyelitis.

Symptoms associated with encephalomyelitis depend upon the area of brain or spinal cord involved, but typically include change in level of consciousness or coma, seizures, weakness or paralysis, and loss of sensation in one or more limbs. Diagnosis is typically made by demonstration of abnormalities of the brain and spinal cord by magnetic resonance imaging.

►Acute Disseminated Encephalomyelitis (ADEM)

## Encephalon

### Synonyms
Brain

### Definition
Encephalon comprises the part of the CNS located in the calvaria.

►General CNS

## Encephalopathy

### Definition

Acute Organic Brain Syndrome; Acute diffuse or multifocal disturbance of the content aspect of consciousness as opposed to chronic impairment, which is called ►dementia. Encephalopathy may result from structural (injurious) or metabolic changes. The first often affect the ascending arousal system originating in the ►brainstem reticular formation. The second are consequences of effects on the ►forebrain of a long list of metabolic or toxic influences, including e.g. lack of nutrients and oxygen, changes in ionic and hormone concentrations, seizures, drugs, consequences of liver and renal failure, inflammation (►encephalitis, ►meningitis).

## Encoder

### Definition

Structure in a sensory receptor (and central and other neurons), which transforms graded, amplitude-modulated changes in membrane potential into series of action potentials.

►Sensory Systems

## Encoding Site

### Definition

In sensory receptors, the encoding site is the place where the generator potential gives rise to (is encoded into) a series of action potentials. It may be located in the receptive terminal or, in myelinated fibers, at the level of the first node of Ranvier (heminode)

►Sensory Systems

## Encoding Specificity

### Definition

The principle postulating that the ability to retrieve information in the episodic memory system depends on the degree to which information in the cue was incorporated into the memory trace of the target event at the time of its original encoding.

►Episodic Memory

## Endbuds

### Definition

Putative electroreceptors of lampreys.

►Electroreceptor Organs
►Evolution of Mechanosensory and Electrosensory Lateral Line Systems

## Endocast

### Definition

Cast made from the internal table of bone of the cranium.

## Definition

Developmental hypothalamus related brain malformations are discussed.

## Characteristics

Development of the human brain is a complex and tightly controlled process. Given its divergent nature, early aberrations can cause major anomalies. Failure of proper neural tube closure or midline defects involve hypothalamic and pituitary related defects that result in severe and lasting neuroendocrine and other disorders [1].

### Anencephaly

Anencephaly is a rare but severe neural tube defect. Its etiology is heterogeneous; various agents and conditions such as maternal nutritional status and teratogens may cause anencephaly, whereas X-linked forms are also known. Anencephaly is thought to result from a failed fusion of the rostral neuropore around the second week after conception. An anencephalic child lacks any definable brain structure rostral of the brainstem (Fig. 1).

The neural tissue in the remaining areas including the hypothalamus is an amorphous mass of primitive nerve cells and blood vessels. Anencephalic fetuses hence display pituitary development in the absence of the hypothalamus, which can reveal functions of the fetal hypothalamus in intrauterine development and onset of birth.

Birth weight and placenta weight is reduced in anencephalic children, their gestational length is generally shorter due to hyramnios and the course of labor is protracted. Also intrauterine growth rate is lower than in controls, suggesting that the fetal brain directly participates in the regulation of its own growth and timing of birth. This idea is consistent with previous observations where gestational length was for example increased in cattle with fetal pituitary aplasia or dystopia. Later studies demonstrated that the fetal hypothalamo-pituitary-adrenal axis is indeed actively involved in the initiation of labor, in particular in the normal timing of the moment of birth around 40 weeks of pregnancy. The marked release of fetal vasopressin from the hypothalamic paraventricular nucleus normally occurring in spontaneous labor and its absence in anencephalics, together with the large proportion of anencephalic children that die during the process of labor, point to the importance of intact fetal brain systems for withstanding the stress of birth. Fetal vasopressin may be involved in redistribution of the fetal circulation to the most vital organs during the process of birth.

### Congenital Midline Defects; Septo-optic Dysplasia (De Morsier's Syndrome)

Congenital midline defects are associated with an impaired midline cleavage of the embryonic forebrain and include various grades of severity of holoprosencephaly, schizencephaly, septo-optic dysplasia and dystopia of the neurohypophysis. Holoprosencephaly is the most common brain malformation in humans with different severities; alobar, semilobar and lobar forms are distinguished. In the first form, the prosencephalon fails to cleave sagittally into cerebral hemispheres, transversely into telencephalon and diencephalon and horizontally into olfactory tracts and bulbs. This results in an absence of large parts of the olfactory system, agenesis of the corpus callosum and hypopituitarism. The centrally located hypothalamus is one of the most severely affected structures and

**Endocrine Disorders of Development and Growth. Figure 1** An anencephalic child showing the absence of definable brain structures rostral of the brain stem.

many holoprosencephalic children exhibit for example diabetes insipidus or anterior pituitary dysfunction.

Septo-optic dysplasia (De Morsier's syndrome) (Fig. 2) is a developmental anomaly of midline structures characterized by uni- or bi-lateral hypoplasia of the optic nerves, tracts and chiasm and by an absence of the septum pellucidum.

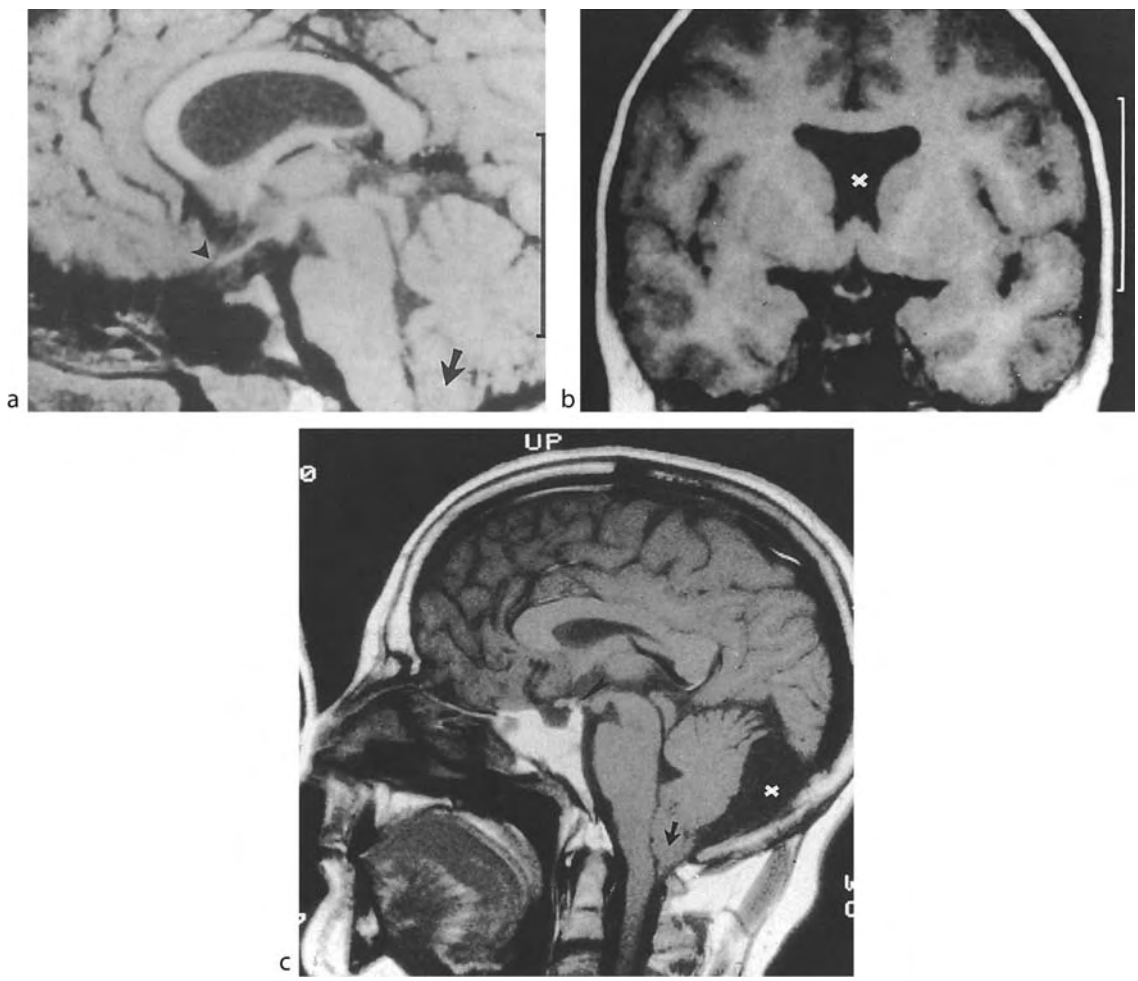
Children with optic nerve hypoplasia are blind in 20–50% of cases or severely visually impaired.

The homeobox gene HESX1 is implicated in a familial form of septo-optic dysplasia and hypopituitarism is an important component of this syndrome. The endocrine deficiencies vary from isolated growth-hormone (GH) deficiency to panhypopituitarism. Neuropathological studies have revealed that the optic nerves are severely affected. The hypothalamic supraoptic and paraventricular nuclei are either absent or affected as well. This may explain the varying degrees of diabetes insipidus in these cases.

## Dystopia of the Neurohypophysis

Pituitary ectopias generally involve a disturbed developmental descent of the neurohypophysis. In true ectopia, the pituitary fossa only contains adenohypophysial tissue and lacks endocrine abnormalities. This condition is very rare and mostly not associated with clinical symptoms.

Acquired dystopia of the pituitary may result from perinatal injury causing stalk transection and subsequent regeneration of fiber tracts of the hypothalamo-neurohypophyseal system resulting in newly formed ectopic posterior lobe tissue at the proximal



**Endocrine Disorders of Development and Growth. Figure 2** (a) Sagittal image of septo-optic dysplasia; severe hypoplasia of the pituitary gland, the stalk and the chiasma (*arrowhead*). Partial ectopy of the cerebellar tonsils in the foramen magnum (*arrow*). (b) Coronal image of septo-optic dysplasia; absence of the septum pellucidum indicated by the *cross*. (c) Sagittal image of posterior pituitary ectopia (*arrowhead*), hypoplastic anterior pituitary, ectopia of the cerebellar tonsils (arrow) and the arachnoid cysts, posterior of the cerebellar hemispheres (*cross*). From [2] figs. 2–4, with permission.

stump. Prenatal congenital disconnection defects that subsequently affect hypothalamo-pituitary function can also occur.

Dystopia of the neurohypophysis in individuals without clinical symptoms has to be distinguished from the dystopia in patients with anterior pituitary abnormalities like pituitary dwarfism (isolated growth hormone deficiency) or other pituitary hormone deficiencies like central diabetes insipidus. In addition, periventricular heterotopias may be present where the adenohypophysis can be hypoplastic, the infundibulum absent and the posterior lobe located ectopically.

A large majority of the patients with anterior pituitary abnormalities experienced perinatal problems. However, the perinatal problems do not seem to be causal, since the presence of several accompanying brain anomalies such as microcephaly, facial or sella abnormalities, an ectopic or absent neurohypophysis, periventricular heterotopias, a thin or absent pituitary stalk, optic nerve hypoplasia and a HESX1 mutation, together suggest primarily early congenital disconnection defects in at least some patients that are later followed by hypothalamo-pituitary anomalies. Because of the active role of the fetus in labor, such congenital developmental brain defects may contribute first to labor problems and later to for example growth hormone deficiency.

### Alterations in the Growth Hormone Axis in Development

Besides gross structural abnormalities, dysregulation of hypothalamic function can seriously impact growth of the body and brain. Growth hormone (GH) synthesis is regulated by several hypothalamic factors delivered to the pituitary gland. Growth hormone releasing hormone (GHRH) stimulates, whereas somatostatin (SOM) inhibits growth hormone production. In addition, GH secretion is controlled by autofeedback connections. GHRH and SOM release are modulated by NPY, POMC, galanin, thyroid, gonadal and adrenal hormones as well as by acetylcholine, which inhibits SOM in the hypothalamus. Growth hormone releasing peptide (GHRP), ghrelin, which is involved in food intake, is an endogenous ligand for the GH secretagogue receptor and stimulates GHRH release. GH itself has further been implicated in feeding, sleep and learning and memory.

Shortly after birth, GHRH induces GH hyperresponsiveness caused by a reduced sensitivity of the pituitary to SOM. After the fourth decade, this response and the GH levels decline, but even when longitudinal growth has stopped, GH continues to affect regulation of body metabolism. Cases with previous hypothalamic or pituitary diseases or patients who are deficient in GH may suffer from adiposity and a reduced physical fitness, which are often paralleled by social phobia and depression. When put on replacement therapy, many patients report improvements, indicating lasting central effects of GH in adulthood. Indeed, GH can act directly on the brain, since GH receptors are present.

### Noonan Syndrome

In 1963, Noonan and Ehmke described children with a typical facial appearance, i.e. hypertelorism, down slanting palpebral fistures, ptosis and low set posteriorly rotated ears. Both familial and sporadic cases exist. Polyhydramnios complicates 33% of the affected pregnancies. Growth rate is reduced, puberty is often delayed and there is hypotonia in young children. In 76% feeding difficulties occur, abnormal hearing is present in 40% and abnormal vision in 94% of affected children. GH secretion in Noonan syndrome is characterized by a low amplitude that is held responsible for the short stature and low growth rate.

### Multiple Pituitary Deficiencies, Isolated Growth Hormone Deficiency

Patients with multiple pituitary deficiencies, including GH deficiencies, generally have suprasellar damage that is paralleled by neuroendocrine changes such as a severe GH deficiency. Isolated growth hormone deficiency is characterized by a hypoplastic anterior pituitary lobe, an absent infundibulum and an ectopic posterior pituitary. Pediatric patients with mitochondrial myopathy, encephalopathy and lactic acidosis may also suffer from GH deficiency. Children with organic causes for GH deficiency such as congenital malformation, tumors or chemotherapy suffer from additional changes in their hypothalamo-pituitary-adrenal axis, possibly due to a disruption of central control pathways.

Children with GH deficiency are generally of normal intelligence, but do have learning and behavioral problems. These children are shy, withdrawn and have problems with mood and attention but these symptoms decline after GH replacement therapy. Early GH therapy leads to a rapid catch up of cranial growth.

Multiple pituitary deficiencies go together more frequently with empty sella (34%) than isolated GH deficiency (less than 10%), in which few abnormalities of the sellar region are found. Empty sella is considered to be of congenital origin but is also common in patients with benign intracranial hypertension where it may occur secondary to pituitary apoplexy. About 50% of the adult patients with primary empty sella have anti-pituitary antibodies indicative of previous autoimmune hypophysitis. Primary empty sella syndrome is frequently accompanied by GH deficiency and hypogonadotropic hypogonadism, but not by central hypothyroidism.

### Genetic Forms of GHRH Deficiency

An autosomal recessive form of hypothalamic GHRH deficiency exists. This is a genetically heterogeneous group of disorders that are generally inherited as an

autosomal recessive trait. The pituitary and hypothalamus appear normal.

1. Several families with GHRH resistance due to an inactivating mutation in the GHRH-receptor gene have been described as well. They resemble in many aspects the "little mouse" animal model that has a single base change (A to G) in the gene for the GHRH receptor. The clinical picture of homozygous individuals with the inactivating GHRH-receptor mutation largely resembles that of severe, isolated GH deficiency. The affected individuals look like miniature versions of normal people. Although intelligence appears normal, the skull is considerably smaller than that which has been described in classic GH deficiency. This is in agreement with the microcephalus described in the "little mouse". The endocrine profile corresponds to that of isolated growth hormone deficiency.

In hereditary Gitelman disease, growth hormone deficiency is associated with a partial vasopressin deficiency, empty sella and a renal tubular disorder. It is caused by mutations in the sodium chloride transporter gene (TSC; SLC12A3). In Down's syndrome, the neuronal control of GHRH secretion is impaired.

## Endocytosis

### Definition

Endocytosis is the process of taking up extracellular components by folding in and pinching off short segments of the cell membrane to form intracellular vesicles.

## End-of-dose Wearing Off

### Definition

The wearing off of the beneficial effects of a dose of levodopa before the next dose takes effect. In this situation, the patient with Parkinson disease feels the need for the next dose of levodopa before the next dose is due.

►Parkinson Disease

## Endogenous Analgesia System

►Descending Modulation of Nociception

## Endogenous Antipyretics

### Definition

Inherent mediators liberated both systemically and within the brain during fever that counter the formation or action of endogenous pyrogens, or inhibit the activity of neural circuits that modulate febrigenesis. They thus prevent the height of fever from reaching a potentially dangerous level. They include certain cytokines, neuropeptides, glucocorticoids, hormones, nitric oxide, and others.

►Endotoxic Fever

## Endogenous Burster

### Definition

A neuron that possesses the intrinsic ability to respond to a prolonged excitatory drive with an oscillation of the membrane potential (i.e. alternating depolarizations and hyperpolarizations) that can drive bursts of action potentials. The membrane potential oscillations are not caused by rhythmic synaptic inputs, but are the result of interactions between different types of voltage-gated ion channels. The depolarization at the beginning of a burst is often due to the activation of a persistent $Na^+$ current or a low-voltage activated $Ca^{2+}$ current. Activation of these currents can be self-sustaining as the depolarization caused by their activation is sufficient to keep these types of channels activated. Their prolonged activation leads to an increase in

intracellular $Ca^{2+}$ or $Na^{+}$ concentrations, which can activate $Ca^{2+}$ – or $Na^{+}$-dependent $K^{+}$ currents. Activation of these channels will terminate the depolarization and cause a hyperpolarization of the membrane potential. Alternatively, the depolarization can be terminated by a slow activating voltage-gated $K^{+}$ current (e.g. $I_A$). The hyperpolarization of the membrane potential at the end of the burst is self-limiting as it will remove the signal that activated the channels responsible for the hyperpolarization. A new burst can either be initiated if the excitatory drive is still present, or it can be triggered endogenously by the action of a slow hyperpolarization-activated inward current, $I_h$. $I_h$ can be activated by the hyperpolarization at the end of a burst leading to a slow depolarization, activating voltage-gated ion channels responsible for the depolarization during a burst. Endogenous bursters are often also referred to as pacemaker neurons.

►Central Pattern Generator

## Endogenous Depression

►Major Depressive Disorder

## Endogenous Oscillations

### Definition

Molecular, physiological or behavioral rhythms that persist in constant conditions without any exogenous time information (free-running oscillations). Endogenous oscillations are generated by an intrinsic pacemaker or clock.

►Circadian Rhythm
►Clock Coupling Factors

## Endogenous Receptor Agonists

►Respiratory Neurotransmitters and Neuromodulators

## Endolymph

### Definition

A unique fluid that resides inside the membranous labyrinth and consists of a solution similar to intracellular fluids with a high potassium and low sodium content.

►The Peripheral Vestibular Apparatus

## Endomysium

### Definition

The fascia that covers the full perimeter of each muscle fiber, with the exception of its ends. It forms the wall of a "tunnel" in which the muscle fiber operates.

►Intramuscular Myofascial Force Transmission
►Skeletal Muscle Architecture

## Endoneurial Pathways

### Definition

Longitudinal basal lamina (equivalent to the basement membrane, with large components of laminin and fibronectin) profiles that provide a track for regenerating axons from the proximal nerve to use as they regrow within the distal nerve. These are synonymous to endoneurial tubes (see Bands of Bungner).

►Peripheral Nerve Regeneration and Nerve Repair

## Endorphins

### Definition

A group of endogenous (produced by the pituitary gland, the hypothalamus other brain areas) hormones (e.g. beta endorphin, met-enkephalin) that are chemically similar

to opiate drugs. Endorphins are involved in coping with acute stress and modulating the perception of pain; they may also have a role in mobilizing the immune system.

►Neuroendocrinology of Psychiatric Disorders

## Endosome

### Definition

Endosome is a membrane-bound compartment within a cell, which is often the target of protein-transporting endocytic membrane vesicles that pinch off from the cell membrane. From there proteins can be recycled back to the plasma membrane or targeted for degradation in lysosomes.

## Endothelial Cell

### Definition

Endothelial cells form the inner lining of blood vessels. The endothelial cell layer may be leaky, with gaps in the junctions between the cells, as in the glomeruli of the kidney, or the cells may be closely associated with one another to form a relatively impenetrable barrier between the blood and the surrounding tissue, as in the brain where the blood-brain barrier is mainly due to the tight association of endothelial cells. The cells have many transport molecules in both sides to allow molecules to be transferred from blood to tissue and vice versa. After injury endothelial cells may proliferate, and are one of the sources of granulation tissue.

►Blood-brain Barrier
►Glial Scar

## Endothelial Nitric Oxide

### Definition

A substance produced and secreted by vascular endothelial cells, and is a potent regulator of vascular function. Nitric oxide diffuses from endothelial cells into underlying smooth muscle, causing relaxation, which results in vasodilation.

## Endotherm

### Definition

An animal that maintains a constant body temperature regardless of the surrounding temperature. Animals in this group include birds and mammals.

►Evolution of the Hypothalamus in Amniotes

## Endothermy

### Definition

Indicative of a physiology in which heat is generated from internal body processes rather than obtained from external heat sources (ectothermy)

►The Phylogeny and Evolution of Amniotes

## Endotoxic Fever

Clark M. Blatteis
University of Tennessee Health Science Center, College of Medicine, Memphis, TN, USA

### Synonyms

Pyrexia, Hyperpyrexia

### Definition

The term ►fever specifically defines the elevation of body core temperature ($T_c$) that characteristically occurs in most animals in response to the invasion of their body by infectious microorganisms such as bacteria (e.g. *Staphylococcus, Salmonella*), viruses (e.g. *influenza*), parasites (e.g. *filaria*), and fungae (e.g. *Candida*). It is also a frequent reaction to non-microbial illnesses, e.g. autoimmune and neoplastic diseases, some host-derived substances, e.g. antigen-antibody complexes,

as well as to certain synthetic products, e.g. antitumor agents and immunoadjuvants. The English word *fever* stems from the Latin word *febris*; pyrexia is a synonym derived from the Greek word *pyretos*. In humans, $T_c$s above 38°C are generally considered clinical fevers. The $T_c$ rise is induced by fever-producing, host-derived mediators called *endogenous pyrogens*, resulting in an elevation of the ►set-point of $T_c$. Accordingly, the higher $T_c$ is established and defended by the *active* cooperation of heat-producing (thermogenic; e.g. shivering, "chills") and heat-dissipating (thermolytic; e.g. shift of blood flow to or away from the skin via cutaneous vasomotion) thermoeffectors. Fever is thus distinct from *hyperthermia*, a condition in which the $T_c$ rise is the *unavoidable* consequence of the *passive* gain of heat (from external [e.g. warm environment] or internal [e.g. physical exercise] sources) in excess of the capability of *active* thermolytic effectors to dissipate it. The two terms should, therefore, not be used interchangeably. Magnitudes, durations and patterns of natural fevers vary, but an upper limit (40.5°C in humans) is seldom exceeded. Hyperpyrexia is a medical emergency defined as a $T_c$ over 41.1°C.

## Characteristics

### Description

The invasion of the body by infectious live or inanimate agents entrains, after a variable delay (termed the *latent* or *prodromal* period), the duration of which depends on the pathogen type, its amount and localization in the body, certain physiological variables of the host, and other conditions), an array of nonspecific, stereotyped, systemic reactions designed to combat the deleterious effects of the invading pathogens and to restore health to the afflicted host. These reactions are collectively termed the *acute-phase reaction* (APR) and comprise both autonomic [1] (e.g. changes in the levels of various plasma proteins ["acute-phase proteins"] and trace metals, in the secretion of certain pituitary hormones, in intermediary metabolism) and behavioral [2] (e.g. somnolence, anorexia, anhedonia) components. They constitute, therefore, the primary host defense response. Fever is the most manifest among these and consequently is regarded as the hallmark of infection; i.e. it is not the disease, but its clinical sign.

Our knowledge of the mechanisms underlying fever derives largely from studies using animals in which a low-to-moderate dose of a fever-producing (*pyrogenic*) agent is administered peripherally as a bolus. In most instances, this material is an extract of the outer wall of Gram-negative bacteria (*bacterial endotoxic lipopolysaccharide*, LPS); a biphasic rise in $T_c$ is consequently generated that, due to its causative agent, typifies ►endotoxic fever. LPS and other fever-producing pathogens that originate outside of the body are termed *exogenous pyrogens*.

It is well established that the brain region that controls $T_c$ is the preoptic area (POA) of the anterior hypothalamus. It receives thermal inputs from the periphery and from other brain regions, it is itself thermosensitive, and it modulates the coordinated effector activities that counteract deviations in $T_c$ due to any cause. Furthermore, it is responsive to both local and peripheral pyrogenic stimuli [3]. The $T_c$ rise of fever is attributed to a regulated change in the characteristics of this neural controller. The details of the neural circuits and molecular mechanisms that underlie the febrile response are, however, still incompletely known.

## The Febrile Process

### *Afferent Pyrogen Signaling*

Exogenous pyrogens that gain access to the body are not, as indicated earlier, the agents that directly induce fever and its non-thermal acute-phase correlates. Rather, these responses arise as the result of a phased sequence of interactions among soluble factors and cells that is initiated in the periphery by the presence of the exogenous pyrogens; relevant signals are transmitted to the POA, which modulates the febrile response. Thus, foreign materials that have penetrated the body are immediately recognized through their unique molecular patterns ("pathogen-associated molecular patterns," PAMPs) by specialized receptors on the host's immune cells. These receptors, called Toll-like receptors (TLRs), occur predominantly on mononuclear phagocytes (e.g. circulating and resident macrophages). Their activation transduces the pathogenic signals into intracellular molecular processes that eventuate in the concatenated production of endogenous factors that mediate the APR. LPS acts via the TLR4, bacterial (CpG) DNA via the TLR9, and viruses via the TLR3 receptors; other PAMPs activate other TLRs, but it would appear that the cascades of mediators thus produced are similar [4].

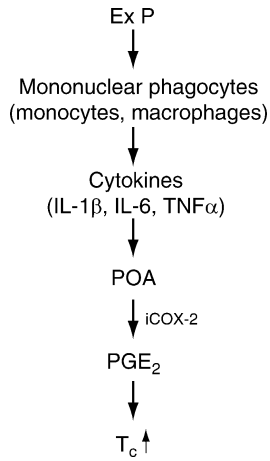
These mediators belong to the class of immunoregulatory, pleiotropic polypeptides called ►cytokines. Most prominent among these for fever induction are interleukins (IL)-1β and IL-6, tumor necrosis factor (TNF)-α, and interferons (IFN)-α and IFN-γ; they are released into the extracellular fluid [5]. Following the intravenous (iv) administration of LPS, TNF-α normally appears in the bloodstream first, followed by IL-1β, and lastly by IL-6; IFNs do not occur or occur late – they are induced predominantly in response to viruses and their products and partially to CpG DNA. The functional levels of these ►cytokines are modulated by the sequential, time-dependent release at different points along the febrile course of their own antagonists, e.g. specific target cell-surface antagonists (e.g. IL-1 receptor antagonist [IL-1Ra]), soluble blood-borne receptors (e.g. soluble TNF receptor type II), and

E

inhibitors of their synthesis (e.g. glucocorticoids) or their actions (e.g. arginine vasopressin in the brain). These ►endogenous antipyretics constitute an essential, autoregulatory feedback that serves to prevent an exaggerated fever from occurring during systemic infectious challenges [6].

The original concept of fever induction posited that these cytokines are transported to the POA by the bloodstream, to activate it. Indeed, they induce fever when microinjected into this site, whereas the administration of their antagonists suppresses it. Specifically, the pyrogenic cytokines inhibit the activity of warm-sensitive (probably by increasing the presynaptic release of GABA) and synaptically excite that of temperature-insensitive (and synaptically also of cold-sensitive) neurons located there, consistent with the diminished heat loss and enhanced heat production that these cells, respectively, mediate [3], suggesting therefore that they could be their direct targets. Subsequent research, however, has indicated that neuronal activity consistent with the generation of fever is more likely modulated by another mediator, prostaglandin (PG)$E_2$, induced secondarily *de novo* by the cytokines in the POA. Further studies have established that its formation depends on the inducible isoforms of the enzymes cyclooxygenase-2 (COX-2) and microsomal PGE synthase-1 (mPGES-1). Indeed, drugs that inhibit $PGE_2$ synthesis, e.g. nonsteroidal anti-inflammatory drugs (NSAIDs; e.g. aspirin), are potent antipyretics. This concept of the process of infectious fever production, now classical, is illustrated in Fig. 1.

The plausibility of this sequence was questioned, however, when the molecular biology of these mediators became better understood. Thus, it was learned that pyrogenic cytokines are not expressed constitutively in phagocytic cells, but induced *de novo* in response to their activation by exogenous pyrogens; this synthetic process requires ~30–45 min. Indeed, cytokines appear in the bloodstream significantly later than the onset of fever induced by LPS injected iv (~10 min). Furthermore, their penetration into the brain became an issue when it was appreciated that, as large hydrophilic peptides, their free diffusion across the blood-brain barrier (BBB) was improbable. Finally in this context, it was found that the cytokine-induced upregulations of COX-2 and mPGES-1 in the POA require, in conscious rats at least, a minimum 45 min. Several alternatives were consequently proposed to counter these inconsistencies [7], but, although all were based on sound experimental data, they did not resolve the issue of the temporal discrepancy between the first appearance of cytokines in blood or of $PGE_2$ in the POA and the short latency of the febrile response to iv injected LPS. Another intermediary evoked by LPS more rapidly than cytokines should therefore be operating.



**Endotoxic Fever. Figure 1** The classical concept of the sequential mechanism of LPS fever induction. Exogenous pyrogens (Ex P) invading the body quickly encounter circulating and resident mononuclear phagocytes, stimulating them to produce pyrogenic cytokines. These mediators, in turn, are released into the bloodstream and transported to the POA, inducing there COX-2 and the consequent production of $PGE_2$, the putative, final, central fever mediator. Modified from [10].

Indeed, this interposed peripheral mediator was very recently identified to be $PGE_2$, produced by hepatic macrophages (Kupffer cells [Kc], the largest population of macrophages in the body) [8]. Its critical involvement is based on the following evidence: (i) the onset of endotoxic fever is best correlated with the first appearance of LPS in the liver, irrespective of its route of administration, (ii) the level of $PGE_2$ rises in hepatic venous blood very quickly after the peripheral administration of both exogenous (e.g. LPS) and endogenous (e.g. IL-1β) pyrogens, and (iii) the febrile response to LPS is abrogated by the prior iv administration of a $PGE_2$ antibody. LPS stimulates Kc $PGE_2$ production by two means. The first is the anaphylatoxic complement (C) component C5a [9]. The C cascade is activated on contact with LPS via the alternative pathway (antibody-independent), resulting in the immediate production of all its components, including C5a; Kc express its receptor, $C5aR_1$. The production of $PGE_2$ is initiated within 2 min after the addition of C5a; C depletion inhibits both its release and fever production. $PGE_2$ is generated under these conditions by the hydrolysis of membrane-associated phosphoinositide (PI, which has a high arachydonoyl chain content) by PI-specific phospholipase C (PI-PLC); arachidonic acid (AA, the substrate of COX) liberation by PI-PLC is tenfold more rapid (within seconds) than that mediated by group IV cytosolic phospholipase $A_2$ ($cPLA_2$, the enzyme activated by LPS that catalyzes the release of AA from cell membrane phospholipids). Moreover,

PI-PLC is activated by C, but not by LPS or IL-1β, and the subsequent conversion of this AA to $PGE_2$ is unselectively catalyzed by COX-1 and/or COX-2, which are both constitutive in Kc. The second means is the TLR4-mediated, direct activation of Kc by LPS. However, the activation by LPS of $cPLA_2$ is slow. Also, as already mentioned, the increased synthesis of $PGE_2$ induced by LPS is selectively catalyzed by inducible COX-2 and mPGES-1, the upregulations of which require time. Hence, a second elevation of plasma $PGE_2$ occurs ~45 min after the first. It is not, however, the signal that triggers the febrile response, but it may sustain its course.

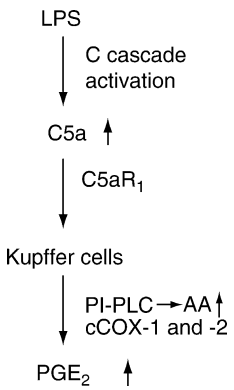
The mechanism by which the $PGE_2$ quickly released by Kc drives the febrile response is controversial. One concept holds that it is transported to the POA by the bloodstream and, being lipophilic, stimulates thermosensitive neurons in the POA either by crossing the BBB or diffusing to this site through the OVLT [8]. Although febrile responses to iv injected $PGE_2$ have been reported, it is, however, uncertain whether $PGE_2$ can simply diffuse from the blood into the brain. An alternative possibility, that the fever-mediating $PGE_2$ is produced by cerebral endothelial cells, although based on well substantiated evidence that circulating LPS and pyrogenic cytokines (particularly IL-6) induced by it upregulate the expressions of COX-2 and mPGES-1 in these cells, is weakened by the finding that the expression of endothelial cell COX-2 evoked by peripheral LPS is not POA-specific, but occurs throughout the brain microvasculature and, moreover, first appears significantly later than the onset of iv LPS-induced fever. Finally, although the rises of $T_c$ and preoptic $PGE_2$ levels caused by iv LPS are both abrogated by peripherally injected antipyretics, findings that they are also prevented by the intraPOA microinjection of COX-2 inhibitors (in quantities undetectable in the blood) indicate that it is more likely that the applicable $PGE_2$ is generated inside rather than outside the BBB.

Hence, another concept is that the fever-triggering message of peripheral $PGE_2$ is transmitted from the liver to the POA neurally rather than humorally. In support, sensory vagal afferents are distributed in the vicinity of the Kc, and bilateral subdiaphragmatic section of the vagus or of its hepatic branches prevents fever development. Furthermore, paraganglia on hepatic vagal branches bind IL-1Ra, and the electrical activity of the vagus is increased by the injection of IL-1β into the hepatic portal vein; the latter effect is blocked by indomethacin, a NSAID. In addition, the expression of c-*fos* is enhanced in the A2 cell group of the nucleus of the solitary tract (NTS, the primary projection area of the vagi) after iv and ip IL-1β and LPS, but prevented by subdiaphragmatic vagotomy; electrolytic lesions of the NTS also attenuate the febrile response to ip LPS [7]. Finally, abundant $PGE_2$ receptors of the $EP_3$ subtype, the class implicated by other studies as mediating the febrile response, occur in nodose ganglion neurons receiving information from the abdominal compartment. Very recently, the trigeminal nerve has also been implicated as a signaling pathway in acute periodontitis.

Thus, novel accumulating evidence suggests that endotoxic fever is initiated by the arrival of LPS in the liver and its uptake by Kc, causing virtually immediately the activation of the C cascade and, hence, the generation of the anaphylatoxin C5a. It, in turn, stimulates the Kc very rapidly to release constitutive COX-1- and COX-2-dependent $PGE_2$. The released $PGE_2$ then most likely activates local sensory vagal terminals that project to the NTS. Fig. 2 summarizes the updated sequence of events that initiates the febrile response triggered in the periphery by the appearance of LPS.

### Central Integration

Various studies have demonstrated that the vagally transmitted pyrogenic signals proceed from the NTS to the POA by way of noradrenergic projections originating in the A2 region and arriving in the POA via the ventral noradrenergic bundle (VNB). The release of norepinephrine (NE) in the POA following the systemic administration of exogenous and endogenous pyrogens is well documented, and it has been shown in rats that subdiaphragmatic vagotomy blocks the ip IL-1β-induced reduction in hypothalamic NE. The involvement of the central noradrenergic system in thermoregulation has also been demonstrated; e.g. electrical stimulation of



**Endotoxic Fever. Figure 2** The course of the production of $PGE_2$ by hepatic macrophages (Kupffer cells) activated by a pyrogenic dose of LPS. LPS activates the complement (C) cascade on contact, quickly generating the anaphylatoxin C5a, which binds to its receptors on Kupffer cells, stimulating PI-PLC and generating arachidonic acid (AA) from membrane phospholipids. Constitutive (c) COX-1 and COX-2 then catalyze its conversion into $PGE_2$.

the ascending noradrenergic system in the brainstem of guinea pigs evokes a $T_c$ rise whereas surgical or pharmacological lesions of this pathway abrogate this response. It has also been shown in the peripheral nervous system that the stimulation of noradrenergic neurons induces the postsynaptic release of $PGE_2$, which then limits the further presynaptic release of NE, thereby modulating the activity of noradrenergic neurons. NE also stimulates the release of $PGE_2$ in POA minces *in vitro*, and the microdialysis of NE into the POA of conscious guinea pigs rapidly augments the local production of $PGE_2$. Accordingly, noradrenergic terminals in the POA, through their NE-induced local production of $PGE_2$, could mediate the febrile response to LPS.

Indeed, recent studies have confirmed that NE and its α-adrenoceptor (AR) agonists microdialyzed into the POA of conscious guinea pigs or injected intracerebroventricularly (icv) into conscious mice evoke two distinct $T_c$ rises: one is $\alpha_1$-AR-mediated, rapid in onset, and $PGE_2$-independent, and the other $\alpha_2$-AR-mediated, delayed, and COX-2/$PGE_2$-dependent. The $\alpha_1$-ARs are located on thermoregulatory neurons and the $\alpha_2$-ARs presumptively on perisynaptic astrocytes. The direct, quick, $PGE_2$-independent inhibition of warm-sensitive neurons by cirazoline, an $\alpha_1$-AR agonist, was recently reported in rat POA slices. It was likewise confirmed that the iv injection of a pyrogenic dose of LPS rapidly induces the appearance of NE in the POA interstitial fluid and the concomitant increases of $T_c$ and preoptic $PGE_2$. Importantly, the level of NE culminates in 30 min, then gradually returns toward its control value; i.e. NE is released at the beginning of fever only. Pre-treatment with an $\alpha_1$-AR antagonist, prazocin, significantly slows the rate of rise of the first phase of fever and eliminates its first peak, but does not affect the onset latency of the response nor the magnitude and time of the second peak of fever. It also does not affect the initial, LPS-induced elevation of preoptic $PGE_2$. However, like NE, this increase is not sustained, $PGE_2$ levels returning from their first highs at 30 min to their control values at 60 min. They then rise a second time and culminate not differently than in untreated counterparts and coincidentally with the second peak of fever. Pre-treatment with an $\alpha_2$-AR antagonist, yohimbine, by contrast, does not change the onset latency and rate of rise of the early febrile response, the first $T_c$ peak reaching the same value and occurring at the same time as that of untreated controls; but it completely abrogates the second peak, consequently significantly reducing the overall magnitude of the febrile response by comparison to that of untreated controls. The fever, moreover, abates more slowly in this group than in controls. Remarkably, this treatment completely suppresses the LPS-induced rise in preoptic $PGE_2$ levels. Collectively, these findings therefore indicate that: (i) the onset of LPS fever is indeed associated with the intraPOA release of NE and accompanied by coincident increases in $T_c$ and preoptic $PGE_2$ levels, (ii) the initial $T_c$ rise is mediated by the NE-induced activation of $\alpha_1$-AR and, its very onset excepted, the first phase of fever is maintained by the direct noradrenergic stimulation of the relevant neurons in the POA, without the intermediation of $PGE_2$, and (iii) the LPS fever of $\alpha_2$-AR-blocked guinea pigs is initiated, maintained, and even extended in the total absence of corresponding increases in POA $PGE_2$ levels; hence, by deduction, it is mediated entirely by $PGE_2$-independent, $\alpha_1$-AR activation. The specific involvement of COX-2 in the formation of the $\alpha_2$-AR-mediated $PGE_2$-was verified by its blockade by selective COX inhibitors. The mechanism of its production under these specific conditions has not yet been determined, however. It has been shown in other systems that NE-stimulated postjunctional $\alpha_2$-ARs activate $cPLA_2$; NE also binds to $\alpha_2$-ARs coupled to PI-PLC and D. Both these processes would generate AA. NE also induces the production of cyclic AMP, which is an activator of COX expression. In sum, NE released in the POA mediates the characteristically biphasic febrile responses of conscious animals to iv LPS by two consecutive processes, viz., the first via direct $\alpha_1$-AR stimulation not associated with $PGE_2$ formation, and the second via $\alpha_2$-AR stimulation and the delayed production of COX-2-dependent $PGE_2$ [10]. Since NE is present in the POA at the onset of fever only, it may be presumed that it activates both $\alpha_1$- and $\alpha_2$-ARs then; the delay in the response of the latter is most likely due to the time required for the upregulations of COX-2 and mPGES-1 and the consequent biosynthesis of $PGE_2$.

But what accounts for the initial rise in preoptic $PGE_2$, including in yohimbine-pretreated animals? The intraPOA microdialysis of selective COX-1, -2, and -3 inhibitors do not prevent it, suggesting that it could be induced by a COX-independent pathway, e.g. the non-enzymatic isoprostane pathway of free radical-catalyzed peroxidation of AA. Some indirect support for this notion comes from the finding that the intraPOA microdialysis of the antioxidant catechin throughout the febrile course has the same effect as pre-treatment with the $\alpha_2$-AR antagonist yohimbine, viz., suppression of both the LPS-induced early and late rises of preoptic $PGE_2$ and of the second peak of fever; the latency of fever onset and its first peak are not affected, the fever continuing at its early phase high level until it abates normally. Hence, its course is sustained by $\alpha_1$-AR activation alone. The free radicals in this case could be generated by the auto-oxidation of NE and/or be nitric oxide (NO); the latter is also released locally in the POA after LPS administration (see below). Since the initial $T_c$ rise provoked by the peripheral administration of LPS is evidently mediated by $PGE_2$-independent $\alpha_1$-AR

activation in the POA and since, moreover, the febrile rise can evidently be sustained by this mechanism alone until its normal abatement, the new question arises whether, in contrast to $PGE_2$ generated in the liver, $PGE_2$ in the POA, however it may occur there, is really material to the febrile response to LPS. It should be noted that other, putative endogenous pyrogens have also been implicated in the direct, $PGE_2$-independent, central mediation of LPS fever, e.g. IL-8, macrophage-inflammatory protein-1, pre-formed pyrogenic factor, and endothelin-1 [7].

Finally, reports that the gaseous transmitter NO stimulates the biosynthesis of $PGE_2$ by increasing the activities of both isoforms of COX have prompted investigations into whether NO could also have a pyretic function in the central mediation of the febrile response. Indeed, the various isoforms of NO synthase (endothelial, neural, and inducible NOS), the enzyme that converts L-arginine into citrulline and NO, occur in the hypothalamus, and circulating LPS and cytokines stimulate the release of NO in the POA. Furthermore, as described above, NE induces the production of COX-2-dependent $PGE_2$ in the POA via an $\alpha_2$-AR-mediated mechanism, and others have shown that NE activates NOS. Hence, the existence of a pyrogenic NE-NO-$PGE_2$ cascade in the POA in response to iv LPS seems plausible. But the testing of this hypothesis revealed that, quite to the contrary, NO donors microdialyzed into the POA of conscious guinea pigs inhibit rather than promote the febrile response to iv LPS and that they do so by inhibiting the LPS-induced release of NE in the POA and consequently preventing the $\alpha_2$-AR-mediated activation of COX-2-dependent $PGE_2$ synthesis. NO scavengers microdialyzed into the POA have exactly the opposite effects. Indeed, previous data regarding a potential role of NO in fever have been conflicting, some indicating pyretic and others antipyretic effects. These results would indicate, therefore, that NO, presumptively released in the POA coincidentally with or very shortly after NE, serves as a local negative-regulatory modulator of NE secretion, i.e. it is a central endogenous antipyretic.

In summary, newly accumulated evidence indicates that the Kc-generated, vagally transmitted message of $PGE_2$ is conveyed from the NTS to the POA via the VNB. NE consequently secreted in the POA activates both local $\alpha_1$- and $\alpha_2$-AR. The stimulation of the first rapidly evokes an initial rise in $T_c$ which is associated with a decrease in the firing rates of preoptic warm-sensitive neurons, inhibiting heat loss and stimulating heat production, but is not accompanied by any change in the levels of preoptic $PGE_2$. Stimulation of the second causes, after a significant delay, a second, more prolonged $T_c$ rise that is associated with a concurrent increase in preoptic COX-2/mPGES-1-dependent $PGE_2$ levels. Hence, two distinctly produced $PGE_2$s would appear to mediate the febrile response: one, generated in the liver, is the immediate distal trigger of the febrile response, and the other, produced in the POA, is its subsequent proximal, albeit not indispensable mediator. The second phase of fever is very likely also supported by meanwhile produced circulating cytokines and $PGE_2$ as well as $PGE_2$ generated by cerebral endothelial and/or other cells in the blood-brain interface.

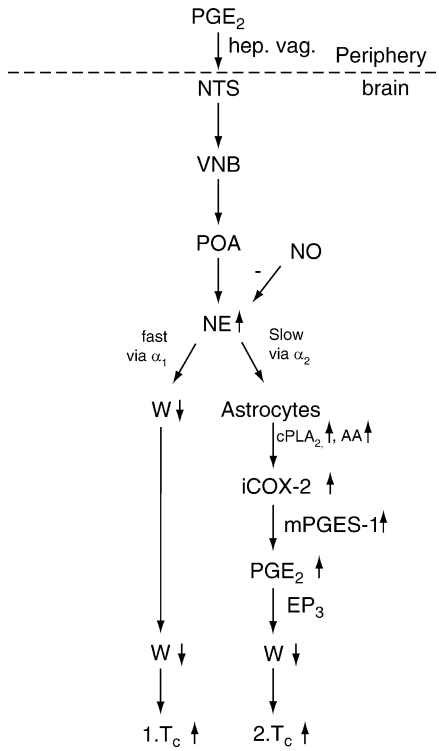
Thus, the key, new findings regarding the initiation of LPS fever are: (i) peripheral $PGE_2$ rather than pyrogenic cytokines initiates the febrigenic process, (ii) NE propagates the pyrogenic signal forward within the POA, (iii) NO modulates its release in the POA and, hence, the intensity of the febrile response, and (iv) preoptic COX-2/mPGES-1-dependent $PGE_2$ mediates the late, but not the early phase of fever; the latter appears to be independent of COX-derived $PGE_2$. The sequence of events occurring in the POA following the arrival of peripheral, $PGE_2$-induced, vagally transmitted, pyrogenic signals is depicted in Fig. 3.

### Pathways to the Effectors

As described earlier, the major effector systems mediating pyrogen-induced fever are the skeletal muscle mass (shivering thermogenesis) in adult animals, brown adipose tissue (BAT) nonshivering thermogenesis (NST) in neonates and rodents, and the cardiovascular system (cutaneous vasoconstriction, for heat conservation). Although these thermoeffector mechanisms are well characterized, the central efferent pathways controlling them are not yet fully known. Recent advances in immunohistochemical mapping and tracing methods have, however, allowed more progress to be made in this area [10].

The efferent signals that mediate shivering (a somatic response albeit that it is driven involuntarily) descend in the medial forebrain bundle (MFB) from the POA to the dorsomedial region of the posterior hypothalamus; stimulation of this region directly elicits shivering. From here, the signals travel caudally through the midbrain via reticulospinal neurons in the reticular formation dorsolateral to the red nucleus; some signals may also be relayed directly from the POA to these neurons. The pathway then courses close to the ventrolateral surfaces of the pons and medulla oblongata, and continues to the lateral columns of the spinal cord and, via the ventral horns, to the α-motoneurons of skeletal muscle, stimulating their contraction.

The signals for BAT NST are transmitted from GABAergic, $EP_3$ receptor-expressing warm-sensitive neurons in the POA via the MFB to the rostral raphe pallidus and raphe magnus nuclei in the medulla oblongata; GABAergic neurons in the dorsomedial hypothalamus projecting directly to these nuclei appear also to lie in this pathway. These nuclei contain vesicular glutamate



**Endotoxic Fever. Figure 3** The two-stage neural pathway of the induction of the biphasic (1. and 2.) febrile response to $PGE_2$ generated by Kupffer cells in response to the peripheral bolus injection of a low-to-moderate pyrogenic dose of LPS. $PGE_2$ generated by Kupffer cells in the liver activates hepatic vagal afferents, which then transmit its message to the POA via the nucleus tractus solitarius (NTS) in the medulla oblongata and the ventral noradrenergic bundle (VNB), culminating in the release of NE in the POA. NE then activates both $\alpha_1$- and $\alpha_2$-adrenoceptors. The stimulation of the first, located on preoptic warm-sensitive neurons, quickly and directly inhibits these, causing the first of the characteristic two core temperature ($T_c$) rises induced by low-to-moderate doses of iv LPS. The stimulation of the second, presumptively located on perisynaptic astrocytes, causes the generation of AA by an as yet indeterminate process and upregulates inducible (i) COX-2 and mPGES-1, resulting in the production of $PGE_2$. The latter then binds to its receptor ($EP_3$) on warm-sensitive neurons, depressing their activity and inducing the second febrile rise. Modified from [10].

transporter 3-expressing neurons that project to the intermediolateral cell column of the spinal cord; this column contains sympathetic premotor neurons that innervate sympathetic preganglionic neurons exiting at various segments of the thoracic spinal cord. These, in turn, synapse on sympathetic postganglionic cells innervating BAT depots throughout the body. Since warm-sensitive neurons are activated by warmth, it follows that their tonic influence on BAT thermogenesis is to inhibit it, probably via GABAergic inputs to the medullary raphe neurons; conversely, the inhibition of these neurons facilitates NST. As mentioned earlier, pyrogens inhibit these neurons and, consequently, the increased NST induced by these agents is presumptively mediated by a reduction in their inhibitory influence on BAT. Stimulation of the inferior olive and caudal periaqueductal gray has also been reported to activate BAT thermogenesis, but their specific roles in the circuitry controlling BAT activity are unclear. Tonic inhibitory areas may exist in the retrorubral field, pedunculopontine tegmental nucleus, and rubrospinal tract of the lower midbrain.

The efferents of the POA thermosensitive neurons controlling vasomotion also descend through the MFB, but to two different midbrain regions: one extends from the caudal edge of the lateral hypothalamus to the reticular formation and the periaqueductal gray, and the other to the ventral tegmental area. Preoptic warming excites the first, inducing skin vasodilation, and inhibits the second, hence mediating cutaneous vasoconstriction. Since pyrogens inhibit POA warm-sensitive neurons, the latter, presumably, is the efferent pathway consequently activated. The pathway continues from the ventral tegmental area to the sympathetic premotor neurons that control skin vasoconstriction. In cats, these are located predominantly in the rostral ventrolateral medulla, but in rats they are located in the caudal medullary raphe nuclei. From the medulla, the neurons project to the intermediolateral cell column of the spinal cord, exciting sympathetic preganglionic neurons and, thence, postganglionic vasoconstrictor neurons.

### *Function*

Fever has been recorded and associated with disease throughout history. From the beginning, it, or rather "fevers" were believed to be diseases in their own right, yet beneficial to the afflicted host, a view that persisted until the late nineteenth century when clinical observations and new techniques of quantitative measurements led to the gradual recognition that the observed rises in $T_c$ were a response to rather than the cause of illness. It was considered, however, that while the heat of fever was probably useful for destroying infectious microorganisms, high or prolonged fevers were detrimental due to their wasting effects on the host's body and, therefore, should be prevented. This, in turn, led to the general view that fever is harmful and should be suppressed, a goal that became practicable with the introduction in the late nineteenth century of salicylates. Indeed, the use of antipyretics became very popular, particularly since the reduction in $T_c$ was also associated with the relief of the other untoward symptoms of sickness behavior, thus moderating the discomfort level

and consequently alleviating the anxiety of both the afflicted patients and their caregivers.

In the last two decades, however, this perspective has again shifted, based on new findings indicating that while, indeed, some pathogenic microbes are killed at febrile temperatures, more are not, and that, more importantly, the heat of fever serves as an adjuvant that enhances the effectiveness of certain stimulus-activated adaptive immune responses, thereby helping to compartmentalize the reactions to the infected site. But probably even more critically, there is evidence that fever modulates the temporal sequence of the co-induced generations of TNFα, IL-1β and IL-6 early during the innate immune response, thereby minimizing the risk of the potentially harmful effects that could result from their dysregulated expression. Indeed, it is now clear that fever and its associated, non-febrile events are a phylogenetically old phenomenon, existing not only in mammals and birds, but also in fishes, amphibians, and reptiles, suggesting therefore, teleologically at least, that it has important survival value. Nevertheless, the pros and cons of managing fever continue to be debated.

## Definition

Control of energy metabolism and signal transduction in skeletal muscle.

## Characteristics

### Quantitative Description

#### *Adenosine 5´-Triphosphate: The Metabolic Intermediary in Energy Metabolism*

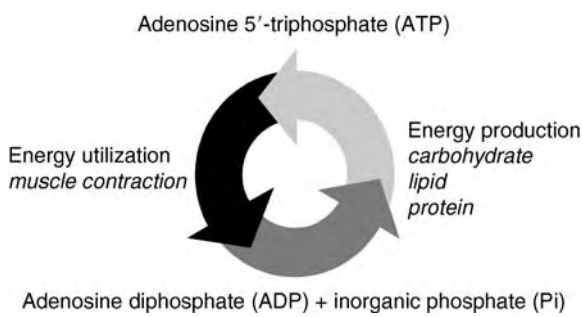
The link between energy-producing and energy-utilizing pathways in skeletal muscle and other tissues is the nucleoside adenosine 5′-triphosphate (ATP). ATP is the only form of chemical energy that can be converted into other forms of energy utilized by living cells, and due to its unique role in energy homeostasis, has been termed the energy currency of the cell. ATP is broken down enzymatically to adenosine diphosphate (ADP) and inorganic phosphate (Pi) to yield energy for muscular activity (Fig. 1).

ATP is regenerated from ADP by the breakdown of fuel molecules, predominantly carbohydrates and lipids stored in skeletal muscle, liver and other locations in the body, via both anaerobic (oxygen-independent) and/or aerobic processes [1].

## Process Regulation

#### *Matching ATP Synthesis with ATP Demand*

One of the most fundamental parameters for any healthy cell is the maintenance of a high of ATP to ADP ratio [2]. In cells with slow ATP-consuming reactions, resting [ATP] can be maintained by an acceleration of ATP-producing reactions, through the oxidation of carbohydrates and lipids. However, in the transition from rest to strenuous exercise, there is a dramatic increase in metabolic rate, such that the demand for ATP by active muscle can rise more than 100-fold. Nonetheless, such an increase in ATP turnover rate is accomplished with only minor perturbations in muscle [ATP]. This is because skeletal muscles have evolved a sensitive and sophisticated metabolic control system, one effect of which is to maintain a constant cellular [ATP]. The maximal rates of ATP resynthesis from aerobic and anaerobic processes and the "lag" time of these systems before their maximal rates are attained following contraction (i.e. whole body exercise) are displayed in Table 1.



**Energy Sensing and Signal Transduction in Skeletal Muscle. Figure 1** The relationship between energy production and energy utilization in human skeletal muscle.

#### *Metabolic Signals that Coordinate the Energy-Producing Pathways*

There are three major metabolic signals in the activation and coordination of the various energy-producing pathways during muscle contraction: (i) those initiated by changes in [$Ca^{2+}$], (ii) those that respond to changes in the "energy charge" of the cell, and (iii) those that are influenced by the mitochondrial reduction/oxidation (redox) state of nicotinamide adenine dinucleotide ([NAD]/[NADH]). Of these, $Ca^{2+}$ release plays the most fundamental role in initiating muscle contraction and activating metabolism in a feed-forward or "early

**Energy Sensing and Signal Transduction in Skeletal Muscle. Table 1** Calculated maximal rates of adenosine 5′-triphosphate resynthesis from anaerobic and aerobic metabolism, along with the approximate lag time before maximal rates are attained following the onset of whole-body exercise

| Metabolic process | Maximal rate of ATP resynthesis (mmol ATP/kg dm/s) | Lag time |
|---|---|---|
| PCr breakdown | 9.0 | Instantaneous |
| Glycolysis | 4.5 | 5–10 s |
| Glycogen oxidation | 2.8 | Several minutes |
| Blood glucose oxidation | 1.0 | 90 min |
| Lipid oxidation | 1.0 | >2 h |

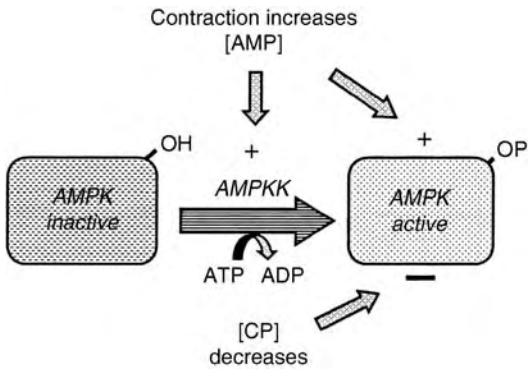
ATP, adenosine 5′-triphosphate; PCr, phosphocreatine; dm, dry mass.

warning" manner [1]. Calcium provides the trigger for force development and ATP hydrolysis, and contributes to the activation of glycogenolysis. Although the feed-forward $Ca^{2+}$ -activated signals are important for events occurring early on in the excitation-coupling processes, the energy charge of the cell (i.e. [ATP]/[ADP] [Pi]) provides the rapid feedback signals that are necessary to balance ATP production with ATP consumption [3]. Finally, the redox state of the muscle activates numerous reactions in substrate/product or activator/inhibitor capacities [1]. All three types of signal are important in coordinating the up-regulation of enzymes that are vital for ATP production in mitochondrial and cytoplasmic compartments during contraction. During the past decade, strong evidence has emerged to suggest that one of the most important energy sensing/signaling proteins of the muscle involved in the regulation of metabolism during both acute contractions and chronic exercise training is the 5′-adenosine monophosphate-activated protein ►kinase (AMPK) pathway.

### The 5´-Adenosine Monophosphate-Activated Protein Kinase Pathway

AMPK is a protein consisting of three subunits, designated α, β and γ. The α subunit, of which there are two ►isoforms (α1 and α2), contains the catalytic domain that transfers a high-energy phosphate from ATP to serine and threonine residues on a number of different target proteins [2]. There are also multiple isoforms of β (β1 and β2) and γ (γ1, γ2, γ3) regulatory subunits that are essential for full enzymatic activity, and also function in localizing the AMPK molecule within cells [4]. All the α isoforms are found in skeletal muscle, with this subunit being most sensitive to AMP. Information about the distribution of the various subunits in different muscle fiber types is not currently available.

AMPK can be considered a protein that monitors the energy state of the muscle cell, triggering metabolic processes that, when activated, are designed to conserve and restore high-energy phosphate levels [2–4]. AMPK is rapidly activated by cellular stresses that deplete ATP (and concomitantly elevate AMP) either by accelerating ATP consumption (i.e. muscle contractions) or inhibiting ATP production (i.e. ischemia, hypoxia, pharmacological inhibition of ►glycolysis and oxidative ►phosphorylation). AMPK is activated allosterically by an increase in [AMP], and inhibited by ATP and CP (Fig. 2), and by increases in fuel reserves, such as muscle glycogen. Once activated, the AMPK cascade switches on catabolic processes both acutely (by phosphorylation of downstream metabolic enzymes such as acetyl CoA carboxylase [ACC]), and chronically (by effects of gene expression), while concomitantly switching off ATP-consuming processes [5].



**Energy Sensing and Signal Transduction in Skeletal Muscle. Figure 2** Activation of the 5′-adenosine monophosphate-activated protein kinase in skeletal muscle. From Winder WW (2001), Energy-sensing and signaling by AMPK-activated protein kinase in skeletal muscle. J Appl Physiol 91:1017–1028. Reproduced with permission of the American Physiological Society.

### Activation of AMPK by Muscle Contraction

The first evidence that AMPK was involved in the coordinated regulation of skeletal muscle metabolism was provided by Winder and Hardie [6]. These workers observed a two- to threefold increase in AMPK activity in the skeletal muscle of rats subjected to treadmill running, which was present 5 min after the onset of exercise. Of interest was that the increase in AMPK was work dependent, and that the activity remained elevated for up to 30 min post exercise, suggesting that AMPK might also be involved during the recovery of muscle energy reserves [6]. With regard to the effects of exercise in humans, low- to moderate intensity cycling in both untrained and trained individuals induces an isoform-specific and intensity-dependent increase in AMPK α2, but not α1 associated activity [7]. Conversely, activation of the AMPK α1 and α2 isoforms occurs after sprint-type exercise [8]. It is likely that activation of the α1 isoform after short-term anaerobic exercise is related to the *rate* of fuel utilization rather than the degree of substrate depletion, as no change in AMPK α1 activity is observed after prolonged, continuous, low-intensity cycling leading to exhaustion and muscle glycogen depletion.

### Modulation of AMPK Response to Exercise by Muscle Fuel Status

Recent studies indicate that the glycogen content of skeletal muscle may modulate the AMPK response to contraction. Well-trained subjects have been studied under conditions of low- and high-glycogen concentration, at rest and subsequently during 60 min of moderate intensity cycling exercise [9]. At rest, both AMPKα1 and α2 activities were elevated in the low- versus high-glycogen states. Low pre-exercise

E

glycogen content also increased AMPKα2 activity and ACC phosphorylation during subsequent submaximal cycling. The low muscle glycogen state was also accompanied by significantly increased leg glucose and net fatty acid uptake, as well as increased plasma concentrations of catecholamines compared to the high-glycogen condition. Thus, AMPK activity during exercise would appear to be regulated by both fuel availability (i.e. the prevailing muscle glycogen content), as well as humoral factors (i.e. circulating hormones and substrates).

### *Effects of Exercise Training Status on AMPK*

There are several lines of evidence to suggest that AMPK plays a role in mediating some of the adaptations to chronic muscle contraction (i.e. exercise training). For example, when AMPK is activated pharmacologically by the use of the chemical 5-aminoimidazole-4-carboxamide-riboside (AICAR), there are significant increases in the levels of several mitochondrial proteins, along with elevations in resting muscle glycogen content [4,10]. If AMPK does play a role in regulating some of the metabolic adaptations to training, then there should be a blunted response of AMPK to standardized exercise in trained versus untrained individuals. This is indeed the case. Several recent studies (reviewed in 5) have reported an attenuation in the rise in AMPK α2 activity in trained versus untrained subjects in response to intense cycling undertaken at the same relative power output. Despite higher absolute energy requirements during exercise in the trained individuals, the phosphorylation potential of the muscle (reflected by the difference in [PC]/[PCr + Cr] ratio) was better maintained in trained individuals. The results of these investigations provide strong evidence that AMPK activity is influenced more as a consequence of the metabolic perturbation induced by muscle contraction than the energy flux of the muscle cell.

### *Summary and Future Directions*

Within the past decade, a growing body of evidence has emerged to suggest that AMPK plays a central role in regulating numerous metabolic processes in contracting human skeletal muscle. It appears that AMPK acts as a "fuel gauge" and can respond in an ultra-sensitive manner to changes in the energy status of the cell. Thus, the AMPK energy sensing and signaling system is involved in counteracting high-energy phosphate depletion during single bouts of exercise, and in the long-term, in inducing adaptations that play a role in up-regulating many of the exercise-induced responses in skeletal muscle that occur after repeated bouts of exercise. The biggest challenge for exercise physiologists in the future will be to link AMPK signaling to specific and defined metabolic responses in skeletal muscle that occur after exercise and other interventions.

## Definition

### Energy

Energy is defined as a conserved quantity associated with the state of a system and indicative of the system's

capacity to impose change on other systems or to undergo change itself. The energy within a system exists in many forms. ►The 1st Law of Thermodynamics [1] states that energy can be converted from one form to another but the total energy remains constant. This is a not a statement of the results of scientific observations but a statement of principle, a definition of the scientific use of the word energy.

In biomechanical studies on a macro scale (whole animal or body segment), the 1st Law can generally be satisfied by considering only these five forms of energy:

1. ►Kinetic energy. The energy associated with motion of an object.
2. ►Elastic energy. The energy stored in a stretched spring.
3. ►Gravitational potential energy. The energy associated with the vertical displacement of an object in a gravitational field.
4. ►Chemical energy. The energy associated with the chemical state of the matter in the system.
5. Heat. The energy associated with thermal motion of the system in all of its degrees of freedom.

In the bioenergetics of micro-scale processes, such as those occurring within the individual axon, chloroplast, mitochondrion or flagella, these further forms of energy will also be required:

6. ►Osmotic energy. The energy associated with a concentration gradient.
7. Electrical potential energy. The energy associated with the movement of an electrical charge (C) through an electrical gradient (V).

Other forms of energy exist, for example, nuclear energy or the energy associated with magnetic fields or large temperature gradients, but these are not known to be exploited in biological movement and need not be considered in biomechanical studies.

►*Free energy*. In principle, all forms of energy are inter-convertible by a suitable machine. However, the ►2nd Law of Thermodynamics [1] tells us that conversion of heat into any other form of energy is limited. The rule is that the maximum fraction of the heat that can be converted is equal to the ratio of the temperature gradient within the machine to its absolute temperature. This ratio would not exceed about 1% in a biological machine, and so it is not surprising that conversion of heat into other forms of energy has not been found in biological systems. Generally, the simplification is made that such systems operate at constant temperature and that no conversion of heat to other energy forms is possible. The conversion of energy into heat within a biological system is thus irreversible and the potential to convert it to another form is lost, for this reason the term energy dissipation is sometimes used for this conversion. In making an energy account, we must therefore distinguish between the part of the energy that cannot be converted to another form, and the part that can be so converted, designated the free energy. Energy in kinetic, elastic, osmotic, electric or gravitational form can be considered entirely free energy: a perfect machine can convert all of it to another form. However, the energy of a chemical reaction is not in general the same as the free energy of the reaction, part of the energy change associated with the reaction cannot be converted to another form, it is an obligatory change in the heat content of the system [1]. Therefore, in considering chemical energy we have to distinguish between the free energy change and the total energy change, the sum of the measured heat and ►work changes, for which the term ►enthalpy is useful.

*Work*. A system may exchange energy with another system or with its environment. We distinguish between flows of energy as heat and as free energy, for which the term work is used. Since by definition the total energy of a system plus its environment remains constant, the change in the energy of the system can be observed by measuring the flows of heat and of work to/from the environment.

►*Efficiency*. The only changes that can occur in a system are those in which the total free energy, including any work done by or on the system decreases. Such changes in the simplest case involve the linkage (coupling) of two processes: one (the "driving" process) in which the free energy is decreasing, and another (the "driven" process) in which it is increasing. Efficiency is a term used to characterize the exchange of free energy between two systems, usually also two different forms of energy. It is ideally defined as the ratio of the free energy increase in the driven process to the decrease in the driving process. The efficiency so defined cannot exceed unity. Unfortunately, free energy flows are hard to measure and so other definitions of efficiency are often used, involving quantities that can be measured more easily (e.g. heat and work flow). With these definitions, the efficiency may not be constrained to a value less than unity. Efficiency calculations that give values greater than unity generally indicate that the identity of the driving process has not been established.

Energetics. The energetics of a system is a description of the flows of energy from one form to another during its operation. For example, the energetics of human walking is dominated by the exchange of energy between gravitational potential energy and kinetic energy, in addition to some conversion of chemical energy into mechanical energy. The experimental energetics of muscle contraction is the study of the flows of energy associated with muscle contraction under different conditions, and an enquiry into the nature of the processes causing these flows. The main experimental findings are summarized in the next section.

## Characteristics

On the macro scale, skeletal muscle contraction is the major driving process in animal movement, and the

following paragraphs address the energetics of muscle contraction.

When it is not being stimulated, muscle is merely a rather compliant spring and its contribution to the energetics of movement can usually be neglected. When it is stimulated by action potentials arriving from the motor nerve, muscle becomes "active" and operates energetically in two modes. When shortening, "concentric activity," the muscle acts as a motor transforming chemical energy into heat and into the mechanical work that is done by shortening against any force acting to stretch the muscle. During "eccentric activity," active muscle is made to elongate by the application of a sufficient external force. The muscle then acts as a brake absorbing the work done on it and converting it to heat. In an ►isometric contraction, muscle neither shortens nor lengthens and the energy output is as heat only.

*Series Elasticity.* Muscles, as identified anatomically, consist of muscle fibers and connective tissues connecting them to the anatomical tendon. These elements add a significant compliance in series with the muscle fibers known as the series elastic component (SEC). The SEC stores and releases elastic energy during muscle contractions, saving energy that would otherwise be dissipated as heat and reducing the need for chemical energy in the muscles. The energetics of muscle is much simplified if these processes are separated from those occurring in the muscle fibers themselves, which are described below. Typically, a period of muscle activity involves both eccentric and concentric phases; during the cyclic processes of locomotion, muscle/tendon units (MTU) often experience length changes of about 5–10% of the muscle fiber lengths. A common type of muscle activity would be for the muscle to be activated towards the end of the period of eccentric phase of the MTU, and for the period of activation to end towards the end of the concentric period. The consequence of this pattern of activity is that the length change in the muscle fibers is much less than that in the MTU, and they may remain almost isometric. The SEC can release stored work much more rapidly than work can be produced by the muscle fibers themselves, temporarily enhancing the power output of the muscles [2].

*Isometric contraction.* Energy is output as heat only. About 2/3 of this energy comes from the activities of the actin and myosin filaments within the muscle, and the remainder from the calcium turnover of the sarcoplasmic reticulum responsible for the activation and relaxation of the contractile system. In most muscles, the rate of energy output declines during a period of activation lasting several seconds, although the force exerted remains almost constant.

►*Concentric contractions*. Energy is output as both heat and work. The total rate of energy output increases with speed of shortening to about 5 times the isometric rate.

►*Eccentric contractions*. Energy is input as work and output as heat. The rate of heat production exceeds the rate of work input, suggesting that chemical energy use is continuing, but at a rate below that in isometric contraction [3].

*Chemical Origin of the Heat and Work Produced.* Both the actomyosin system and the calcium turnover system of the SR use ATP as their energy source, splitting it to ADP and inorganic phosphate (Pi). The ADP produced is rapidly re-phosphorylated by the abundant phosphocreatine (PCr) in the muscle. The principle net chemical change *during* contraction is thus the splitting of phosphocreatine to creatine and Pi. Most of the energy output as heat and work can be explained by this reaction, but some is also probably derived from changes in the distribution of calcium within the muscle and changes within the actomyosin system itself. In some muscles, glycolysis occurs significantly even in short contractions and contributes to the energy output (see [2] for further information in this area).

After relaxation, PCr is rebuilt by oxidative phosphorylation in the following minutes. This process produces heat generally rather greater in amount than the energy output during the contraction itself.

*Muscle Efficiency.* As explained above, efficiency can only be determined unambiguously when the chemical source of the free energy is known. Considering the energy output both during and after contraction, the chemical source of the heat and work can be identified as oxidation of substrates. For this process, the free energy is closely similar to the enthalpy and the efficiency, therefore, is equal to the ratio of heat/(heat + work). Experimental values range from 20 to 40% depending on species used (see [2,4] for further information in this area).

When we consider only the processes occurring during contraction, the reported values of the ratio of heat to (heat + work) vary from 0.3 to 0.8 (see Table 2 in [4]). However, this overestimates the thermodynamic efficiency because the source of the heat + work is largely PCr splitting, for which the free energy change is about 50% greater than the amount of heat + work produced. The efficiency of the initial processes can be recalculated after taking account of this factor and allowing for the fact that part of the inefficiency is due to the use of ATP for calcium pumping, rather than for the mechanical processes themselves. The resulting values range from 25 to 65%, depending on fiber type and species of animal. The highest efficiency is found in the muscles of the tortoise, which have an unusually low power output. Efficiency can also be measured in skinned muscle fibers in which the source of energy is the ATP provided in the bathing solution and for which the free energy can be calculated. Results are in

the range of 14 to 40% (summarized with corrections in [4, Table 3].

The values for efficiency of the recovery process itself, which is the transfer of free energy from oxidative phosphorylation to free energy of ATP splitting, is about 70% [4].

## ENGs (Electroneurographic Recordings)

### Definition

Extracellular recordings from a peripheral nerve. In many cases, the ENG is recorded from a peripheral nerve that innervates a particular muscle.

►Extracellular Recording

## Enhancer

### Definition

Enhancer is a short stretch of nucleotides that are bound by trans-activating factors that increase the levels of gene transcription. An enhancer does not need to be in close proximity in terms of nucleotide sequence, to the gene whose activity it regulates, but comes in close proximity to the DNA promoter when DNA is folded in the chromatin complex.

## Enhancer Trap

### Definition

Enhancer trap – an enhancer trap element is a mobile DNA element that is usually a P element. The P element can carry a reporter gene and an eye color marker as well as various bacterial elements necessary for cloning. Expression levels of the reporter require that the enhancer trap insert and come under control of an endogenous enhancer element.

►GAL4/UAS

## Enhancing Function

### Definition

One of two mechanisms (the other being conditioned motivation) by which reinforcers cause changes in future behavior.

►Neuroethological Aspects of Learning

## Enkephalin

### Definition

Enkephalin either of two closely related pentapeptides (methionine enkephalin and leucine enkephalin) having opiate-like qualities and occurring in the brain, spinal cord and other parts of the body. Binding to specific receptors, they may act as neuromodulators in a variety of brain structures, in some cases producing analgesic and sedative actions or affecting mood and motivation.

## Ensemble Code

### Definition

In this code many neurons together and not one neuron alone carry information.

## Enslavement

### Definition

Unintentional production of force by digits other than the digit with which a subject attempts to exert force voluntarily, as if the other digits slavishly follow the voluntarily activated digit.

►Motor Cortex – Hand Movements and Plasticity

## Entelechy

### Definition

In Greek an entity that "bears its goal within itself." The vitalist Hans Driesch (1867–1941) reinvented the word to refer to a non-physical, non-spatial causal factor in living beings, which he claimed would direct the physical and chemical processes during an organism's development.

►Emergence

## Enteric Dysfunction

### Definition

Enteric dysfunction is impairment of enteric functions such as motility, absorption and secretion. Enteric dysfunction is more prevalent with increasing age.

►Autonomic/Enteric Dysfunction

## Enteric Excitatory Musculomotor Neurons

### Definition

Enteric excitatory musculomotor neurons are motor neurons in the enteric nervous system that release excitatory neurotransmitters to initiate contractions in the musculature of the digestive tract.

►Autonomic/Enteric Reflexes

## Enteric Inhibitory Musculomotor Neurons

### Definition

Enteric inhibitory musculomotor neurons are motor neurons in the enteric nervous system that release inhibitory neurotransmitters to inhibit contractile activity in the musculature of the digestive tract.

►Autonomic/Enteric Reflexes

## Enteric Nervous System

John B. Furness
Department of Anatomy and Cell Biology and Centre for Neuroscience, University of Melbourne, Parkville, VIC, Australia

### Definition

A division of the autonomic nervous system whose component neurons lie within the walls of the digestive organs (esophagus, stomach, intestines, pancreas, gall bladder and pancreato-biliary ducts). The ►enteric nervous system (ENS) contains entire nerve circuits for digestive organ control, and can function autonomously.

The enteric nervous system is the intrinsic nervous system of the gastrointestinal tract through which gastrointestinal motility, gastrointestinal intramural blood flow and fluid movement across the mucosal lining of the intestine are controlled.

### Characteristics

#### Organization and Relationships

The enteric nervous system is composed of thousands of small ganglia that lie within the walls of the esophagus, stomach, small and large intestines, pancreas, gallbladder and biliary tree, the nerve fibers that connect these ganglia, and nerve fibers that supply the muscle of the gut wall, the mucosal epithelium, arterioles and other effector tissues [1,2,3]. Large

numbers of neurons are contained in the enteric nervous system, about 200–600 million in human. This is far more neurons than occurs in any other peripheral organ and is similar to the number of neurons in the spinal cord.

The ganglia contain nerve and glial cells, but not connective tissue elements, and in many respects are similar in structure to the central nervous system, except that there is no significant blood-enteric nervous system barrier. Nerve fiber bundles within the enteric nervous system consist of the axons of ►enteric neurons, axons of extrinsic neurons that project to the gut wall, and glial cells. Two major sets of ganglia are found, the myenteric ganglia between the external muscle layers, and the submucosal ganglia (Fig. 1).

The ►myenteric plexus forms a continuous network, extending from the upper esophagus to the internal anal sphincter. The ganglionated ►submucosal plexus is present in the small and large intestines, but is absent from the esophagus and contains only very few ganglia in the stomach.

The enteric nervous system originates from neural crest cells that colonize the gut during intra-uterine life. It becomes functional in the last third of gestation in human, and continues to develop following birth.

The enteric nervous system receives inputs from the parasympathetic and sympathetic parts of the nervous system, and the gastrointestinal tract also receives a plentiful supply of afferent nerve fibers, through the vagus nerves and spinal afferent pathways. Thus, there is a rich interaction, in both directions, between the enteric nervous system, sympathetic prevertebral ganglia and the central nervous system.

The gastrointestinal tract also harbors an extensive endocrine signaling system, and many gastrointestinal functions are under dual neuronal and endocrine control [4]. Enteric neurons also interact with the extensive intrinsic immune system of the gastrointestinal tract.

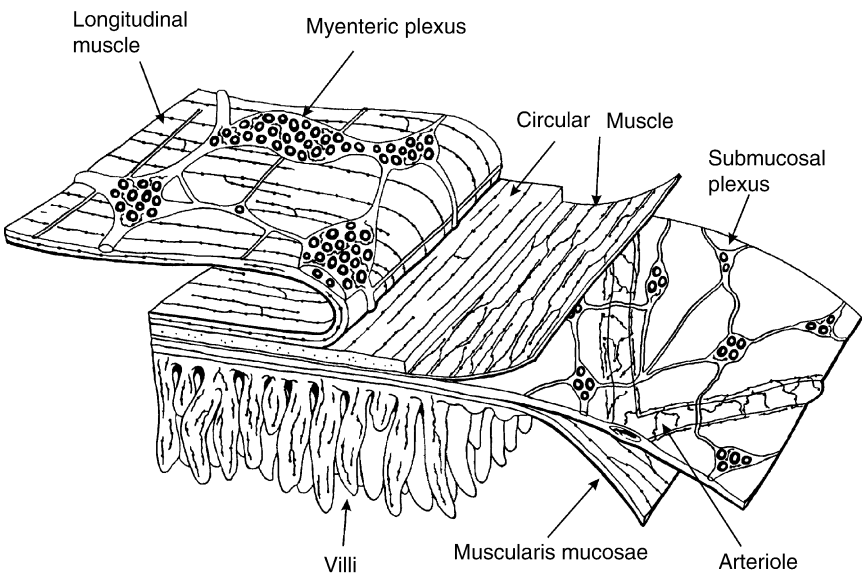
## Types of Enteric Neurons

There are approximately 20 types of enteric neurons can be defined by their functions. Combinations of features (morphology, neurochemical properties, cell physiology and projections to targets) help to define each type. Amongst the 20 types, three classes can be identified, ►intrinsic primary afferent neurons (IPANs) [5], interneurons and motor neurons. IPANs detect the physical state of the organs (for example, tension in the gut wall and chemical features of the luminal contents. They react to these signals to initiate appropriate reflex control of motility, secretion and blood flow. IPANs connect with each other, with interneurons and directly with motor neurons; interneurons connect with other interneurons and with motor neurons. Amongst the motor neurons are muscle motor neurons, secretomotor neurons, secretomotor/vasodilator neurons and vasodilator neurons.

## Functions of the Enteric Nervous System

### *Control of Motility*

The gastrointestinal tract has an external muscle coat whose purposes are to mix the food so that it is exposed



**Enteric Nervous System. Figure 1** The enteric plexuses of the small intestine. There are two plexuses that contain nerve cell bodies, the myenteric and submucosal plexuses, and plexuses of nerve fibers in the muscle, mucosa and around arterioles. Nerve cells are represented by the black circles in ganglia of the myenteric and submucosal plexuses. The lines represent nerve fibers innervating the muscle, villi of the mucosa, arterioles and ganglia.

to digestive enzymes and to the absorptive lining of the intestine, and to propel the contents of the digestive tube. The muscle also relaxes to accommodate increased bulk of contents, notably in the stomach. The enteric reflex circuits regulate movement by controlling the activity of both excitatory and inhibitory neurons that innervate the muscle. There neurons have co-transmitters, for the excitatory neurons, acetylcholine and tachykinins, and for the inhibitory neurons nitric oxide, vasoactive intestinal peptide and ATP.

Intrinsic reflexes (►Gastrointestinal reflexes) of the enteric nervous system are essential to the generation of the patterns of motility of the small and large intestines. The major muscle movements in the small intestine are mixing, propulsive reflexes that travel for only small distances, the migrating myoelectric complex, peristaltic rushes and retropulsion associated with vomiting. The enteric nervous system is programmed to produce these different outcomes. In contrast to the intestine, peristalsis in the stomach is a consequence of conducted electrical events (slow waves) that are generated in the muscle. The intensity of contraction is determined by the actions of the vagus nerves, which form connections with enteric neurons in the gastric wall. The proximal stomach relaxes to accommodate the arrival of food. This relaxation is also mediated through vagus nerve connections with enteric neurons. Thus, the primary integrative centers for control of gastric motility are in the brain-stem, whereas those for control of the small and large intestines are in the enteric nervous system. In most mammals, the contractile tissue of the external wall of the esophagus is striated muscle, and in others, including humans, the proximal half or more is striated muscle. The striated muscle part of the esophagus is controlled, via the vagus, by an integrative circuitry in the brain stem. Thus, although the myenteric ganglia are prominent in the striated muscle part of the esophagus, they are modifiers, not essential control centers, for esophageal peristalsis.

The smooth muscle sphincters restrict and regulate the passage of the luminal contents between regions. In general, reflexes that are initiated proximal to the sphincters relax the sphincter muscle and facilitate the passage of the contents, whereas reflexes that are initiated distally restrict retrograde passage of contents into more proximal parts of the digestive tract.

The progress of the contents in an oral to anal direction is restricted when sympathetic nerve activity increases. To achieve this, transmission from enteric excitatory reflexes to the muscle is inhibited and the sphincters are contracted. The post-ganglionic sympathetic neurons utilize noradrenaline as a transmitter. Under resting conditions the sympathetic pathways exert little influence on motility. They come into action when protective reflexes are activated.

### Regulation of Fluid Exchange and Local Blood Flow

The enteric nervous system regulates the movement of water and electrolytes between the gut lumen and tissue fluid compartments. It does this by directing the activity of secretomotor neurons that innervate the mucosa in the small and large intestines and control its permeability. Neurotransmitters of secretomotor neurons are vasoactive intestinal peptide (VIP) and acetylcholine. Secretion is integrated with vasodilatation, which provides some of the fluid that is secreted. Most secretomotor neurons have cell bodies in submucosal ganglia.

Fluxes of fluid, greater than the total blood volume of the body, cross the epithelial surfaces of the gastrointestinal tract each day. Control of this fluid movement via the enteric nervous system is of prime importance for the maintenance of whole-body fluid and electrolyte balance. The largest fluxes are across the epithelium of the small intestine, with significant fluid movement also occurring in the large intestine, stomach, pancreas and gall-bladder. Water flows between the lumens of digestive organs and body fluid compartments in response to movement of osmotically active molecules. The greatest absorption of water, 8–9 l/day, accompanies inward flux of nutrient molecules and $Na^+$, and the greatest secretion accompanies outward fluxes of $Cl^-$ and $HCO_3^-$ in the small and large intestine, gall-bladder and pancreas. In each of these organs, fluid secretion is controlled by enteric reflexes. In the small intestine and most of the colon the reflex circuits are intrinsic, in the enteric nervous system. They balance secretion with absorptive fluxes, and draw water from the absorbed fluid and from the circulation. The activity of the secretomotor reflexes is under a physiologically important control from inhibitory sympathetic nerve pathways that respond to changes in blood pressure and blood volume through central reflex centers.

Local blood flow to the mucosa is regulated through enteric vasodilator neurons so that the mucosal blood flow is appropriate to balance the nutritive needs of the mucosa and to accommodate the fluid exchange between the vasculature, interstitial fluid and gut lumen. Overall blood flow to the gut is regulated from the central nervous system, via sympathetic vasoconstrictor neurons.

### Regulation of Gastric and Pancreatic Secretion

Gastric acid secretion is regulated both by neurons and by hormones. Neural regulation is through cholinergic neurons with cell bodies in the wall of the stomach. These receive excitatory inputs both from enteric sources and from the vagus nerves.

Gastric secretion of HCl and pepsinogen in the stomach, and secretion of pancreatic enzymes, is largely dependent on vago-vagal reflexes. Enteric motor neurons are the final common pathway, but the roles of intrinsic reflexes are minor. Pancreatic secretion of bicarbonate, to neutralize the duodenal contents, is

controlled by secretin, a hormone released from the duodenum, in synergy with activity of cholinergic and non-cholinergic enteric neurons. Secretion into the gall-bladder and bicarbonate secretion in the distal stomach are also nerve controlled.

### *Regulation of Gastrointestinal Endocrine Cells*

Nerve fibers run close to endocrine cells of the mucosa of the gastro-intestinal tract, some of which are under neural control. Gastrin cells in the antrum of the stomach are innervated by excitatory neurons that utilize gastrin releasing peptide as the primary neurotransmitter.

### *Defense Reactions*

Enteric neurons are involved in a number of defense reactions of the gut. Defense reactions include diarrhea to dilute and eliminate toxins, exaggerated propulsive activity that occurs when there are pathogens in the gut, and vomiting.

Fluid secretion is provoked by noxious stimuli, particularly by the intraluminal presence of certain viruses, bacteria and bacterial toxins. This secretion is due in large part to the stimulation of enteric secretomotor reflexes. The physiological purpose is undoubtedly to rid the body of pathogens and their products. However, if the pathogens overwhelm the body's ability to cope, the loss of fluid (diarrhea) can become a serious threat to the organism.

### *Pathology*

There are a large number of pathologies associated with the neural regulation of digestion, most of these arising from abnormalities of the enteric nervous system [6,7]. One neuropathology of the gut is Hirschprung's disease, in which an agenesis of the enteric nervous system, that extends proximally from the rectum for various distances, occurs. It is fatal if untreated. Other enteric neuropathologies include hypertrophic pyloric stenosis, esophageal atresia, gastroparesis, slow transit constipation, some cases of esophageal reflux, Chagas' disease and irritable bowel syndrome.

# Enteric Neuron

## Definition

Two networks or plexuses of enteric neurons are embedded in the wall of the entire length of the digestive tract. The myenteric plexus is located between the circular and longitudinal layer of the muscularis externa, and is primarily involved with the control of gut motility. The submucous plexus, within the submucosa, is involved in the regulation of blood flow within the digestive tract and in the control of epithelial functions such as the secretion of enzymes, acid or mucous. Every neuron whose cell body is in the enteric nervous system is named as "enteric neuron." The enteric neurons are classed in three groups: sensory neurons sending their sensory afferents to chemo- and mechanoreceptors in the gut wall, motor (either excitatory or inhibitory) neurons regulating gut activities, and interneurons forming synaptic linkages among enteric neurons. The enteric neurons are classified according to their electrophysiological/chemical properties and shapes; good correlations among these are established. Dogiel type I neurons, morphologically classified, correspond to S/Type 1 neurons, electrophysiologically identified, acting as motor and/or interneurons; while Dogiel type II neurons are AH/Type 2 neurons as afferent sensory neurons.

## Entorhinal and Perirhinal Cortices

### Definition

The entorhinal and perirhinal cortices are situated in the parahippocampal gyrus and mark the transition from allocortex of the hippocampus to the cerebral cortex of the temporal lobe. The area stretches from the amygdaloid body to the prepiriform cortex and already features a 6-layered structure. Afferents: rhinencephalon, Ammon's horn, septum verum, cortex, thalamus.

Efferents: hippocampus, thalamus, tegmentum of ►Mesencephalon.

►Telencephalon

## Entorhinal Area (Cortex)

Menno P. Witter
Kavli Institute for System Neuroscience, Centre for the Biology of Memory, Department of Neuroscience, Norwegian, University of Science and Technology (NTNU), Trondheim, Norway; Institute for Clinical and Experimental Neurosciences, Department of Anatomy and Neurosciences, VU University medical center, Amsterdam, The Netherlands

### Synonyms

Brodman area 28

### Definition

The entorhinal (inside rhinal) area is a part of the cortex that is partially enclosed by the ►rhinal (►olfactory) ►sulcus. It is a major part of the ►medial temporal lobe memory system and constitutes the major gateway between the *hippocampal formation* and the *neocortex*. It is involved in higher-order cognitive processing, in particular in memory processes. The entorhinal area exhibits pathological and pathophysiological changes in a number of diseases including Alzheimer's disease, epilepsy, and schizophrenia.

### Characteristics

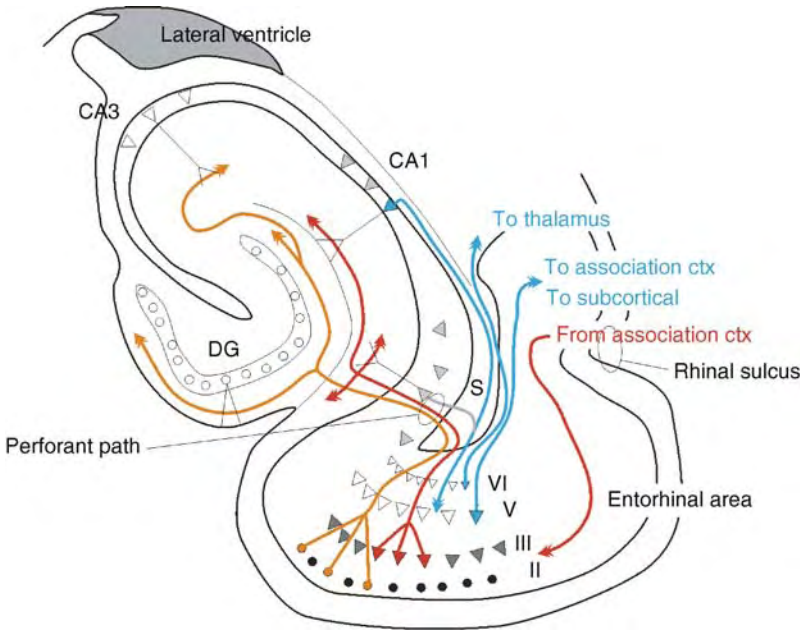
#### Anatomical Organization

The entorhinal area is part of a densely interconnected group of cortical areas that together form the ►*parahippocampal region*, an area closely associated with the *hippocampal formation*. The name of the entorhinal area, similar to that of other components of the parahippocampal region, is derived from the ►rhinal sulcus, which can be distinguished in all mammals. However, its particular features differ quite a bit between species. Whereas in rats it is essentially the only distinguishable sulcus that runs along the rostrocaudal extent of the hemisphere, in humans it is only present in about 50% of the cases as a shallow and short indentation in the most medio-anterior temporal lobe.

The entorhinal area is uniquely positioned as an interface between the *neocortex* and the *hippocampal formation*. It is also closely associated with a larger group of cortices, referred to as *limbic* cortex. The entorhinal area is traditionally divided into the lateral and medial entorhinal area. Similar to other cortices, in the entorhinal area, neurons are grouped into different layers that are each characterized by a dominant cell type. Six layers are commonly distinguished, of which layers I and IV are relatively free of neurons. All remaining layers do contain a variety of neuronal subtypes that have been characterized on the basis of their anatomical and/or electrophysiological properties The principal neurons of the entorhinal area, i.e. the neurons that are the main recipients of incoming axons and the major source of entorhinal output to a variety of cortical and subcortical structures are generally pyramidal cells or modified versions, the so-called stellate cells. These mainly utilize *glutamate* as an excitatory *neurotransmitter*. A second group of neurons are the interneurons that mainly provide intrinsic, local connections that use *GABA* as an inhibitory transmitter. Many of these interneurons are characterized by expressing a variety of different peptides in their cellbody [1,2] (Fig. 1).

#### Functional Organization

The entorhinal area is part of the cortical domain, called the *parahippocampal region* which in addition to the entorhinal area includes the perirhinal and



**Entorhinal Area (Cortex). Figure 1** Schematic representation of the entorhinal area and its main connectivity that puts it in a pivotal position to mediate the communication between the hippocampal formation and the association cortex. Dentate gyrus (DG), Cornu ammonis fields 3 and 1 (CA3, CA1) and the subiculum are components of the hippocampal formation.

parahippocampal (postrhinal) cortices and the pre- and parasubiculum. The parahippocampal region in turn is virtually inseparable from the *hippocampal formation*, and together they form the major constituents of the system mediating conscious (declarative) memory. Together these regions appear to specifically deal with the translation of neocortical exteroceptive information into higher order complex representations that, when combined with motivational and interoceptive representations, will serve cognitive functions, in particular conscious memory.

Since prominent species differences are apparent with respect to size and organization of cortical areas, also the organization of the entorhinal area may be expected to be different in for example primates and non-primates. However, despite considerable diversity of the majority of cortical regions, the anatomy and functional role of the entorhinal area appear to be largely conserved [3].

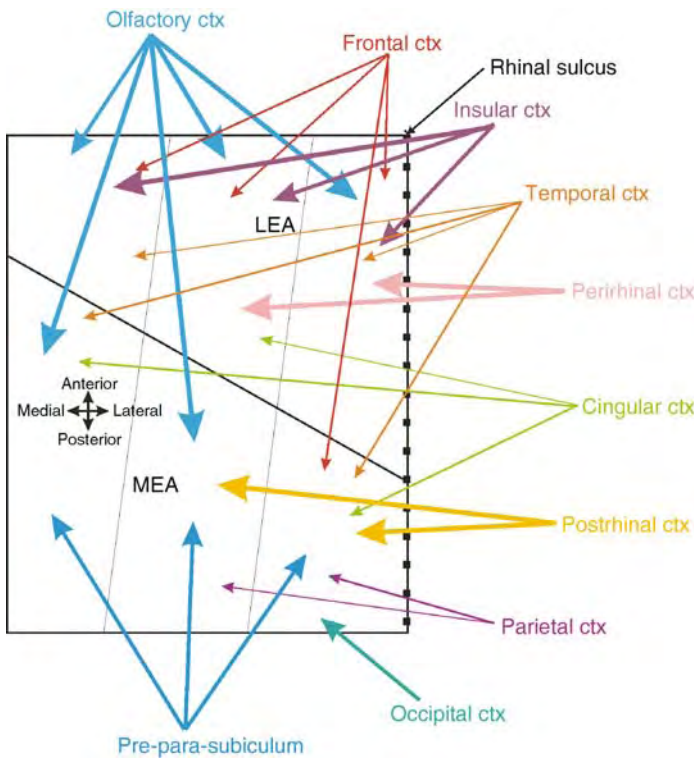
The entorhinal area receives a variety of cortical and subcortical inputs. The strongest cortical inputs arise from the adjacent cortical domains in the *parahippocampal region*. Additional inputs originate in other higher order association cortices such as prefrontal (►prefrontal cortex), *insular* and ►cingulate cortex. To a large extent, these cortical inputs terminate in the superficial layers II and III, providing inputs to neurons that give rise to the so-called ►perforant path, projecting to the *hippocampal formation* [1]. Neurons in layers II and III of the entorhinal area are the major source of cortical input to all of the different subfields within the hippocampal formation. Layer II neurons mainly project to the *dentate gyrus* and hippocampal field *CA3*, and cells in layer III distribute their axons largely to field *CA1* and the *subiculum*. Cortical output of the *hippocampal formation* is preferentially distributed to layer V of the entorhinal area, which in turn is the origin of projections to the *parahippocampal region* and a number of other cortical regions. In addition, projections for layers V and VI target a number of subcortical structures including the *striatum*, the *amygdala* and the ►thalamus. Overall, cortical inputs to superficial layers of the entorhinal area are reciprocated by projections from the deep entorhinal layers.

The overall connectivity of the entorhinal area shows a strong topography organized along a gradient that runs from its border with the rhinal sulcus towards the border between the entorhinal cortex and the adjoining hippocampal formation. Multimodal sensory cortex providing inputs from the outside world, such as those from the perirhinal and postrhinal cortex preferentially target a strip of entorhinal area which is adjacent to the rhinal sulcus. Parts of entorhinal area that are more distant from the rhinal sulcus receive information representing motivational or visceral dependent input, such as projections from ►infralimbic cortex and almost all nuclei of the *amygdala*. Outputs of the entorhinal area follow a comparable gradient [1]. This

overall anatomical organization is reflected in results of lesion studies indicating that animals with lesions of the strip close to the rhinal sulcus show spatial memory problems, while animals with lesions of the more distant strip do not. These latter animals show altered fear-related behavior [4].

The lateral and medial entorhinal cortices differ with respect to their major inputs. The lateral entorhinal area receives considerable input from the perirhinal cortex, *olfactory* and *insular* cortex and the *amygdala*. The medial entorhinal area receives major inputs from the postrhinal cortex, the presubiculum, visual association cortex and ►cingulate and *parietal cortices* and the ►anterior complex of the thalamus. These overall differences in cortical connectivity are reflected in recent findings that the medial entorhinal area, but not the lateral, is a major hub in the brain's circuitry for spatial navigation [5]. A key component of this network is the ►grid cell. When rats run around in two-dimensional environments, grid cells fire selectively at regularly spaced positions, such that for each cell, the multiple firing fields define a repeating triangular pattern that tiles the entire environment covered by the animal, almost like the cross points of graph paper, but with an equilateral triangle as the unit of the grid rather than a square. Grid cells are predominant in layer II of the entorhinal area, but exist also in layers III and V. Grid cells intermingle with *head-direction cells* as well as cells with conjunctive grid and head-direction properties. Directionally tuned cells are located primarily in layers III and V of the medial entohinal cortex, which are major target areas of presubicular projections most likely conveying signals from the head direction cells in the presubiculum. It is of interest that neighboring grid cells in different layers show a striking coherence in the spacing and orientation, suggesting the presence of column-like modules that span across layers of the entorhinal area [5].

In the lateral entorhinal area, neurons exhibit little spatial modulation, and their precise functional correlates



**Entorhinal Area (Cortex). Figure 2** Schematic representation of the major cortical inputs to the entorhinal area, emphasizing the differences between the lateral and medial entorhinal area, LEA and MEA respectively, and between the zones that are differently positioned in relation to the rhinal sulcus. Clear differences are apparent such that MEA receives preferentially visual-spatial information from occipital, parietal and postrhinal/parahippocampal cortices and pre-parasubiculum, whereas LEA receives stronger inputs from olfactory, insular (taste) and perirhinal cortices. Also note that most multimodal sensory association cortex reaches entorhinal cortex via adjacent zones of the parahippocampal region terminating preferentially in the entorhinal zone, directly adjacent to the rhinal sulcus, i.e. the most laterally positioned zone.

are not well understood [5]. Since it is likely that a comparable intrinsic and extrinsic column-like connectional architecture is present in lateral and medial entorhinal area what needs to be established is whether a non-spatial counterpart for the grid cell in the medial entorhinal area exists in the lateral entorhinal area. This non-spatial counterpart, most likely is to be found within the domain of memory for single items and the association between them in view of findings that many cells in the lateral entorhinal area respond to memory cues such as odors or visual stimuli [3] or that the lateral entorhinal area is specifically involved in olfactory based conspecific recognition [6].

The notion of two functionally different parts of the entorhinal area should be tempered since the lateral and medial portions of the entorhinal area are strongly interconnected, as are two of the major input structures, the perirhinal and parahippocampal (postrhinal) cortices. It is thus likely that at the level of the entorhinal area relations between the two input components will already occur. This is in line with the finding that in the entorhinal area cells respond to both object and place stimuli and that lesions do not result in impairments in, for example, object recognition but do impair the relational organization of memory [7].

Entorhinal functions are most likely modulated by a number of subcortical inputs, including those from the *thalamus*, mainly originating from the midline structures, and *cholinergic* inputs. High levels of *acetylcholine* sets the appropriate dynamics to facilitate the storage of stimuli, whereas removal of the cholinergic inputs to the entorhinal area dramatically interfere with the memory performance of the animal [8]. These subcortical inputs also play an essential role in occurrence of oscillatory activity that is an elementary component of normal entorhinal function [1,2] (Fig. 2).

### Clinical Relevance

Severe alteration of the entorhinal area is associated with many disorders of the human brain, including *Alzheimers disease*, ►Picks disease, *Huntingtons disease temporal lobe epilepsy* and *schizophrenia* [1]. In case of Alzheimer, the initial pathological changes reportedly occur in layer II of the entorhinal area; *temporal lobe epilepsy* is associated with marked degeneration in layer III, whereas in case of *Huntingtons disease* the most dramatic initial changes are seen in layer V with some additional but minor involvement of layers II and superficial III.

The widespread pathology throughout the cortex seen in later stages of Alzheimers disease stands in marked contrast to the much more focal initial damage in the entorhinal area and other adjacent structures of the medial temporal lobe. Volume reduction of the entorhinal area is now considered a relevant and reliable measure to identify individuals at risk for Alzheimers disease [1]. Entorhinal atrophy is associated with mild memory loss as seen in individuals with mild cognitive impairment and it precedes hippocampal volume reduction seen in mild Alzheimer patients [9]. A comparable sequence of entorhinal atrophy before hippocampal alterations have been reported in case of temporal lobe epilepsy [10].

# Entrain

### Definition

To synchronize an endogenous circadian rhythm to a rhythm in the environment.

►Circadian Rhythm
►Seasonality

## Entrainment

### Definition

The process by which a biological oscillator with a free-running period (Tau, τ) that is close to 24 h is adjusted to the exact 24-h period (T) of the environment. When entrained, the period of the biological rhythm equals the period of the entraining stimuli and the two oscillations exhibit a stable phase relationship. The entraining stimuli can also alter the waveform of the processes driven by the circadian system. The daily cycle of light and dark is the dominant cue responsible for entrainment, though other environmental and social cues can play a role. The entraining cue is referred to as a "zeitgeber" (translated from German "time giver"). In order to establish that a periodic environmental signal is a zeitgeber, it is necessary to demonstrate that the period of the biological rhythm equals the period of the zeitgeber and that there is a stable phase relationship between the two rhythms. For example, in the most common case for circadian rhythms, there should be a fixed time interval between the peak of the biological rhythm and the time of lights-on or lights-off when the organism is held in a light/dark cycle. Upon releasing the biological oscillator into constant conditions, the phase of the endogenous oscillator must be shown to be determined by the phase of the previous zeitgeber cycle. In order for a biological oscillator to provide a reliable estimation of time in the external world, the oscillator must be entrained to the environment. Thus, entrainment is critical for one of the key adaptive functions of circadian clocks.

## Entropy

### Definition

A quantity postulated by the second law of thermodynamics. For a continuous body, it is given by the integral over the body of the entropy density, assumed to be a function of state of the system (that is a quantity specified via a constitutive law).

►Mechanics

## ENU Mutagenesis

### Definition

Mutagenesis using N-ethyl-N-nitrosourea (ENU). This chemical is an ethylating agent that is cytotoxic to mouse spermatogonial stem cells. It is injected intraperitoneally into male mice reaching maturity (G0 mice, 6–8 weeks of age). These mice are then used in breeding programs; G1 mice can be used to screen for dominant mutations, whereas the identification of recessive mutants requires further backcrossing. Large scale phenotypic screens are then used to identify interesting mutants.

►Retinal Ganglion Cells

## EPI, Echo-Planar Imaging

### Definition

Echo-planar imaging is an ultra-fast method for acquiring MR images, which is typically used in functional MRI experiments to investigate functional organization of the human brain non-invasively. EPI permits an image acquisition time of 100 ms or less, which allows forMRscanning of the brain in 2–3 s with functional (BOLD) contrast.

►Magnetic Resonance Imaging

## Epidemic Encephalitis

### Definition

Infections of the brain caused by arthropod-borne viruses primarily from the families togaviridae,

flaviviridae, bunyaviridae, reoviridae and rhabdoviridae. The life cycles of these viruses are characterized by zoonoses, with birds and lower mammals serving as intermediate hosts; the virus is transmitted to humans by the bite of mosquitoes or ticks; clinical manifestations include fever, ►headache, alterations of mentation, focal neurologic deficits, and ►coma.

## Epilepsy

### Definition

A medical condition in an individual characterized by recurrent, unprovoked seizures. There are many different types and causes of epilepsy which are characterized and described by criteria established by the International League Against Epilepsy (http://www.ilae-epilepsy.org/).

►Anticonvulsants

## Epileptiform Pattern of EEG

Interictal discharge of brain activity in the EEG recording, which, based on its shape, may be divided into sharp waves, spikes, spike-and-slow-wave complexes, and multiple spike-and-slow-wave complexes. The epileptiform activity may be revealed in the majority of epileptic patients and, therefore, EEG is an important diagnostic tool for this disease.

►Electroencephalography

## Epimuscular Myofascial Force Transmission and Intermuscular Interaction

Peter A. Huijing
Research Instituut Faculteit Bewegingswetenschappen, Vrije Universiteit, Amsterdam, The Netherlands

### Definition

Myofascial Force Transmission between the Intramuscular Stroma and Neighboring Structures. In the accompanying essay of this Encyclopedia on ►intramuscular myofascial force transmission, we have argued that this stroma functions as an integrator for force within a muscle.

►Epimuscular myofascial force transmission occurs if force is transmitted from or onto this stroma by paths other than the muscle's own tendons. In any case, such transmission will lead to differences in force exerted at proximal and distal tendons of a muscle (or other forms of its origin and insertion).

Two types of such force transmission are distinguished:

1. Intermuscular myofascial force transmission [1,2]: Force is transmitted between the connective tissue stromata of adjacent muscles, which can be viewed as continuous.
2. ►Extramuscular myofascial force transmission [3,2]: Force is transmitted between the connective tissue stroma and non- muscular tissues of a compartment.

A muscle is shown with connections to a neighboring muscle and to non-muscular structures.

1. Assumed initial positions of the extra- and intermuscular connections.
2. After distal lengthening exclusively of the muscle of interest, a distribution of lengths of linking elements (both extra- and intermuscular) is present. Distal links increase in length because this variable is influenced not only by the length change of the muscle part to which they are attached, but also by the cumulated sum of length changes of the more proximal muscle part, which causes displacement of distal muscle parts.
3. After exclusively changing the position of the muscle of interest, without changing its length. Note that the direction of the linking elements (both extra- and intermuscular) is reversed, as the distribution of their lengths is reversed. This would also reverse the direction of force transmission.

### Characteristics

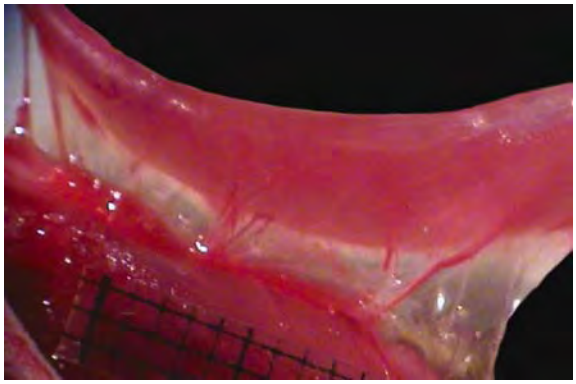
#### Quantitative Description

In animal experiments under conditions of full recruitment, for fully activated muscle the absolute value proximo-distal force difference (i.e. percentage of muscle force transmitted by epimuscular pathways) varied from 0 to 40% of optimal force. Even for submaximally activated muscle (lower firing frequencies), this difference may reach maximal values as high 30% of the optimal force exerted for a specific firing frequency. Such values are an indication of the potential importance of epimuscular myofascial effects.

The magnitude of a proximo-distal force difference has been shown to be a function of muscle length

(Fig. 1), but also the relative position of a muscle with respect to its surroundings [4,5]. This means that as a muscle is moved relative to the structures surrounding it, its physiological properties will change (e.g. sarcomere lengths, stiffness of the intramuscular stroma) even if the length of the muscle has not (Fig. 2). Note that, depending on muscular relative position, the sign of the difference may change from positive to negative.

For passive muscle, the level of such force transmission (expressed in N) is of course much lower, but very substantial normalized proximo-distal force differences are found (e.g. ref. [3]).



**Epimuscular Myofascial Force Transmission and Intermuscular Interaction. Figure 1** Typical example of the length dependence proximo-distal force differences in rat extensor digitorum longus muscle. EDL muscle-tendon complex length ($l_{m+t}$) was changed by pulling on the proximal tendon. Active forces (*black curves, use left vertical axis*) are plotted for maximally activated muscle. Note that proximal and distal forces are only equal at one length (crossover point). Grey curves indicate passive forces (*use right vertical axis*).

## Higher Level Structures

### *Relevant Connective Tissue Structures*

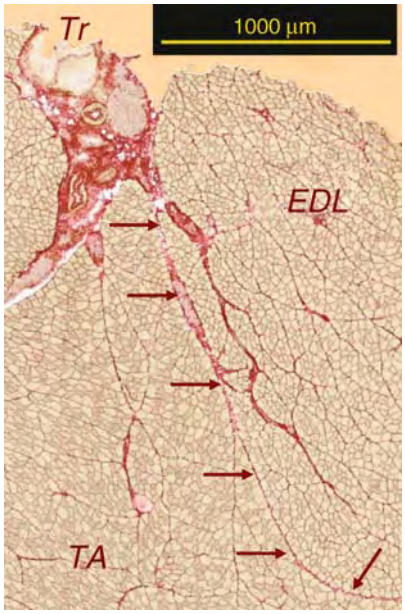
The type of honeycomb-like structure, described for all levels of the intramuscular stroma (c.f. the accompanying article on intramuscular myofascial force transmission of this Encyclopedia: Fig. 3), repeats itself at higher levels of organization and size:

1. Muscular compartments
   The walls of a compartment containing a synergistic muscle group consist of the following connective tissue:
   a. Sheets covering the bones (►periost).
   b. Sheets connecting bones (intermuscular membrane, e.g. between tibia and fibula).
   c. Sheets separating two muscle groups (►intermuscular septum). It should be noted that these structures are suspended from bones and from ligaments crossing joints.
2. The ►general fascia or whole body fascia
   This is the highest level of the connective tissue structure, extending all the way from the endomysium surrounding one muscle fiber to whole body cover.

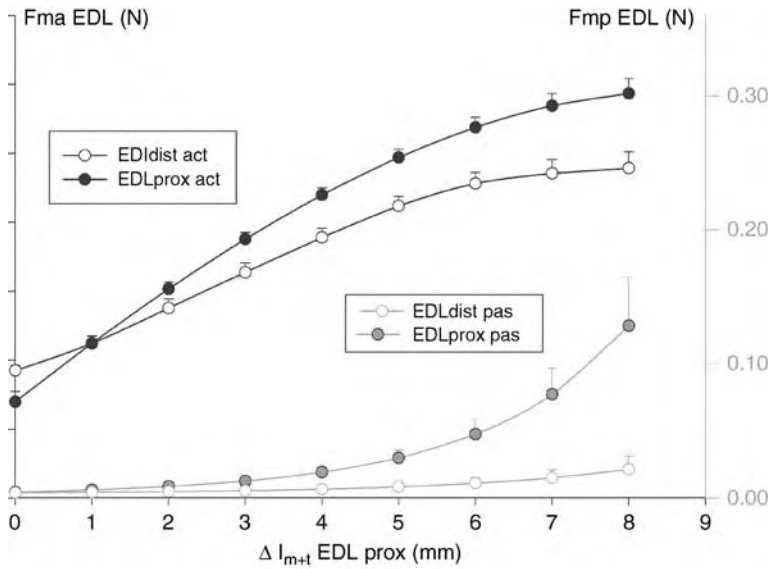
It should be noted that the compartment related structures described frequently form a major location of attachment of muscle fibers (e.g. ref. [6]). Therefore, these connective tissue structures act as an extension of the bony skeleton in this respect. It should also be noted that these structures form connections with or may even be continuous with the capsule and ligaments of the joints.

Within each compartment, besides muscles two additional potentially relevant structures are found [7]:

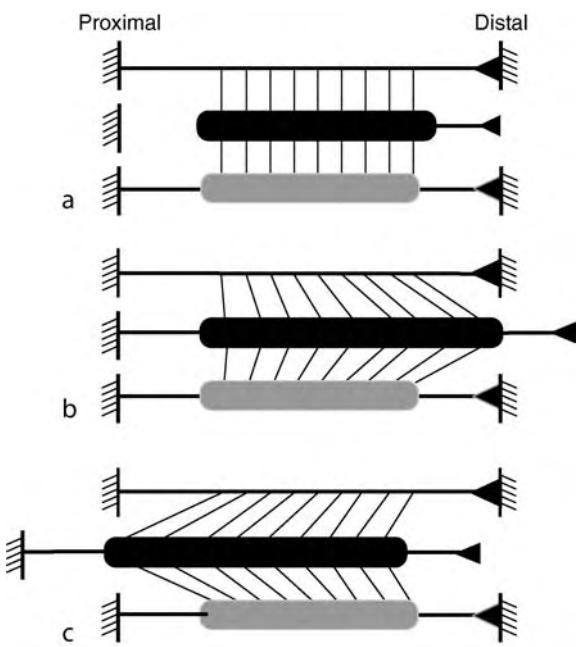
1. Extramuscularly, the nerves and blood vessels remain embedded in a sheet or column of connective tissue that is called the ►neurovascular tract (Fig. 3). This structure can also be considered mechanically as some form of continuation of the intramuscular stroma. The neurovascular tract is also attached to elements that form the compartment walls and pass from compartment to compartment via windows in the intermuscular septa or ►interosseal membrane (Fig. 4).
2. The intramuscular connective tissue stromata of neighboring muscles are connected (Fig. 4). Even though this type of connective tissue is usually



**Epimuscular Myofascial Force Transmission and Intermuscular Interaction. Figure 2** Schematic representation of effects of length change and relative position on the length of extra- and intermuscular connections.



**Epimuscular Myofascial Force Transmission and Intermuscular Interaction. Figure 3** Schematic representation of effects of length change and relative position on the length of extra- and intermuscular connections.



**Epimuscular Myofascial Force Transmission and Intermuscular Interaction. Figure 4** Schematic representation of effects of length change and relative position on the length of extra- and intermuscular connections.

labeled as "loose connective tissue," we know very little of its stiffness under physiological loading. If it is stiff enough, it could potentially transmit force between adjacent muscles.

## Lower Level Components

The intramuscular stroma has been described in the accompanying essay on intramuscular myofascial force transmission of this Encyclopedia.

## Higher Level Processes

### *Compartment Walls, Joint Stabilization and Extramuscular Myofascial Force Transmission*

As force is transmitted myofascially to extramuscular tissues including compartment walls, it will make these structures more stiff and stable. This should facilitate their function as origin or insertion for muscle fibers, which are not attached to bone.

As elements of these extramuscular structures are mechanically continuous with the joint capsule and joint ligaments (i.e. reinforcements of the capsule by concentrated collagen fibers within it), forces will be exerted at the joints. If coordinated appropriately, such forces may stabilize the joints during movement and static conditions.

### *Extramuscular Myofascial Force Transmission will Affect Neural Receptors within Compartment Walls*

Force transmitted myofascially, or myotendinously for that matter, onto elements forming walls of ▶muscle compartments from muscular and joint origins, will affect any mechanoreceptor or free ending of afferent nerves present there by straining or other specific stimuli. Even though not a great deal of effort has been devoted to describing receptors and nerve endings in such structures, it is clear that Pacianian corpuscles and free nerve endings do occur at substantial numbers at

specific sites within the periosts, interosseal membranes and intermuscular septa [8,9,6]. In addition, Wal [6] argued that the specific locations of such receptors is related to global organization of connective tissue and muscles within the compartment.

### *Intermuscular Interaction through Myofascial Force Transmission*

#### *Between Synergistic Muscles*

In animal experiments, it has been shown that if one muscle is lengthened and neighboring muscle is kept at constant length, the force in the lengthened muscle increases at the tendon location of lengthening. In contrast, at the same side in neighboring muscle the force falls despite their constant length [4]. The two muscles interact mechanically through myofascial force transmission: Force originating from the active sarcomeres of one muscle is exerted at the tendon of a neighboring (synergistic) muscle. This can be understood as follows: Any active sarcomere will shorten until opposing forces prevent further shortening. The myotendinous junction may exert, via sarcomeres arranged in series, such an opposing force. Also, the inter- and extramuscular connective tissues transmit such forces from neighboring muscles or from non-muscular structures. As one of neighboring muscles is stretched, the length of linking structures will increase, as will their stiffness. Therefore, the length of some sarcomeres within the muscle kept at constant muscle-tendon complex length will decrease and force will fall. Some force that was exerted at the tendon of the constant length muscle will be transmitted to neighboring (lengthened) muscle and exerted at that tendon. We cannot presently distinguish the contributions of extramuscular and intermuscular paths for synergistic muscles within one compartment, but the arguments to be presented in the paragraph on antagonistic muscles do suggest that extramuscular pathways will prove to be important.

It should be realized that some relative movement of a muscle with respect to extramuscular tissues and even between synergistic muscles is a likely occurrence in vivo. Any differences between moment arms of adjacent muscles (which are not uncommon) will cause such relative movement of muscles. Even more important may be the effect of some muscles of a compartment being polyarticular. For example, if the ankle joint angle is kept constant and the knee joint angle is changed, changes of relative position and mechanical interaction will occur between several muscles of the lower limb, even if the muscles had identical moment arms at the ankle joint.

#### *Between Antagonistic Muscles*

By definition, antagonistic muscles (causing opposite movements at a given joint) are separated by an intermuscular septum or interosseal membrane, and therefore do not have intermuscular connections between the connective tissue stromata.

Despite that fact, the same phenomenon of force decrease in a muscle, kept at constant muscle-tendon complex length, was found experimentally [4] as its antagonistic muscle was lengthened. In such a case, the mechanism is as described above, but an interaction between muscles mediated by myofascial transmission of force between muscles must be extramuscular in nature. The collagen fiber reinforcement of the neurovascular tract forms the most likely path for such transmission.

By definition, changes of muscular relative position for antagonistic muscles are the only possibility during movement: Shortening of the agonistic muscle (group) and lengthening of the antagonistic muscle (group), or vice versa, always accompanies joint movement. Changes of relative position of these muscles will be extreme, which makes substantial interaction by extramuscular myofascial force transmission very likely.

## Lower Level Processes

Intramuscular myofascial force transmission has been described in the accompanying essay of this Encyclopedia.

## Process Regulation

Considering the rather high number of potential paths for force transmission, the process that actually determines division of force across paths needs to be considered in some more detail. The rules for such division may be derived from biomechanics. For serial connections, the force borne must be equal. If force is exerted at a node of two serial paths of equal stiffness arranged in parallel, the force will be divided equally across the two. If the stiffness of two or more serial paths in parallel differs, more force will be borne by the stiffest path.

Therefore, the division of force across serial paths in parallel is governed by the relative stiffness of the available paths.

## Function

In a classical view, muscles are independent generators of active and passive force. Epimuscular myofascial force transmission constitutes additional mechanisms of force transmission from muscle: Force is transmitted between the intramuscular stroma at the muscle level and the tissues of a higher level of organization. The latter acts as an integrator of forces exerted by different muscles and non-muscular structures. It has been concluded that the tissues of a compartment play an important role in modifying muscular properties. A major consequence is that muscles should no longer be considered as independent units, but may show

considerable interaction, even with antagonistic muscles. Such interaction is highly dependent on the relative position of a muscle with respect to surrounding muscular and non-muscular structures.

Even though not all force of a muscle may be exerted at the tendons, force transmitted via extramuscular structures should not be considered as lost for the creation of movement. It may actually be essential for the ability to move, as well as the use of specific muscles (whose myofibers do not attach to tendon or bone) to contribute efficiently to moments exerted at the joints.

Furthermore, the connective tissue stroma, acting as an integrator of force of the body, also provides locations for neural receptors or nerve endings, which provide global information to the central nervous system about the condition of the limbs, rather than information about very localized processes within muscles or extramuscular tissues.

From the above, visions emerge of motor control as a manipulation of the ratio of stiffness of different elements of the integrating connective tissue structures of a whole limb or body part, allowing the exertion of specific combinations of moments and forces at joints that would allow efficient specific desired movement. It is obvious that such hypotheses still require experimental verification.

### Pathology

Effects of epimuscular myofascial force transmission have also been shown for human muscle with experiments on patients undergoing tendon transfer surgery because of spasticity. For example, after distal tenotomy of flexor carpi ulnaris muscle (FCU), extension of the wrist still caused substantial lengthening of FCU, even though the muscle did not cross the wrist joint anymore [10]. After partial dissection of FCU from its surroundings, in similar groups of patients, length-force characteristics were not compatible with the idea that the limitation of movement was caused by elements of the muscle itself, but suggest the hypothesis that inter- and extramuscular connections may actually cause the limitations in range of joint movement in this group of patients with spastic muscles.

## Epimysium

### Definition

The fascia that covers the full longitudinal perimeter of each muscle, but not its ends. It forms the wall of a "tunnel" in which the muscle operates. The epimysium is continuous with the endomysial-perimysial stroma of the muscle. It covers the aponeuroses of the muscle but is not attached to it, except at locations of muscle fiber attachment.

## Epiphenomenalism

Sven Walter
Institute of Cognitive Science, University of Osnabrueck, Osnabrueck, Germany

### Synonyms

Epiphenomenalism; Automaton-theory; Automatism

### Definition

Epiphenomenalism holds that mental states or ►events are caused by physical states or events in the brain but do not themselves cause anything. Although mental events appear to bring about behavioral effects, thereby influencing the causal course of the physical world, psychobehavioral sequences are merely reflections of the real causal processes at the underlying physical level.

### Description of the Theory

An epiphenomenon is a *secondary symptom*, a mere "afterglow" of real phenomena. As a label for a philosophical theory of the mind, "epiphenomenalism" was coined by William James (see [1]) in his criticism of the position of the British biologist, physiologist and philosopher Thomas Henry Huxley. Huxley's *Presidential Address to the British Association for the Advancement of Science* from 1874 contains the most famous articulation of epiphenomenalism. Mental events are said to be caused by physical events in the brain but themselves incapable of causing anything. Just as the steam-whistle is an effect of the engine's operations without any causal influence on it, mental events are causally inefficacious effects of the workings of neurophysiological mechanisms [2, p 240]. According to epiphenomenalism, for instance, a pain does not cause wincing; rather, the pain is caused by the same neurophysiological event that also causes the wincing. To assume that the regular successions of mental and physical events – volitions giving rise to appropriate behavior, momentary pangs resulting in one's wincing etc. – reflect genuinely causal processes is to commit the fallacy of *post hoc*, *propter hoc*. Awareness of those regular successions cannot reveal their causal nature. Awareness of the psychological or psychophysical sequences that make up one's everyday life is no more awareness of causal processes (or of the fact that these sequences reflect causal processes) than awareness of the sequence of shadows a moving car casts.

Epiphenomenalism is typically considered to be a wildly counterintuitive theory of last resort to which one is driven only because all alternatives are even less satisfying. The trust in ►*mental causation* – the mental's ability to causally influence the physical – seems to be too much part and parcel of the common sense conception of human beings as freely deliberating agents who are the causal origins of their actions and do what they do because they have the beliefs and desires they do for epiphenomenalism to be true. Why, then, did reputable scientists ever take epiphenomenalism seriously?

Epiphenomenalism evolved in a particular intellectual climate in the late Nineteenth century in which classical ►dualism with respect to the mind and the body was as well received scientific wisdom as a decidedly scientific attitude with regard to the body. Epiphenomenalism resulted from the attempt to reconcile the scientific confidence that the world consists of purely physical causes governed by purely physical laws with the sustained trust that human minds are ultimately non-physical. Epiphenomenalists are would-be ►materialists who hold back from endorsing ►materialism because they do not want to give up the autonomy and uniqueness of the human mind.

To thinkers of the late Nineteenth century it seemed to be an obvious fact of experience that human beings are subjects of mental events which apparently resist incorporation into a materialist ►ontology. Thoughts, sensations, desires etc. just seem to be too dissimilar from physical events for them to be "nothing but" physical events. At the same time, however, a scientific naturalism evolved, motivated by the successes of a mechanistic physics and characterized by a desire to

identify the underlying causal structure of observed phenomena in terms of matter and motion alone. In particular, early neurophysiological research found no mental influence upon the brain (or the body), and eventually, with the demise of ►vitalism regarding the forces governing animate life, the ►*causal closure of the physical* was nearly universally accepted. The conception of the physical as a causally closed system in which physical forces are the only forces, combined with the naturalistic view that human beings are a part of the physical world and governed by its laws left no room for causally efficacious mental events. There simply seemed to be "no gaps" [3, p 278] in the causal mechanisms to be filled by mental events outside the physical domain.

The solution was epiphenomenalism. Human beings are part of the causally closed physical world and as such exhaustively governed by physical laws. Hence, no non-physical causes must be invoked to explain physical, e.g. behavioral, effects. But since human beings are also subjects of non-physical minds, the only conclusion was that these minds are incapable of exerting any causal influence. As Alex Hyslop has put it, "[t]he case for Epiphenomenalism is the case for Materialism, together with the case against Materialism. The case for Materialism is the Argument from Science, from a triumphant, or at least steadily triumphing Science. The case against Materialism is that there are features of our conscious experience that are not accounted for by Science" [4, p 61].

The dichotomy between mental and physical events characteristic of traditional epiphenomenalism is nowadays no longer uncontroversial. More and more philosophers endorse a psychophysical *event identity theory* according to which every concrete mental event is (identical to) a concrete physical event. On such a view, the question of traditional epiphenomenalism no longer arises because, say, pain is identical to (rather than caused by) the neurophysiological event which causes wincings and thus a cause of wincings, too. However, the threat of epiphenomenalism re-arose in a different guise. Although modern philosophy of mind tends to turn more and more of the mental over to the physical side, some dualistic residue – for example in form of *mental properties* – remains, and this mental residue threatens to become epiphenomenal. According to a forceful intuition, for instance, events cause what they cause in virtue of certain of their properties and not in virtue of others. Suppose a soprano sings the word "shatter" at a high pitch and amplitude, causing a window to shatter. The particular cause *c* of the shattering – the soprano's singing – has the property *being a singing of a high C* and the property *being a singing of the word "shatter."* Yet, *c*'s being a singing of the word "shatter," in contrast to its being a singing of a high *C*, seems to be *causally irrelevant* for its causing the shattering – no matter whether the soprano sung "shatter," the window would have shattered as long as she sung a high *C*, but had she sung "shatter" with a lower pitch and amplitude, it would not have shattered.

If events cause their effects in virtue of their properties, it makes sense to ask whether mental events cause their effects in virtue of their mental, in virtue of their physical or in virtue of both kinds of properties. Some fear that mental properties (unless identical to physical properties) are as causally irrelevant for physical effects as the singing's being a singing of the word "shatter" is for the shattering. If mental events cause their effects only in virtue of their physical properties, their being the kinds of mental events they are is causally irrelevant and mental *properties* are, in a sense, epiphenomena. Philosophers thus distinguish between *event-* and *property-epiphenomenalism* (see [3,5,6]). According to the former, physical events are causes, but mental events cannot cause anything; according to the latter, events are causes in virtue of physical properties, but no event is a cause in virtue of mental properties. If event-epiphenomenalism is wrong, mental events can be causally efficacious; but if they are causally efficacious solely in virtue of their physical properties, property-epiphenomenalism is correct, and some consider this to be no less disconcerting than Huxley's original epiphenomenalism.

Epiphenomenalism undoubtedly appears to be at odds with the manifest image of the world; it appears incompatible with those features of human beings without which they would apparently not be the kind of being they are and without which they would apparently not be able to occupy the place in the world they occupy. Unless further specified, however, this is little more than the claim that epiphenomenalism is *counterintuitive*, and that is something its defenders should not find in the least problematic since a host of widely accepted and feted theories – like Einstein's theory of special relativity or quantum mechanics – are riotously counterintuitive. Those who urge that epiphenomenalism is deeply problematic must say what precisely it is about epiphenomenalism that makes it incompatible with the manifest image of man.

It has been urged that epiphenomenalism undermines the ascription of *moral* or *legal responsibility*, Donald Davidson's distinction between the reason(s) for which an action was performed and causally irrelevant *post hoc* rationalizations, the standard response to the ►*other minds problem*, and the application of epistemic norms like justification, warrant, or reasonableness to processes of belief formation. Apart from that, causal theories of *knowledge*, *meaning*, *reference* or *memory* have been said to entail that causally otiose mental phenomena cannot be subject of knowledge, reference, memory or meaningful statements. Finally, causally otiose mental phenomena could apparently not have endowed human

beings with an evolutionary advantage and thus not have evolved, and if one assumes that to be real is to have some causal powers, epiphenomenalism even appears to collapse into outright eliminativism. Yet, it is at least disputable whether any of these objections suffices to refute epiphenomenalism once and for all (for an overview over objections against epiphenomenalism and possible replies on behalf of it see [3,4,7]).

## Episodic Behavior

### Definition

A behavior which repeats without inherent regularity in the interval of time between adjacent events.

## Episodic Event

### Definition

A personally experienced event, generally occurring at a particular time and place and consisting of a coordinated sequence of scenes that are experienced as a unit. The term is rarely used, because it is synonymous with "episode" in the field of memory research.

►Episodic Memory

### Definition

Episodic memory is a type of long-term memory for personally experienced events occurring at particular times and in particular places.

### Characteristics

#### Episodic Memory as one of the Memory Systems

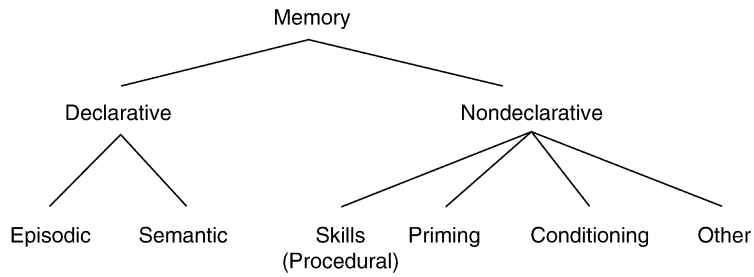
Memory refers to (i) the information retained in the mind/brain, (ii) the cognitive function of encoding, retention (storage), and retrieval of information about personal experiences, semantic knowledge, or skills, and (iii) the hypothesized system in the mind/brain that sustains memory function. On the basis of previous psychological, neuropsychological, and neurobiological evidence, researchers have classified memory into several types of memory systems (Fig. 1).

In this formulation, memory is divided into declarative memory and nondeclarative memory, episodic memory being a type of declarative memory [1–3]. Episodic memory is what most people mean when they use the term "memory."

#### Encoding of Episodic Memory

The encoding of episodic memory involves cognitive processes that lead to the formation of a unique ►episodic representation (a memory trace or an engram for an episode) for a personally experienced event such that it can subsequently support the conscious recollection of one's past experiences. An experiencer, as an observer and also often as an actor, encodes all the information that is attended or consciously perceived if the brain regions responsible for the formation of the episodic representation are intact. Experiencers who have damage to the brain regions responsible for the formation of episodic representations are unable to make a complete episodic representation, although they can consciously experience the event while it is occurring.

The episodic representation for a personally experienced event as a whole is probably composed of several types of memory traces. Every ►episodic event we experience is considered to consist of a focal element and a setting [4]. The focal element refers to the salient occurrence within the setting (content information),



**Episodic Memory. Figure 1** A taxonomy of memory. The major distinction is between declarative memory and nondeclarative memory [1,2]. Declarative memory refers to memory that can be accessed consciously and is further classified into episodic memory and semantic memory [3]. Episodic memory is memory of personally experienced events that occurred in a certain place at a particular time; semantic memory is memory of organized knowledge about words, objects, facts, and concepts. In contrast, nondeclarative memory refers to memory that cannot be accessed consciously and demonstrated through performance. It includes skill (procedural) learning, priming, conditioning, etc.

whereas the setting refers to the time and place in which the individual experienced the event (contextual information).

The properties of the memory traces for focal elements are determined by the aspects to which the individual paid attention during a particular event. The focal elements comprise interactions between various animate (including the experiencer) and inanimate objects. These are typically experienced through several sensory modalities as a continuous series of gradually changing scenes, each of which is made up of several objects, including the experiencer and objects located in spatial positions relative to each other and to the experiencer, over a limited period of time. In addition, most of this sensory information about the objects and the interactions is likely to be automatically interpreted in terms of the individual's available semantic knowledge. Consequently, the memory traces for focal elements include very different kinds of information, such as visual information, auditory information, spatial information about the objects and the self, and automatically interpreted meanings of the objects and interactions. The experiencer may or may not be aware of the setting (a global spatio-temporal context) in which the events are experienced. However, the memory trace for the setting is required to make a unique episodic representation as a whole [5,6]. The successful retrieval of memory for contextual information is thought to be one of the most crucial characteristics of episodic memory retrieval, as discussed later. Furthermore, the individual's internal physical state (e.g. hunger or satiety) or mental state (e.g. mood or emotional aspects evoked by the event) is likely to be encoded [7]. In addition to the various memory traces described above, it is thought that there are various types of binding codes that are stored in the brain and enable the episodic representation to allow the experience to be brought back to mind.

## Retrieval of Episodic Memory

Retrieval of episodic memory refers to the cognitive processes that enable an individual to recover previously experienced events. This differs from the retrieval of semantic memory in that it requires access to information about focal elements that includes the individual perspective of the rememberer and where and when the event occurred.

Episodic retrieval is thought to involve an interaction between a retrieval cue (self-generated or provided by the environment) and a previously stored memory trace, leading to the reconstruction of certain aspects of the event represented by the memory trace. This interaction process is called ►ecphory [4], and enables the memory traces for the focal elements (perceptual and semantic representations) and for the setting (spatial and temporal context) to be bound together with the individual's awareness of personal experiences, probably aided by binding codes.

There are two principal types of episodic retrieval: recall and recognition. In the recognition situation, a copy of the target item is generally presented as a retrieval cue, and the rememberer only needs to decide whether he/she has experienced a particular item before. In contrast, in the recall situation, either no specific cues or cues other than copy cues are provided, and the rememberer has to describe or reconstruct some aspect of the original item-event. Recognition is usually better than recall because it involves greater overlap between encoding and retrieval situations (see "►encoding specificity," described below). This means that remembering reflects the interaction between the encoding and retrieval processes.

## Interactions between Encoding and Retrieval

Whether or not episodic retrieval is successful is influenced by the cues available and the processes involved during the retrieval situation. The importance of retrieval cues is

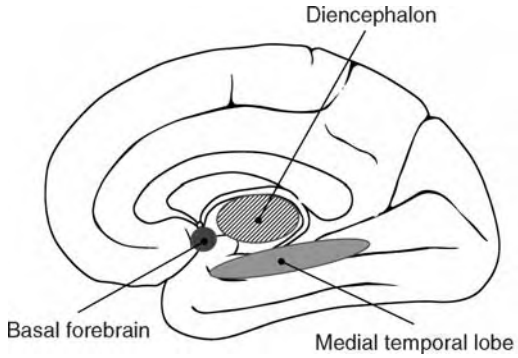
emphasized in the principle of encoding specificity [4]. The encoding specificity principle states that the effectiveness of a retrieval cue is dependent on the extent to which information in the cue was incorporated into the memory trace of the target event at the time of its original encoding. The importance of processes engaged during the retrieval situation is emphasized in the concept of ►transfer-appropriate processing [8]. The concept of transfer-appropriate processing postulates that memory performance is a function of the degree to which the cognitive operations engaged at encoding are recapitulated at retrieval.

Specific examples of encoding specificity or transfer-appropriate processing are context-dependent memory and state-dependent memory [7]. As retrieval depends on the effectiveness of the cues available and the processes involved during the retrieval situation, it also depends on the congruity of the context or the individual's state between the encoding and retrieval situations. Context-dependent memory is based on the concept that people retrieve information better when they are asked to recall it in the same environmental setting (context) as that in which it was acquired. State-dependent memory is based on the concept that people retrieve information better when they are in the same physical or mental state as they were when they acquired it. (When a mental state is related to an individual's mood, this is called mood-dependent memory.) The context in which an event was encoded and the individual's internal state at the time of encoding appears to be two of the most powerful retrieval cues.

## Neural Substrates

In humans, disorders of episodic memory that cannot be explained by a state of delirium or dementia are often called amnesic syndrome. Patients with amnesic syndrome usually manifest both anterograde amnesia (the inability to encode or retrieve information acquired after the onset of brain damage) and retrograde amnesia (the inability to retrieve information acquired prior to the onset of brain damage). Unlike patients with dementia, those with amnesic syndrome usually have normal intelligence. This syndrome can result from focal damage to the medial temporal lobe (MTL), the medial diencephalon, or the ►basal forebrain [9] (Fig. 2).

The MTL includes the ►hippocampal complex and the amygdala; the former is considered to be an essential region for episodic memory and the latter for emotion and emotional modulation in episodic memory. The medial diencephalon includes various midline thalamic nuclei, the mamillothalamic tract, and the internal medullary lamina. The basal forebrain includes the septal area, the diagonal band nuclei, and the substantia innominata. The literature concerning patients with disorders in episodic memory indicates that the MTL and the medial diencephalon may have roles in both the encoding and retrieval of episodic memory, and that the basal forebrain has a particular role in its retrieval. Recent functional nueroimaging studies also indicate that the MTL has a role in both the encoding and retrieval of episodic memory, and a few that the basal forebrain has a role in the retrieval of episodic memory. However, the precise roles of these three regions, or of subregions within each region for episodic encoding, storage, and retrieval, is not still well understood.



**Episodic Memory. Figure 2** Brain areas causing amnesic syndrome (an isolated disorder of episodic memory).

As for episodic representations for some focal elements of events, it is thought that these are retained as complex patterns of neural activity that are primarily located in sites within those parts of the posterior neocortex that represent both meaningfully interpreted and relatively uninterpreted sensory information. Recent functional neuroimaging studies support this view. It is likely that which of the specific posterior association cortices is involved in episodic representations relies on the nature of the focal elements and on the experiencer's mental processing of the focal elements. Within this context, some researchers have argued that the encoding of episodic memory entails the formation of a code embodied in the MTL that binds neurons in the posterior neocortex (heteromodal and unimodal association cortices) that represent the information attended to.

It is widely accepted that damage to the prefrontal cortex does not lead to memory disorders involving deficits in the storage and retention of information about focal elements of episodes. Such disorders are associated with damage to the MTL, medial diencephalon, and basal forebrain. Memory disorder following frontal lobe lesions seems to involve the strategic aspects of memory that are necessary for devising strategies for encoding, guiding search at retrieval, correctly placing retrieved memory in the setting in which the event was experienced, and other aspects of episodic memory [10]. Although the prefrontal cortex plays specific roles during the encoding and retrieval of episodic memory, future studies are required to

provide evidence of the roles of the various distinct areas within the prefrontal cortex.

## Definition

Epistemology (from Greek "episteme": knowledge): The study of the nature and the problems of knowledge, especially, the conditions, sources, and limits of knowledge.

## Characteristics

### The Concept of Knowledge

According to a view already discussed by Plato, knowledge is *justified true belief*. That is, a person x *knows* that p if and only if (i) x believes that p, (ii) p is true, and (iii) x can justify her belief. Imagine that x believes she passed her exam, and that she really passed it, and was told so in a letter from the university. In this case we can say that x *knows* she passed her exam. Many philosophers still think that the "standard view" states the essence of the idea of knowledge. There are, however, counterexamples in which x seems to lack knowledge though she has a justified true belief. In those cases, x's ►justification is not appropriately related to the facts that make p true. Epistemologists still try to solve this problem [1].

### Kinds of Knowledge

The standard view refers to cases in which a subject is (or can become) conscious of the proposition believed and the justifying reason(s). This is called *explicit* (declarative) knowledge. However, people do not only know *that* things are such and such, they also know *how to do* things, for example, how to drive a car, play the violin, or speak in accordance with the rules of grammar without being able to state them. Such *tacit* (implicit, procedural) knowledge plays an important role in all kinds of action. Until recently, epistemology was merely concerned with explicit knowledge.

With respect to the sources of knowledge, epistemology distinguishes knowledge that is justified independently of perceptual experience (*a priori*) from knowledge based on such experience (*a posteriori*). The standard case of the former is knowledge of logical and mathematical truths; as a standard case of the latter serves knowledge of physical objects and facts.

### The Concept of Truth

In the standard definition of knowledge, "truth" has usually been understood as *correspondence to* ►reality. That is, a proposition p is true if and only if what p says is actually the case; otherwise it is

false. "Correspondence" must not be confused with "likeness" or "similarity." There is of course no similarity between words (or concepts) and real objects. "Correspondence" simply means "agreement" between a proposition and some real situation. The correspondence ►theory of truth is the view of common sense and is still held by many philosophers. It has however not been generally accepted. Critics insist that the idea of correspondence has remained unclear. Some of them propose to relate truth and justification (in order to bridge the gap between them). In one version, truth is understood as *coherence* with some ideal background of beliefs. A further major account of truth is James's ►pragmatic *theory* according to which true assumptions are, by definition, those that would be confirmed by experience in the long run. Closely related to the pragmatist view is a contemporary theory (due to Dummett and Putnam) that connects truth with ►verification: To say that p is true is to say that p would be *verified* by an appropriate procedure. All those alternatives to the correspondence theory of truth are faced with serious problems.

## Justification, Foundationalism, and Coherentism

According to *foundationalism* (Aristotle, Descartes, C. I. Lewis), we have to distinguish between *mediate* (indirect, inferential) and *immediate* (direct, non-inferential) justification. Many beliefs are mediately justified by some appropriate relation to other justified beliefs, e.g., by being (►deductively or ►inductively) inferred from, or based on them. The central thesis of foundationalism is that all mediately justified beliefs owe their justification ultimately to foundational ones, that is, to immediately justified beliefs [2]. There are, however, different views about which kinds of beliefs should count as foundational. Some construe immediate justification as *self-justification*. Others hold that foundational beliefs have their justification from non-belief mental states, especially, sensation, perception, and memory. For example, a ►scientific hypothesis may be regarded as mediately justified by some particular statements, which may in turn be immediately justified as based on *observation*. Foundationalists argue that, only by adopting some beliefs as immediately justified, one can escape an infinite regress or epistemic circularity. The main problem of foundationalism is how to avoid dogmatism.

*Coherentism* (Neurath, Sellars), the traditional competitor to foundationalism, holds that a belief is justified if it coheres with a background system of beliefs [3]. For example, a scientific hypothesis may be deemed justified because of its coherence with the laws of the leading ►paradigm (Kuhn), or with the total of statements expressing experimental results. A major problem of coherentism is to make plausible why mere coherence should be the ultimate source of justification, and should be regarded as a reason for accepting any belief as true.

## The Challenge of Skepticism

For more than 2000 years skeptics have hold that knowledge does not and cannot exist. In order to justify a belief A, we have to accept another belief B. But now we have to justify B, which requires still another premise C. Thus we end up in a regress. The retreat to perception does not help either. There is illusion and hallucination. We can be sure that things appear such and such, but this does not guarantee that they really are how they appear. Consequently, no belief (about real things) can be better justified than any alternative belief, so that we should refrain from any claim to knowledge (Pyrrhon).

## Rationalism and Empiricism

Two attempts to meet the skeptical challenge were classical rationalism (Descartes, Leibniz, Spinoza) und British empiricism (Bacon, Locke, Berkeley, Hume), both movements being a reaction against traditional scholastic philosophy. According to rationalism, the only source of (certain) knowledge is (pure) reason [4]. Ideally our knowledge ought to be organized into a deductive system, in which all truths are derived from a small number of axioms whose truth is guaranteed by their self-evidence. In contrast, empiricists claimed that, prior to experience, the human mind is a "tabula rasa." All knowledge about the world comes from sensory and perceptual experience, or has to be inferred from perceptual knowledge.

Both movements were very influential and obtained important insights. However, as attempts to overcome skepticism and demonstrate that certain knowledge is possible, they did not reach their ultimate goal. Rationalists could not prove that the self-evidence of axioms is a guarantee of their truth. Descartes was not successful in demonstrating a priori that there is an external world that is truly represented by our senses if we only make careful use of them. The empiricists, on the other hand, could not escape the conclusion that we can only know the contents of our own minds. In addition, Hume [5] denied the rationality of inductive reasoning, which had been considered the fundamental method of inference in the natural sciences. Classical empiricism ended up in a skeptical view about the aim to obtain knowledge of the real world and the laws of nature.

## Kant's Epistemology

Kant tried to solve the problems left by rationalism and empiricism [6]. He started with the conviction that there are propositions about the world whose truth we know a priori. His central question was: How is such knowledge possible? His answer instituted his "Copernican Revolution" in epistemology: We have such knowledge because the objects depend on our cognitive faculties, especially our forms of intuition (space, time) and our categories (e.g. substance, cause). Kant explained the

features of appearances by reference to traits of the observer rather than traits of the objects themselves. For example, we know Euclid's laws a priori because these laws characterize the structure of our form of intuition that determines how objects in space appear to us. Nevertheless Kant deemed it necessary to assume a world of *things-in-themselves*. Since there are appearances, that is, objects of representation, there must be something that appears to us. But it follows from his premises that we cannot have knowledge of the things-in-themselves. We can only know the world as it appears to us.

However, Kant could not prove that his theory is the only possible explanation of how our mind works. Many objections have been raised against his view. For example, some critics have questioned his table of categories. A major objection refers to the rise of alternative geometries, which casts doubt on Kant's assumption that Euclidean geometry is necessarily true. Empiricists have insisted that we cannot have a priori knowledge about the world. Nevertheless Kant's theory had an enormous influence on epistemology.

## Realism and Anti-Realism

The main alternative to skepticism and Kant's philosophy is *realism* according to which we can and do have knowledge of the real, mind-independent world. Realism is the view of common sense, and has been maintained by many philosophers and scientists since the Presocratics. It was Kant who convinced many philosophers that realism is untenable. Few accept his system in all detail, but many adopt his central idea that the objects of knowledge are somehow *constituted* or *constructed* by us. However, while Kant considered the forms and categories that determine the appearances as fixed, contemporary anti-realists see them as variable ("anti-realism" is here understood as any view that rejects realism). They claim that the world we can know is a world that depends on some context: on language, social rules, forms of life, paradigms (Kuhn), or values (Putnam). Some also say that the world is a "social construction." "Radical ►constructivism" claims the world is a construction of the brain.

## Fallibilism, Justification, and Rationality

It turned out to be far more difficult to meet the challenge of skepticism than traditional epistemology had assumed. As a consequence, philosophers had to lower the claims associated with knowledge, justification, and truth. Most of them gave up the idea that the human mind can guarantee the truth of a belief beyond any doubt. Attempts to justify beliefs can never achieve certainty. All beliefs are fallible. *Fallibilism* was explicitly stated by pragmatists (Peirce, James). Popper made it a central principle of his *critical rationalism* [7]. Fallibilism was controversially discussed until some decades ago but seems now generally accepted in philosophy as well as in science. Consequently, the traditional aim of certain knowledge had to be replaced by the aim of *conjectural knowledge*.

It is obvious that fallibilism is compatible with coherentism. But it is compatible with foundationalism as well? Contemporary foundationalists, unlike Descartes, separate claims to foundational justification from claims to certainty. To say that some beliefs are foundational is to say that they are justified though they can be criticized and eventually rejected. For example, observational statements may, other things being equal, be regarded as better justified than hypotheses, so that the latter can be tested with the help of the former. But observational statements, too, may be rejected if further observations prove them as erroneous.

Some philosophers believe that fallibilism is a reason to give up realism. But others think that both principles can be combined. Critical rationalism, e.g., holds that we can have *conjectural knowledge* of the *real world* [8]. Such knowledge is represented by observational statements, or by hypotheses (theories) that have withstood serious criticism.

## Naturalized Epistemology

On the traditional view, epistemology has to solve its problems independently of, and prior to, scientific research. (Descartes therefore called it "first philosophy.") Quine argued that this project was a failure. Instead, he proposed to make epistemology a branch of natural science that investigates with empirical means how people develop beliefs on the basis of sensory stimulation [9].

But how can natural science answer normative questions concerning justification and foundation? *Externalists* recommend giving up the justification condition in the traditional definition of knowledge and replacing it by a *causal* condition [1]. The idea is, roughly, that, in order to qualify as knowledge, a belief in p should be caused by the fact that makes p true, or that this belief should be brought about by a *reliable* process (not necessarily accessible to the believer's mind), that is, a process which produces true rather than false beliefs. For *internalists*, on the other hand, knowledge requires reasons that should be consciously accessible to the believer. Furthermore, internalists ask the critical question how it could be *justified* to qualify a process as "reliable," or truth-conducive.

An important kind of naturalist approach is *evolutionary epistemology* [10], which claims that our cognitive mechanisms are the result of natural selection (Konrad Lorenz) and that the development of human knowledge is governed by a process analogous to biological natural selection (Campbell, Popper).

Naturalist approaches to philosophical problems are controversially discussed. Most contemporary philosophers do not think that the traditional normative

questions can be reduced to questions of natural science. This, however, does not preclude interdisciplinary approaches to the problems of knowledge. More and more have become convinced that epistemology, even if not reducible to empirical science, needs and has to take into account its results, especially, those of cognitive science and neuroscience.

Equilibrium point hypothesis; Set point control; The λ model; Threshold (position) control

### Definition

Originated from empirical studies in humans [1], the ►equilibrium point (EP) hypothesis describes basic rules underlying the control of ►motor actions. Such actions occur when the ►steady state of the system comprised of the organism and the environment is

disturbed, either by the environment (e.g., due to changes in external forces acting on the body) and/or by the organism itself following neural control influences on neuromuscular elements. These elements tend to minimize the imposed activity by establishing the same or another steady state, depending on internal and external constraints. The EP is a combination of variables (including the equilibrium positions of body segments *and* muscle forces or torques at these positions) characterizing the motor output of the system in a steady state. The neural ►control variables that shift the EP and thus elicit intentional actions are identified in the λ model [2], which also offers solutions to several classical problems in motor control.

## Description of the Theory

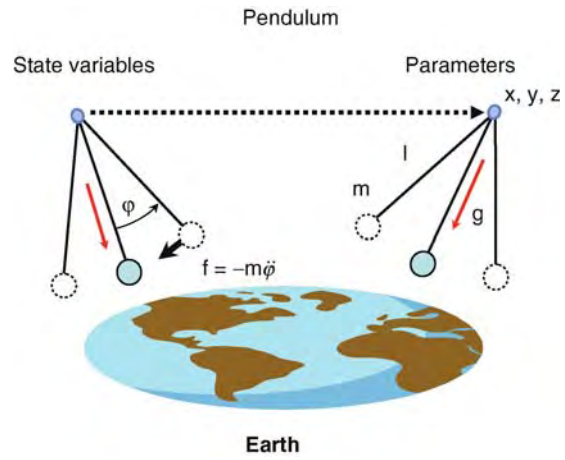
### The Essence of Control Processes

The behavior of the system obeys natural laws. These laws express the relationships between certain variables called ►state variables (SVs; e.g., forces and kinematic variables related by laws of motion). Constrained by natural laws, SVs, *including the EP*, cannot be specified directly by the nervous system.

Natural laws include ►parameters, some of which are not conditioned by these laws but define essential characteristics of the system's behavior under the action of the laws. Fig. 1 shows the difference between SVs and parameters in a simple physical system – a pendulum (a mass on a rope). This example illustrates a general physical rule: Although in an ►equilibrium (steady) ►state all forces are balanced, it is not forces (or other SVs) but the system's parameters that predetermine where, in the torque-position space, this state can be achieved [2]. Therefore, in order to bring the system from one EP to another, neural control levels *must change parameters that are independent of SVs*. Our motor skills are thus based on the ability of the brain to organize, exercise, memorize, select in a task-specific way, and modify during learning ►*parametric control* of the system.

Control variables (CVs) are those parameters that can be altered by the nervous system in a task-specific way. In some tasks, CVs can be changed in relation to SVs but in other tasks, they can be changed independently of SVs or be kept constant. Such freedom of manipulation distinguishes CVs from SVs. By changing CVs, the nervous system may elicit and modulate motor actions, *thus taking advantage of natural laws without any knowledge of these laws.*

By specifying CVs, control levels reduce the range of possible EPs to a set called the invariant characteristic of the neuromuscular system. A specific EP from this still ►redundant set emerges in the process of interaction of the organism with the environment. Fig. 2 illustrates this point and summarizes known properties of EP shifts for reaching movements.

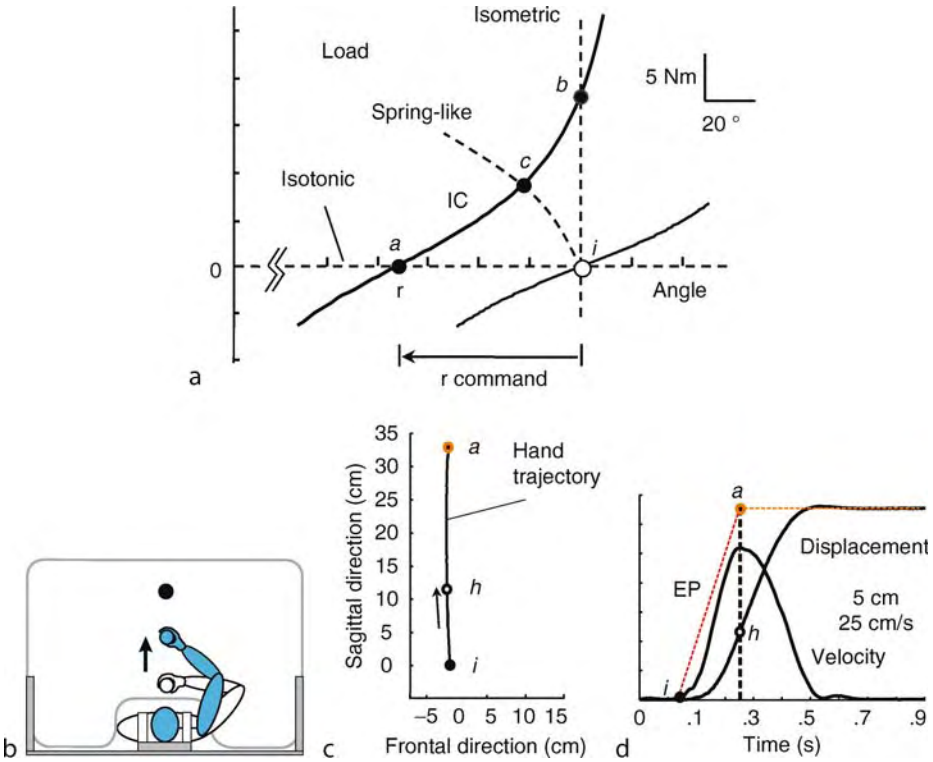


**Equilibrium Point Control. Figure 1** State variables (SVs), parameters, and parametric control. Related by the law of mechanics, f = – mφ̈, the force (f) acting on the mass of the pendulum and kinematic variables (position, φ, and its time derivatives) are SVs. The coordinates of the suspension point (*x*, *y*, *z*), the length (l) of the pendulum, the mass (m) and the local direction of gravity (*red arrows*) are parameters, i.e., quantities that can be specified independently of SVs, for example by a person who made the pendulum. The system's behavior can be controlled without direct specification of forces or other SVs, by changing parameters, for example, the coordinates of the suspension point, thus transferring the oscillations to a new location in space (*dashed arrow*). Frequency of oscillations can be controlled by changing parameter l.

A central notion of the λ model is that all CVs represent various forms of one, empirically well-established phenomenon – ►threshold control.

### Threshold Control and a Solution to the ►Posture-Movement Problem

A given posture of the body or its segments is usually stabilized such that deviations from it are met with forces tending to restore that posture. In order to produce an intentional change in position, the system must readdress these stabilizing mechanisms to a new posture. Otherwise, the new posture would be seen as a deviation from the initial posture and the system would generate forces to resist it [2,5]. Studies in humans have shown that such readdressing is achieved by shifting the threshold position of body segments, i.e., the position at which all skeletal muscles spanning these segments are silent. Deviations from the threshold position result in the generation of muscle activity and resistive forces tending to restore it (Fig. 3) [2,5]. When the threshold position is shifted, the initial position of body segments appears as a deviation from the newly specified threshold position, and posture-stabilizing mechanisms provide forces driving the system to the new threshold



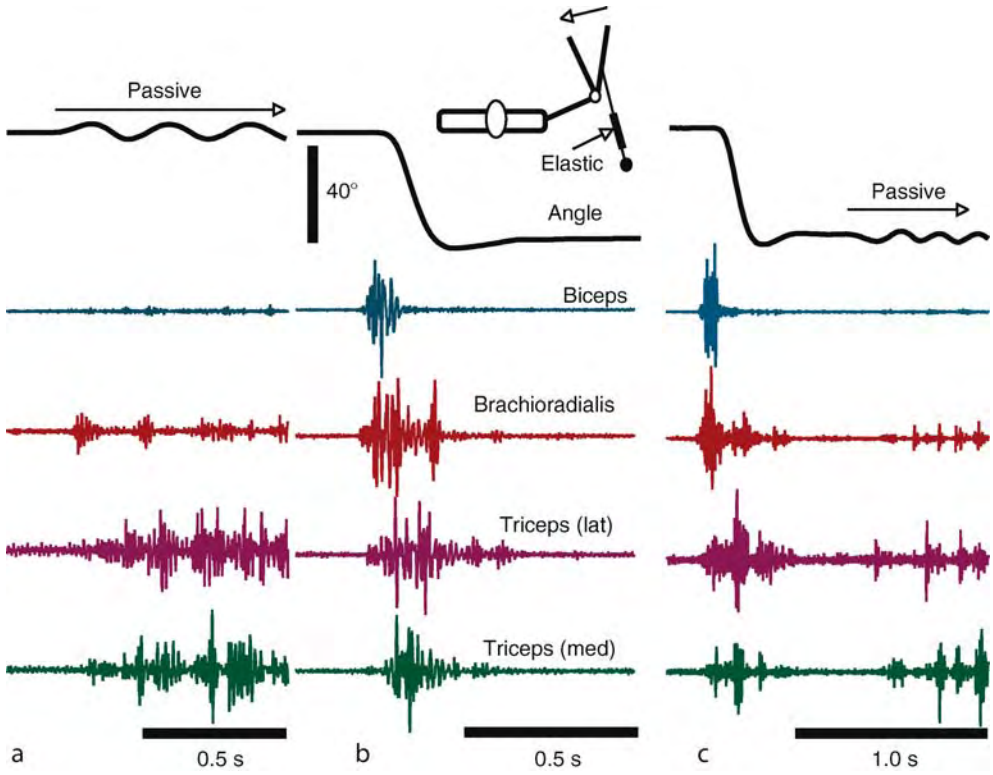
**Equilibrium Point Control. Figure 2** Relationship between control variables, equilibrium points and motor actions. Point *i* (*upper panel*) is the initial equilibrium point (EP) of a single joint in the absence of external forces. By changing a control variable, r (*arrow*), the nervous system replaces one set of possible EPs with another set of EPs comprising a curve called the invariant characteristic (IC; thick curve that passes through point *a*). The redundancy problem (a choice of one EP from this set) is solved through the interaction of the joint with the environment: Depending on the characteristic of external forces (*dashed lines*), different EPs are established (*a*, *b*, or *c*) resulting in different actions – a movement to a new position, isometric torque generation, or a transition of the joint to a new combination of position and torque, respectively. *Lower left panel* shows an experimental set in which subjects moved a handle along the surface of a table. In randomly selected trials, the movement was blocked at the initial position by activating an electromagnet embedded in the table, thus transforming the movement into isometric force production. It was found (*lower middle panel*) that the equilibrium position reaches its final destination (*a*) when the hand (*h*) has covered only about 1/3 of the total movement distance, about the time when the hand velocity is maximal (*lower right panel*). Thus, although the equilibrium and actual hand trajectories may be similar [3], they are not isochronal. Due to the distance between the actual and the equilibrium positions, agonist muscles generate substantial accelerating torques required for fast movement. The results imply that, to correct movement errors, the system may initiate new EP shifts while the motor response to the previous EP shifts continues. Rapid sequences of EP shifts can also be generated without waiting for the end of each motor response, an option that might be essential in piano playing, typing and speech. Adapted from Ghafouri and Feldman [4].

position. In such a way, intentional motor actions are harmonized with natural laws: the system not only eliminates resistance to movement from the previous posture, but actually *takes advantage of posture-stabilizing mechanisms to drive the body to a new posture*, as has been shown by simulations of different movements, including locomotion [2].

If the desired motor goal is not reached by the initial shifts, control levels may produce additional shifts in the threshold position in the same or repeated movements until the goal is reached. The correct pattern of shifts in thresholds can be stored in memory and recalled to reproduce the motor action in similar conditions [2]. In this way, threshold control underlies intentional posture and movement regulation as well as motor learning.

## Physiological Origin of Threshold Control

For a single muscle or a motoneuron in the intact organism, the threshold position is identical to the threshold muscle length, a parameter that can be changed by descending input [10,11]. Note that control-descending signals are electrical in nature. The λ model explains how they are converted into a position-dimensional



**Equilibrium Point Control. Figure 3** Threshold position resetting in rapid elbow flexion movement [7]. Note that the activity of elbow muscles (four lower traces in B) at the initial elbow position was practically zero (background noise level) and, after transient EMG bursts, returned to zero at the final position. Muscles were activated in response to passive oscillations of the arm at the initial (A) and final (C) positions, implying that motoneurons of these muscles were initially just in a sub-threshold state and that the threshold state was readdressed to the final position when the movement was made. To exclude the influence of external forces and small passive forces of inactive flexor muscles on the movement from the initial position of about 140°, the arm was placed on a horizontal manipulandum and an elastic connector (sketch in B) was used to compensate for the passive muscle forces. The compensation was unnecessary for the final position (about 90°) since it is known that at this position the net torque of passive elbow muscles is zero.

quantity – the threshold muscle length. Figure 4 shows that the conversion is accomplished at the level of the motoneuronal membrane, in the presence of electrical threshold and proprioceptive feedback. Note also that the threshold length can be changed by independent control input, even if the electrical threshold of the motoneuron remains constant. It follows that *threshold control does not exist in proprioceptively* ►*deafferented subjects*. As a result, deafferentation causes substantial motor deficits.

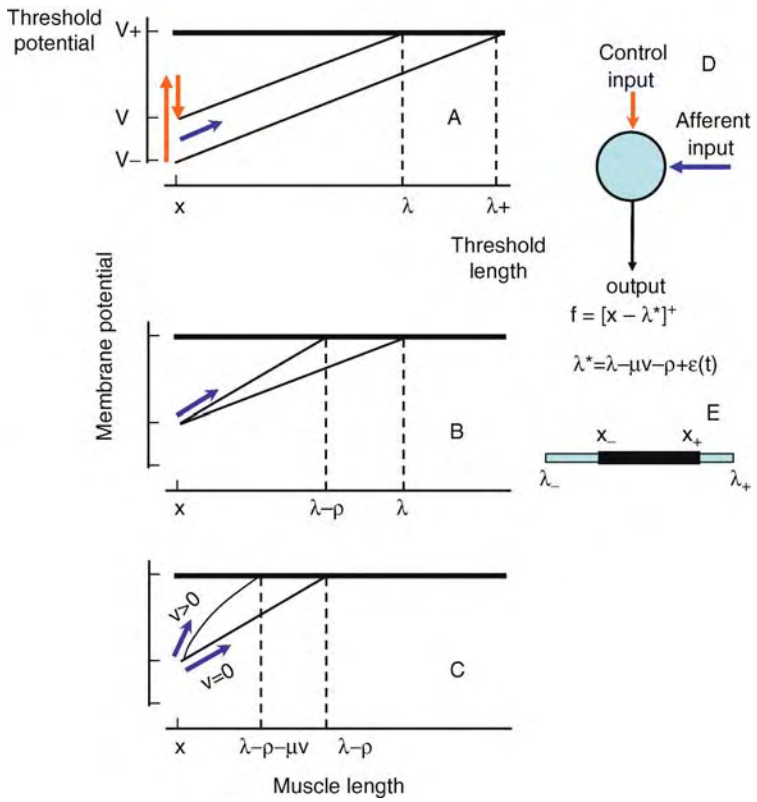
Control levels must be able to elicit activation or, conversely, relaxation of the muscle at any length within the biomechanical range [$x_{-}$, $x_{+}$]. To meet these requirements, the threshold must be able to be regulated in a range [$\lambda_{-}$, $\lambda_{+}$] that exceeds the biomechanical range (Fig. 4). In some subjects with hemiparesis and cerebral palsy, the range of threshold regulation is reduced, resulting in weakness, spasticity, and inter-joint discoordination [8].

Central shifts in the activation threshold length are associated with sub-threshold changes in the membrane potentials of motoneuron (Fig. 4). Thus, control levels may influence essential characteristics of motor actions in advance, i.e., before these actions are actually initiated and accomplished. This implies that threshold control is ►feedforward in nature.

The threshold length is not entirely specified by control levels: It consists of several components and only one of them, λ, can be changed independently of other components by different descending systems via mono-, poly-, pre- or post-synaptic influences on α-motoneurons or, indirectly, via γ-motoneurons or interneurons of proprioceptive loops (Fig. 4).

## Threshold Control of Muscle Co-Activation, Damping, and Intermuscular Interaction

Not only the control of posture but also *other control processes must use threshold control to avoid a conflict*



**Equilibrium Point Control. Figure 4** Physiological basis of threshold control. (a) Due to proprioceptive feedback, the motoneuronal membrane potential increases (lower diagonal line) when the muscle is stretched quasi-statically from an initial length, x. At some length, $\lambda_+$, (threshold length), the motoneuron begins to generate spikes at a frequency increasing with further muscle stretch. When independent control inputs are added at the same initial length (*red arrows*; up for depolarization and down for hyper-polarization), the threshold position is shifted to λ. Motoneurons thus equalize the dimensionality of their input electrical signals with that of a physical variable (muscle length) transmitted by afferent signals. Thereby the effect of independent, control inputs to motoneurons is measurable in terms of shifts in the threshold length. Motoneurons of single muscles are recruited sequentially, according to their individual threshold length. (b) Independent control influences can be transmitted by interneurons that also receive inputs from afferents of muscle spanning the same or other joints and terminate on the motoneuron (reflex intermuscular interaction). This interaction is responsible for an additional shift, ρ, in the threshold length. (c) Activity of muscle spindle afferents mediating proprioceptive feedback is velocity-dependent such that when the muscle is stretched at a non-zero velocity ($v > 0$), the motoneuron is recruited at a shorter length (to a first approximation, by μv) compared to the static threshold length. Factor μ is controlled by γ-dynamic motoneurons, influencing damping of the system. (d) Summary diagram with formulas describing the output (f) of motoneurons. Note that the threshold length, λ*, plays the role of a referent with which the actual length is compared, so that motoneuron is activated or not depending on the result of this comparison ($[u]^+ = u$ if $u > 0$ and 0 otherwise). Motoneurons thus recognize when the referent muscle length matches the physical muscle length and act accordingly. With respective referent and physical variables, this cognitive scheme may be valid for many other neurons. (e) The range of regulation, $[\lambda_-, \lambda_+]$ of the central component, λ, of the threshold should exceed the biomechanical range $[x_-, x_+]$ of muscle length, x, in order to meet the need to activate or relax muscles at any position within the biomechanical range.

*with natural laws*. In particular, this is the case for ►damping control. The muscle activation threshold is velocity-dependent (Fig. 4). The coefficient of this dependency (μ) is regulated by γ-dynamic motoneurons. Considered a CV in the λ model (command μ), the coefficient efficiently, although indirectly, influences damping, which is also enhanced with muscle activation and ►co-activation.

Independent control influences may be transmitted to motoneurons via interneurons that also receive proprioceptive afferent inputs from muscles spanning the same or other joints (reflex intermuscular interaction;

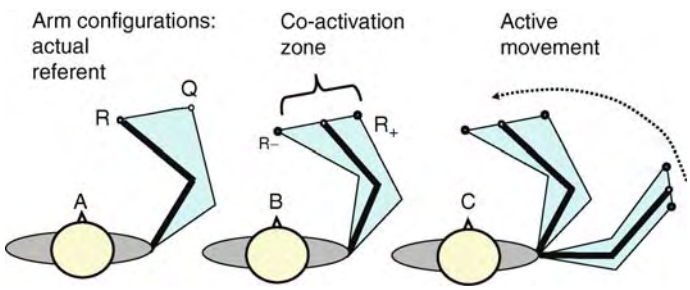
Nichols [9]). These interneurons not only transmit changes in the independent component, λ, but are also responsible for a component, ρ, representing the contribution of intermuscular interaction to the total threshold, λ*, of a given muscle (Fig. 4).

Co-activation of muscles can be produced to enhance resistance to deviations from the initial position. Threshold control allows the system to surround this position with a spatial zone in which muscles are co-activated, and to shift this zone to a new location when movement to a new posture is made (Fig. 5). In this way, the posture-stabilizing mechanisms amplified by muscle co-activation will not resist the deviation from the initial position and, instead, will assist in bringing the body or its segments to the new position.

## Action-Producing Frames of Reference

Not only motoneurons (Fig. 4), but also many other neurons may integrate sensory-dependent and independent signals. Due to threshold properties, neurons, like motoneurons, equalize the dimensionality of the independent, control input with that of variables delivered by sensory input and characterizing the physical world. Transformed in this way, the control input influences the threshold value that the sensory input should exceed in order to influence other neurons and muscles. Here is where the notion of the action-producing ►frames of reference (►FR) emerges: The threshold can be considered as the origin of the FR in which the neuron functions. By shifting the origin, control levels delineate the area in the FR in which sensory input may influence groups of neurons and/or effectors, such as muscles. Due to these actions, the FRs are called *action-producing* or *physical*, unlike formal, mathematical FRs for which shifting the origin modifies the description of the behavior of a system but not the behavior itself [2]. In particular, the threshold muscle length, λ*, can be considered as the origin of a spatial FR, {λ*, x}, in which motoneurons of the muscle may be silent or recruited depending on the difference between the actual (x) and threshold muscle lengths. FRs can be different for different neurons depending on the combination of sensory inputs that neurons receive and the actions (motor or cognitive) that they produce. Fig. 5 and Table 1 give examples of physical FRs for different actions, including reaching and locomotion.

In addition to threshold positions defining the origins of spatial FRs, other parameters (CVs) can specify the metrics of FRs that define how strongly neurons and/or muscles are activated depending on the distance of each point in the FR from the origin. CVs may also define the orientation of one FR in another FR. FRs can be numerous, but one can assume that there are certain relationships between them, so that the whole set of FRs is analogous to a tree with the trunk representing hierarchically ordered *major* FRs, whereas branches of the tree represent FRs embedded within major FRs. Like FRs for muscles and motoneurons, other FRs are defined by the existing anatomical, neurophysiological, biochemical and biomechanical relations between elements of the neuromuscular system. Therefore, physical FRs appear to be tools always available for action production. Control levels may choose a FR that is most appropriate for the motor task (*leading* FR; Fig. 6) and



**Equilibrium Point Control. Figure 5** ►Referent configuration of the arm, spatial organization of co-activation of opposing muscle groups, and the cooperation of the two types of threshold control in the production of active arm movement. In the absence of co-activation of opposing muscle groups, the referent (R) configuration represent a threshold configuration at which all muscles of the arm are silent but generate activity (symbolized by blue in the *left panel*) and forces resisting deviations of the arm from it. By changing the thresholds of the two groups of muscles in opposite directions (*middle panel*) control levels create a range of referent configuration [$R_-$, $R_+$] surrounding the R configuration with a zone in which these groups are co-active. The absolute changes in the threshold may not be identical as long as they do not influence the net (zero) torque at position R. Active movement (*right panel*, *dashed arrow*) is produced by changing the R configuration that simultaneously relocates the co-activation zone. If necessary, the extent of the zone can also be changed. In this way, threshold control eliminates resistance to the deviation from the initial arm position and instead amplifies the forces driving the arm to a new position. Readdressed to a new arm position, muscle co-activation contributes to the speed of transition to this position while increasing damping of the system and thus suppressing terminal oscillations [2].

**Equilibrium Point Control. Table 1** Physical or action-producing frames of reference (examples)

| Type of FR | Possible afferent systems involved | Examples of actions for which the FR may be leading |
|---|---|---|
| Body in the environment {E*, F} | Vestibular, visual, somatosensory | Stabilization of vertical posture, single step, locomotion, jumps, somersaults |
| Hand in peripersonal space {H*, S} | Vestibular, visual, somatosensory | Reaching for objects or other manual actions in the environment |
| Hand in relation to the body {h*, s} | Somatosensory | Reaching for, touching, scratching body parts, and feeding |
| Body configurations {R*, Q} | Somatosensory | Actions with a primary focus on body expressions, such as dancing |
| Body configurations in the limits [$R_-$, $R_+$] defining co-activation (c) zone (Fig. 5) {R*, $Q_c$} | Somatosensory | Re-location of the co-activation zone in order to accelerate movement and stabilize new position |
| Muscle; activated when muscle length x exceeds threshold λ* of first recruited motoneuron {λ*, x} | Proprioception | Actions specifically focused on muscle contraction |
| Motoneuron; activated when the muscle length, x, exceeds the individual threshold, $\lambda_i$*, of this motoneuron | Proprioception | Control of single motor unit |
| Neuron; activated when variable w signaled by afferent inputs exceeds threshold u* {u*, w} | Neuron-specific | Cognitive processing |

The first symbol in the brackets is the origin of the FR, i.e., the threshold values for coordinate(s) shown as the second symbol in the same brackets. Asterisk (*) refers to the origins of FRs – dynamic values of the threshold modified, compared to its static value, be velocity of changes in the coordinate(s), as exemplified for the threshold muscle length in Fig. 4. Actions of neuromuscular elements associated with each FR result from shifts in its origin or/and changes in the coordinate(s) elicited, for example, by external forces.

switch comparatively rapidly to another FR when task requirements change, as has been shown by Ghafouri et al. [see 2]. New FRs may be formed during learning for tasks requiring integration of sensory stimuli not found in the available FRs.

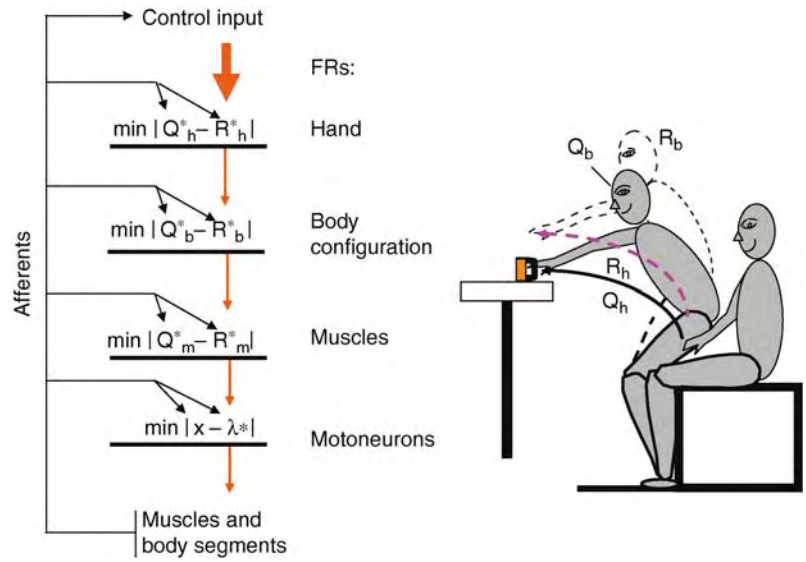
## Principle of Neurological Minimization

Biological systems are not unique in the tendency to reach an EP. This tendency is an expression of optimization described in physics and characteristic of many non-biological systems (e.g., a pendulum). In contrast, threshold control of EP suggests optimization of behavior that is unique for neurophysiological systems. As described above, the activity of neuromuscular elements results from the difference between the referent and the actual values of physical variables. The reaction of neuromuscular elements to the imposed activity seems to be guided by the ►*principle of neurological minimization*: each element separately and in cooperation with other elements tends to drive the system to a state in which the difference between the referent and actual values of variables, and thus the overall activity in the system, becomes minimal, in the limits defined by the task constraints (cf. Gelfand and Tsetlin [10]). For muscles, the minimization is accomplished by: contraction in response to the initial activation; a subsequent decrease in the activity of motoneurons resulting from muscle shortening; reciprocal inhibition of motoneurons of antagonist muscles. Threshold control temporary enhancing muscle co-activation and readdressing it to a new position (see above) accelerates the achievement of the state when the activity of motoneurons and co-activation are minimized (Fig. 3). Indeed, when a movement is blocked, the minimization process is interrupted. However, the occurrence of substantial activity of muscles opposing the perturbation is indicative of the tendency to minimization: when the movement is allowed to proceed, the activity rapidly decreases.

The minimization process is global: neurons of the leading FR that is primarily used to produce a motor action cannot reach an activity minimum, unless neurons of subordinate FRs and eventually muscles and motoneurons also minimized their activity, to a level consistent with the task constraints (Fig. 6).

## Guiding Movements Without Redundancy Problems

Threshold control and the principle of neurological minimization provide a solution to the ►redundancy problem [2], by finding a unique way of coordinating abundant degrees of freedom of the body each time a motor action is produced. For example, reaching movement is produced by shifting the referent coordinates ($R^*_h$) of the hand, by influencing neurons that receive afferent inputs related to actual coordinates ($Q_h$) of the hand in space. The movement will proceed



**Equilibrium Point Control. Figure 6** Principle of neurological minimization and its capacity to guide movements made by multiple muscles and degrees of freedom without redundancy problems (schematic diagrams). Some spinal and supraspinal neurons projecting to motoneurons mono- or poly-synaptically may integrate somatosensory, visual and vestibular inputs and proprioceptive signals from muscle, joints and skin receptors to receive information about coordinates ($Q_h$) of the hand in an external frame of reference. Like for motoneurons, independent, control influences on these neurons can be measured by the amount of shifts in the threshold (referent) position ($R^*_h$) of the hand. Such neurons may or may not be recruited depending on the difference between $Q_h$ and $R^*_h$. In the task of reaching for a cup (*right panel*), control levels shift $R^*_h$ to move the hand in the desired direction. This strategy is reminiscent of using the steering wheel to direct the car motion: the focus is on the direction of car motion, rather than on the means (turning the steering wheel) used to accomplish it. As long as the hand approaches the cup, it is not essential whether or not the actual ($Q_h$) and referent ($R_h$) trajectories of the hand coincide. In the *left panel*, reaching for a cup is controlled by shifting the origin $R^*_h$ of the leading FR in which the hand position ($Q_h$) is localized. The leading FR influences the origin ($R^*_b$) of the body configuration FR. The output of the latter FR, in turn, influences the origins ($R^*_m$) of FRs of individual muscles and eventually threshold lengths ($\lambda^*$) of motoneurons. The activity of neural elements in each FR tends to minimize (min) the discrepancy between the actual and referent coordinates, forcing the arm and other body segments to move until the hand reaches a final position at which a global minimum in the system, in the limits of intrinsic and external constraints, is reached. Because of the weights of the body segments, the absolute minimum (zero activity) at all subordinated levels will not be reached: the body will continue to move until at some equilibrium position, Q, the activity of appropriate muscles will produce torques balancing the weight torques. Vertical brackets denote a measure of the distance between the variables inside the brackets, determining how strongly neural elements in each FR are activated.

until the difference between these variables become minimal, which occurs when neurons of subordinate levels, including motoneurons, also minimize their activity (Fig. 6). In each trial, there will be no uncertainty in choosing one coordination pattern of a set of many other patterns that meet the task demands – each time, the minimizing process will produce a unique coordination pattern. If necessary, with additional corrective shifts in H*, the target will be reached. The coordination pattern can, indeed, naturally vary with task repetitions, history-dependent changes in the system (e.g., due to fatigue), task constraints (e.g., if the movement is obstructed), intentional involvements or restrictions of some degrees of freedom of the body. One prediction of this strategy – the invariance of the hand ▶trajectory regardless of the number of degrees of freedom involved in pointing movements – has been confirmed by Adamovich et al. [see 2]. Walking can be performed by choosing a FR in which a stable body posture in the environment is maintained (Table 1). By shifting the origin and thus translating this FR, control levels will provoke minimizing reactions of all systems, so that the initial body posture will be restored but at a new location in the environment, thus producing a step. Walking will emerge when the system continues shifts of the same FR.

Several minimization principles have been suggested for movement production (e.g., the smoothness criterion that well describes movement trajectories; Hogan and Flash [see 2]). Formulated in terms of SVs, these

principles lack an essential element, CVs. Therefore, their applicability and explanatory power are restricted, as would be the case if optimization of motor behavior implied by EP control were considered without identifying CVs. These principles may appear to be reduced forms of the more general principle of neurological minimization.

## Erythromelalgia

### Definition

Erythromelalgia (also called “burning feet syndrome”) is characterized by episodes of excruciating pain in the extremities and associated skin redness due to periodic blockage of blood vessels (usually in the lower extremities). Common triggers include mild heat, alcohol consumption, or exertion. Inherited erythromelalgia (IEM) (also known as erythermalgia) can start early in life with a mean age of onset of 3 years and typically affect feet and hands, whereas symptoms of adult-onset IEM typically start in mid-life. While early- and juvenile-onset IEM have been linked to mutations in Nav1.7, the genetic cause for adult-onset IEM remains to be identified (see Voltage-gated sodium channels: multiple roles in the pathophysiology of pain).

## Essential Tremor

Ali Samii
Department of Neurology, University of Washington, Seattle, WA, USA

### Synonyms

Benign essential tremor; Benign familial tremor

### Definition

A common movement disorder characterized by ►action tremor that is usually hereditary.

### Characteristics

#### Epidemiology and Clinical Features

In essential tremor, action tremor is the typical presentation, but other signs such as subtle gait disturbance and non-motor features including mild cognitive deficits and personality changes may accompany the tremor [1]. The extent to which subtle neurological findings other than action tremor are seen in essential tremor is debated, and the old view of essential tremor being a mono-symptomatic tremor syndrome is gradually changing into the view that it is a complex heterogeneous neurological disorder. Action tremor can be postural (hands in the outstretched position), intention (finger-nose-finger), or task-specific (seen while performing a specific activity, e.g., writing). Essential tremor is prevalent and is probably the second most common movement disorder behind restless legs syndrome. The worldwide prevalence of essential tremor ranges from 0.41 to 3.92% based on studies that provided diagnostic criteria for essential tremor, defined it as an action tremor, and used community-based rather than service-based designs [2]. Tremor is present during action and involves the hands, head, and voice to variable degrees. Although it is labeled as "benign essential tremor," it can be far from benign, quite disabling with devastating consequences for persons whose job and livelihood depend on manual dexterity. In addition, the social disability that it causes should not be underestimated. Persons with moderate to severe tremor avoid social events, such as eating in restaurants or social gatherings, because they cannot cut meat, eat soup, or drink out of a cup. The inability to sign checks or other legal documents poses another challenge. Essential tremor may also be a risk factor for alcoholism as alcohol is an effective means of dampening the tremor but with a short duration of action.

#### Pathophysiology and Genetics

The etiology of essential tremor is unknown and the pathophysiologic mechanism of essential tremor is not well understood. Mechanical, reflex oscillators, and central neuronal circuits (e.g., ►olivocerebellothalamic circuit) have all been implicated in essential tremor [3]. Essential tremor is different from the tremor in Parkinson disease in two important ways: essential tremor is more symmetric than the tremor of Parkinson disease, and Parkinson tremor is more prominent while the arm is resting on the lap, while essential tremor is more pronounced with action. Rigidity and bradykinesia are not seen with essential tremor. The frequency of essential tremor is higher (8 Hz) than that of Parkinson disease, but decreases with age. In severe cases, essential tremor may be present at rest, making it quite difficult to differentiate from the tremor seen in Parkinson disease. Unlike Parkinson disease, essential tremor does not significantly improve with anti-Parkinson medications. A family history is positive in most patients with essential tremor, with a ►dominant inheritance pattern and variable ►penetrance. Three gene loci (ETM1 on 3q13, ETM2 on 2p24.1 and a locus on 6p23) have been identified in patients and families with essential tremor [4]. In rare cases, action tremor combined with gait ataxia in older men can be due to fragile X-associated tremor/ataxia syndrome [5]. This syndrome occurs in male carriers of pre-mutation alleles of the fragile X mental retardation gene. However, screening patients with essential tremor for the presence this pre-mutation allele has extremely low yield and is not cost effective [6].

#### Treatment

Essential tremor is worsened by caffeine, stress, and associated medical disorders such as hyperthyroidism and it is relieved by alcohol. Essential tremor can be

exacerbated by certain medications such as lithium, valproate, cyclosporine, levothyroxine, and corticosteroids. Patients should minimize the use of caffeine and be warned about the risk of alcohol dependence in the setting of essential tremor. Medical therapy for essential tremor usually starts with either primidone or propranolol [7]. The usual therapeutic dose of propranolol is 60–320 mg daily. Potential adverse effects of propranolol include slow heart rate, low blood pressure, reduced exercise tolerance, impotence in men, fatigue, worsening of asthma or obstructive pulmonary disease, and depression. The usual therapeutic dose of primidone is 50–500 mg daily. Potential adverse effects of primidone include sedation, impaired cognition, fatigue, and unsteadiness of gait. Topiramate, gabapentin, and benzodiazepines may also relieve tremor. Topiramate may cause a sensation of diffuse body tingling (paresthesia), weight loss, cognitive impairment, unsteadiness of gait, and sedation. At higher doses, gabapentin and benzodiazepines can also cause sedation and unsteadiness of gait. Injections of botulinum toxin may help tremor in selected patients who have inadequate tremor control with drug therapy alone. Head and voice tremor may respond better to injections of botulinum toxin than hand tremor. When focal dystonia (such as writer's cramp or cervical dystonia) is superimposed on top of essential tremor, the first line therapy would be injection of botulinum toxin. In severe essential tremor intractable to medical therapy, unilateral ►thalamotomy (surgical destruction of a small part of the thalamus) improves contralateral tremor [8]. Bilateral thalamotomy is rarely performed as it can cause cognitive and gait disturbances [9]. Deep brain stimulation is a procedure whereby an electrode is placed into a deep target within the brain (e.g., thalamus) in order to electrically stimulate that target and "mimic" a lesion without destroying tissue. The mechanisms of action of deep brain stimulation are not well understood and most experts agree that the mechanism is much more complicated than simply mimicking a lesion effect through high frequency stimulation. Thalamic deep brain stimulation is considered safer than thalamotomy [10], presumably because there is no significant destruction of brain tissue, and the degree to which the target is "suppressed" is adjustable with variations in stimulation voltage, frequency, and pulse width. Serious surgical complications include symptomatic brain hemorrhage (usually less 3%) and death (usually less than 0.5%).

## Definition

### Evanescent Field

Light traveling from a substance of one ►refractive index toward another refractive index is ►refracted based on ►Snell's law

$$n_1 \sin(\theta_1) = n_2 \sin(\theta_2), \quad (1)$$

where $\theta_1$ and $\theta_2$ are the angles of the incident and refracted light defined, respectively, and $n_1$ and $n_2$ are the refractive indices of the media that the incident and refracted beam travel in. Note that $\theta_1$ and $\theta_2$ are defined relative to the perpendicular of the interface of the two media (see Fig. 1). Snell's law can be rearranged to solve the angle of the refracted light

$$\sin(\theta_2) = (n_1/n_2) \sin(\theta_1) \quad (2)$$

From (2), it is easy to see that for incident angles $> \sin^{-1}(n_2/n_1)$, $\sin(\theta_2) > 1$. At these angles, light is no longer refracted, but instead is totally reflected internally within the incident medium. $\sin^{-1}(n_2/n_1)$ is defined as the ►critical angle. Note that critical angles only exist (and total internal reflection can only occur) for situations where $n_1 > n_2$.

Although light does not propagate through the lower refractive index substance during total internal reflection, the light intensity does not drop to zero immediately at the interface of two substances. Instead, light in the lower refractive index substance drops off exponentially with distance from the interface. This thin layer of light is known as an "►evanescent field." This evanescent field is described by (3)

$$I = I_0 \exp(-z/d), \quad (3)$$

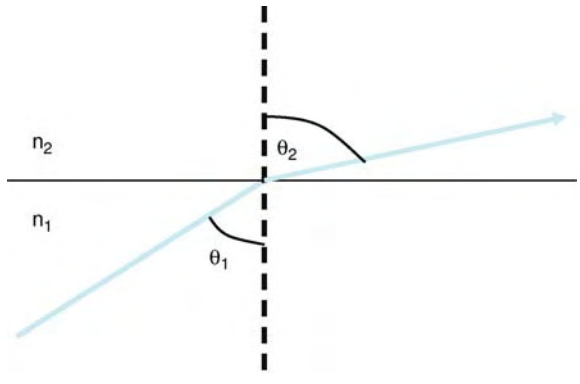
where I is the intensity of the light, $I_0$ is the intensity at the interface and z is the distance from the interface. The value d is a function of the angle of incidence and the relative refractive indices of the two media as detailed in (4)

$$d = \lambda/4\pi (n_1^2 \sin^2(\theta_1) - n_2^2)^{-0.5}, \quad (4)$$

where $\lambda$ is the wavelength of light. From (4), one can see that the evanescent field becomes shallower with larger excitation angles and with more disparate refractive indices for the two substances.

### Evanescent Field Fluorescence Microscopy

Evanescent field fluorescence microscopy takes advantage of the thin "evanescent field" of light created during



**Evanescent Field Fluorescence Microscopy. Figure 1**

total internal reflection, to preferentially excite fluorophores near the interface in the lower refractive index substrate. Typically, the evanescent field is set up such that the length constant of the evanescent field (d from (3) and (4)) is considerably shorter than the wavelength of light used, thus illuminating a much thinner section than is typical for other microscopy methods. This allows one to confine illumination to a smaller region than the focal plane of an objective lens, thus greatly reducing out-of-focus light. Evanescent field microscopy is typically performed using standard fluorescence microscopes modified for evanescent field illumination. The two most common methods for introducing excitation light for evanescent field microscopy are prism-type and objective-type evanescent field microscopy. These two methods are briefly discussed below. For more detailed descriptions of these techniques and other related methods, see Axelrod [1].

## Prism-Type Evanescent Field Microscopy

In order to generate an evanescent field, one needs to introduce light at an acute angle through a highly refractive substance. One way to achieve this is to introduce the light through a prism made of higher refractive material than your sample. For this method, light shown at an acute angle travels through the prism, a refractive index matched immersion fluid and coverslip to the interface between the sample and the coverslip, where it suffers total internal reflection. The evanescent field generated during total internal reflection is used to excite fluorophores in the sample, and the fluorescent light is collected using an objective lens and standard fluorescence microscope. Such a method can be employed using either an upright fluorescence microscope with excitation light introduced from below the sample, or with an inverted fluorescence microscope and light brought in from above. Using this method, the excitation light and the objective used for light collection are on opposite sides of the sample. Since most biological samples are studied in aqueous buffers, this technique requires either the use of water immersion objective lenses with lower ►numerical aperture and poorer light collection than oil immersion lenses or placing the sample between two layers of glass, which restricts access to the cell. To get around these problems, a second method, objective-type evanescent field microscopy [2], using a high numerical objective on an inverted microscope has become more popular since the introduction of very high numerical aperture objective lenses by several microscope companies.

## Objective-Type Evanescent Field Microscopy

A second technique often used for evanescent field illumination, through-the-objective type (or prismless) evanescent field illumination was pioneered by Stout and Axelrod [2]. This technique takes advantage of very high numerical aperture objectives (NA = 1.4 to 1.65) to introduce totally internally reflected light for evanescent field illumination. This is usually achieved in one of two different ways. (i) A laser beam is focused off-axis to the back focal plane of the objective. Light focused off-axis to the back focal plane emerges collimated at an angle that becomes more acute with increasing distance from the center of the back focal plane. (ii) An arc lamp is focused onto an opaque disk in the center of the conjugate back focal plane of the objective. This opaque disk is set up in such a way to block all subcritical angles of light.

## Purpose

### *Applications*

Evanescent field microscopy has been used for a variety of applications including: the visualization of cell surface contacts (e.g., Weiss et al. [3]); visualizing single molecules [4] and events occurring at the cell surface such as endocytosis of clathrin coated pits [5], visualization of single secretory granules in neuroendocrine cells [6] and synaptic vesicles in dissociated neurons (e.g., Zenisek et al. [7]); and near membrane ionic transients (e.g., Omann and Axelrod [8], Zenisek et al. [9]).

## Advantages and Disadvantages

Evanescent field microscopy provides several advantages over conventional light microscopy. First, the very thin layer of excitation light illuminates a much smaller region than with other conventional techniques, thus eliminating the interference from fluorescent objects more distal to the glass–cell interface. In fact, the evanescent field can be much thinner than the focal plane of the objective lens, thereby theoretically eliminating out-of-focus excitation light from the image. In practice, however, scattered excitation and emission light prevents reaching this theoretical ideal. Second, the sharp drop in excitation light allows one to monitor subtle movements of an object by tracking its intensity over time. Third, since optical sectioning is provided by the excitation light rather than by introduction of a pinhole (as is the case for confocal microscopy), light collection is more efficient than with confocal.

The utility of evanescent field microscopy is limited to the visualization of structures within 500 nm of a highly refractive substrate. Within cells, such as neurons, it limits its uses to the study of processes within 200 nm of a membrane of a cell adherent to a coverslip. Structures deeper within cells or within tissue cannot be visualized with this technique.

## Event-related Potentials

### Definition

Electrical response from the brain elicited by an event. Encephalographic (EEG) recordings are made following a stimulus presentation (sound, light, touch). Typically, event-related electrical activity is smaller than ongoing spontaneous activity, thus signal averaging is employed to combine time-locked responses to multiple repetitions of the event.

►Auditory Evoked Potentials
►Electroencephalography

## Events

### Definition

Among the most prominent theories of *events* are Jaegwon Kim's account of events as structured entities constituted by objects, properties and times and Donald Davidson's account of events as concrete, datable and non-repeatable happenings. According to Kim, events are exemplifications by objects of properties at times. An event e is represented by an expression of the form "[*o*, *F*, *t*]," where o is e's constitutive object, *F* is *e*'s constitutive property (exemplified by *o*), and *t* is *e*'s constitutive time (the time at which *o* exemplifies *F*). According to Davidson, events resemble ordinary objects; they are concrete, datable and non-repeatable happenings such as births, assassinations, excitations of neural areas or beliefs.

►Epiphenomenalism

## Evoked Potential (EP)

### Definition

Summed electric response of many cells recorded by surface electrodes and evoked by stimulation of some neural, including sensory, or skeleto-muscular structure. For instance, repeated electric shocks delivered to a peripheral cutaneous nerve evoke waveforms of potential changes in the electroencephalogram (EEG), which upon averaging yield averaged sensory EPs. So do brief stretches to muscles, brief light flashes delivered to the retina or acoustic clicks delivered to an ear. Likewise, repeated transcranial magnetic stimulation (TMS) evokes changes in electromyograms (EMGs).

# Evolution and Brain-Body Allometry

Harry J. Jerison
Department of Psychiatry & Biobehavioral Sciences, UCLA Health Sciences Center, Santa Monica, CA, USA

## Definition

Allometry is the relationship of size or weight between a particular part of the body or part of an organ and the size or weight of the body or organ itself, respectively.

## Characteristics

If you have weighed the brains and bodies of a lot of animals and want to know their relationship, a good place to begin is with a graph of your data on a scatter diagram. You would be beginning an allometric analysis. Brain-body allometry is a description of what you have done, a discussion of how and why you did it, and the theory, such as it is, of what is going on. You will quickly learn to work with logarithmic rather than linear data. You may undertake regression analyses to fit lines to your data showing how brain size is related to body size. You might, on the other hand, prefer a simpler description without the assumptions that go into a statistical regression analysis by drawing minimum convex polygons about your data. For many inferences it may be enough simply to inspect the graph. You can, in addition, try to relate your results to what is known about the geometry of living brains [1,2]. At the very least you will be able to describe the diversity of adaptations of brain size. If you also have estimated and graphed brain and body size in fossil animals, you would learn something about the evolution of the brain by comparing the fossils with living species.

### The Development of Brain-body Measurements and Their Theoretical Issues

The issue is ancient, beginning with one of Aristotle's many mistakes about the brain and what it does. In ►*The Parts of Animals*, Aristotle wrote that "of all animals, man has the largest brain in proportion to its size." He was prescient in placing man among the animals, but when people dissected moles and shrews they knew that Aristotle got the rest of it wrong, at least if "proportion" meant a simple ratio of brain weight to body weight. Snell [3] tried to correct the error by relating brain weight to the surface area of the body rather than its weight. This was enough to restore ►*Homo sapiens* to top rank, to be jostled only by dolphins (►*Tursiops truncatus*), which continue to challenge us for the glory. Snell's was, perhaps, the first clear statement of the allometric equation.

The classic story was reviewed some years ago [4] listing the main contributors to the field of brain-body analyses, especially Eugen Dubois, the discoverer of "►*Pithecanthropus erectus*." Dubois analyzed brain-body relations to determine where his ►*Pithecanthropus* belonged in human evolution.

Snell did not recognize that the equation relating brain size to body size must be dimensionally balanced. Bodies are three-dimensional objects as are brains. Snell's solution was to take the 2/3rds power of body size, which makes it a dimensional surface. He wrote the classic allometric equation, taking the allometric exponent, $\alpha = 2/3$:

$$E = k\ P^{\alpha} \tag{1}$$

E is brain size, P is body size, and k is a multiplier, which then has the *dimension*, length. The idea is that the dimensions are part of the equation; the balanced dimensional equation is: *volume* = *length* × *area*.

One usually works with the log transform, Eq. 1a, and rather than choosing 2/3 as the exponent it can be determined empirically, by fitting a line to your data. The log transform is a regression equation, $\alpha$ is its slope and log $k$ is the Y-intercept.

$$\log E = \log k + \alpha \log P \tag{1a}$$

The dimensional approach is discussed in depth by Bridgman [5]. If one takes $\alpha = 2/3$, the dimension of $k$ could refer to the depth of the cortex. It is a *length* and has to vary with the 1/3rd power of brain size. Cortical depth has not been studied in detail, but it is known to vary slightly with brain size across species, at about the 1/6th power.

In the scatter diagram, $k$ is also the basis of a kind of encephalization quotient (*EQ*), determined for each brain relative to the overall regression. The computed value of $k$ in the regression equation, Eq. 1a, is a kind of average (by least-squares) of the deviations from the regression line. It could be calculated for each measured brain as the Y-intercept of a line parallel to the regression line, drawn through that measured brain-point. The computed *EQ* is thus the ratio of the measured brain size to the measured expected brain size at its body size (its X-value). It is a ratio rather than a difference or linear distance from the regression line because of log scaling: recall that log y − log x = log (y/x). Following this logic, *EQ* also has a dimension. For $\alpha = 2/3$, it is 1/3 minus a function of the depth of the cortex as related to body size. This feature of allometric analysis has not been formally explored.

Despite the unresolved dimensional problems with *EQ* and the multiplier $k$, there is some support for this approach [6], because the brain may be thought of as a mapping machine. Mapping is exemplified by the two-dimensional cortical maps of sensorimotor systems in mammals. The dimensional problem makes sense,

because the maps are sheets of brain tissue. Although very thin (about 1 mm thick, ranging from about 0.5 mm in the mouse to about 3.0 mm in humans), the cortex has a thickness and is a measurable depth.

Gould [7] has published a detailed discussion of the basic issues in allometric analysis. The "dictionary" by Medawar and Medawar [8] includes short essays on "allometric growth," "form and mathematics," "growth laws," and "transformations," which are excellent reviews. Martin ([9]: pp. 179–190) discusses it as applied to between-species data with emphasis on brain evolution. Perhaps the most novel development is based on Mandelbrot's "fractal geometry of nature"; in his second edition [10] he discusses the brain briefly using data in Figure 4, below. Hofman [11] has analyzed the same surface-volume as Mandelbrot and can be read as an introduction to fractals as applied to brain-body analysis.

The idea that the brain is a mapping machine is one theoretical approach to the meaning of brain size and to allometric analysis of brain-body relations [12]. Another theoretical approach is based on fractals. In most reports, however, brain-body allometry is primarily a descriptive method to present data with few inferences about fundamental properties of brains. With the discovery of the empirical 3/4 exponent [9], there has been renewed interest in metabolic constraints on brain growth [13] and on deriving a theoretical allometric exponent from fractal geometry [14].

Snell's use of $\alpha = 2/3$rds may define a fundamental constant reflecting the mapping of the body's sensorimotor surfaces on the brain. However, as just noted, the empirical exponent for mammals from a statistical regression analysis of all available mammalian data is approximately 3/4. The issue is that for brain-body relations the exponent from empirical curve-fitting exercises does not account for the mapping phenomenon nor does fractal geometry. An important problem is to explain the difference between the empirical 3/4 and a theoretical 2/3 exponent.

## Data Handling

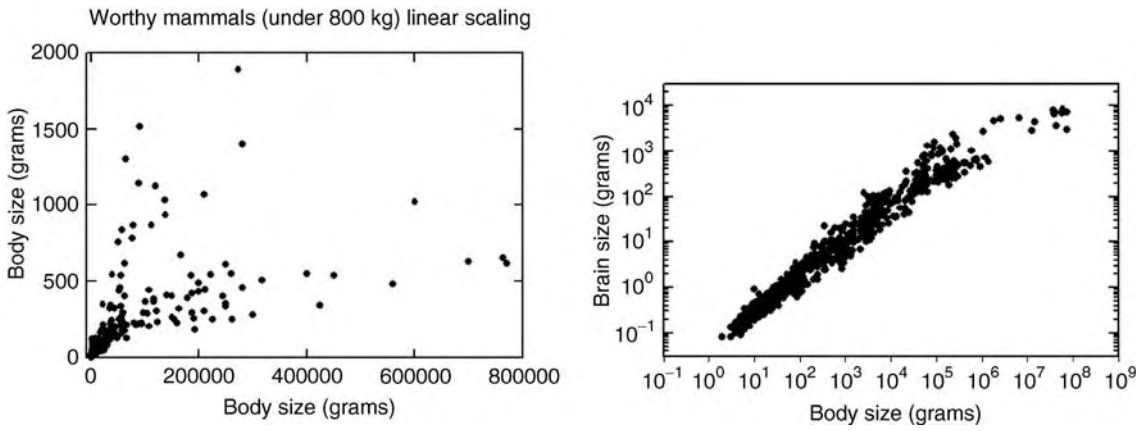
The remainder of this essay is concerned with handling the data after entering the numbers in a data sheet, independently of theoretical analysis. Two examples of the analysis will then be presented. One analysis is with minimum convex polygons, a nonparametric approach that illustrates the present diversity of brain size and is sufficient to describe several unusual aspects of brain evolution. The second is a regression analysis with implications for structural differences in the mammalian brain and illustrates the use of fractal geometry.

Computations with Eq. 1 are performed with logarithmically transformed data as indicated in Eq. 1a, which is a regression equation for bivariate data. Graphs of data on brain sizes and body sizes drawn on log-log graph paper (Fig. 1) will produce a cloud of points for which Eq. 1a can be a best-fitting line. Fig. 1 compares linear with logarithmic scaling, and is one of the justification for the latter. A "best-fitting" line determined by regression analysis applied to a very large sample of mammals results in $\alpha$ as approximately 3/4 (Fig. 2 below). The usual method for determining the regression line, "reduced major axes," is essentially the first principle component of multivariate analyses applied to bivariate data. Standard regression analysis assumes error-free body sizes and error only in the measures of brain sizes, and the residuals are then easier to work with. In brain-body data the residual for each species is the frequently used measure *EQ* (encephalization quotient). This is the ratio of measured brain size to expected brain size for a particular species at its body size according to the regression equation.

The main lesson so far is to graph the data using logarithmic scales for brain-body allometry and to be prepared to analyze the regression. It is reasonable to assume that brain size will vary as a function body size, hence brain size is the dependent variable, the Y-coordinate, and body size is the independent variable, the X-coordinate. The units should be commensurate, such as in the centimeter-gram-second (cgs) system. Mixing scales, such as taking brain size in grams and body size in kilograms or mixing English and metric scales (ounces and grams) should not be done. Logarithms are the natural units for analyzing biological size, because they scale multiplicatively rather than additively [16], reflecting the role of cell division in growth and in determining adult size.

To emphasize logarithmic scaling, linear and logarithmic scales were compared for the same mammalian data in Fig. 1. In addition to being inappropriate for the analysis of biological size, the linearly scaled data were limited to mammals weighing less than 800 kg to keep the points on a manageable graph. With logarithmic coordinates the entire sample of 647 mammal species that had been measured could be placed on a single graph. One can confirm that Eq.1a is an appropriate regression equation; for these mammalian data the best-fitting $\alpha$ is about 3/4 (actually 0.74), a better fit than 2/3. Because there are good arguments for the choice of either exponent they are compared for didactic purposes in Fig. 2.

To return to the wherefore of the analysis, why does an allometric equation fit the data as well as it does? The answer can be that the instructions encoded in the genome of all mammals include a requirement that the peripheral sensorimotor cells, which communicate with the brain, be mapped on the brain. The size of the brain is determined by the size of the map, which in turn is determined by the number of cells in the



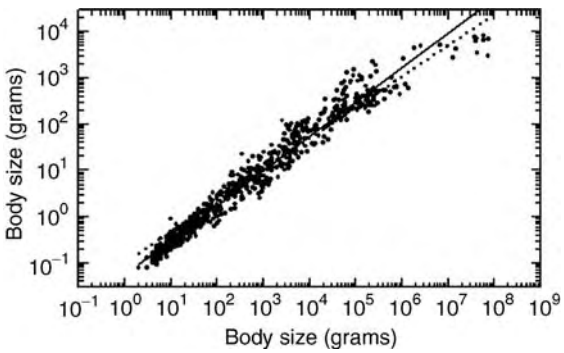
**Evolution and Brain-Body Allometry. Figure 1** Linear and logarithmic scales for brain-body weight data in mammals. Data from Worthy GAJ, Hickie JP [15].

brain map. This implies an allometric exponent $\alpha = 2/3$. The exponent of 3/4 has been related to a metabolic constraint on the size of a brain that can be supported by an animal programmed to grow to a particular body and organ size. This limits the growth of the brain, but within this constraint species can "grow" different sized brains at a given body size. As indicated in Fig. 2, either exponent could be correct.

Although curve fitting with regression analysis assumes that scatter in the cloud of points are random, in brain-body analysis the deviations from the regression ("residuals") are not random. They are the effect of another factor that determines brain size in a species. Opossums, cats, and monkeys, each weighing about 5 kg, may typically have brains weighing 5, 30, and 60 g respectively. (The species could be ►*Didelphis virginiana*, ►*Felis catus*, and ►*Cebus capucinus*.) The difference in brain size relative to body size is a difference in ►*encephalization*. Cats are average living mammals in this respect, whereas opossums are small-brained and monkeys large-brained. When Snell discovered the allometric equation he recognized this difference and described it as reflecting a "psychic" factor. The term, "encephalization," which is purely descriptive, is better.

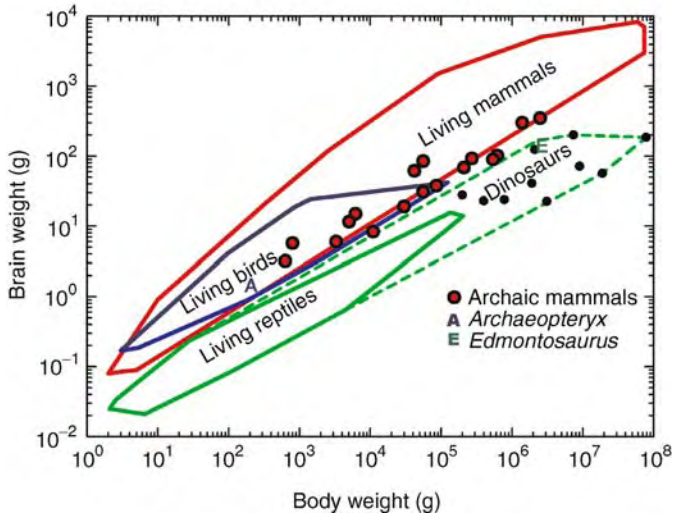
## Minimum Convex Polygons for Brain-Body Ratios

A graphic analysis with little theorizing is enough to provide important insights into both the diversity of brain size and its evolution. It is not even necessary to calculate regression equations or to make precise judgments of encephalization in different species. It is enough to draw a minimum convex polygon ("convex hull") about sets of points of special interest. Fig. 3 shows such an analysis for living and fossil amniotes. The method of measuring brain and body size in fossil species is beyond the scope of this article (see [4,6]).



**Evolution and Brain-Body Allometry. Figure 2** Regression of brain size on body size (solid line), Eq. 1a, $\alpha = 0.74$, $k = 0.06$. Dotted line is Eq. 1a, with $\alpha = 2/3$ run through the centroid.

There are simple inferences from this nonparametric analysis. First, the polygons are oriented similarly about an upward slope within each class of vertebrates, which shows that brain size is determined significantly by body size. The vertical differences between the polygons show that birds and mammals are about equally encephalized and that both of these vertebrate classes are more encephalized than reptiles. A secondary point involves the present consensus that sees birds as surviving dinosaurs. This analysis is enough to show that with respect to brain size, dinosaurs were at a reptilian grade, whereas the earliest bird was at an avian grade of brain size. (Other fossil data on later bird brains supports the differentiation of an avian grade with respect to brain size.) Finally, adding the "archaic" mammals reported in Jerison [4] has them clustered about the bottom border of the living mammalian polygon, indicating that progressive encephalization was one of the features of mammalian brain evolution.

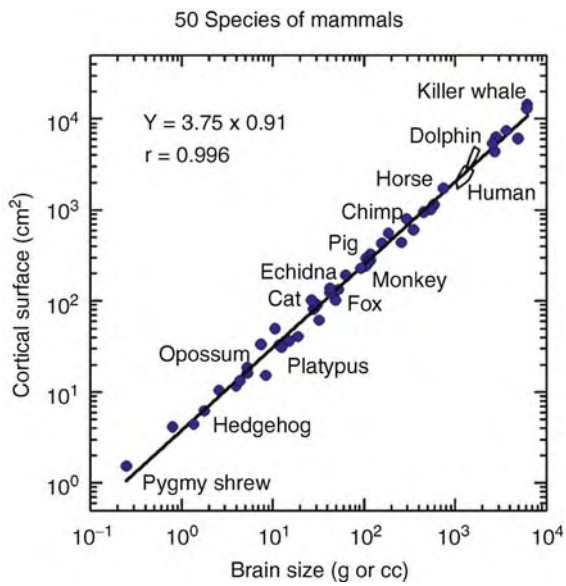


**Evolution and Brain-Body Allometry. Figure 3** Encephalization in living amniotes, with minimum convex polygons drawn about very large samples of mammal species (N = 647), bird species (N = 219), and reptile species (N = 59). Data on the earliest bird, the Jurassic *Archaeopteryx*, 13 dinosaurs, and 17 archaic fossil mammals indicate trends in brain evolution.

The archaic species are from extinct orders of mammals that became extinct between 3 and 50 million years ago. Although this gross procedure does not permit a very fine analysis, it is fine enough to enable us to reach these conclusions about the diversity and evolution of brain size.

### Regression Analysis Comparing Cortical Surface Area and Gross Brain Weight

The final case history is an allometric analysis in which regression analysis provides important clues about the organization of the brain. It is not a brain-body analysis but instead compares two measures of the brain in living mammals: cortical surface area and gross brain weight. Such surface-volume comparisons across mammalian brains are undertaken primarily to clarify the meaning of brain size for inferences about fossil "brains" that are known only as endocranial casts. Some have argued that cortical surface area is a measure of information processing capacity, contending that the number of neurons and of synapses in the cortex per unit area appears to be approximately constant across species of mammals. According to that argument, if volume estimates surface area then it estimates the information processing capacity of the brain for a species. Fig. 4 [12] shows that cortical area is indeed directly related to gross brain weight, a relationship that is in accord with the previous observation of intra- and cross-ordinal correlation of the degree of gyrification of the cortical surface area with the gross body weight of a given species.



**Evolution and Brain-Body Allometry. Figure 4** The relation between cortical surface area and brain weight in 50 species of mammals. (From [12], by permission.)

The unusual feature in Fig. 4 is the slope, the allometric exponent, which is 0.91. This means that as mammal brains evolved to larger size, the surface area increased disproportionately. There was an orderly change of shape with increasing volume. Were shape constant the exponent would be exactly 2/3. The change in shape took the form of the appearance of convolutions.

Mandelbrot's fractal geometry interprets this graph as indicating a fractal dimension of 2.70. Whether fractal analysis proves to be fruitful, or older approaches, such as the dimensional analysis of Bridgman [5], are preferable remains to be resolved. From the older perspective, an exponent of 0.91 for Fig. 4 implies a change of shape with increasing size, and the very high correlation coefficient, essentially 1.0, indicates that the change is very orderly. The change is, of course, the appearance of convolutions, i.e., gyri, as noted above, and the implication is that convolutedness of brains is almost entirely a function of brain size and does not necessarily signify increased intelligence. Resolving these issues is among the challenges for future research.

## Synonyms

Neurogenesis; Radial and tangential neuronal migration; Abventricular division; Ventricular zone; Subventricular zone

## Definition

The cortex in amniotes ranges from the relatively simple cytoarchitecture of three-layered reptilian dorsal cortex to the more complex six-layered neocortex (isocortex) of mammals and the pseudo-laminated but hypertrophied Wulst, or hyperpallium, of birds. New findings on the development of these pallial regions shed new light on how their cytoarchitectonic features evolved in the different amniote taxa that are extant today.

## Characteristics

The human neocortex supports many of our most advanced behaviors and cognitive abilities. Understanding the evolutionary processes that led to the enlargement of mammalian and the human brain is a major goal of neuroscience and evolutionary biology. Subcortical structures of the mammalian brain are largely similar to those of birds and reptiles [1]. However, several major qualitative differences distinguish the mammalian telencephalon from that of sauropsids: the laminar expansion of the cortex to six layers and the reorganization of the lateral region of the pallium. Within mammals, the massive tangential expansion of the neocortex is the hallmark of the primate brain, although it is also observed in several other orders. The goal of this article is to highlight the developmental processes that may underlie major changes in the telencephalon by reviewing elaborations of the amniote brain and recent comparative work on neurogenic compartments of the developing telencephalon [2–4]. In all amniotes, cortical excitatory neurons are produced by progenitors that divide along the ventricle surface. However, in mammals (and to a much lesser extent in birds) cortical excitatory neurons are also produced in the ►subventricular zone (SVZ), a zone superficial to the ventricle surface [5,6]. Recent work in primate and rodent revealed that the SVZ is

responsible for producing upper-layer neurons that are absent in the cortex of reptiles and birds [2,7]. Comparative developmental studies suggest that SVZ elaboration has contributed to tangential expansion of the cortex and the appearance of more elaborate cell types especially in supragranular layers. Future work on the molecular mechanisms that regulate the formation of the SVZ will provide insight on mammalian and primate brain evolution.

## Elaboration of the Telencephalon in Amniote Evolution

Major brain structures have largely been conserved in amniote evolution, but the telencephalon has diverged rapidly since the stem amniote [1]. In the common ancestor of all mammals, the cortex expanded from three to six layers and extended along the lateral region of the pallium. Within mammalian orders, the neocortex has also expanded tangentially, and cortical areas have been associated with advanced cognitive functions. Meanwhile, in sauropsids (reptiles and birds), the dorsal cortex has remained a three-layered structure, but in birds, the dorsal cortex (hyperpallium) has been elaborated into a pseudo-layered structure [8]. Additionally, the lateral region of the pallium of birds has been elaborated from the simple and presumed ancestral-like laminated structure in the tuatara, *Sphenodon punctatum*, to an enlarged dorsal ventricular ridge (DVR) [9]. In birds, the hyperpallium and nuclei of the DVR have been associated with advanced cognitive functions.

Evolution must have acted on developmental processes in order to produce these differences in amniote telencephalon structures. It is believed that there were some major transformations at the corticostriatal junctions [10–12], together with the generation of a new developmental process to increase cortical cell numbers to produce supragranular layers on a much larger cortex. This chapter briefly reviews the elaboration of the differences in the cortical lamination and tangential extension of the mammalian neocortex and reviews evidence that SVZ formation has been a critical developmental process enabling this laminar and tangential expansion of the mammalian cortex. The developmental processes underlying DVR elaboration are less well-understood, but it is interesting to note that a SVZ also forms during ►neurogenesis in the avian DVR.

## Differences in the Cortical Lamination and Tangential Expansion of the Mammalian Neocortex

Mammals uniquely possess a six-layered cortex (isocortex or neocortex), which develops in a strict inside-out pattern. In contrast, reptiles possess a three-layered cortex with considerable similarity to layers I, V and VI of mammals. The hyperpallium of birds also shares no homologues to layers II, III, and IV of the mammalian cortex. However, based on morphology, connectivity, and neurotransmitters, it may have independently evolved cell populations that are at least analogous to these layers [1,8]. Thus, the laminar expansion of the cortex in mammals from the stem amniote required an increased number of neurons and cell types, and much debate exists about the developmental source of these neurons.

Harvey Karten originally proposed that the mammalian neocortex evolved from a rearrangement of elements already present in other vertebrates. He demonstrated that equivalent circuits are present in the visual and auditory pathways in avian and mammalian telencephali [13,14]. While these components are arranged into cortical layers in mammals, they are mostly situated in the DVR in birds, hinting that tangential migration could have been responsible for a cortical rearrangement in mammals. Initial reports that the mammalian subpallium, a region outside the cortical neuroepithelium, contributes tangentially migrating neurons to the mammalian cortex appeared to support Karten's theory [14,15]. However, tangentially migrating neurons are purely inhibitory (GABAergic). Additionally, tangential migration is not unique to mammalian brains, but occurs in birds and reptiles. Finally, tangentially migrating cells in all amniotes originate from the subpallium, which is not considered homologous to the DVR [16]. Therefore it is more conceivable that changes in the local dorsal cortical neurogenetic program, together with some major rearrangements at the corticostriatal junction [12], provided the foundation for remodeling the mammalian cortical lamination [2,17].

The tangential expansion of the cortex within mammals also required increased cortical neurogenesis. In contrast to the relatively constant features of mammalian radial columns [18], a more noticeable change in the evolution of the neocortex is the tangential expansion of the cortical sheet associated with the transformation of lissencephalic cortex typical of smaller brains, including those of some rodents, to the gyrencephalic cortex typical of larger brains, including those of some primates, cetaceans and other orders. The total surface area of the cerebral cortex has increased exponentially from lesser shrew (0.8 $cm^2$), rat (6 $cm^2$), and cat (83 $cm^2$) to human (2,500 $cm^2$), bottlenose dolphin (3,745 $cm^2$), and African elephant (6,300 $cm^2$).

## Evidence for Neurogenesis in the Subventricular Zone

Recent experiments suggest that the generation of neurons in the subventricular zone (SVZ) could have increased neural production in the neocortex of mammals. The majority of neurons in the adult brain are produced during embryonic development. In the amniote telencephalon, embryonic neurogenesis occurs at several sites. Early precursor cells and radial glia

produce neurons along the ►ventricular zone (VZ). Away from the ventricle, scattered abventricular cells also produce neurons. However, in mammals, but not in turtles and possibly other reptiles, cortical neurons are also generated by a discrete mitotic compartment called the SVZ that is located radially above the VZ [19].

The progenitor cells of the mammalian SVZ and of abventricular regions differ from progenitors in the VZ. In the VZ, neuroepithelial cells give rise to early born neurons and radial glia. The nuclei of radial glia undergo interkinetic migration, passing through S phase away from the ventricle surface and returning to the ventricle surface during M phase. At the ventricle, a radial glia cell divides asymmetrically to produce another radial glia and either a mature neuron or an intermediate progenitor cell that migrates to the SVZ. In contrast to radial glia, SVZ (intermediate) progenitors do not undergo interkinetic nuclear migration, and instead remain away from the ventricle surface where the cells divide symmetrically to produce two neurons, or occasionally, two daughter progenitors [5] (Fig. 1). Thus the two-step pattern of neurogenesis in which a radial glia cell produces a SVZ progenitor increases the overall rate of neurogenesis relative to the one-step pattern in which a radial glia cell produces a single neuron directly by asymmetric division.

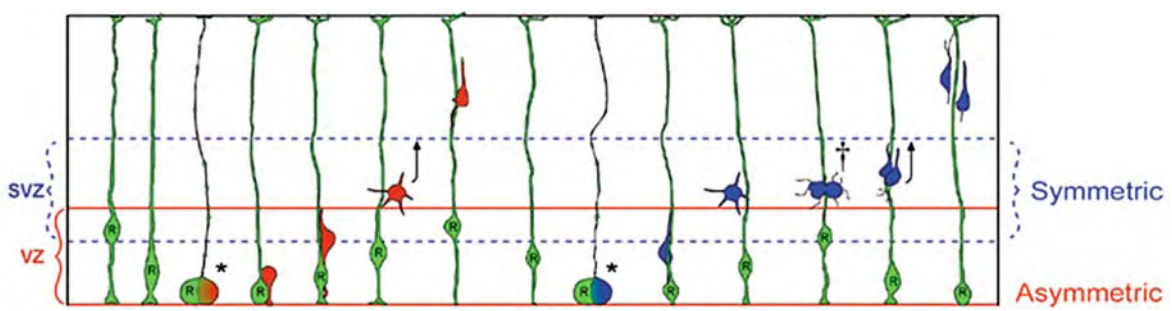
The appearance of the cortical SVZ in the common ancestor of mammals coincides with the appearance of the six layered neocortex. Turtles and birds lack upper layer cortical neurons and also lack an SVZ in their pallial and Wulst (hyperpallium) regions, respectively [3,20]. This can be demonstrated by labeling sections from embryonic brains with an antibody against the mitotic marker phospho-histone H3. (Fig. 2a) shows that in both the pallium and subpallium of turtles, cell divisions occur along the VZ and in abventricular cells but never in an organized SVZ. Abventricular cell divisions may also increase the rate of neurogenesis, But, the proportion of such divisions in the dorsal cortex remains small (less than 1/6th) and stable throughout neurogenesis, whereas in mammals, the proportion of SVZ and ►abventricular divisions dramatically increases [3,4,20]. Thus, the SVZ and a substantial role for intermediate progenitor cells appear in conjunction with the six-layered neocortex. However, this suggestion is based on a few species in the supramimate clade, Species from other order should be looked at before generalization could be made.

E

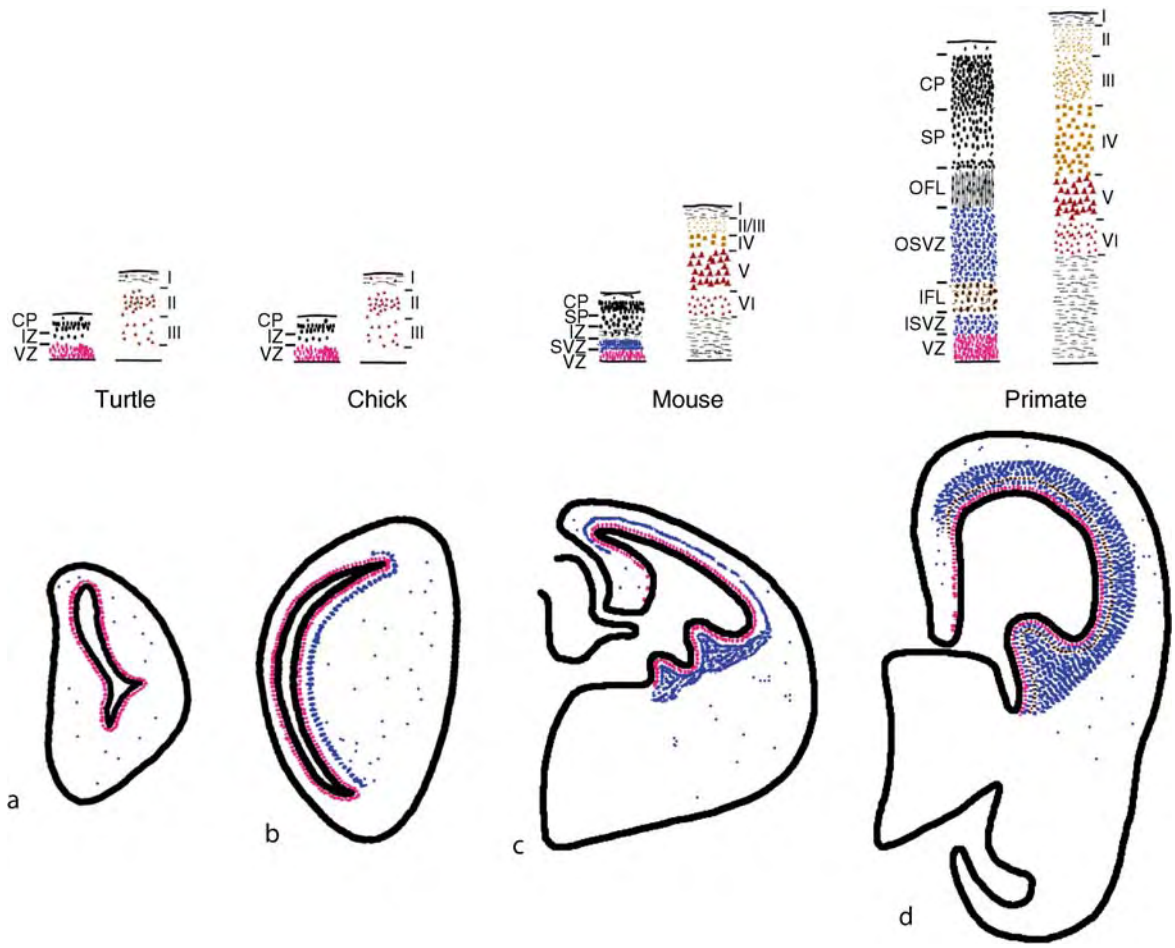
## Elaboration of Mitotic Compartments in the Avian Brains

Although reptiles and birds lack a SVZ in the dorsal cortex and hyperpallium respectively, a SVZ has been reported in ventral regions of the telencephalon in birds. Striedter and Keefer [22] described a 100–200 μm thick band of labeled cells superficial to the VZ in the ventral telencephalon of E6 chick. The observed SVZ appeared to be prominent in subpallial regions. However, recent work indicates that the chick SVZ also extends across the entire DVR, terminating at the lateral edge of the cortex [4]. Thus, the entire VZ of the chick pallium commonly expresses transcription factors such as Pax6, and yet only the lateral portion produces a SVZ.

The SVZ in the embryonic DVR of the chick shares several similarities with the cortical SVZ of mammals. SVZ progenitors in both species are present during phases of neurogenesis. Additionally, in mammals, transcription factors such as Tbr2, Ngn1 and Ngn2 are locally expressed in the SVZ. Prior to the identification of the pallial SVZ in birds, Tbr2 expression was observed to reach the proliferative zone in the chick DVR, but not hyperpallium, and Ngn1 and Ngn2 were shown to be more strongly expressed in the DVR than hyperpallium [23,24]. These early results intimate that similar factors may regulate the formation of the SVZ in the chick and mouse.



**Evolution and Embryological Development of the Cortex in Amniotes. Figure 1** A radial glial cell (green) in the ventricular zone (VZ) undergoes asymmetric division to produce two daughter cells of different fates (one radial glial cell plus one neuron (red), or one radial glial cell plus one intermediate progenitor cell (blue)). The intermediate progenitor cells then undergo symmetric division in the subventricular zone (SVZ) which produces either two neurons or two intermediate progenitor cells to replenish the cell pool. Reproduced with permission from ref. [5].



**Evolution and Embryological Development of the Cortex in Amniotes. Figure 2** In turtle (a), cell division occurs at the VZ (red) and in abventricular cells (blue), but an organized SVZ is absent. In chick (b), an organized SVZ is absent from the dorsal cortex (hyperpallium), shown here, but present in ventral pallial regions (DVR). In mouse (c) and primate (d), an SVZ is present in the dorsal cortex and in the ganglionic eminences. Upper panel demonstrates a correlation between the size of the SVZ and the increase in supragranular layer complexity in the adult cortex. In turtle and chick, the absence of an SVZ (upper panel a, b: left column) corresponds to an absence of supragranular layers in the adult (right column). In primate, the SVZ is much larger than in mouse (upper panel c, d: left column) and the supragranular layers are larger and more complex (right column). The compartmentalization of germinal zone might have increased the pool of neural progenitors and prolonged the period of neurogenesis during vertebrate evolution. Figure is reproduced with permission from ref. 4 using the data from refs. [3,17,21].

## Elaboration of Mitotic Compartments in the Primate Brains

The rodent-monkey (possibly lissencephalic-gyrencephalic) differences in the post-mitotic compartments are accompanied by major differences in the dimensions, configurations and developmental timing of the germinal zones. In rodents with small, lissencephalic brains, the VZ remains the major proliferative zone well past mid-corticogenesis [21] and the SVZ accounts for no more than 35% of the cortical proliferative population at E15 [25]. Accordingly, the supragranular layers occupy no more than a third of the thickness of the mature cortex (Fig. 3). In monkeys with larger, gyrencephalic brains, SVZ cells are found at a relatively earlier stage in corticogenesis and show a much greater expansion compared to the rodent, so that by mid-corticogenesis the SVZ has become the predominant germinal zone [21]. This coincides with the predominance of supragranular layers in the mature, gyrencephalic primate cortex.

The primate SVZ also differs structurally from that of small sized rodents. From E65 onwards, a specialized component of the SVZ, the outer (O) SVZ emerges [21]. Histologically the OSVZ has very different features from the randomly organized cells that are typical of the SVZ described in rodents and the early pre-E65

SVZ in the monkey. The dense, radially orientated precursors of the OSVZ constitute a unique primate feature and birth-dating experiments show that the OSVZ generates the supragranular layers of the cortex [7]. The predominance of OSVZ in primates could be due to the increased importance of the cortico-cortical connections and therefore the supragranular layers in this order. It is possible that different micro-environmental cues in the SVZ compared to the VZ are responsible for creating certain neuronal subtypes. It is also possible that further compartmentalization of SVZ in primates is a correlate of higher neuronal diversity of supragranular layers. The contribution of the SVZ in neuronal production appears to grow in evolution as the complexity of the cortex increases (Fig. 3). The emergence of an additional proliferative zone and its diversification during cortical evolution might have been triggered by the necessity to produce more neuronal subtypes in different morphological compartments.

There are numerous unanswered questions concerning the embryonic compartments of the developing monkey cortex. For instance, the identity of the inner fiber layer that separates the inner (I) SVZ from the OSVZ is unknown. Smart et al. [21] showed that the outer fiber layer (OFL) houses the fibers from the lateral geniculate nucleus. Thus thalamic fibers may be much more closely connected to the germinal zone in monkeys compared to rodents and carnivores, intimating that the ascending pathways influence rates of proliferation in the cortex and ultimately contribute to establishing distinct proliferative programs in the germinal zone and distinct cortical cytoarchitecture in adults [7,27]. It is currently not clear whether the compartmentalization of the germinal zone mentioned above is a primate characteristic or similar partitioning occurs in the development of other gyrencephalic brains [17].

The expression pattern of transcription factors in the more elaborate primate germinal zone has not been studied in detail during embryonic development. It is conceivable that the new compartments enable novel combinatorial effects of the same transcription factors producing more variety of cell types. In rodent and primate, there also seem to be great differences in the proportion of GABAergic neurons generated locally in the pallium and the striatum/subpallium (lateral and medial ganglionic eminences). In human, gene expression evidence suggests that a substantial fraction (65%) of cortical interneurons are generated by the pallium whereas in rodents this estimate is only 5%, the rest having a subpallial origin [26].

## Presumed Role of the SVZ in Laminar and Tangential Expansion of the Cortex

The laminar expansion of the cortex that occurred in the common ancestor of all mammals and the tangential expansion of the cortex that has occurred within several mammalian orders each required increased neuron production during embryonic neurogenesis. The two-step pattern of neurogenesis in the SVZ could have increased the rate and duration of neurogenesis, and recent studies provide evidence for a role of the SVZ in the laminar and tangential expansion of the cortex [6,20].

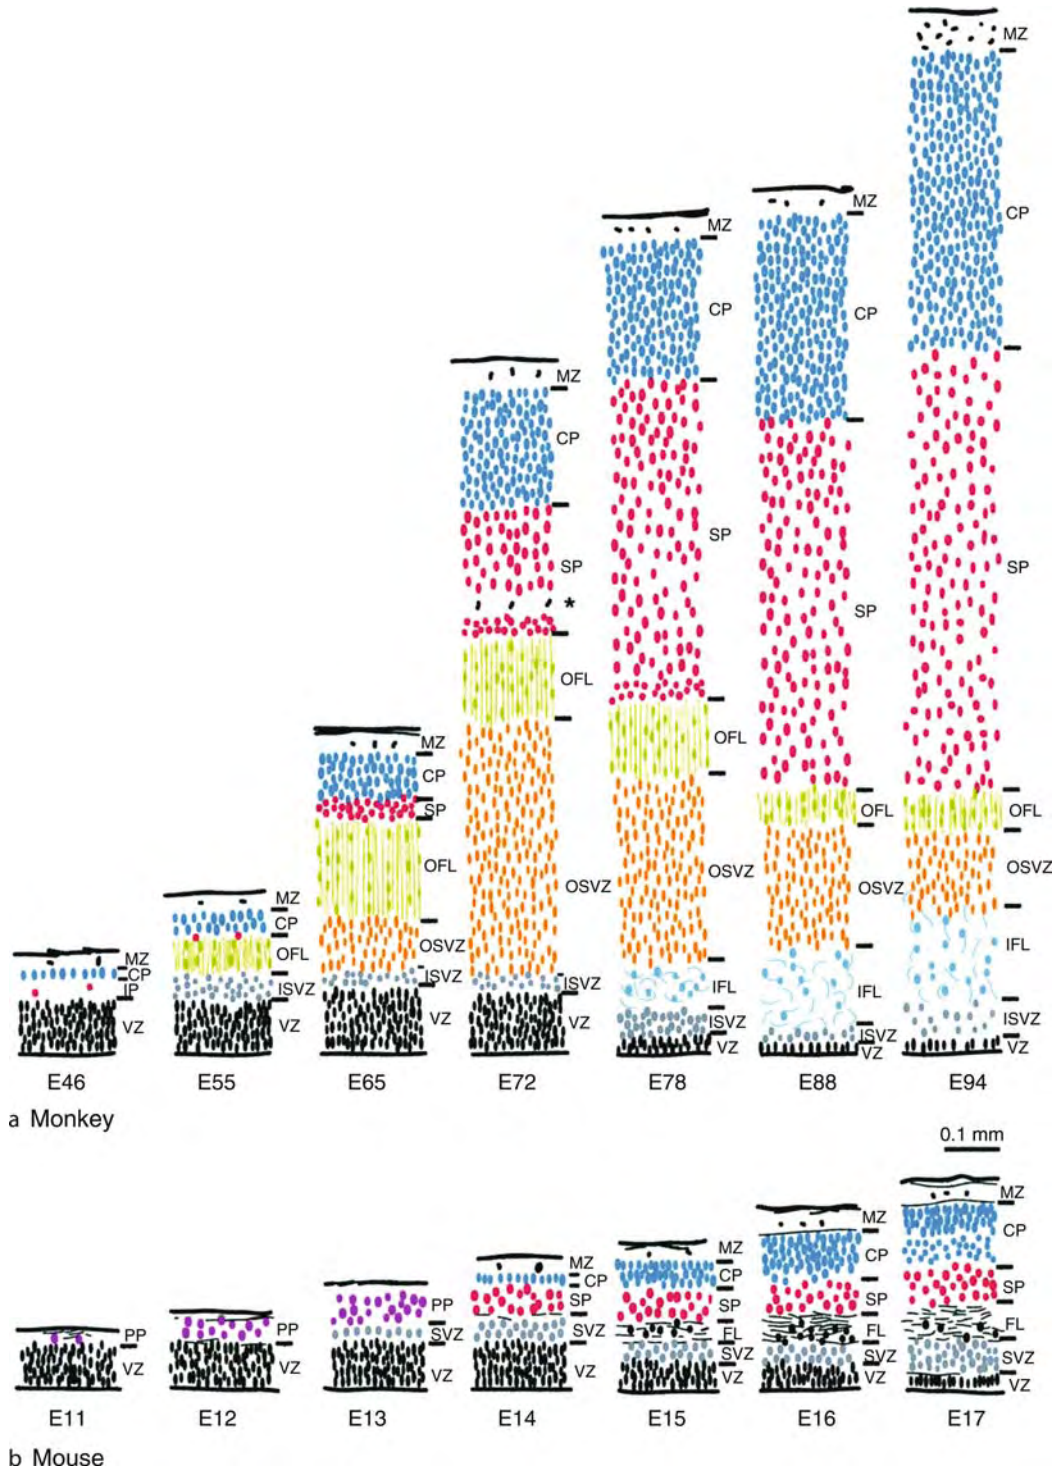
As mentioned earlier, the appearance of the cortical SVZ correlates with the appearance of upper layer pyramidal neurons. Additionally, progenitor cells of the SVZ play a direct role in generating upper cortical layers in mammals. Tarabykin et al. [28] linked SVZ progenitors to upper layer neurons because the expression of the gene Svet1 was restricted to both sets of cells, and reduced expression of Svet1 in the SVZ corresponded to the absence of upper layer pyramidal neurons in Pax6 mutant mice. Since this proposal, time-lapse photography of GFP-labeled progenitor cells in cultured brain slices [5,6], and direct *in vivo* labeling of SVZ cells [29] have confirmed that SVZ cells are neurogenic and generate upper layer pyramidal neurons (Fig. 1). Taken together, these observations strongly suggest the appearance of the SVZ was integral to laminar expansion of the cortex.

The evidence for a contribution of the SVZ to the tangential expansion of the cortex is based on comparative studies. Martínez-Cerdeño et al. [20] compared progenitor cells in rats which have a smooth lissencephalic cortex and ferrets which have a folded gyrencephalic cortex. In ferrets, the proportion of total cell divisions that occur in the SVZ is higher and remains at peak levels for a longer duration than in rats. These data suggest that the increased proportion and duration of SVZ divisions could relate to the tangential expansion of the ferret cortex. Meanwhile, in the monkey, the SVZ has expanded to include the OSVZ which becomes the major proliferative component during development, and the primate cortex is disproportionately expanded compared with other mammals [21]. Thus comparative studies intimate a role for SVZ regulation in the tangential expansion of the cortex [2].

## Molecular Mechanisms of SVZ Regulation

Neurogenesis in the SVZ may have been involved with the formation and tangential expansion of the six layered neocortex in mammals. Thus the molecular mechanisms regulating SVZ formation may have played a major role in the diversification of the amniote telencephalon. However, the molecular mechanisms regulating SVZ formation are only beginning to be elucidated.

Descriptive studies demonstrate that progenitor cells in the cortical SVZ express several transcription factors that are absent or much less abundant in VZ progenitors. Tbr2, Ngn2, and Svet1 are expressed early as progenitor cells approach the SVZ [6,28] followed by NeuroD and



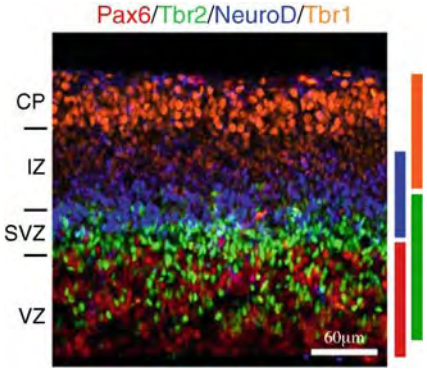
**Evolution and Embryological Development of the Cortex in Amniotes. Figure 3** Comparison of histological sequences in the developing mouse and monkey telencephalic wall. These drawings are of transects through putative area 17 in (a) monkey and (b) mouse at comparable developmental stages. The depth of each layer is drawn to a common scale. The internal detail of each layer is not to scale but depicts the orientation, shape and relative packing density of nuclei in each layer. The vertically aligned pairs have been chosen with reference to birthdating experiments so as to illustrate corticogenesis at equivalent developmental stages. Reproduced with permission from ref. [24].

other markers such as Slc17a6 and Cutl2 [30–32; Fig. 4] As a group, these transcription factors may be involved in the decision of SVZ cells to halt interkinetic nuclear migration, to divide symmetrically, and to differentiate into upper layer excitatory neurons. Miyata et al. [4] further observe that SVZ progenitor cells lose their apical contact with the ventricular surface prior to division in the SVZ.

Several functional studies have further explored factors influencing SVZ cell fate. Radial glia infected with a retrovirus containing the proneural gene Ngn2 were more likely to produce SVZ progenitors than radial glia infected with a control virus [6]. Interestingly, Ngn2 knockout mice, and double knockouts with Ngn1 do not appear to have a reciprocal phenotype of a reduction in SVZ progenitors, but a null mutation in Pax6 does reduce the SVZ progenitor population [33]. Future studies may reveal factors downstream of Ngn2 and Pax6 that induce cell division in the SVZ.

Magdalena Götz's lab has explored whether the basal and apical processes of radial glia are involved in SVZ formation. The basal process of radial glia contacts the pial surface. In three mutant strains of mice with defects in basal processes of radial glia, the proportion of VZ and SVZ progenitors remained normal and abnormalities only appeared later in the migration of neurons to the cortical plate [34].

However, apical processes appear important for normal SVZ regulation. Apical processes of radial glia form adherens junctions with the ventricle surface. Götz's lab genetically impaired adherens junction formation by creating a conditional knockout in the dorsal telencephalon for the rho-GTPase cdc42, an enzyme that indirectly regulates adherens junctions with the ventricle surface. Adherens junctions deteriorated more quickly in the absence of cdc42, and overall, the number of SVZ cells, and the number of neurons produced increased [31]. The authors speculate that the loss of the apical process of radial glia affects interkinetic migration by reducing the pulling force of cells back to the ventricle and thereby freeing cells to divide in the SVZ. Interestingly, the expression of SVZ specific transcription factors including Tbr2, NeuroD, Svet1 and others increased dramatically in the absence of cdc42, suggesting that cells were able to switch to an SVZ-like fate. Thus molecular pathways and cellular events are now being identified that influence SVZ formation, but many questions remain.



**Evolution and Embryological Development of the Cortex in Amniotes. Figure 4** Zonal expression of transcription factors Pax6 (red), Tbr2 (green), NeuroD (blue) and Tbr1 (orange) in embryonic murine cortex. By elucidating the sequential expression of fate-determining factors, we will be able to understand the specification of different projection neurons. Reproduced with permission from ref. [30].

## Conclusion

The recent comparative studies on cortical development are beginning to provide insight into the events that enabled the expansion of the mammalian cerebral cortex. These data suggest that the regulation of the SVZ formation might have been a key factor in the increased neuronal production, contributing to the supragranular layers and to increased cortical surface areas. The key current questions include understanding the cellular and molecular mechanisms molecular mechanism regulating SVZ formation in different vertebrates. The understanding of this basic developmental process may provide clues about the genetic changes that have restructured the mammalian telencephalon and enlarged the primate neocortex.

# Evolution and Embryological Development of Forebrain

Loreta Medina
Department of Experimental Medicine,
Faculty of Medicine, University of Lleida, Institut of Biomedical Research of Lleida (IRBLLEIDA), Lleida, Catalonia, Spain

## Synonyms

Prosencephalon (synonym of forebrain)

## Definition

Series of molecular, cellular and morphological gradual changes that take place in the anterior or rostral part of the neural tube during the course of embryonic development and in evolution, that lead to the morphological and functional complexity and diversity found in the forebrain of vertebrates.

## Characteristics

### The Forebrain: A Region Supporting Sophisticated Behaviors in Different Vertebrates

The forebrain is the most rostral and complex part of the brain and, in all vertebrates, includes the thalamus, the hypothalamus and the ►telencephalon [1,2] (Fig. 1).

This part of the brain plays a key role in the control of motivated behavior (from motor control to decision-making) and the modulation of instinctive reflex-like behavior (ingestion, reproduction, defense) in response to external or internal stimuli. It is also the brain region responsible of our conscious thoughts, memories, learning capabilities, emotion, and social behavior, and it is the region that makes us unique as humans and confers each person individual attributes and capabilities. In spite of this, the basic subdivisions of the forebrain and many aspects of their organization are quite conserved in vertebrates. Moreover, from fish to mammals, the forebrain contains comparable centers that are apparently involved in similar basic aspects of behavior. For example, in most vertebrate groups the basal part of the telencephalon (or subpallium) includes a center called "basal ganglia" that shows similar neurochemical features, cell types and basic connections, and appears to be involved in similar functions such as motor control, motivation and reward [3].

However, not everything is similar in the forebrain of different vertebrates, which reflects the existence of divergent evolution in the different lineages [2,3]. Divergent evolution of the forebrain has resulted in an increase in size and complexity of specific centers and their projections, and in the appearance of highly sophisticated behaviors in some vertebrate lineages, such as mammals or birds. For example, the telencephalon has independently evolved or elaborated centers and pathways related to song/vocalization learning and production in songbirds or parrots, or to language in humans.

What make us different from other vertebrates, or what differs between a zebrafish, a frog and a mouse, or between an owl, a chick and a parrot? It appears that, while the basic forebrain subdivisions are rather constant across vertebrates (but see below), different vertebrates differ in the degree of elaboration/complexity of these subdivisions. Each vertebrate group (or each species within a group) is characterized by elaboration of specific subdivisions and/or by differing degrees of elaboration of these subdivisions. For example, birds, reptiles and mammals show an important or extremely important development and elaboration of the telencephalic pallium (cortical region), but while mammals are characterized by the greatest development of the dorsal pallium (giving rise to the neocortex), birds and reptiles have primarily developed the ventrolateral pallium (producing a prominent pallial center called "dorsal ventricular ridge" or DVR). Among birds, owls

are characterized not only by a great elaboration of the ventrolateral pallium but also by an important development of the dorsal pallium [2,3].

What produced either the conservation or divergence of forebrain regions and pathways in evolution? It is now clear that divergent evolution is the consequence of changes in developmental mechanisms. Non-lethal modifications in developmental mechanisms produce phenotypic variations that are then exposed to natural selection; but what developmental mechanisms produce forebrain complexity and how have these changed in evolution? These fundamental questions need to be answered in order to achieve a complete understanding of the forebrain. Although the questions are still far from being answered, below we consider some clues based on recent genetic and experimental evidence.

## Similar Mechanisms of Neural Induction and Formation of the Anterior Neural Plate in Vertebrates

In all vertebrates, the forebrain develops from the anterior part of the neural plate during gastrulation [4,5] (Fig. 2). The mechanisms responsible of its formation and subsequent patterning are highly conserved in evolution and result in the production of similar forebrain subdivisions/compartments along the rostrocaudal and dorsoventral axis (explained below).

It appears that a prospective neural plate is initially induced by FGF (fibroblastic growth factor) signals released from the ►node (a primary ►organizer), and its neural character is subsequently established by antagonists of BMP signaling that inhibit the formation of non-neural ectoderm [5,6]. This early neural plate is anterior in character and is going to become the forebrain. As the node regresses, caudal regions of the plate are formed (midbrain, hindbrain, spinal cord) due to exposure to caudalizing signals. The initial anteroposterior (AP) partition of the neural plate is rather crude, but it is subsequently refined due to later signals (as explained below).

## From Bidimensional Molecular Compartments in the Neuroepithelium to Tridimensional Radial Units in the Brain

The anterior neural plate is initially a simple sheet of neuroepithelium, but through different steps is going to become the most complex part of the brain. As a consequence of its highly complex morphogenesis, it is not easy to identify the basic units/subdivisions in the mature forebrain or to understand the topological relationships between units. This leads to serious difficulties in the comparison of basic forebrain units or cell groups in different vertebrates and greatly complicates forebrain evolution studies. As noted below, developmental studies are extremely important for unraveling forebrain organization and constitute a great support for comparative and evolution studies.

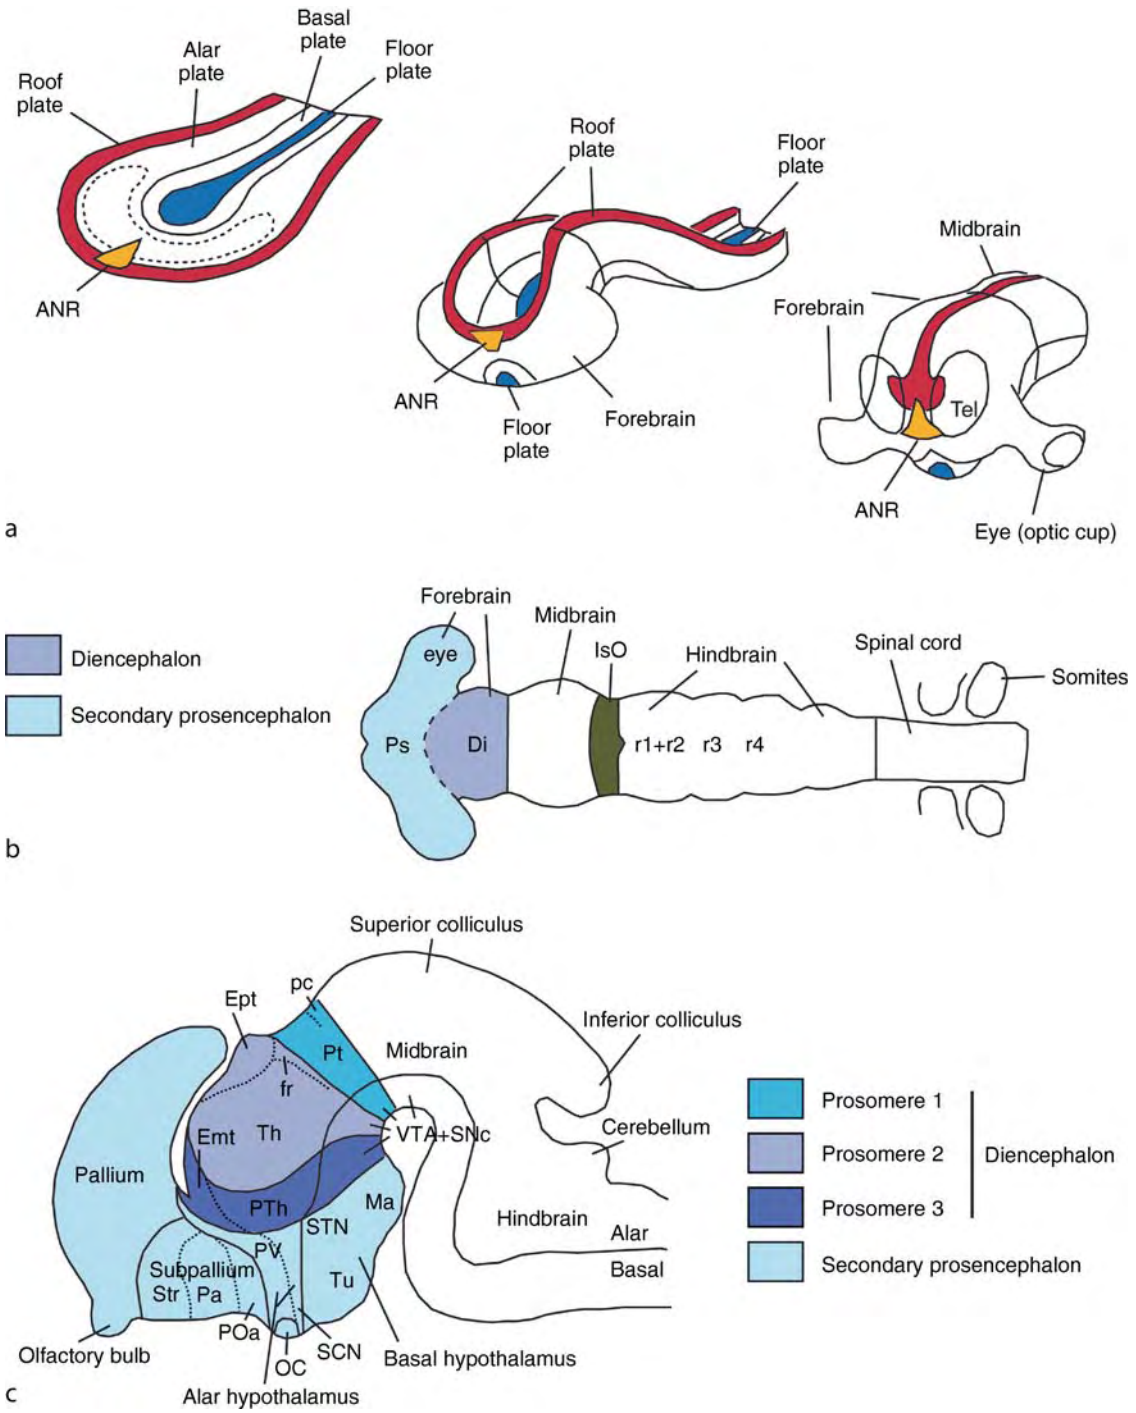
Recent molecular/genetic specification data together with fate-map experimental analysis in different vertebrates have indicated that divisions and subdivisions of the brain and, in particular, the forebrain, start to appear at neural plate stage, before they become morphologically visible [4]. Molecular specification data are based on the restricted, combinatorial expression and action of ►developmental regulatory genes (key or master control genes, encoding transcription factors or ►signaling proteins) that regulate important aspects of development. These data indicate the existence of distinct molecular domains at neural plate stages, and fate-map analysis indicates that each of these molecular domains correlates well with a specific fate (region/cell population) in the adult brain.

Each molecular subdivision of the neural plate/tube is thus characterized by the expression of a specific combination of developmental regulatory genes, and -by the action of these genes- is going to produce a specific set of brain derivatives. Therefore, each subdivision represents a true morphogenetic field or compartment. Based on genetic and embryological evidence, these are considered basic units of development, linking genotype to phenotype [7]. Since ►morphogenetic compartments are able to change independently of the surrounding fields, they also represent basic units of evolution.

Under the action of different combinations of regulatory genes, the neural plate (and later the tube) is going to become simultaneously subdivided into several dorsoventral (DV), longitudinal subdivisions and into a series of rostrocaudal (or anteroposterior; AP) subdivisions (Figs. 2 and 3).

This process is explained in detail below. Initially, the compartments are established at the neuroepithelial level and affect the proliferative neural cells. At the neuroepithelial level, each compartment shows clonal restriction. Following proliferation, most immature neurons born in each neuroepithelial compartment migrate into the mantle following primarily radial glial fibers (although examples of tangential cell migration are described in some regions, as explained below). Neuroepithelial compartments, initially established in a bidimensional coordinate system, are thus transformed into tridimensional radial units of the brain (Fig. 3).

Each molecular subdivision/compartment and derived radial unit occupies a specific position within the DV and AP brain axes (►topological position), which remains invariable independent of subsequent deformations due to differential growth of neighbor units (Fig. 3). The expression patterns of orthologous regulatory genes in the neural plate/tube are highly conserved throughout vertebrate phylogeny (with a few exceptions noted below), and so are the brain subdivisions/units and their molecular profile [4,7–9]. This facilitates one-to-one comparison of the molecular brain subdivisions/units



**Evolution and Embryological Development of Forebrain. Figure 2** (a) Schemes showing the anterior neural plate and some of the gradual changes that occur during neurulation and later, which lead to the formation of the early forebrain vesicle (modified from [4]). (b) Dorsal schematic view of the early developing brain, showing the two major divisions of the forebrain: the diencephalon proper (Di; caudally), and the secondary prosencephalon (ps; rostrally). Both the eye and telencephalic vesicles are paired evaginations from the secondary prosencephalon. (c) Lateral schematic view of a rodent brain during mid-embryonic development, showing the major divisions and subdivisions of the forebrain. Note that the diencephalon proper is subdivided into three major transverse segments, called prosomeres 1, 2 and 3. The dorsal (alar) parts of prosomeres 2 and 3 give rise to the thalamus and prethalamus, respectively. In contrast, the hypothalamus develops from the secondary prosencephalon (i.e., rostral to the diencephalon proper). Since the longitudinal axis is highly bended in the forebrain, the hypothalamus appears located

across vertebrates. Subdivisions/units with identical position and molecular profile in different vertebrate groups, if traced back to a common ancestor (using cladistic analysis), are considered field ►homologues [7]. Given that molecular brain subdivisions are the basic units of development and evolution, any homology consideration of specific cell groups should start by analyzing whether the neurons under study originate in the same molecular compartment or, in the adult, are located in the same radial unit. However, although less likely, the latter may have changed in evolution due to tangential migration. In that case, the embryological origin is a prevalent criterion for homology consideration.

## Formation and General Disposition of Major Forebrain Regions

During the course of development, the neural plate folds up and fuses dorsally forming the neural tube (a process called neurulation) (Figs. 3 and 4).

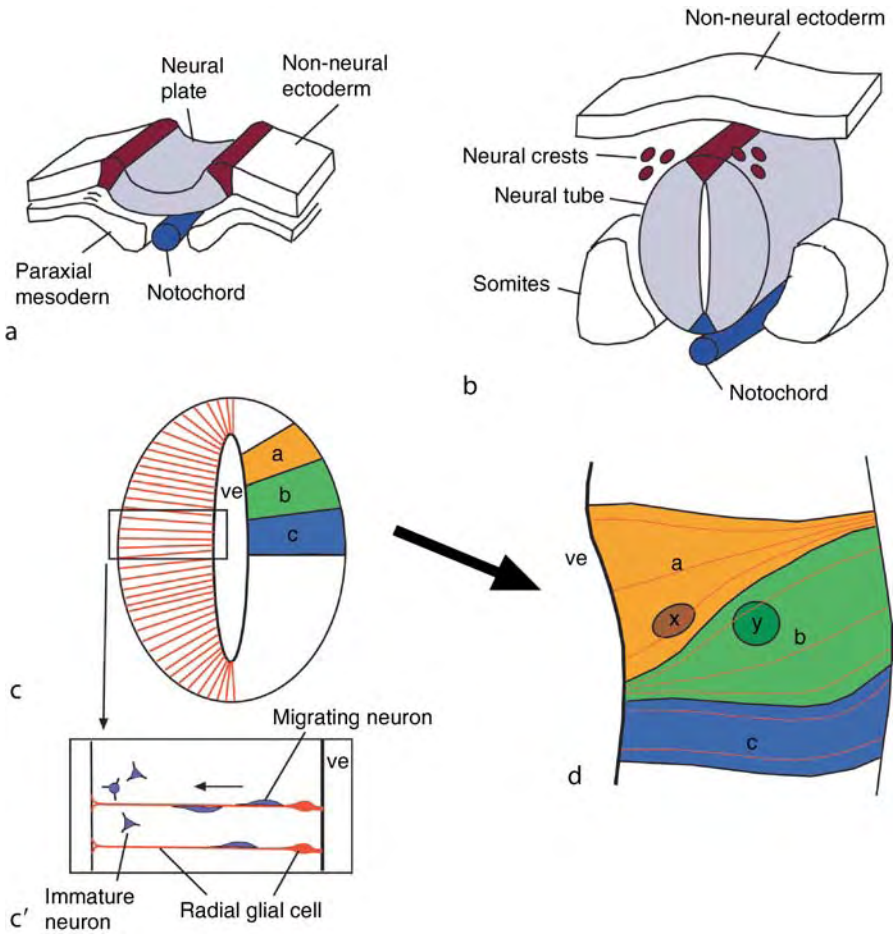
As a consequence, the lateral part of the neural plate is going to become dorsal, whereas the medial part of the neural plate becomes ventral in the neural tube. Shortly after neural tube closure, the anterior part of the neural tube starts to show three primary vesicles, forebrain, midbrain and hindbrain, which become morphologically visible due to differential growth; the forebrain constitutes the rostralmost of them (Fig. 2). The forebrain becomes later subdivided into the ►diencephalon proper (caudally) and the ►secondary prosencephalon (rostrally) (Fig. 2). Regardless the observation of a clear "forebrain vesicle" as defined by classical embryologists (this is clear in amniotes, but less so in fish), from a molecular point of view, the forebrain is the domain of the anterior neural plate/tube showing expression of Pax6 in the alar territory, a situation that is highly conserved in all vertebrates studied thus far, from the lamprey (a jawless fish) to the mouse [4,10].

Simultaneous to the appearance of the forebrain vesicle, the anterior neural plate/tube begins to subdivide through gradual steps into distinct longitudinal (DV) and transverse (AP) subdivisions, under the action of different regulatory signals and transcription factors (see below). Transverse and longitudinal subdivisions were initially proposed in the forebrain based on classical embryological studies, but their existence has been unequivocally shown by modern genetic evidence and fate-map analysis [4,11]. All these data together have led to the proposal by Puelles and Rubenstein of a parcellation model for the forebrain, called the prosomeric model, according to which the forebrain of different vertebrates becomes subdivided during development into a comparable set of longitudinal and transverse subdivisions [reviewed in 4]. The same set of subdivisions has been observed in the forebrain of all vertebrates, from the lamprey to mouse and human, and subdivisions in different species with the same position and basic molecular features are considered field homologues [4]. Therefore, this parcellation model is not only very useful for understanding the anatomical and functional organization of the forebrain and its development, but also for studies of forebrain evolution. For example, by using the model one realizes that major fiber tracts usually follow trajectories parallel to boundaries between domains. Moreover, the model provides a framework for understanding gene expression patterns and the effects of null mutations of specific regulatory genes.

As in the rest of the neural tube, the major longitudinal (DV) subdivisions of the forebrain are the roof, alar, basal and floor plates (Fig. 2; see next section). Transverse domains or segments of the forebrain are the ►prosomeres (as initially called by Puelles, Rubenstein and colleagues in the prosomeric model). These are orthogonal to the longitudinal axis, which as explained below is highly bended in the forebrain [4] (Fig. 2). Each prosomere contains roof, alar, basal and floor subdivisions.

In the caudal forebrain, the diencephalon proper subdivides into three prosomeres, called prosomeres 1–3 [p1, p2, p3] from caudal to rostral (Fig. 2). The main derivatives of each subdivision are shown in Fig. 2. Briefly, the alar part of p1 includes the pretectum, the alar part of p2 includes the thalamus and epithalamus, whereas the alar part of p3 includes the prethalamus (previously called ventral thalamus) and the thalamic eminence. According to this model (supported by molecular and fate-map data), the thalamus and prethalamus are located caudal and rostral, respectively,

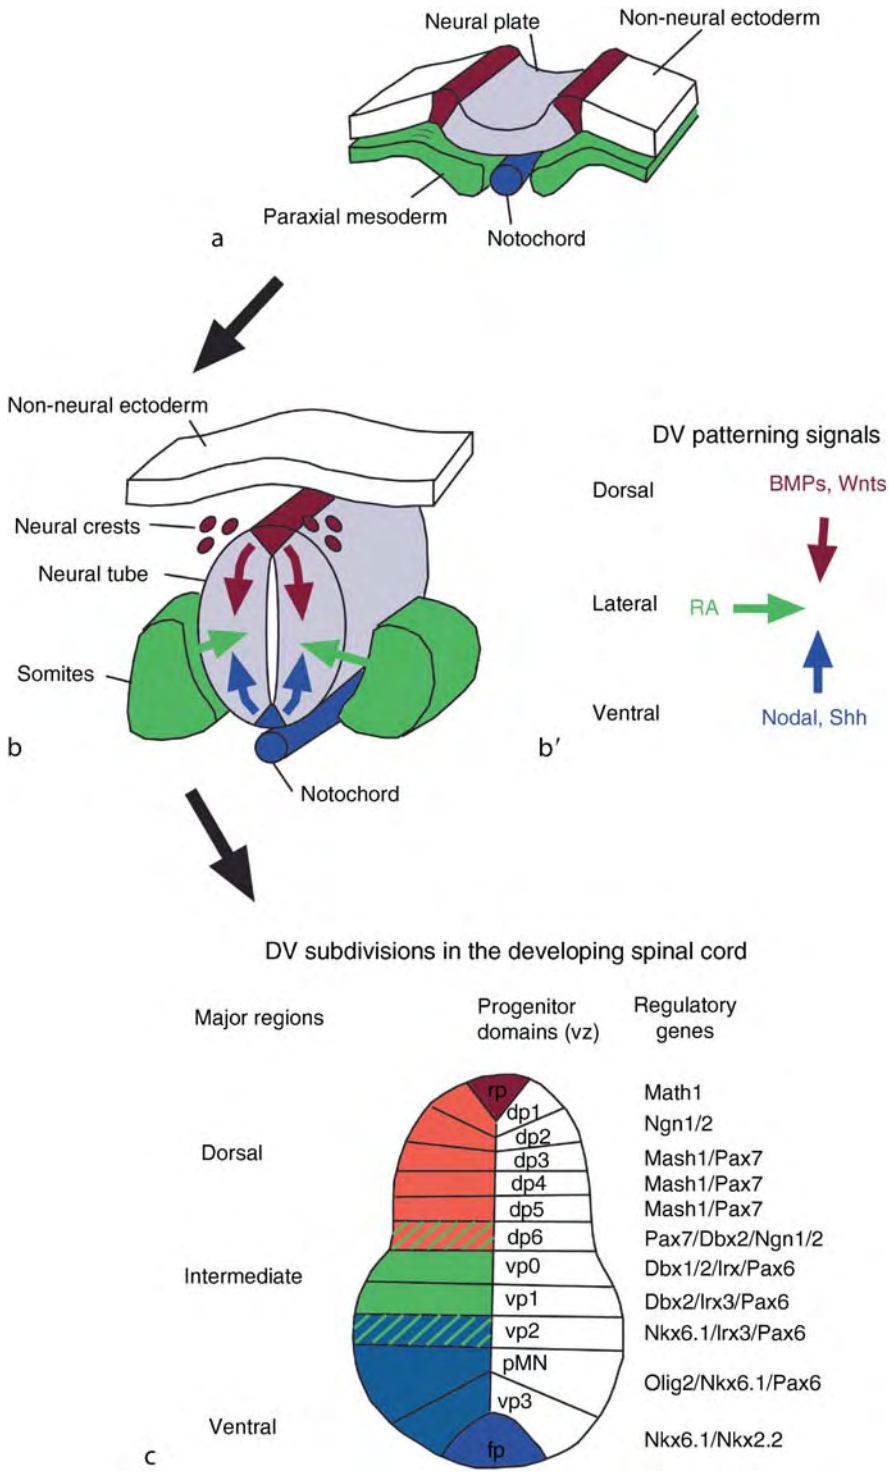
below the prethalamus, and the prethalamus below the thalamus. For this reason, in classical studies the hypothalamus is considered to represent the "ventral diencephalon," the prethalamus is called the "ventral thalamus" and the thalamus is called "dorsal thalamus." Developmental studies indicate that these conceptions are wrong. Instead, the prethalamus is located rostral to the thalamus, whereas the hypothalamus is rostral to the diencephalon proper. Abbreviations: *Emt* eminentia thalami; *Ept* epithalamus; *fr* fasciculus retroflexus; *Ma* mammillary hypothalamic region; *oc* optic chiasm; *Pa* pallidum; *pc* posterior commissure; *POa* anterior preoptic area; *Pt* pretectum; *PTh* prethalamus; *PV* paraventricular hypothalamic nucleus; *SCN* suprachiasmatic nucleus; *SNc* substantia nigra pars compacta (A9 dopaminergic cell group); *STN* subthalamic nucleus; *Str* striatum; *Th* thalamus; *Tu* tuberal hypothalamic region (it contains the ventromedial hypothalamic nucleus); *VTA* ventral tegmental area (A10 dopaminergic cell group).



**Evolution and Embryological Development of Forebrain. Figure 3** (a, b) Schemes showing the neural plate during the process of neurulation (a), and the neural tube after closure (b); (c, c′, d) Formation of ►radial histogenetic domains. Morphogenetic compartments are initially established in the neuroepithelium along the anteroposterior (*AP*) and dorsoventral (*DV*) axis. Since cells produced in each compartment migrate into the mantle following primarily radial glial fibers (c, c′), the bidimensional compartments of the neuroepithelium are transformed into tridimensional radial units. The topological position of each unit (i.e. its relative position within the neural tube, and with respect to neighbour units) remains unvariable independent of deformations taking place during subsequent development (d). For example, if units a, b, and c (orange, green and blue in panel c) are initially located in dorsal, intermediate and ventral positions with respect to each other, this remains the same in the mature neural tube (panel d), and so do their derivatives (nucleus x is dorsal to nucleus y). In contrast, based only on topographic position, nucleus x is medial to nucleus y, providing a less accurate information on the real position of nuclei. Abbreviations: *ve* ventricle.

to the p2/p3 boundary (instead of dorsal and ventral, as classically considered). The roof plate also appears to produce specific cell groups at each rostrocaudal level, such as the subcommissural organ in p1, the pineal gland in p2 and choroid tissue in p3. The basal and floor plates of p1-p3 include several prerubral reticular groups and a major diencephalic part of the A9-A10 dopaminergic cell groups (i.e., a large part of the substantia nigra pars compacta and ventral tegmental area).

Rostral to the diencephalon proper is the secondary prosencephalon, giving rise to the hypothalamus ventrally, the eye vesicle dorsolaterally, and the telencephalon dorsally (Fig. 2). It also produces the choroid tissue related to the lateral ventricles (in the telencephalon), which is a roof plate derivative, and the neurohypophysis, which derives from the floor plate. The hypothalamus includes alar and basal components, but the eye field and the telencephalon are exclusively derived from the alar region. The alar hypothalamus includes the suprachiasmatic, supraoptic and paraventricular hypothalamic nuclei (among other nuclei). The basal hypothalamus includes the retrochiasmatic, ventromedial, and mammillary hypothalamic nuclei (among other). It also includes the subthalamic nucleus.



**Evolution and Embryological Development of Forebrain. Figure 4** Schemes representing the mechanisms of dorsoventral (*DV*) patterning and formation of compartments in the caudal neural tube. Patterning along the *DV* axis occurs by the confluence of ventral, dorsal and lateral signals (in the schemes, these are represented in blue, purple and green, respectively). Ventral signals initially originate in the ►notochord underlying the neural plate/tube and include nodal and Shh. Later, ventral signals of Shh also originate in the floor plate. Ventral signals induce the expression of specific transcription factors in the ventral tube, such as Nkx2.2 and Nkx6.1, which trigger the formation of specific ventral cell types (motorneurons or specific ventral interneurons). Dorsal signals (BMPs, Wnts) initially originate in the non-neural ectoderm and later also in the roof plate, and induce the expression of transcription

The telencephalon is located dorsal to the hypothalamus and includes two major subdivisions: pallium and subpallium (Fig. 2). The pallium gives rise to the cortical regions, olfactory bulb, claustrum and pallial amygdala in mammals, and to the cortical/pallial regions in non-mammals (including the dorsal ventricular ridge in birds and reptiles). In different vertebrates, the subpallium is going to produce the basal ganglia, the centromedial-extended amygdala, the cholinergic corticopetal cell groups of the basal telencephalon and most of the septum.

## DV Patterning

### *Classical DV Subdivisions*

Classically, the neural tube has been subdivided into four major longitudinal domains in all vertebrates: floor plate, basal plate, alar plate and roof plate (from ventral to dorsal; Fig. 4). In general, these major regions are morphologically distinct during development. For example, at caudal levels the roof and floor plates show negligible proliferation and include cells that will become glial. In contrast, the alar and basal plates show abundant proliferation and will produce numerous neuroblasts that, at caudal levels, will become either sensory or motor neurons, respectively [6]. Recent studies based on expression of developmental regulatory genes indicate that the classical DV subdivision of the neural tube is roughly true. For example, during development the roof plate is induced to express bone morphogenetic proteins (BMPs) and Wnts, most of the alar plate is generally characterized by expression of the transcription factor Pax7, an important part of the basal plate expresses Nkx (NK family) transcription factors, whereas the floor plate is induced to express Sonic hedgehog (Shh) (Fig. 4). Expression of regulatory genes also constitutes a great help for correctly identifying major DV subdivisions at forebrain levels, as explained in detail below [4].

However, genetic and experimental data indicate that the DV compartmentation of the neural tube is more complex that this, and it involves the confluence of different external signals that ultimately produce the formation of multiple compartments along the DV axis [6,12] (explained in the next section).

### *Confluence of Dorsal, Lateral and Ventral Signals and Formation of Multiple Compartments*

The initial stages of neural patterning are controlled by signaling proteins (morphogens) that are secreted from primary organizers (in the adjacent mesoderm or non-neural ectoderm) and spread over variable distances across neural tissue [12]. Later, the signals are also produced locally from the roof and floor plates. These signals are going to induce, in the presence of specific receptors in the tissue, the expression of specific ►transcription factors in a concentration-dependent manner [6,12]. The induced transcription factors become the effectors for the specification and subsequent formation of specific neural domains. Induction also involves qualitative differences in the effects of distinct signaling proteins, as well as temporal changes in the response of the tissue. This process starts prior to neurulation and is remarkably similar in different vertebrates, from zebrafish to mouse [6,12]. It is also highly similar from caudal to rostral parts of the neural plate/tube.

The ventral signals initially originate from the ►notochord or the prechordal plate/rostral mesendoderm (at rostral levels) underlying the neural plate, and later also in the ventral neural tube (floor plate and, at rostral levels, the basal plate), and include Sonic hedgehog (Shh) and Nodal [12] (Fig. 4). Dorsal signals originate in the non-neural ectoderm adjacent to the tube, and later also in the dorsal neural tube (roof plate) (Fig. 4), and include bone morphogenetic proteins (BMPs) and Wnt proteins (the latter are primarily involved in proliferation, but recent studies indicate that some Wnt proteins, such as Wnt1 or Wnt3a, also play a role in dorsal patterning, as recently reviewed by Victor Chizhikov and Kathleen Millen and also by Clifton Ragsdale and Elizabeth Grove) [6]. Lateral signals originate in the paraxial mesoderm (somites) or, at rostral levels, the ectoderm adjacent to the neural tube at early stages (including the olfactory placode, or mesenchymal cells inside it), and include retinoid acid (RA) [12] (Fig. 4). Ventral and lateral signals also include antagonists of BMP-mediated dorsal signals, such as noggin, chordin and follistatin. Shh induces the expression of Nkx transcription factors in the ventral tube, and is required for the ventral midline formation and for ventral neural fate specification. In the absence of Shh signals, spinal motoneurons and several ventral interneuron subtypes are not formed, and animals are born with cyclopia and holoprosencephaly (for example, in Shh-►knockout or null mutant mice, or in humans affected with a mutation disrupting Shh signaling) [12]. It appears that Shh acts by neutralizing the repressive form of Gli transcription factors (Gli3, which is promoted by BMPs), and by inducing the activating forms of Gli that mediate the subsequent

factors typical of the alar plate, such as Pax7. Lateral signals of retinoic acid (RA) originate in the paraxial mesoderm (somites), and induce the expression of Dbx1/2 and Iroquois 3 (Irx3) in an intermediate sector of the neural tube, thus triggering the formation of specific neurons in this position. Abbreviations: *dp1-dp6* dorsal progenitor domains 1 through 6; *pMN* motorneuron progenitor domain; *vp0-vp3* ventral progenitor domains 0 through 3.

molecular parcellation and specification of the ventral neural tube [12]. Once Gli3 is inactivated, the role of Shh for ventral specification is largely dispensable. Nodal acts upstream of Shh, and is responsible for the induction of Shh expression and specification of the most ventral part of the neural plate/tube [12]. Mutations disrupting Nodal signaling abolish Shh expression in the ventral neural tube and reproduce the phenotype of Shh null mutant. On the other hand, BMP dorsal signals promote expression of Pax7 and Msx1/2 in the dorsal region (among others), whereas RA lateral signals promote expression of Dbx1/2, Iroquois 3 (Irx3) and Pax6 in an intermediate region in the caudal neural tube [6].

Thus, in general terms, the confuence of signals induces the formation of three major subdivisions located between the roof and floor plates, namely dorsal, intermediate and ventral regions, and these can be found from caudal to rostral regions of the neural tube [12]. However, more subdivisions are formed at caudal and rostral levels. For example, the concerted action of ventral, dorsal and lateral signals will ultimately produce the parcellation and specification of at least thirteen [13] distinct DV molecular sectors in the spinal cord, each characterized by a specific combination of transcription factors and producing a specific set of neurons [6,12] (Fig. 4).

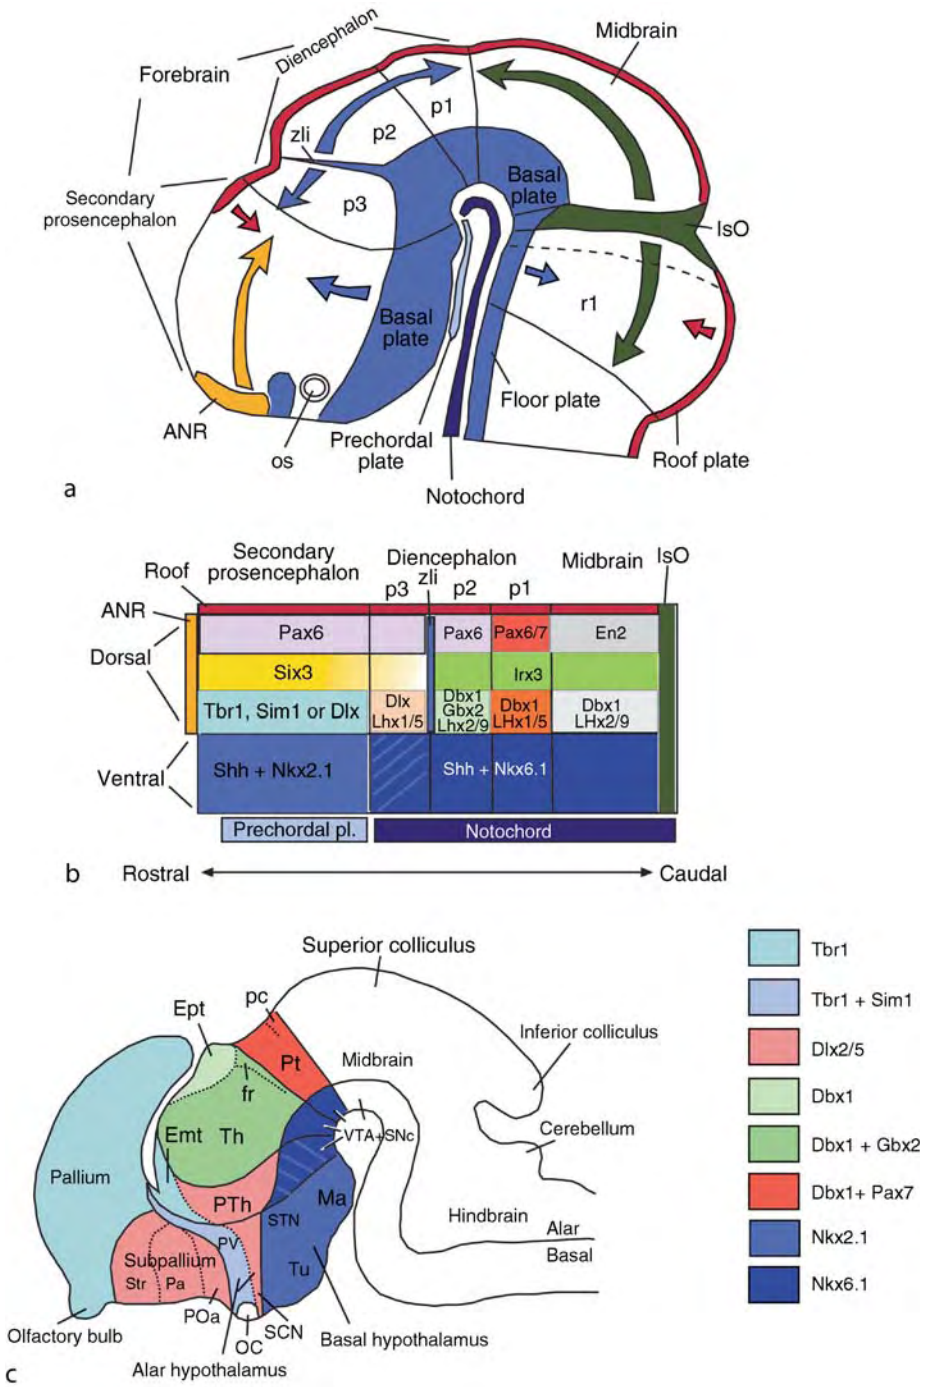
As noted above, the molecular mechanisms for dorsoventral patterning are generally similar from caudal to rostral levels of the neural plate/tube (Fig. 5), and involve similar ventral, dorsal and lateral inductive signals from Shh/Nodal, BMP/Wnt and retinoid acid, respectively. However, although following a general rule, different transcription factors (sometimes different members of the same family) are induced along the rostrocaudal axis (Fig. 5), indicating intrinsic differences between rostral and caudal levels of the neuroepithelium and/or the existence of other signals acting on the rostrocaudal dimension (such as FGF8; see next section). In the forebrain, as in the caudal neural tube, signals from the roof plate (which include BMPs and Wnts) appear to be important for dorsal patterning and for the formation of roof specializations of the diencephalon and secondary prosencephalon (choroid plexus, pineal gland and subcommissural organ) (reviewed by Ragsdale and Grove, 2001; Chizhikov and Millen, 2005). In fish and mouse, these structures are not formed or are defective following diencephalic roof plate loss, or after abrogation of BMP or Wnt3a signaling in the telencephalon. In the diencephalon, this also produces downregulation of Pax6/7 in the adjacent alar plate. In the telencephalon, Wnt signals from the roof appear to be important for inducing Lhx2, Ngn2 and Pax6 in the adjacent dorsomedial pallium. Moreover, mice lacking Wnt3a (but not Wnt8b) have a near complete deletion of the hippocampus. On the other hand, the basal forebrain expresses Nkx family transcription factors from rostral to caudal levels, which are induced by Shh ventral signals, resembling the situation at caudal levels [12]. Again, rostrocaudal differences in the expression of Nkx factors likely reflect the existence of additional signals acting on the AP dimension, as well as changes in the ventralizing signals along the AP axis (this is explained in more detail in a separate section).

In addition to dorsal and ventral signals, RA lateral signals appear to play a role in patterning an intermediate sector of the forebrain. In the telencephalon, RA signals induce the expression of Pax6 and Dlx transcription factors in the intermediate sector encompassing the ventral pallium and striatal subdivision (Dlx genes are induced in the striatal subdivision, whereas Pax6 is strongly induced in the ventrolateral pallium, with decreasing gradients towards the striatum and the dorsomedial pallium) [12]. As in the spinal cord, RA may also induce Dbx1 expression in the telencephalic ventral pallium. In the diencephalon, these signals may be important for induction of Pax6/7 in the alar plate (from the alar hypothalamus to the pretectum), Dlx in the prethalamus and part of alar hypothalamus, and Dbx1 in the thalamus and pretectum, although this needs to be investigated. The effect of different signals on telencephalic patterning will be explained in more detail in a separate section.

### The Longitudinal Axis

Analysis of molecular signals involved in DV patterning along the rostrocaudal axis, such as Shh, helps to understand the disposition of the longitudinal axis along the entire length of the neural tube (Fig. 5). This is particularly relevant in the forebrain, where the axis is extremely bended (specially in mammals and birds) obscuring the interpretation of anatomical data and the comparison across vertebrates. Mechanisms involved in DV patterning are highly similar across vertebrates, from fish to mammals [12], and so are the resulting DV brain domains. Therefore, the correct identification of the longitudinal axis and DV domains along the axis is extremely relevant for studying forebrain evolution and also for interpreting the action of patterning or other developmental regulatory genes. Due to the inclination of the longitudinal axis, the diencephalic vesicle (giving rise to the thalamus) is going to lie above the secondary prosencephalon (giving rise to the hypothalamus and telencephalon) (Fig. 5).

For this reason, classical studies have considered the thalamus as dorsal diencephalon and the hypothalamus as ventral diencephalon. This interpretation is now considered erroneous, and in the new scheme the diencephalon proper (including the thalamus) is caudal to the hypothalamus [4]. For this reason, and to keep partially with the classical terms, in some modern text



**Evolution and Embryological Development of Forebrain. Figure 5** (a) Lateral schematic view of the embryonic brain, representing some of the organizer centers and signals that operate for patterning the forebrain along the *DV* and *AP* axis. As at caudal levels, dorsal signals initially originate in the non-neural ectoderm and later in the roof plate, and include BMPs and Wnts (purple in the scheme). Ventral signals initially originate in the notochord (caudally) and prechordal plate (rostrally), and include Nodal and Shh. Nodal induces the expression of Shh in the ventral forebrain (first including both the floor and basal plate, but later only the basal plate), which becomes a secondary source of ventral signals (blue arrows in the scheme). Later, Shh signals extend dorsally in the zona limitans intrathalamica (*zli*), a secondary organizer center at the p2/p3 boundary, from which signals emanate caudally and rostrally. Rostral (anterior) signals originate in the anterior neural ridge or ANR and initially include Wnt antagonists (such as Tlc), which oppose to Wnts expressed in the caudal forebrain. These opposing gradients are going to induce the expression of Irx3 caudally and Six3 rostrally (see panel b). The boundary between Irx3 and Six3 expression domains

books or articles the hypothalamus is sometimes considered as the rostral diencephalon (although derived from the secondary prosencephalon and not from the diencephalic vesicle), whereas the thalamus is considered part of the caudal diencephalon. The disposition of forebrain subdivisions with respect to the AP axis is described in detail elsewhere in the text, and its patterning is explained in the following section.

## AP Patterning

From a molecular point of view, the forebrain parcellation along the AP axis occurs by two major factors: 1) the distinct action of prechordal plate versus notochord signals; 2) the action of signals derived from secondary organizers, such as the isthmic organizer (IsO), the zona limitans intrathalamica (zli) and the anterior neural ridge (ANR) [4,13] (Fig. 5).

It appears that signals derived from either the notochord or the prechordal plate are somewhat different and produce different effects on the expression of transcription factors in the overlying neural plate/tube. For example, it appears that Shh signals are primarily involved in patterning the caudal plate, whereas Nodal plays a dominant role in the anterior plate (recently reviewed by Marysia Placzek and James Briscoe). Interestingly, the transition from the notochord to the prechordal plate roughly coincides with a spike-like dorsal extension of basal molecular features, secondarily formed at the zona limitans intrathalamica (zli; the transverse boundary between thalamus and prethalamus) (Fig. 5). Actually, the zli is slightly caudal to the notochord-prechordal plate transition level, which is coincident with the boundary between p3 and the hypothalamus [4,11], as explained later in the text. The zli shows a core of Shh expression that is covered by a band (shell) of Nkx2.2 expression, which is typical of the basal plate [4,13]. Curiously, at this same position the dorsal signals typical of the diencephalic roof plate (such as Wnt1) show an opposed, although smaller ventral spike [4,13]. Thus, the zli constitutes a secondary organizer center from which signals emanate caudalwards and rostralwards, possibly inducing, modulating or refining the expression of specific transcription factors and subsequent parcellation in adjacent territories (Fig. 5).

Before the zli is formed, other local organizers are present, the ANR and the IsO, which produce signals that contribute to the AP patterning of the forebrain, including the formation of the p3/p2 boundary and the zli (Fig. 5). It appears that early signals from the ANR play a key role. The earliest ANR signals include antagonists of Wnt proteins (secreted Frizzled-related proteins) such as Tlc, which are opposed to Wnt proteins produced in the caudal forebrain [5]. The secreted Frizzled-related proteins antagonize Wnt activity by binding to Wnt proteins and sequestering them. Wnt proteins are going to caudalize the forebrain (forming the diencephalon proper), whereas Wnt antagonists produced at the ANR are important for the formation of rostral forebrain, including the telencephalon, eye field and hypothalamus. Zebrafish embryos that carry a mutation affecting the intracellular Wnt pathway (Masterblind mutants) show loss of telencephalon and eyes, and expansion of the diencephalon proper to the front of the neural plate. That Wnt signal promote posterior forebrain fates (diencephalon proper) but suppresses anterior forebrain fates is also supported by studies in frog, chick and mouse [5].

Interestingly, during embryonic development, caudal and rostral forebrain regions express different transcription factors in response to Wnt signaling [5]. It appears that Iroquois 3 (Irx3) is expressed in response to high levels of Wnt in the caudal forebrain, and constitutes an important effector of Wnt signaling for posterior forebrain formation (Fig. 5). In contrast, the rostral forebrain is characterized by expression of the transcription factor Sine-oculis (Six; in particular Six3 and related proteins) (Fig. 5), which is extremely important for rostral forebrain formation, and is expressed in areas of low Wnt activity [5]. Removal of the ANR (the source of Wnt antagonists) or enhanced Wnt activity suppresses Six3 expression in the anterior neural plate.

Initially, Six3 expression shows a caudal boundary adjacent to the rostral limit of Irx3. It appears that the mutual repression of Six3 and Irx3 is going to determine the formation of the p3/p2 boundary (where the zli locates). The posterior border of Six3 expression is dynamic and regresses rostrally over time, leaving the prethalamus free of expression. As note above, it is likely that the zli is a source of signals (including Shh) that help to refine patterning of the alar diencephalon [5,13]. Signals from the zli possibly act in conjunction with other signals from the ANR (rostrally) and IsO

appears to determine the formation of the p2/p3 boundary, and perhaps the formation of the zona limitans intrathalamica (zli). Subsequently, the confluence of ANR versus zli signals rostrally, and zli versus isthmic organizer (IsO) signals caudally contribute to further parcellation of the forebrain. Later, the ANR produces FGF8 signals that are important for patterning the telencephalon. (b) Diagram representing the organizer centers and molecular compartments that are formed in the forebrain from rostral to caudal levels. (c) Lateral schematic view of the major molecular compartments observed in the mouse forebrain at mid-embryonic development. Each major compartment is characterized by expression of a specific combination of transcription factors, and is going to produce a specific set of neurons. For abbreviations see Figure 2 legend.

(caudally) and under the action of specific effector transcription factors are going to produce further partition of the forebrain in smaller subdivisions. Previous studies have indicated that IsO signals include FGF8 and Wnt1 and have an effect on patterning the territory rostral and caudal to isthmus [13]. The confuence of zli and IsO signals may be important for establishing the boundary between pretectum (diencephalon) and midbrain. On the other hand, the confuence of zli and ANR signals may be important for establishing the boundary between prethalamus and hypothalamus (or between p3 and secondary prosencephalon, in general).

In addition to Wnt antagonists, the ANR expresses FGF signals (including FGF8) that seem to be very important for patterning the telencephalon, eye and hypothalamus [5,12,13]. It appears that the expression of FGF by ANR is a downstream consequence of inhibition of Wnt activity by local antagonists [5]. The role of FGF on telencephalic patterning is explained in more detail in a separate section.

## Patterning and Formation of Specific Cell Groups in the Forebrain Basal/Ventral Region. Evolutionary Trends and Questions

The basal region of the forebrain shows two major subdivisions, characterized by distinct expression of transcription factors and by production of distinct cell groups. These two subdivisions are located caudal or rostral to the boundary between diencephalon and secondary prosencephalon (i.e. between p3 and hypothalamus).

The basal region (floor and basal plates) caudal to this boundary is epichordal, expresses Nkx6.1 [4], and produces dopaminergic neurons of the substantia nigra and ventral tegmental area (A9 and A10 groups) in different vertebrates (Figs. 5 and 6) [4,14; see also reviews by Marín et al., 1998, and Reiner et al., 1998].

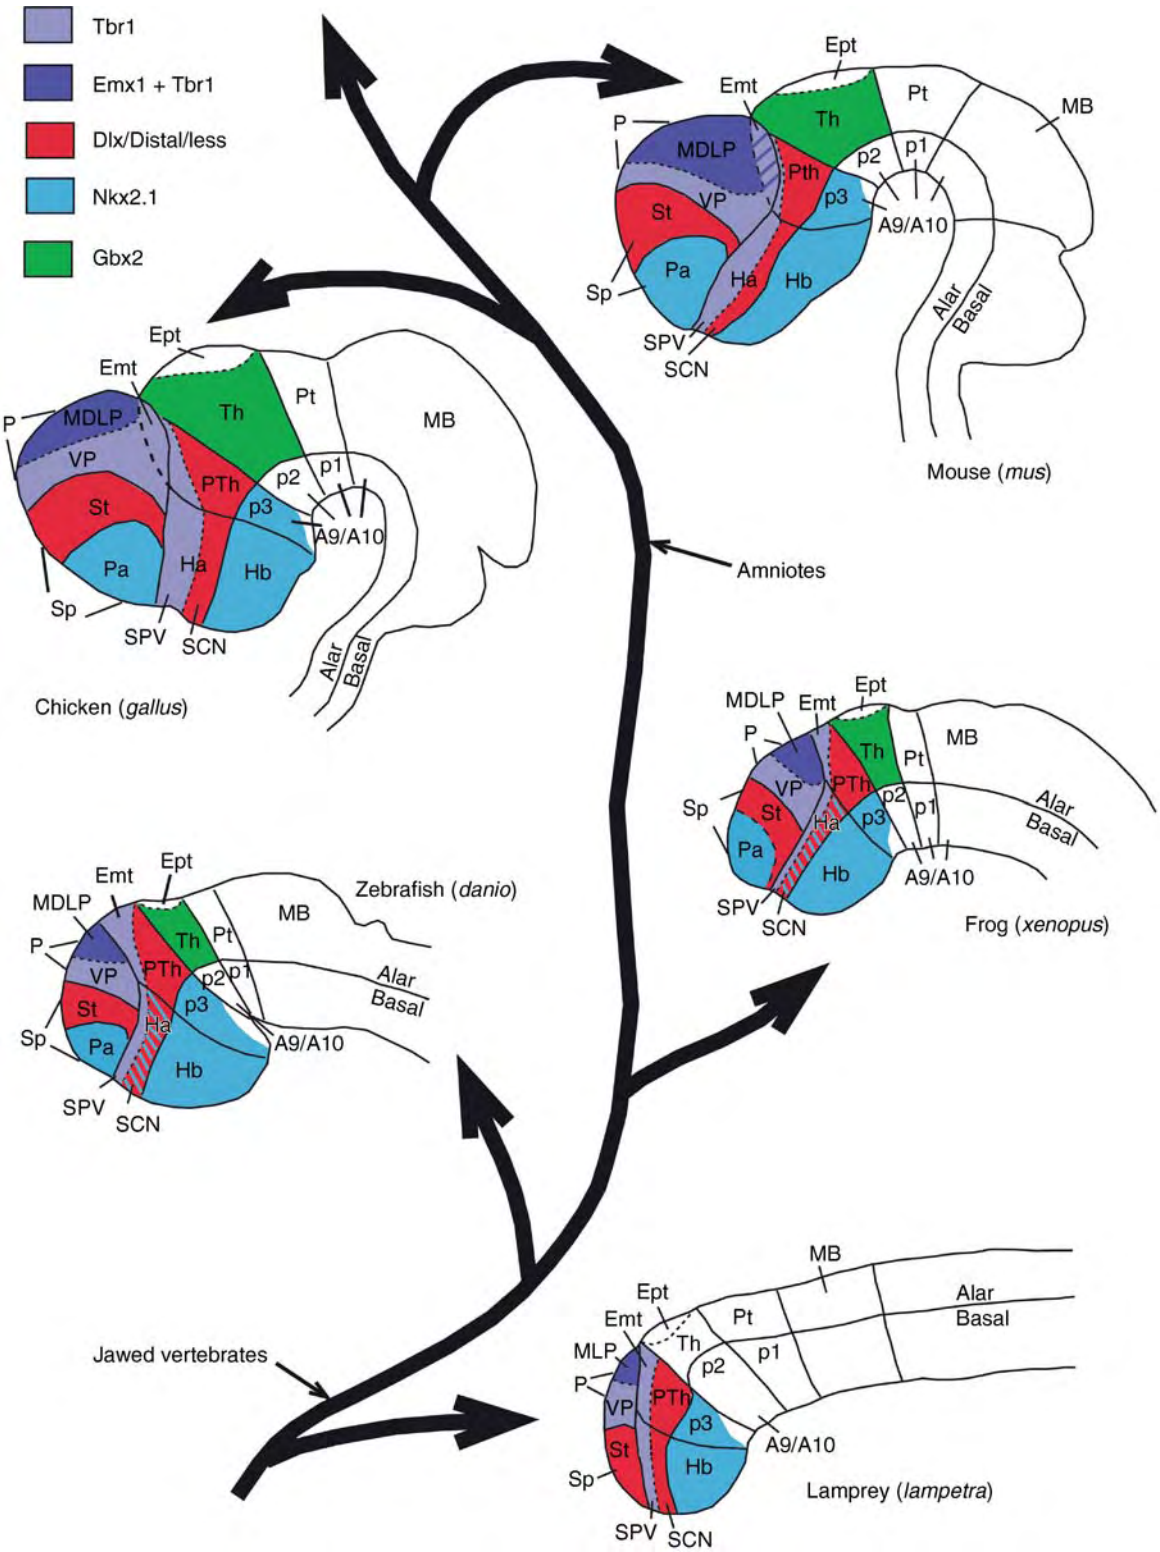
The dopaminergic neurons in the meso-diencephalic tegmentum appear to be induced by cooperative signals of Shh from the floor plate/notochord and FGF8 from the IsO [14]. The differentiation of dopaminergic neurons requires the expression of the regulatory genes Nurr1 and Pitx3 [14]. Pitx3 is highly conserved in vertebrates, but its relation to the differentiation of dopaminergic neurons in non-mammals requires further investigation. An interesting aspect of the dopaminergic neurons of this region is that in fish they are only formed in the diencephalon ventral to p2 (posterior tubercle) (Fig. 6). In amphibians, birds and mammals, these cells extend caudally and also form in the ventral parts of p1 and midbrain (Fig. 6). This suggests that rostral diencephalic dopaminergic cells are evolutionarily older. In mammals, the rostral dopaminergic cells are also observed at earlier developmental stages than the caudal ones. In some reptiles (such as the lizard *Gallotia*), dopaminergic neurons are only formed in p1 and midbrain, and this is presumably due to secondary loss of the rostralmost group in evolution. Thus, dopaminergic cells of the meso-diencephalic tegmentum have undergone some changes in evolution regarding where they are formed, but it is currently unclear what has caused these changes.

The basal region rostral to the p3/hypothalamic boundary is primarily under the influence of prechordal plate/rostral mesendoderm signals, expresses Nkx2.1, and produces the ventral hypothalamus (including the neurohypophysis, and the ventromedial/tuberal, mammillary and tuberomammillary hypothalamic regions) (Figs. 5 and 6). Expression of Nkx2.1 in this ventral region is induced by prechordal Shh signals. Based on the effect of lack of function or hypofunction of Nkx2.1 in mouse and frog, this transcription factor appears to play a key role in the specification and formation of the ventral hypothalamus in different vertebrates [15,16]. In some fish, such as the teleost zebrafish, the ventral hypothalamus is greatly developed (relative to other forebrain domains). In adult teleosts, the ventral hypothalamus contains many specific centers related to the gustatory/visceral system (this system is greatly developed in ray-finned fishes, particularly in some teleost species). It is unknown what triggered the great development and growth of this forebrain region in these animals. It possibly was a multifactorial event, but it surely involved changes affecting the proliferation and morphogenesis in this region. In relation to this, it is noteworthy to mention that the prospective ventral hypothalamus expresses two copies of Nkx2.1 in zebrafish, Nkx2.1a and Nkx2.1b [15]. Since during early development these genes are expressed in the proliferative zone (ventricular zone), this may have resulted in changes in proliferation (higher proliferation rate or during a longer period), producing an overgrown region.

## Patterning and Formation of the Dorsal Diencephalon and Hypothalamus. Evolutionary Trends and Questions

As noted above, patterning of the alar diencephalon and hypothalamus is induced by confluence of dorsal signals from the roof plate (BMP, Wnt), lateral signals (possibly mediated by RA), anterior signals from the ANR (including Wnt antagonists and, later, FGF8), posterior signals from the IsO (Wnt, FGF8), and anterior/posterior signals from the zli (including Shh; Fig. 5) (see above). The confluence of these signals ultimately produces the parcellation of the alar territory into four major transverse subdivisions: alar hypothalamus and dorsal parts of p3, p2, and p1 (Fig. 5). These major subdivisions are present in all vertebrates, from jawless fish to mammals (Fig. 6). Each major subdivision is further subdivided into smaller longitudinal or transverse

E



**Evolution and Embryological Development of Forebrain. Figure 6** Phylogenetic diagram representing the embryonic forebrain of representative species of different vertebrate groups, including a jawless fish (the lamprey), a teleost fish (the zebrafish), an anuran amphibian (the frog *Xenopus*), a bird (the chicken), and a mammal (the mouse). In all species, the forebrain includes comparable molecular compartments, showing identical position and similar expression of transcription factors. Nevertheless, during subsequent development each compartment shows varying

subdomains, which show distinct gene expression. A similar set of these smaller subdomains appears to be present in all tetrapods (from amphibians to mammals), although their relative size changes depending on the group [17].

### Subdomains in the Alar Diencephalon

For example, in p3 there is a dorsal subdomain expressing Tbr1 that gives rise to the eminentia thalami and a ventral subdomain expressing Dlx2/5 that gives rise to the prethalamus [4,8] (Figs. 5 and 6). Like other forebrain regions expressing Dlx genes, the prethalamus is rich in GABAergic neurons, whereas the eminentia thalami contains glutamatergic neurons (as is typical in domains expressing Tbr1).

On the other hand, p2 shows several subdomains that give rise to the epithalamus and thalamus. The thalamus expresses Gbx2 and Lhx2/9 but lacks Dlx expression and is typically rich in glutamatergic neurons that project to the telencephalon (including the cortex/pallium) (Figs. 5 and 6). The thalamus is subdivided into even smaller subdomains that express different combinations of *Cadherin* genes or proteins, involved in later morphogenesis events [17]. Each thalamic subdomain produces cell populations that are going to project to a specific part of the telencephalic pallium/cortex [17]. For example, the dorsal thalamic subdomain gives rise to nuclei globally included in the "lemnothalamus" [18] and projects to the dorsomedial pallium. The intermediate and ventral thalamic subdivisions produce nuclei that globally correspond to the "collothalamus," and project to the lateroventral pallium. In addition, the area adjacent to the Shh-expression of the zli is induced by Shh to express Nkx2.2 (leading to secondary downregulation of Pax6 expression), and this area has been proposed to be the source of the subpopulation of GABAergic interneurons observed in the thalamus [4]. Interestingly, the dorsal thalamic subdomain is greatly developed in mammals, and this is correlated to the great development of the dorsal pallium (neocortex) in these animals. In contrast, the great development of the intermediate/ventral subdomains in birds and reptiles is correlated with the great development of the ventrolateral pallium (DVR) in these sauropsids. Given this evidence, it would be tempting to suggest that the expansion of specific thalamic subdomains triggered the expansion of specific cortical/pallial subdivisions. However, patterning and regionalization of the thalamus and the cortex/pallium appear to be primarily induced by local or intrinsic factors [16]. This is partially supported by the analysis of mice lacking Gbx2, in which thalamocortical axons fail to reach their target, but still the cerebral cortex is normally patterned. Nevertheless, it appears that growing thalamocortical axons release a mitogenic factor, which may affect the proliferation and growth of the targeted cortical areas.

When studying the development and organization of the thalamus in different vertebrates, two major questions are raised: 1) what produced the thalamic enlargement during evolution of amniotes, but specially in birds and mammals?, and 2) what produced the distinct expansion of different thalamic subdomains in different amniotes. Regarding the first question, a recent study has suggested that a reduction of the Nkx2.1 expression in the alar hypothalamus during evolution to amniotes (see below) may have produced an expansion on the territory caudal to it, including the thalamus [15]. Regarding the second question, we are still far from understanding what produces the subdivision of the thalamus into smaller domains. Only after we understand this, we will be able to make testable proposals.

### Subdomains in the Alar Hypothalamus

Similar to the major subdivisions of the dorsal diencephalon, the alar hypothalamus also is subdividied into smaller subdomains, which show distinct molecular features and produce different cell groups. For example, it shows the following two major longitudinal subdomains (Figs. 5 and 6):

1. a dorsal subdomain adjacent to the subpallial preoptic area (ventral to it, from a topological point of view), that expresses the transcription factors Tbr1, Sim1 (Singled-minded 1), and Otp (Orthopedia) and is rich in glutamatergic neurons (as typical of forebrain domains expressing Tbr1). This subdomain produces the paraventricular, supraoptic and anterior hypothalamic nuclei [4]. For this reason, this molecular subdomain is often referred to as the supraopto-paraventricular domain (SPV) and contains magnocellular neurons that produce oxytocin or vasopressin (vasotocin in non-mammals). These cells project to the neurohypophysis, forming the

degrees of growth and elaboration in the different species. In contrast to the subpallium of jawed vertebrates, the subpallium of jawless fish does not appear to be subdivided, based on the absence of Nkx2.1 expression in the telencephalon. This is correlated with the absence of a pallidum in the basal telencephalon of these animals. See text for more details. Abbreviations: *A9-A10* A9 and A10 dopaminergic cell groups (substantia nigra pars compacta and ventral tegmental area); *Emt* eminentia thalami; *Ept* epithalamus; *Ha* alar hypothalamus; *Hb* basal hypothalamus; *MB* midbrain; *MDLP* medial, dorsal and lateral pallium; *MLP* medial and lateral pallium; *P* pallium; *Pa* pallidum; *Pt* pretectum; *PTh* prethalamus; *p1-p3* ►prosomeres 1–3; *SCN* suprachiasmatic domain; *Sp* subpallium; *SPV* supraopto-paraventricular hypothalamic domain; *St* striatum; *Th* thalamus; *VP* ventral pallium.

hypothalamo-neurohypopysial system. It appears that Sim1 and Otp transcription factors are involved in the differentiation of oxytocin (isotocin in fish) and vasopressin producing cells of the SPV. These cells are missing in Sim1 knockout mice, as well as in Sim1 knockdown zebrafish, as recently found by Jennifer Eaton and Eric Glasgow, indicating that the mechanisms for their development are highly conserved in vertebrates.

2. a ventral subdomain that expresses Dlx2/5 transcription factors but not Tbr1/Otp/Sim1 and is located between the supraopto-paraventricular domain and the basal plate. This subdomain produces the suprachiasmatic nucleus, among other cell groups and is rich in GABAergic neurons (as other Dlx-expressing forebrain domains).

The same two main subdomains of the alar hypothalamus noted above are present in non-mammals, including chick, frog, and apparently zebrafish (Fig. 6). One interesting difference between groups recently noted is that the alar hypothalamus in frog and zebrafish shows expression of Nkx2.1 (possibly overlapping the Dlx-expressing subdomain), but this transcription factor is either not expressed or done at a very low level in the alar hypothalamus of mouse and chick [15] (Fig. 6). This means that the expression of this transcription factor was greatly downregulated during evolution to birds and mammals. What was the consequence of this loss? This is no doubt a question difficult to answer because we cannot repeat evolution in a laboratory. However, knowdown experiments of Nkx2.1 in frog embryos produce a shrinkage of the alar hypothalamus and an expansion of the thalamus, and based on these results it has been proposed that the loss or downregulation of this transcription factor during evolution was possibly one of the factors that triggered the great expansion of the thalamus in these animals [15]. Another consequence of the loss or reduction in the expression of Nkx2.1 in the alar hypothalamus is that this may have involved a relative shrinkage of the domain that gives rise to the suprachiasmatic nucleus and the expansion of the adjacent SPV domain. This possibility requires further investigation, first by analyzing the relative importance of both domains throughout phylogeny. Meanwhile, it is interesting to note that the hypothalamo-hypophysial system (related to the SPV) is extremely important not only for homeostasis control, but also for social, sexual and maternal behaviors. Among vertebrates, social and maternal behaviors generally show the greatest development in mammals and birds, and this may be associated to a great development of SPV domain and the hypothalamo-hypophysial system. However, although most anamniotes (including most fish) would consider their young and fish eggs simply a tasty food, a few fish species show parental care behavior (for example, mouthbreeders). It would be interesting to analyze the SPV domain n these species relative to that of fishes that show no parental care.

## The Telencephalon: A Specialization of the Rostral and Dorsal Forebrain

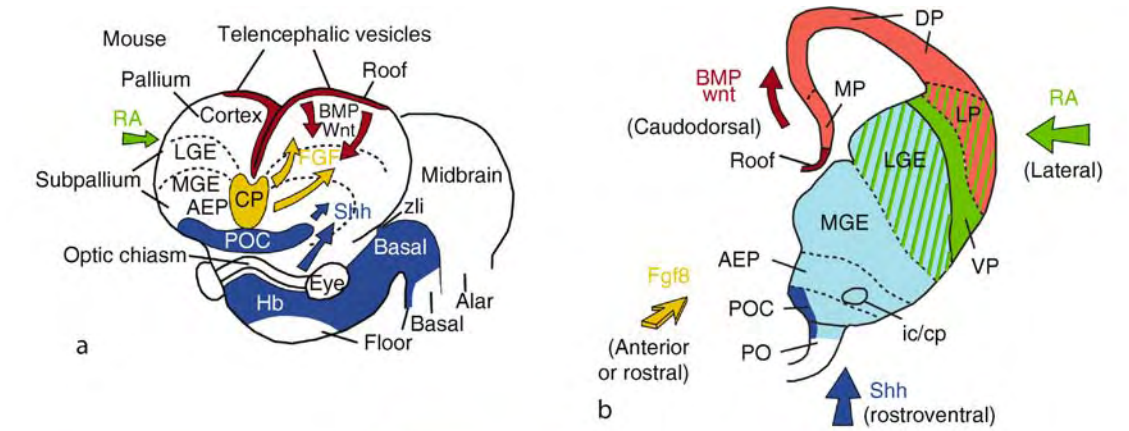
### *Molecular Definition*

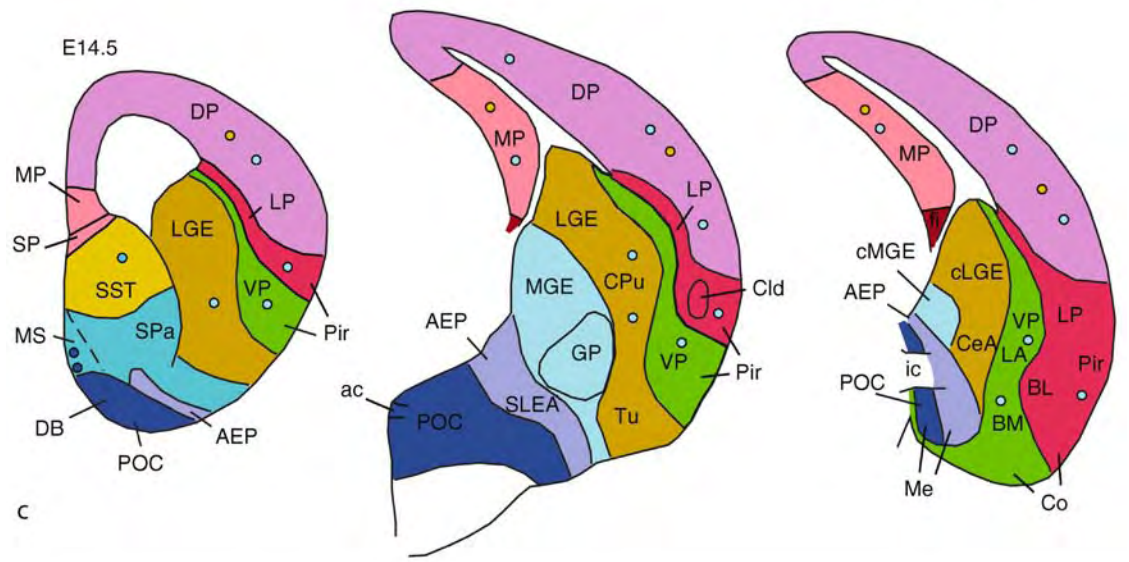
Regardless the existence of paired evaginated vesicles or not (or everted vesicles in ray-finned fishes), the telencephalon is present in all vertebrates, from jawless fish (such as the lamprey) to mammals. From zebrafish to mouse, it is characterized by expression of BF1, and animals carrying a null mutation in this gene lack a telencephalon. It shows two major divisions, pallium and subpallium (Fig. 6), which express different combinations of transcription factors. In different vertebrates, the pallium expresses Emx1/2 and Pax6 (Figs. 6 and 7), which are involved in specification, regionalization, and growth of the pallium.

It also expresses Tbr1, a transcription factor involved in differentiation of glutamatergic neurons, which are typical in the pallium in all vertebrates [16; see also recent articles by Isabelle Bachy and her colleagues and Aurora Brox and her colleagues]. On the other hand, the subpallium expresses Dlx/Distal-less transcription factors (Figs. 6 and 7), among many other (see below); Dlx transcription factors are involved in the acquisition of the GABAergic phenotype, which is typical in subpallial neurons and their projections [8]. Analysis of BF1 and transcription factors typical of the subpallium (including Dlx5, Nkx2.1, Lhx6 and Lhx7/8) indicates that the telencephalon includes the anterior preoptic region (POa). This includes a novel subpallial domain called the commissural preoptic area (POC), related to the anterior commissure [4,19]. Functional studies have usually linked the preoptic area with the hypothalamus, although classical anatomical studies in non-mammals considered the preoptic area as part of the telencephalon "impar," which is a non-evaginated part of the telencephalon. Genetic developmental data support the classical view and indicate that at least part of the preoptic area belongs to the telencephalic subpallium.

## Major Telencephalic Subdivisions and Their Patterning. Evolutionary Trends and Questions

Each major division of the telencephalon contains at least four main subdivisions (4 in the pallium and 4 in the subpallium), and each is characterized by a specific combination of transcription factors and by the production of specific cell populations. The same major domains are apparently present in all tetrapods, from amphibians to mammals (Figs. 6–8). These are located in identical topological positions within the telencephalon, show





| Major progenitor domains (vz/svz) | Regulatory genes in vz/svz | Regulatory genes in iz/mantle | Main derivatives |
|---|---|---|---|
| MP | Emx1/2 (high), Ihx2/9 (high), Pax6 (low) | Emx1/2, Lhx2/9, Lhx1/5, Tbr1 | Hippocampal formation (HF) |
| DP | Emx1/2 (high), Lhx2 (high), Pax6 (low) | Emx1/2, Ihx2, Tbr1 | Neocortex (NCx) |
| LP | Emx1/2 (low), Lhx2 (low), Pax6 (high) | Emx1/2, Lmo3 (high), Tbr1 | Pird, Cld, BL, PLCo |
| VP | Emx2 (low), Lhx2 (low), Pax6 (high), Dbx1 | Emx1/2, Lhx2/9, Lmo3 (high), Tbr1 | Pirv, Clv, En, LA, BM, ACo, PMCo |
| LGE | Gsh1/2, Dlx2/5, Mash1, Pax6 (low) | Dlx5, Islet1 | Striatum (CPu, Acc), CeA, IM, IPAC |
| MGE | Dlx2/5, mash1, Nkx2.1 | Dlx5, Nkx2.1, Lhx6, Lhx7/8 | Pallidum (GP, VPa), BSTL |

d

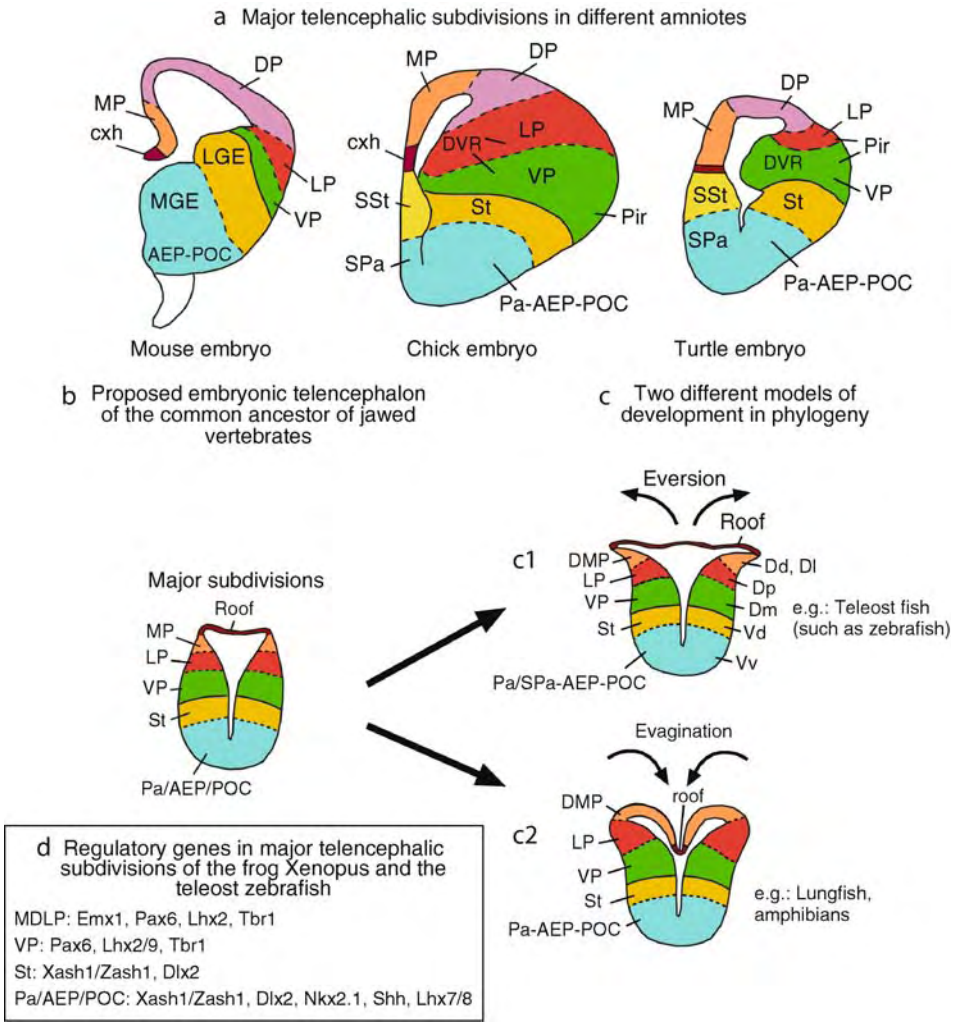
**Evolution and Embryological Development of Forebrain. Figure 7** (a, b) Schemes of the forebrain or a frontal telencephalic section of a mouse during early development, showing the organizers and signals involved in telencephalic patterning. These include dorsocaudal signals from the roof (BMP, Wnt; purple arrows); anteroventral signals from the ANR (FGF; yellow arrows), and from the ventral forebrain and later the commissural preoptic area or POC (Shh, blue arrows); and lateral signals (RA, perhaps from the olfactory placode or mesenchyme cells inside; green arrows). The confluence of these signals is going to produce the parcellation of the telencephalon into several pallial and subpallial compartments. The expression patterns and derivatives of each compartment are shown in panels c and d. (c) Schemes of frontal sections from rostral (*left*) to caudal (*right*) levels of the mouse telencephalon at a mid-embryonic stage, showing the different molecular compartments, and main derivatives. (d) Diagram showing

similar combinations of transcription factors, and can therefore be regarded as field homologues.

Based on molecular and anatomical features, the pallium appears to be subdivided into medial, dorsal, lateral and ventral pallial subdivisions in all tetrapods [4,8,20; see also recent, related articles by Luis Puelles and his colleagues, Isabelle Bachy and her colleagues, and Aurora Brox and her colleagues] (Figs. 7 and 8). Nevertheless, the dorsal pallium in amphibians, if present, appears to be very small. The dorsomedial pallial territories show strong expression of Lhx2 and Emx1/2 and lower expression of Pax6, whereas the lateroventral pallia show strong expression of Pax6 and Lhx9, and low or no expression of Emx1. In particular, the ventral pallium of tetrapods is characterized by no expression of Emx1 in the proliferative zone and by strong expression of Pax6 and Lhx9 in the mantle. In mammals, the ventral pallium is also characterized by expression of Dbx1 in the proliferative zone (Yun et al., 2001; Medina et al., 2004), but this transcription factor is not found in the ventral pallium of non-mammals. Based on these expression patterns together with anatomical features, the medial subdivision gives rise to the hippocampal formation in different tetrapods, whereas the dorsal pallium gives rise to the neocortex in mammals, to a small dorsal cortex/dorsal pallium in reptiles and amphibians, and to the hyperpallium (Wulst) in birds (Figs. 7 and 8). In mammals, the lateral and ventral pallial subdivisions give rise to the piriform (olfactory cortex), claustrum and endopiriform nuclei, as well as the cortical areas and the basal complex of the amygdala (Fig. 7). In birds and reptiles, the lateral and ventral pallia also give rise to the piriform cortex, as well as to the dorsal ventricular ridge or DVR (the latter includes the nidopallium, mesopallium and arcopallium of birds) (Fig. 8). This implies that the claustrum, endopiriform nuclei and pallial amygdala of mammals are ►homologous as a field to the DVR of birds and reptiles and to the corresponding lateral and ventral pallia of amphibians. Interestingly, the caudal part of the DVR in birds and reptiles, and the caudal part of the lateroventral pallia of amphibians have been proposed to include the pallial amygdala on the basis of position, neurochemistry and some basic connections [2,17; see also a related article by Laura Bruce and Timothy Neary, where the amygdalar comparison was first broached, and more recent articles by Luis Puelles and his colleagues and Fernando Martínez-García and his colleagues]. For example, the caudal DVR of reptiles and birds and the caudal ventral pallium of amphibians include an auditory area receiving input from the collothalamus, and this area appears comparable to the lateral amygdala of mammals (also a ventral pallial derivative), which receives input from medial geniculate nucleus of the mammalian collothalamus. A major question that remains to be answered is how much of the DVR is amygdalar-like. The finding of transcription factors restricted to the pallial amygdala, but avoiding other parts of the ventrolateral pallium, will help to resolve this issue.

On the other hand, the subpallium in mammals includes at least four molecularly and anatomically distinct subdivisions (Figs. 7 and 8): the striatal subdivision (lateral ganglionic eminence [LGE]); the pallidal subdivision (medial ganglionic eminence [MGE]); the anterior peduncular area (AEP) and the commissural preoptic area (POC) [4,19]. The LGE/striatal subdivision expresses Dlx1/2/5, Gsh1/2, and Islet1 transcription factors and gives rise to the striatum and central amygdala in mammals. The MGE/pallidum, AEP and POC of mammals express Dlx1/2/5, Nkx2.1, Lhx6/7/8, and Shh (the latter is restricted to POC and derivatives), and give rise to the pallidum, extended amygdala (including most of the bed nucleus of the stria terminalis [BST] and medial amygdala), and the cholinergic corticopetal cell groups [19] (Fig. 7). In addition, the septum also contains septo-striatal and septo-pallidal domains that show combinatorial

the major progenitor domains of the embryonic telencephalon, the transcription factors that each expresses, and the main derivatives of each compartment. See text for more details. Abbreviations: *ac* anterior commissure; *Acc* nucleus accumbens; *ACo* anterior Co; *AEP* anterior peduncular area; *BL* basolateral amygdalar nucleus; *BM* basomedial amygdalar nucleus; *BMC* basal magnocellular complex; BSTL bed nucleus of the stria terminalis, lateral part; *BSTM* bed nucleus of the stria terminalis, medial part; *CeA* central amygdalar nucleus; *Cld* dorsolateral claustrum; *cLGE* caudal part of LGE ((in the caudal ganglionic eminence); *Clv* ventromedial claustrum; *cMGE* caudal part of MGE (in the caudal ganglionic eminence); *Co* cortical amygdalar areas; *cp* cerebral peduncle; *CP* commissural plate; *CPu* caudate-putamen complex; *DB* diagonal band nuclei; *DP* dorsal pallium; *En* endopiriform nuclei; *fi* fimbria; *GP* globus pallidus; *Hb* basal hypothalamus; *ic* internal capsule; *IM* main intercalated amygdalar masses; *IPAC* interstitial nucleus of the posterior limb of the anterior commissure; *LA* lateral amygdalar nucleus; *LGE* lateral ganglionic eminence; *LP* lateral pallium; *Me* medial amygdalar nucleus; *MePD* posterodorsal part of Me; *MePV* posteroventral part of Me; *MGE* medial ganglionic eminence; *MP* medial pallium; *MS* medial septal nucleus; *Pir* piriform cortex; *Pird* dorsal part of Pir; Pirv ventral part of Pir; *PLCo* posterolateral Co; *PMCo* posteromedial Co; *PO* preoptic area; *POC* commissural preoptic area; *SLEA* sublenticular extended amygdala; *SP* pallial part of the septum; *SPa* pallidal-like part of the septum; *SSt* striatal-like part of the septum; *Tu* olfactory tubercle; *VP* ventral pallium; *VPa* ventral pallidum; *zli* zona limitans intrathalamica.



**Evolution and Embryological Development of Forebrain. Figure 8** (a) Schemes of frontal sections through the embryonic telencephalon of different amniotes (a turtle, a chicken and a mouse), showing the major molecular compartments. Basically, all groups show the same set of pallial and subpallial compartments, although their size and elaboration varies depending on the group. (b, c, c1, c2) Proposed model of the basic molecular compartments present in the embryonic telencephalon of the common ancestor of jawed vertebrates (b). From this basic organization scheme, the telencephalon underwent partial or almost complete evertion (B1) or evagination (B2) in different ratiations. (d) Diagram showing the major telencephalic subdivisions and the regulatory genes they express in the frog *Xenopus* and the teleost zebrafish. Many of these are the same as in amniotes. Abbreviations: *AEP* anterior peduncular area; *cxh* cortical hem; *Dd, Dol, Dm, Dp* dorsal telencephalic area (pallium), dorsal, lateral, medial or posterior parts; *DP* dorsal pallium; *DMP* dorsomedial pallium; *DVR* dorsal ventricular ridge; *LP* lateral pallium; *MP* medial pallium; *Pa* pallidum; *Pir* piriform cortex; *POC* commissural preoptic area; *SPa* pallidal-like septum; *St* striatum; *SSt* striatal-like septum; *Vd* ventral telencephalic area (subpallium), dorsal part; *VP* ventral pallium; *Vv* ventral telencephalic area (subpallium), ventral part.

expression of regulatory genes comparable to those of either LGE or MGE/AEP/POC. The subpallium of non-mammals, from frog to chick, also shows striatal, pallidal, and AEP-POC molecular domains comparable to those of mammals, giving rise to striatal and pallidal parts of the basal ganglia and septum, to the extended amygdala, and the cholinergic cells groups of the basal telencephalon (Fig. 8).

How are these basic subdivisions of the telencephalon patterned? The answer to this question may also help to propose possible evolutionary changes that led to differential growth of subdivisions in each vertebrate lineage.

The telencephalon constitutes a dorsal specialization of the rostral forebrain and appears to be patterned by signaling mechanisms similar to those that operate in

DV and AP patterning of the diencephalon and caudal neural tube [4,5,12,16] (Fig. 7). However, it should be noted that, from a topological point of view, internal boundaries between telencephalic subdivisions do not fit well into the general scheme of AP or DV boundaries of the rest of the neural tube [4]. Nevertheless, pallium and subpallium develop from caudal or rostral domains of the anterior neural plate, respectively. In the telencephalon, BMPs and Wnt signals from the dorsal midline (roof plate, including the cortical hem; Fig. 7) induce the expression of Lhx2 and Emx2 in the adjacent dorsomedial pallium (with a decreasing gradient towards the lateroventral pallium), whereas RA induces expression of Dlx2, Gsh2, and Pax6 in the lateral, intermediate region (Dlx2 and Gsh2 in LGE, and Pax6 primarily in the lateroventral pallium, with decreasing gradients towards the medial pallium and the LGE) [12; also Ragsdale and Grove, 2001] (Fig. 7). In addition, FGF8 and Shh anteroventral signals induce the expression of Nkx2.1 in the most basal telencephalic region (MGE and the most basal parts of the subpallium) (Fig. 7).

Initially, FGF8 signals from the ANR are extremely important for telencephalic patterning [12]. Ablation of ANR or blockage of the FGF8 signals eliminates or reduces BF1 expression in the prospective telencephalon at neural plate stages, and this is rescued by FGF8-soaked heparin beads [13]. Moreover, FGF signals are able to induce the expression of genes typical of the subpallium, such as Dlx2, Gsh2 and Nkx2.1 [12]. Later in development, Shh starts to be expressed in a small subpallial domain in close relation to the ANR [13] (Fig. 7), and this new signal is also related to induction of subpallial marker genes [12]. Thus, both FGF8 and Shh induce the expression of subpallial marker genes. FGF8 also represses retinoid acid signaling in the developing telencephalon leading to the formation of MGE instead of LGE [12]. In addition, FGF8 signals - in conjunction with BMP/Wnt and RA - are important for cortical regionalization and area formation.

These mechanisms contribute to pattern the telencephalon in mammals and non-mammals (including zebrafish), and appear to be conserved in vertebrates. Based on this, perhaps differences in the relative proportion of dorsocaudal versus lateral versus anteroventral inducing signals triggered the great development of the ventral pallium in birds and reptiles (producing the DVR), or the great development of the dorsal pallium in mammals (giving rise to the neocortex).

## Evolution of a Novel Morphogenetic Domain in the Subpallium

The major molecular domains observed in the telencephalon of tetrapods (from amphibians to mammals) are also present in zebrafish, suggesting that they were likely present in the telencephalon of stem jawed vertebrated (Figs. 6–8). This includes a pallium and subpallium, and several subdivisions in each. For example, in the subpallium there are striatal and pallido-AEP-PO subdivisions, which express either Distal-less/Dlx or both Dlx and Nkx2.1 transcription factors. These subdivisions appear to produce, respectively, striatal and pallidal cell groups described in the ventral telencephalic region of teleosts, although these may be mostly comparable to septal or limbic striatal and pallidal subdivisions of mammals [3] (Figs. 6 and 8). The pallido-AEP-PO subdivision also expresses Shh and is possibly related to the cholinergic neurons observed in the subpallium of teleosts. It is however unclear whether the pallido-AEP-PO domain can be further subdivided into separate pallidal, AEP and PO subdivisions in teleosts. Regarding the pallium, there are at least three major subdivisions comparable to the medial pallium, lateral pallium and ventral pallium in teleosts (the latter including the pallial amygdala) (Fig. 8). However, due to the eversion process that occurs during development of the telencephalon in teleosts, the topographic positions of these pallial subdivisions are shifted from lateral to medial (Fig. 8). Thus, the so-called dorsomedial pallium of teleosts really corresponds to the ventral pallium, whereas the true medial pallium (hippocampal) is located in a lateral position. Nevertheless, the topological relationships of each pallial subdomain (regarded with respect to intrinsic coordinates of the neural tube), remain unchanged in comparison with other vertebrates. For example, the true medial/hippocampal pallium of teleosts is immediately adjacent to the choroid tissue (roof derivative), which is typical of the medial pallium in all vertebrates (Fig. 8).

As that of jawed vertebrates, the subpallium of the lamprey (a jawless fish) expresses Distal-less/Dlx transcription factors [10]. However, the subpallium of the lamprey does not appear to be subdivided, based on the absence of expression of both Shh and Nkx2.1 in the basal telencephalon of these animals [3,10,15; see also Osorio et al., 2005] (Fig. 6). In fact, the basal telencephalon of adult lampreys contains a structure suggested to be comparable to the basal ganglia, but this structure appears to show basically striatal features and there is no evidence for the presence of a pallidum in these animals [3]. This suggests that the evolution from jawless to jawed vertebrates involved the novel appearance of a pallido-AEP-PO subpallial domain, possibly as a consequence of the novel expression of Shh and Nkx2.1 in the basal telencephalon. Possibly, the novel expression of Nkx2.1 was induced by Shh and/or perhaps by FGF8. Alternatively or additionally, the novel expression of Nkx2.1 in the basal telencephalon may be related to changes at the level of the regulatory region of the Nkx2.1 gene, a possibility suggested recently on the basis of computer-based

sequence analysis of this gene in different vertebrates, from lamprey to human [15]. Another important question that remains to be answered is what triggered the appearance of the novel expression of Shh in the basal telencephalon.

The most obvious consequence of the novel expression of Shh and Nkx2.1 is the appearance of new cell populations in the basal telencephalon, including the pallidum and apparently the cholinergic cells that are typical of the basal telencephalon of jawed vertebrates [3]. In addition to this, the appearance of the new morphogenetic domain likely had consequences for the striatum and pallial/cortical regions, since in tetrapods (from amphibians to mammals) the MGE-AEP domain is a known major source of GABAergic interneurons that migrate tangentially to these regions.

## Function

Not applicable. See Thalamus, Hypothalamus, Telencephalon. Basal Ganglia, Cerebral Cortex, Hippocampus, Amygdala, Substantia Nigra, Ventral Tegmental Area, Dopaminergic Systems.

## Pathology

A number of neurological and neuropsychiatric disorders observed in humans, such as squizophrenia, some types of epilepsies, and autism (among other), are caused by developmental alterations, leading to abnormal formation of specific parts of the cerebral cortex and/or the amygdala. For example, in some cases of squizophrenia in humans there is a mutation in the neuroregulin-1 gene, encoding a molecule involved in the migration of GABAergic interneurons from the subpallium into the cortex, as Nuria Flames and her colleagues recently demonstrated. Other developmental alterations that lead to forebrain malformations produce cyclopia, holoprosencephaly, lissencephaly or callosal agenesis (among many others), which can be associated with mental retardation or other less severe cognitive deficits, as recently discussed by Lynn Paul and her colleagues. Knowing the developmental mechanisms and genes involved in forebrain formation can help to identify possible mutations or other causes of malformation, as a first step for a therapy design. An example of the value of this knowledge is found with the Nkx2.1 (or Titf-1) transcription factor, involved in the specification and formation of the basal hypothalamus and basal telencephalon, as well as in the formation of the thyroid gland and the lungs/bronchi. This was learned following analysis of Nkx2.1 null mutant mice. After reading about this, a group of physicians identified a number of patients with associated hypothyroidism, lung and motor (basal ganglia-related) problems, and decided to run a genetic test for possible mutations in the human Nkx2.1 gene; the test turned out to be positive.

## Therapy

Not applicable. See gene therapy, stem cell therapy.

# Evolution and Phylogeny of Amniotes

Susan E. Evans
Research Department of cell and Developmental Biology, UCL, University College London, London, UK

## Definition

Amniotes (Amniota) form a monophyletic group that encompasses the last common ancestor of living mammals and reptiles, and all descendents of that ancestor. They are characterised by the possession of an amniote egg (or at least amniotic membranes in live-bearers) that contains the essentials for embryo development, but is protected by a leathery or calcareous outer shell. This key innovation enabled tetrapods to reproduce on land. Amniotes had larger brains and sense organs, better feeding systems, more mobile necks, and stronger limbs than their predecessors. As a result, amniotes rapidly came to dominate the terrestrial environment, and subsequently colonised the air and recolonised the water.

The classification used in this essay is cladistic and recognises only monophyletic groups (see Phylogeny of Vertebrates for a fuller explanation). Ages in millions of years before the present (Ma BP) are based on the most recent geological timescale [1] and the earliest records of occurrence, but should be understood to carry error bars.

## Characteristics

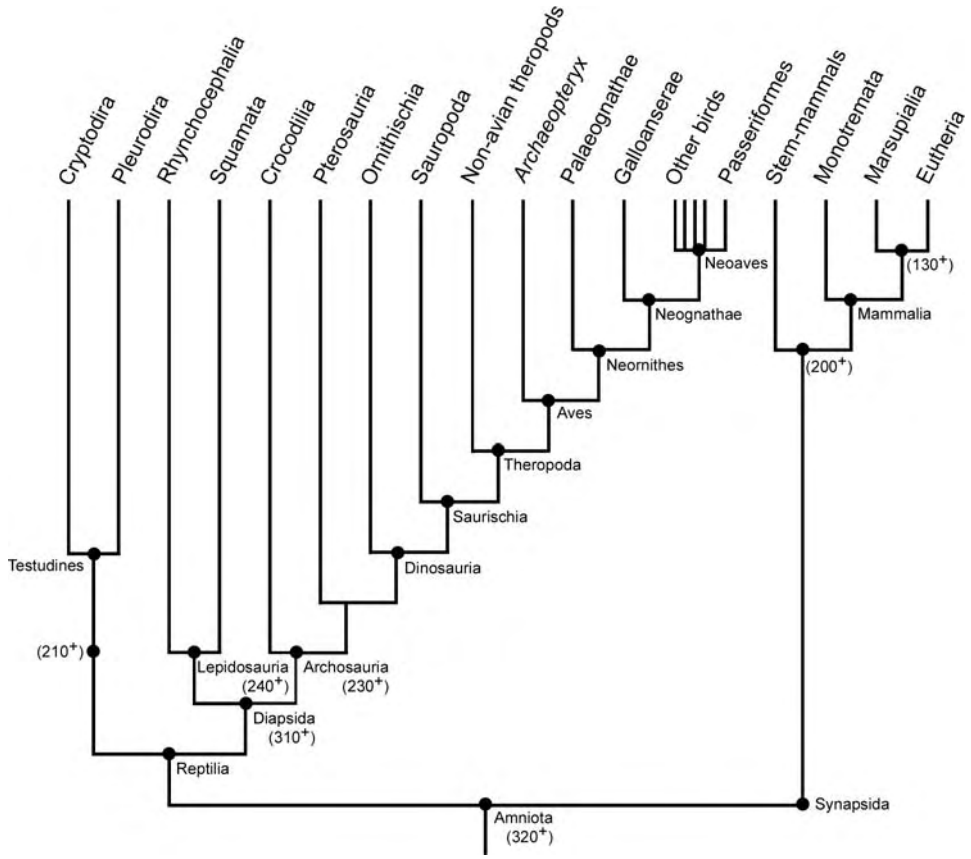
The first amniotes are recognised from the Carboniferous period (c. 320 Ma BP) based on skeletal characters (e.g. two sacral ribs, ankle structure), because until the development of calcareous shells, eggs were rarely fossilised. These early fossil amniotes were already split between two major clades, Synapsida and Sauropsida (Fig. 1). The latter is almost equivalent to Reptilia, and this is used in subsequent discussion. However, under its cladistic definition, Reptilia is the monophyletic group that encompasses the last common ancestor of living lizards and snakes, crocodiles, birds and turtles, and all (but only) the descendents of that last common ancestor. In the past, and even in some recent literature, reptile was used in a paraphyletic sense equivalent to basal amniote (e.g. in the inaccurate term "mammal-like reptile" for early synapsids). Modern reptiles have a long independent evolutionary history and should not be used simplistically as morphological surrogates for the ancestral mammalian condition. For decades, understanding of mammalian ear evolution was obfuscated by attempts to derive the mammalian condition from that of a lizard. Only with the acceptance that the lizard and mammalian eardrums were not phylogenetically homologous (i.e. were not present in the last common ancestor of the two lineages, c. 320 Ma BP), was the problem resolved [2].

## Sauropsida

Reptilia sensu stricto includes living turtles and tortoises (Testudines), lizards, snakes and tuatara (Lepidosauria), and crocodiles and birds (Archosauria), as well as several important extinct groups such as the plesiosaurs, ichthyosaurs, and dinosaurs. Under this cladistic framework, birds (Aves) do not form a group distinct from reptiles – they are part of the monophyletic Reptilia.

Turtles are first recorded from the Late Triassic period (c. 310 Ma BP), but these fossils are already too highly specialised to shed much light on their immediate ancestry. There is general agreement that turtles are more closely related to lizards, crocodiles and birds than to mammals [3], but the details of that relationship remains unresolved. The traditional view is that turtles are the sister group of the ►*lepidosaurs* and ►*archosaurs* [4]. However, over the last decade increasing numbers of studies have suggested that turtles might be diapsid derivatives, related either to ►*lepidosaurs* [3] or ►*archosaurs* (most molecular analyses, e.g. [5]).

Lepidosauria and Archosauria, with their immediate ancestors, constitute the Diapsida. (The term diapsid refers to the presence of two bony fenestrae in the temporal region of the skull.) Lepidosauria today encompasses two unequal clades – Rhynchocephalia and Squamata. Once a globally widespread group, Rhynchocephalia is now represented by a single surviving genus, Sphenodon, restricted to a few islands off the coast of New Zealand. Sphenodon has been much misunderstood, regarded as a "living fossil" and sometimes cast into the role of archetypal primitive reptile. Over the last 25 years, our knowledge of extinct Rhynchocephalia has improved considerably. Within Rhynchocephalia, Sphenodon is a relatively derived form. Many of the skull characters previously used to



**Evolution and Phylogeny of Amniotes. Figure 1** Tree showing relationships amongst major amniote groups. Clade names have been added to appropriate nodes. The numbers at some nodes represent the minimum age estimates (in millions of years) for the last common ancestor of the descendant lineages.

argue for a primitive position are now recognised as secondary specialisations. Nonetheless, compared to lizards, Sphenodon does show some apparently primitive features, as well as a low basal metabolic rate and a longevity rivalling that of turtles. The last common lepidosaurian ancestor of squamates and rhynchocephalians lived around 240 Ma BP, and both lineages have undergone evolution in the interim, although squamates diversified more rapidly than other reptiles. This may explain why Sphenodon sometimes groups with other reptilian clades in molecular analyses [6].

Squamata is a highly successful clade, with more than 7,000 living species of lizards, amphisbaenians and snakes. There is common agreement that snakes (Serpentes) and "worm lizards" (Amphisbaenia) each constitute monophyletic groups, but that "lizards" are simply squamates that are neither snakes nor amphisbaenians. For this reason formal names like "Lacertilia" should not be used for them. Within squamates, most morphologists recognise four distinct clades, Iguania (iguanas, chamaeleons, agamas), Gekkota (geckos and their relatives), Scincomorpha (e.g. Lacerta, Scincus) and Anguimorpha (e.g. Varanus, Anguis), with a fundamental early split (c. 200 Ma BP) between Iguania on one side and all other squamates (=Scleroglossa) on the other. Snakes typically group within Anguimorpha, but amphisbaenians are more problematic [7]. To complicate matters further, recent molecular analyses have proposed that Scleroglossa is not monophyletic and that Iguania is nested within it [8].

The earliest definitive archosaurs (Archosauria) arose more than 230 Ma BP, but their separation from the ancestors of lepidosaurs occurred before this. Archosaurs were the dominant group throughout the Mesozoic (250–265 myrs), culminating in three major clades – crocodilians, pterosaurs, and the dinosaurs/birds. However, extant birds and crocodilians represent end points of lineages that separated at least 230 Ma BP. Modern crocodiles are amphibious but early forms were small terrestrial reptiles with a parasagittal quadrupedal gait. In contrast, the first dinosaurs were small active bipeds. These diversified into the herbivorous Ornithischia (e.g. Stegosaurus, Triceratops, Iguanodon) and the Saurischia. The latter group, in turn, split to produce the quadrupedal herbivorous sauropods (e.g. Diplodocus, Brachiosaurus) and the bipedal,

predominantly carnivorous, theropods (e.g. Tyrannosaurus). One group of theropods evolved into a clade of active, small-bodied, large brained raptors (e.g. Velociraptor) that were the direct ancestors of birds.

The earliest recorded bird (Aves) is Archaeopteryx (c. 140 Ma BP). In many respects this animal was more like its dinosaurian forebears than modern birds (teeth, claws, bony tail), except that it was capable of flight (and had a brain to match). Modern birds seem to have undergone an explosive radiation around 50 Ma BP, and most modern groups (Neoornithes) can be traced back to at least that time, or earlier [9]. The most primitive living birds are the ratites (Palaeognathae, e.g. ostriches, emus). Of "higher" birds (Neognathae), the group that encompasses ducks, geese and pheasants (Galloanserae) is thought to be basal [9], with a postulated divergence time of about 90 Ma BP. The remaining birds (Neoaves) fall into a series of groups for which the relationships are poorly resolved, but the large and diverse Passeriformes (e.g. sparrows, blackbirds, robins) is probably the most derived.

### Synapsida

Synapsida, the second amniote division, is represented today by the mammals, but includes a wide range of extinct stem taxa. (Synapsida may be defined as incorporating all amniotes more closely related to living mammals than to living reptiles and birds; the term synapsid refers to the presence of one bony fenestra in the temporal region of the skull.) Indeed, the synapsids seem to have undergone the first successful amniote radiation, dominating early terrestrial ecosystems for more than 50 Ma. By 250 Ma BP, some of the most derived synapsids resembled mammals in having a parasagittal stance (that is with the body held upright on limbs that move parallel to the midline of the body, in contrast to the sprawling gait of many small reptiles and amphibians), a differentiated dentition, a hard palate to separate air and food, and bone histology suggestive of at least incipient endothermy. However, the end of the Permian period (c. 250 Ma) was marked by a cataclysmic extinction that destroyed about 80–96% of species, including many lineages of synapsids. In the period that followed, reptiles (and particularly archosaurs) gained the upper hand. Small synapsids survived, perhaps by adopting more nocturnal habits (driving the further evolution of mammalian endothermy, more acute hearing, dark-adapted cone rich retinae, and improved olfaction). A second major extinction at the end of the Cretaceous (65 Ma BP) decimated the reptile lineages and mammals regained control.

Living mammals fall into three major groups – the egg-laying Monotremata, the pouched Marsupialia, and the placentals (Eutheria), and thus Mammalia in the strict sense encompasses the last common ancestor of these three groups and all descendents of that ancestor. Monotremes (Platypus, Echidnas) were once more widespread (e.g. South America) but are today restricted to Australia (earliest record c. 110 Ma BP), surviving on a continent that was not colonised by placentals until relatively recently. On the basis of fossil evidence (supported by molecular analyses), marsupials and placentals separated at least 130 Ma BP. Marsupials are today are restricted to Australia except for the American opossums (e.g. Didelphis), which probably separated c. 68–72 Ma BP. Placentals are more diverse. Morphological data suggests that the Xenarthra (sloths, armadillos, anteaters) are the most basal of living lineages, but several recent molecular studies instead recognise a basal African clade, Afrotheria, including elephants, tenrecs, elephant shrews, aardvarks and sirenians [10].

## Evolution and Phylogeny of Vertebrates

Susan E. Evans
Research Department of Cell and Developmental Biology, UCL, University College London, London, UK

### Synonyms

Evolution of vertebrates; Phylogeny

## Definition

The phylogeny of a group, in this case back-boned animals (vertebrates), represents the course of evolutionary change undergone by that group over time. It is typically represented in the form of a ►dichotomous branching tree in which the vertical axis represents time and the horizontal axis represents closeness of relationship (Fig. 1).

## Characteristics

### Underlying Methodology

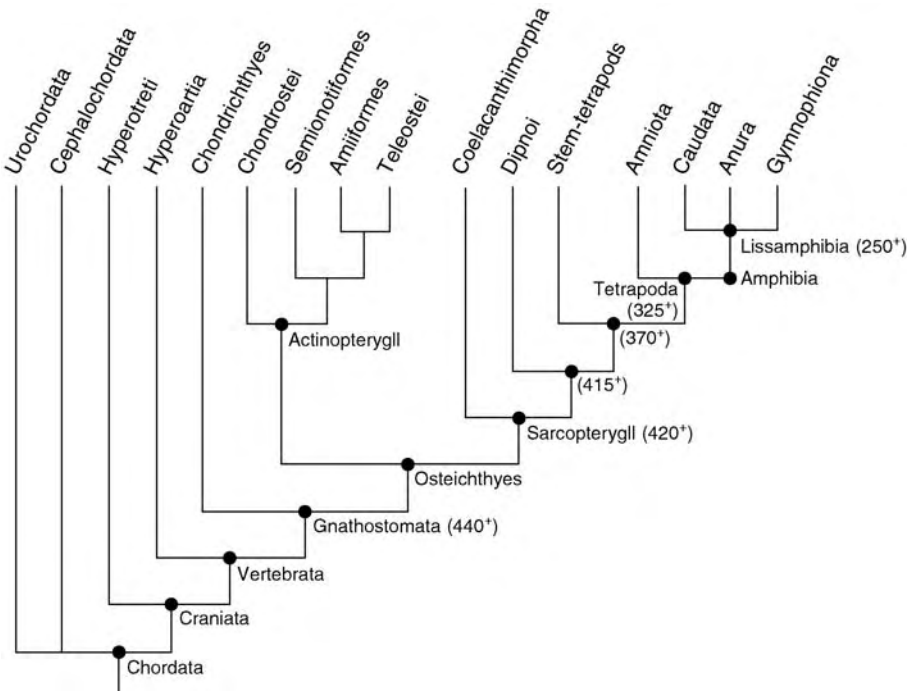
The framework used here is cladistic. Groups must be monophyletic (including the common ancestor and all its descendents) and are diagnosed on the basis of shared ►derived characters. Only monophyletic groups are given formal scientific names. The primitive absence of a derived trait (e.g. the absence of jaws, absence of hair) cannot be used to group organisms. The use of paraphyletic, gradal, groups confuses the discussion of morphological evolution. For example, the old view that reptiles gave rise to mammals (instead of being their ►sister group) left many comparative anatomists trying to derive mammalian structures (e.g. the middle ear) directly from those of living reptiles, despite more than 300 million years of independent history.

Ages in millions of years before present (Ma BP) are based on the most recent geological timescale [1], but should be regarded as minimum estimates reflecting the earliest known occurrence of a fossil group or its phylogenetic sister taxon. Given that individual geological strata cannot always be dated with precision, such dates should also be understood to carry error bars.

### Vertebrates

Vertebrates (backboned animals) are part of the wider group Chordata (see ►Phylogeny and Evolution of Chordates), characterized by the possession of an axial stiffening rod (notochord), a perforated pharynx, a dorsal hollow nerve cord, and a post-anal tail. Chordata has a long fossil record, the earliest known representatives occurring some 570 Ma BP. Today, only two groups of basal chordates survive – the Urochordata (e.g. ►*Ciona*) and the Cephalochordata (e.g. the lancelet, ►*Branchiostoma*). All remaining chordates are craniates (Craniata). The name acknowledges the common possession of an organized head with a brain, well-developed sense organs, cranial nerves, and the beginning of a skull (all linked to the evolution of ectodermal placodes and migratory neural crest).

Craniates are divided informally into ►agnathans and ►Gnathostomata. Agnathans are a gradal concept rather than a valid monophyletic group since they include a range of primitive craniates (mostly now extinct) that lack jaws. Some agnathans (e.g. the



**Evolution and Phylogeny of Vertebrates. Figure 1** Tree showing relationships amongst major vertebrate groups. Clade names have been added to appropriate nodes. The numbers at some nodes represent the minimum age estimates (in millions of years) for the last common ancestor of the descendant lineages.

extinct ►osteostracans) are more closely related to derived vertebrates (gnathostomes) than are others (e.g. lampreys). Today, only two agnathan lineages survive – the primitive hagfish (Hyperotreti) and the lampreys (Hyperoartia). However, researchers are divided as to whether lampreys are more closely related to hagfish (to form a monophyletic Cyclostomi [2,3]) or to gnathostomes [4]. Under the second hypothesis, lampreys and gnathostomes form the Vertebrata, while hagfish would be considered craniates but not vertebrates. Under the first, Craniata and Vertebrata are synonymous [2]. Fig. 1 illustrates the second hypothesis in order to clarify the conceptual distinction between craniate and vertebrate, but with the recognition that a monophyletic Cyclostomi is more widely accepted amongst neontologists.

## Gnathostomes

The evolution of jaws from gill arch (branchial arch) cartilages occurred at least 440 Ma BP. Unlike their predecessors, early gnathostomes were adapted to an active predatory niche, with paired pectoral and pelvic fins and a streamlined body shape. Aquatic fusiform gill-breathing gnathostomes are traditionally, and colloquially, called fish (and were once grouped as Pisces), but "fish" do not form a monophyletic group. A zebrafish is more closely related to a human than either is to a shark. All living "fish" are grouped into one of two major clades – the Chondrichthyes (with a cartilaginous skeleton, like sharks, rays [Elasmobranchii] and parrot-fish [Holocephali]), and Osteichthyes (with true bone). The monophyletic Osteichthyes includes ALL vertebrates with a bony endoskeleton, ranging from goldfish and lungfish through to dinosaurs, birds and monkeys.

Living osteichthyans are themselves subdivided, based on fin type, into Actinopterygii and Sarcopterygii that separated at least 420 Ma BP. Actinopterygii are the ray-finned fish. As the name suggests, this group encompasses fish in which the fins consist of a fan of delicate rays. The most derived actinopterygians are the teleosts (e.g. zebrafish, cod, tuna), but some members of more ancient stem clades have also survived, including Amiiformes (the bowfin, ►*Amia*), Semionotiformes (gars, e.g., *Lepisosteus*), and Chondrostei (paddlefish, e.g., ►*Polyodon*, and sturgeons, e.g., ►*Acipenser*).

## Sarcopterygians

The Sarcopterygii, or lobe-fins, differ from actinopterygians in having a skeletal axis to the pectoral and pelvic appendages. The largest living group of sarcopterygians is comprised, of course, of the tetrapods, but two extant fish groups also fall into this clade – the Coelacanthimorpha or ►coelacanths (►*Latimeria*) and the Dipnoi or lungfish (►*Lepidosiren, Neoceratodus*, ►*Protopterus*). The freshwater lungfish, as the name suggests, have functional lungs, internal nostrils, and a pulmonary circulation. Both lineages (lungfish and coelacanths) go back more than 415 Ma, but of the two, lungfish are probably the more closely related to tetrapods [but see 5], although not on the tetrapod stem. Paleontological and molecular evidence suggests a rapid diversification of the major sarcopterygian lineages, including the immediate fossil ancestors of tetrapods, within a relatively short space of time around 420–400 Ma BP [5].

## Tetrapods

In common parlance, a tetrapod is an animal with four limbs (tetra-pod), but Tetrapoda ►*sensu stricto* encompasses the last common ancestor of living amphibians and living amniotes, and all descendents of that ancestor. This definition omits some of the earliest truly limbed vertebrates and these are best termed ►stem-tetrapods. The earliest known stem-tetrapods date from the later part of the Devonian period, around 370 Ma (e.g. ►*Acanthostega, Ichthyostega*, [6]). They were still aquatic, using a combination of lung and gill breathing, like the living Australian lungfish, ►*Neoceratodus*.

The main vertebrate colonization of the land appears to have begun during the Carboniferous (c. 340–320 Ma BP), perhaps coinciding with a sharp rise in atmospheric oxygen levels, and the fossil record documenting a gradual radiation of stem-tetrapods into available ►*niches*. The phylogenetic tree is rather "bushy" at this stage, but two major lineages emerged: amphibians and amniotes. The latter clade includes all truly terrestrial groups (e.g. birds, tortoises, lizards and snakes, mammals) that possess an ►amniote egg (or a derivative structure such as the placenta). This group is covered in more detail elsewhere (see ►The Phylogeny and Evolution of Amniota). Amphibia are rather more challenging. Under traditional usage, Amphibia is a paraphyletic group for tetrapods that are not amniotes, but under a cladistic definition, Amphibia encompasses those tetrapods that are more closely related to living amphibians (frogs, salamanders, caecilians) than to amniotes. Unlike amniotes, they still generally require water to reproduce, typically have an aquatic larva, and undergo ►metamorphosis. Paleontologists do not agree as to the ancestry of living forms. For neontologists, this is relatively unimportant except that it impacts on the timing of the divergence between the ancestors of Amphibia and of Amniota. Nonetheless, by any estimate, the last common ancestor of amniotes and amphibians lived more than 325 Ma BP [7].

Modern amphibians comprise of the Lissamphibia: frogs, salamanders and the limbless caecilians. The relationships of the three living clades are not fully resolved. Many workers place frogs (Salientia) and salamanders (Caudata) as close sister taxa but others argue for separate origins from distinct fossil lineages [7]. Caecilians are even more problematic: they may be the sister group of frogs plus salamanders (most

morphological analyses and some molecular ones), they may be the sister group of salamanders alone, or they may be unrelated [7]. This affects estimated divergence times for the three major groups (325–200 Ma BP). The earliest known fossil stem-frogs are recorded from c. 245 Ma BP, while the equivalent dates for salamanders and caecilians are 170 Ma BP and 190 Ma BP respectively [7,8].

Amongst living frogs, the North American ►*Ascaphus* and New Zealand ►*Leiopelma* represent the oldest and most basal lineages, followed by discoglossids (e.g. ►*Alytes*, *Discoglossus*), and then pipids (e.g. ►*Xenopus*), pelobatids and rhinophrynids. The most diverse and derived frog clade is the Neobatrachia (e.g. ►*Bufo, Hyla, Rana*). Fossil ascaphids have not been identified with certainty, but discoglossids are recorded with confidence from around 145 Ma BP, basal pipids from 120 Ma BP, and early neobatrachians from at least 80 Ma BP, these dates giving the latest possible divergence times for each lineage [9]. Living salamanders fall into two major groups, Cryptobranchoidea (e.g. ►*Cryptobranchus*, *Hynobius*) and Salamandroidea (e.g. ►*Salamandra*, *Ambystoma*) and, judging from recent fossil finds in China and the USA, these groups had already separated by at least 145 Ma BP. Nonetheless, the position of sirenids (e.g. ►*Siren*) is still uncertain (basal or highly derived, [6]), as are the interrelationships of living families. The fossil record of caecilians is extremely poor and no certain representative of modern families has been recovered from Mesozoic deposits.

# Evolution and Phylogeny of Primates

Ann M. Palkovich
Krasnow Institute for Advanced Study, Department of Sociology and Anthropology, George Mason University, Fairfax, VA, USA

## Definition

The evolutionary lineage of arboreal placental mammals exhibiting sociality and stereoscopic, color vision as primary adaptations, taxonomically designated as "primates".

## Characteristics

Primates represent a taxonomic order within the class Mammalia. Primates are characterized by a generalized mammalian limb structure including retention of pentadactylism (five digit hands and feet), a tendency toward vertical body posture and extensive head rotation ability. Limb mobility is facilitated by the unfused radius and ulna that maximizes forearm rotation, dorsally located scapulae accommodating free-swinging and suspensory arm motions and ball-and-socket joints of the hip accommodating climbing, quadrupedal and bipedal locomotion. Most primate species have tails (except great apes), with Platyrrhines (New World monkeys) exhibiting prehensile tails able to hold and manipulate objects. Hands and feet display enhanced grasping ability with friction skin on finger and palmer surfaces, sensitive tactile pads at fingertips, flat nails rather than rigid claws and varying degrees of thumb opposability. Eyes are generally enlarged compared to other mammals and enclosed in a complete bony ring with front-facing stereoscopic vision and varying degrees of sensitivity to low light levels. Color vision is also variable, being uniformly trichromatic in Catarrhines—Old World monkeys, great apes, and humans—but variably dichromatic or trichromatic among Platyrrhines [1]. Heterodont dentition (incisors, canines, premolars and molars) and a tooth count reduced from that of primitive mammals are features exhibited by all primates as are complete bony orbits. Reduced prognathism (i.e. projecting muzzle) of the lower face and jaws appears to be associated with a

marked disruption (circa 30%) in olfactory receptor genes, particularly in Old World monkeys and apes. The percentage of disrupted genes that disable olfactory receptors reaches nearly 60% in humans [2]. Strong selection for binocular color vision at the expense of smell may have enhanced preferential exploitation of fruits and flowers for cattarrhine and some platyrrhine primates subsisting in arboreal niches. The auditory bulla (forming the osseous case of the inner and middle ears) forms as an expansion of the petrous portion of the temporal bone rather than from a separate ossification center, a developmental feature apparently unique to primates. Sociality is characteristic of all primate species and is associated with longer gestation periods than most mammals, a lengthened period of maturation, low reproductive rate, parental care of offspring and a relatively long life span [3,4,5,6].

## Primate Origins Hypotheses

Two complementary hypotheses of primate origins stress the selective advantages of primates as visual predators. Cartmill's visual predation hypothesis states that the optic convergence of stereoscopic vision and dexterous extremities equip primates to focus on and capture insects and other small prey. He suggests primates became insect-hunting specialists rather than another arboreal mammalian lineage [7,8]. Alternatively, Sussman notes that some bats exhibit analogous primate-like visual systems yet subsist primarily on angiosperms rather than insects. With the burgeoning angiosperm diversity during the Paleocene filling tropical forests with abundant flowers and fruits, Sussman proposes that in tiny mammals depth-perception and color acuity combined with grasping ability proved highly successful in exploiting fruits and flowers on small terminal branches [9]. This angiosperm hypothesis accounts for the combination of early primate specializations equally well, leading other researchers to suggest a combined angiosperm-insect exploitation hypothesis. Emphasis on visual predation, small body size, exploitation of arboreal habitats and manipulative abilities of extremities suggest early primates depended on visual acuity to identify color distinctions in flowers and fruits on the small branches of trees while opportunistically eating insects drawn to these same food resources.

## Primate Phylogeny

Current interpretations identify two semiorders within the order Primates, the Euprimates (true primates) and the Plesiadapiformes (extinct and archaic predecessors to the Euprimates). DNA dating places the divergence of the order Primates from other placental animals around 90 million years ago. The Paleocene fossil *Purgatorius* (68 million years BP) is cited by some researchers as the earliest primate, predating the Euprimates [10]. Plesiadapiformes or archaic primates exhibit primate-like molars yet have long, low crania lacking postorbital bars and procumbent rodent-like incisors. They also lack grasping hands and feet and retain rigid claws. These fossil species appear to exhibit adaptations distinct from later Euprimates. Having no extant counterparts, Plesiadapiformes have been placed taxonomically as a semiorder within the order Primates; however, their intermediate morphological status could easily place them in their own separate order. There is also speculation whether Plesiadapiformes are ancestral to Euprimates or whether they represent a sister lineage. Current fossil evidence does not allow us to unequivocally identify the ancestral primate lineage before the Eocene (55 million years ago). How closely related Euprimates may be to other mammalian orders [Scandentia (tree shrews), Chiroptera (bats) or Dermoptera (colugos or flying lemurs)] is also unknown, leading some scholars to lump these orders into an archontan clade [4,5,11,12].

The semiorder Euprimates is believed to have appeared during the early Eocene (approximately 55 myr), coincident with the appearance of other arboreal mammals. However, Euprimate fossils that clearly exhibit the suite of traits seen in extant primates are documented only from about 35 myr. Euprimates appear globally as an adaptive radiation. North American Euprimate forms only persist through the end of the Eocene before becoming extinct, while living primates are believed to represent descendant lineages that were established in Africa and Asia [3,5,11,12].

Two suborders—Strepsirhines and Haplorhines—are established by 53 myr (though some scholars place this divergence at approximately 25 myr). Strepsirhines ("wet-nosed" primates) are a cluster of small primates represented by four living families of lemurs and three additional families including lorises, pottos and galagos. The family Daubentoniidae is also included among the Strepsirhines, though its taxonomic history within the suborder is debated. Strepsirhines are characterized by long muzzles and sensory whiskers (tactile vibrissae), a mandibular toothcomb, relatively large olfactory lobes for their body size and a smaller brain to body ratio than Haplorhines. Strepsirhines also exhibit a frenulum that serves to anchor the upper lip to the face, thus limiting the range of facial expression in these species. Many Strepsirhines are also nocturnal, show enlarged eyes for their body size and have a light-reflecting retinal layer. All Strepsirhines exhibit a postorbital bar that serves to form a bony eye socket. Tarsiers have been previously classified along with lemurs, lorises, pottos and galagos in the suborder Prosimii (prosimians). It has since been demonstrated that tarsiers share an extensive list of traits with simians and thus have been reclassified into the Anthropoidea

with other monkeys and apes. However, tarsiers retain unfused mandibular symphyses, a three-cusp upper molar pattern, some clawed toes and nonopposable thumbs, which are characteristics of Strepsirhines. Cladistic coherence and a common ancestry for the Strepsirhines, which also places tarsiers as a distinct genetic outlier has also been recently demonstrated by mitochondrial sequence analyses and retroposon analyses (presence/absence analysis of RNA derived transposable elements which episodically insert at DNA locations within the genome) [13]. As a result, the suborder Strepsirhine now includes only non-tarsier forms once considered Prosimians [4,5,11,12,14,15].

Haplorhines ("dry-nosed" primates) represent the tarsiers (hyporder Tarsiiformes) and monkeys and apes (hyporder Anthropoidea), which are further organized into two infraorders, New World monkeys (Platyrhinii) and Old World monkeys and apes (Catarrhini). New World and Old World monkeys diverged as separate lineages during the Oligocene (35–40 myr). Haplorhines are characterized by shorter muzzles that lack prominent sensory whiskers, anterior dentition proportional to other teeth thus lacking a toothcomb, reduced olfactory lobes and a mobile upper lip with a greatly reduced or absent frenulum, which permits an enhanced range of facial expressions. Most Haplorhines are diurnal, lack a light-reflecting retinal layer and exhibit a retinal fovea, which heightens visual acuity. Haplorhines exhibit a complete bony orbit in contrast to the postorbital bar seen in Strepsirhines. Haplorhines also exhibit fused frontal bones, fused mandibular symphyses and a larger brain to body size ratio. Larger social groups exhibit more complex social interactions and a longer period of maternal dependence by offspring.

Living Platyrrhines (found in tropical Central and South America) are distinguished by round, lateral facing nostrils, three premolars in each dental quadrant and a body size intermediate between Strepsirhines and Catarrhines. Trichromatic or dichromatic color vision occurs for individuals within some species based on the particular complement of cone opsin genes [1]. Some cebus monkeys also have prehensile tails, while some callitrichid monkeys exhibit specialized compressed nails that form pseudoclaws [15]. Living Catarrhines (found in tropical Africa, India, Asia, Australia and nearby island chains) are distinguished by narrow anterior facing nostrils, two premolars in each dental quadrant and larger body size. A more limited range of shoulder movement is distinct from the hominoid arm swing and is related to the habitual quadrupedal arboreal locomotion of most smaller monkeys [4,5,6,11,12,15].

The superfamily Hominoidea are the largest bodied primates that appeared during the early Miocene (25 myr) and are represented by *Proconsul* and *Morotopithecus* in the fossil record. They exhibit shorter torsos in comparison to limbs, broad chests, scapulae located dorsally and a broad range of motion in limbs that variously accommodates suspensory arboreal movement and brachiation as well as bipedality. Hominoids have no tails, exhibit the flattest facial profiles of all primates, have five cusp mandibular molars and show the greatest reduction in olfactory lobes. A higher brain to body size ratio, more highly convoluted cerebral cortex, more complex social behaviors, greater developmental immaturity of infants at birth, insight learning and self-recognition among hominids distinguish these species from other primates [4,5,6,11]. Molecular evidence shows Hylobatidae (gibbons and siamangs) experienced the earliest divergence from the Hominoid common ancestor at approximately 17 myr and subsequently show the strongest selection for arboreal life as a medium bodied brachiator. Divergence from a common lineage for other extant great apes based on DNA-DNA hybridization branching times places orangutans at 12 myr, gorillas at 9 myr and the ►*Pan-Homo* split at 7 myr. Molecular evidence also shows much closer phylogenetic affinities among great ape species that has led researchers to place all great apes into the family Hominidae. Taxonomic distinctions within Hominidae now parallel times of divergence, placing orangutans (subfamily Ponginae; genus *Pongo*) and gorillas (subfamily Gorillinae; genus *Gorilla*) into separate categories, acknowledging the close genetic similarities among chimpanzees, bonobos and humans (subfamily Homininae) and differentiating chimpanzees and bonobos (tribe Panini; genus *Pan*) from humans (tribe Hominini; genus *Homo*) at the taxonomic level of tribe. Divergence between chimpanzee and bonobo lineages appears to occur around 5 myr, shortly after the split with the genus *Homo* [12].

Retrogenes, also known as retrotransposons or processed pseudogenes are providing new insights into primate phylogeny and evolution. Retrogenes are common genetic elements in ancestral primates, as is generally true of mammalian genomes. At approximately 40 million years BP, retrotranspositional substitutions in ancestral primates accelerated to 30–200 times the rate observed for the previous 10 million years. This retrogene explosion appears to mark the beginning of the main adaptive radiation of higher primates (hyporder Anthropodea), and occurs just prior to the establishment of Platyrrhines (New World monkeys) and Catarrhines (Old World monkeys) as separate infraorders [16,17,18,19]. These novel retrogene combinations may have promoted new simian phenotypes and lineages, as well as the appearance of new varieties of morphological complexity through domain specific positive selection. Recent studies also suggest that this abundance of new gene combinations may play a role in the rapid appearance of hominin

phenoTypes through inactivating (or down regulating) conserved ancestral primate traits. For example, inactivation of the myosin heavy chain (MYH) associated with substantial reductions in masticatory muscles appears to have occurred at approximately 2.4 million years BP, thus removing contractile force constraints on craniofacial morphology [20]. Similar selective inactivation of the common mammalian sialic acid gene in brain tissue (hydroxylase inactivating substitution of CMP-Neu5Ac for CMP-Neu5Gc) occurs at approximately 2.8 million years BP [21,22]. Both of these proteomic events are coincident with a surge in hominin encephalization.

Monkeys most commonly used in scientific experimentation include baboons, marmosets, various species of macaques, capuchins and African green monkeys. Chimpanzees as well as bonobos, gorillas and orangutans continue to be used in biomedical and neuroscience experimentation despite the endangered status of these non-human great apes.

The following primate taxonomy represents current consensus among researchers for the phylogenetic and adaptative relationships among primates. Details and even broad characterizations of any taxonomy undergo continual review as additional fossils are recovered and new molecular studies reveal previous unknown phylogenetic relationships.

ORDER PRIMATES [4,22]

- Semi-Order Plesiadapiformes: archaic, extinct primate predecessors
  - Superfamily Paramomyoidea
  - Family Paromomyidae
  - Family Picrodontidae
  - Superfamily Plesiadapoidea
  - Family Plesiadapidae
  - Family Carpolestidae
  - Family Saxonellidae
- Semi-Order Euprimates
  - Suborder Strepsirhini lemurs, lorises, pottos, galagos, Aye-Aye
  - Infraorder Lemuriformes
  - Superfamily Lemuroidea
  - Family Lemuridae: lemurs
  - Family Lepilemuridae: sportive lemurs
  - Superfamily Indriodea
  - Family Indriidae: woolly lemurs
  - Family Lepilemuridae: sportive lemur
  - Family Daubentoniidae: Aye-aye
  - Superfamily Lorisiformes
  - Family Lorisidae: lorises, pottos and allies
  - Family Galagidae: galagos
  - Family Cheirogaleidae: dwarf lemurs and mouse-lemurs
  - Suborder Haplorhini: tarsiers, monkeys and apes
  - Hyporder Tarsiiformes
  - Family Tarsiidae: tarsiers
  - Hyporder Anthropoidea
  - Infraorder Platyrrhini: New World monkeys
  - Family Cebidae: marmosets, tamarins, capuchins and squirrel monkeys
  - Family Atelidae: howler, spider, sakis, owl monkeys and woolly monkeys
  - Infraorder Catarrhini
  - Superfamily Cercopithecoidea
  - Family Cercopithecidae: Old World monkeys (21 genera including macaques, colobus, languars, baboons)
  - Superfamily Hominoidea
  - Family Hylobatidae: gibbons, siamangs
  - Family Hominidae: bonobos, chimpanzees, orangutans, gorillas, humans, all ancestral hominin fossils

# Evolution and Phylogeny of Chordates

Jon Mallatt
School of Biological Sciences, Washington State University, Pullman, Washington, WA, USA

## Synonyms

Phylogeny; Phylogeny and evolution of chordates

## Definition

Chordates are the group of animals to which vertebrates including humans belong. Like so many other phyla of ►*bilaterian animals*, they originated in the ocean over 520 million years ago, before or during the Cambrian period. Their early evolution is of interest to neuroscientists because this was when the basic structure of the vertebrate brain and spinal cord was assembled. Early chordates were soft-bodied so they seldom fossilized, but we reconstruct their origin using the modern chordates and their relatives plus some miraculously preserved fossils.

Living chordates consist of three subgroups: (i) the vertebrates (informally, the fishes, amphibians, reptiles and mammals), (ii) cephalochordates (also known as amphioxus or lancelets) and (iii) tunicates (or urochordates, including "sea squirts"). Representatives of these three subgroups are shown in Figs. 1 and 2. The chordates belong to a larger group of animals called deuterostomes, whose other members are the hemichordates (such as enteropneusts or "acorn worms:" Fig. 1h), echinoderms (the crinoid sea lilies, the sea stars, sea urchins, etc.), and a rare worm-like animal called *Xenoturbella* (Fig. 2) [3].

## Characteristics

### Descriptions of the Structures and Animals

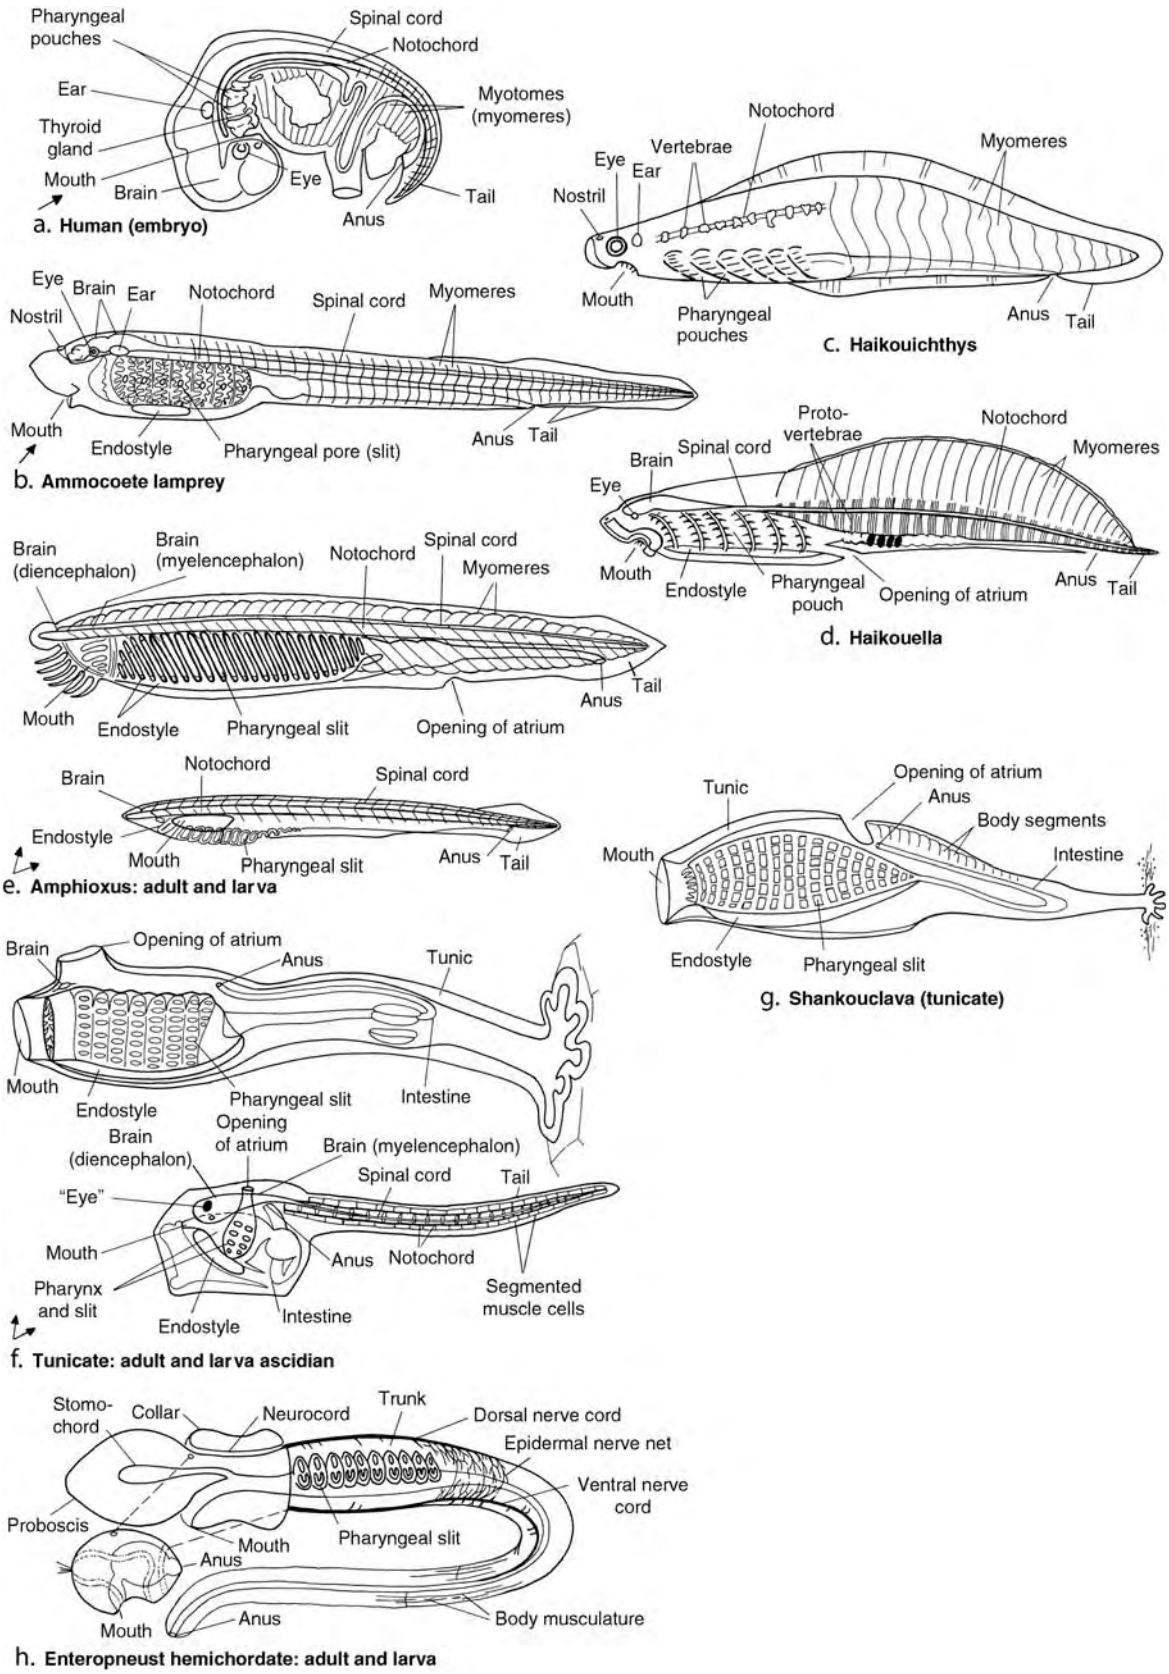
#### *Structures*

At some time in their life cycle, all chordates have five major structures, some of which they share with the other deuterostome animals. These chordate-defining structures are: (i) a dorsal, hollow nerve cord, (ii) a notochord, (iii) pharyngeal slits or pouches, (iv) an endostyle or thyroid gland and (v) a tail behind the anus. These are shown in the various chordates in Fig. 1 and will now be considered.

The dorsal, hollow nerve cord develops from the ectoderm layer of the back in chordate embryos, usually as a tubular invagination, and then becomes the brain in the head and the spinal cord in the neck and trunk. The brain is associated with special sensory receptors that detect light and other stimuli.

The notochord is a turgid stiffening rod in the back. In vertebrates, the notochord forms in the embryo, marks the position of the backbone and is then mostly replaced by the vertebrae. However, in the invertebrate chordates and in a few fishes that do not develop complete vertebrae, the notochord remains complete throughout life and is important for swimming. Not compressible from front to back but bendable from side to side, it allows swimming by lateral undulations of the body. Incidentally, human biologists might be interested to know that the human notochord forms the springy nucleus pulposus in each intervertebral disc of the backbone; this nucleus bursts out in the common back injury called a herniated or slipped disc.

In the primitively aquatic chordates (tunicates, cephalochordates, fishes and larval amphibians), the pharyngeal slits allow water that has entered the mouth to leave the body through the pharynx. This function is important for ventilation in fishes, but it is also a part of suspension feeding (filtering tiny algae, bacteria and detritus particles from the ventilatory water), which is the feeding mode of all the invertebrate chordates. In chordate embryos, the pharyngeal slits form as openings in lateral outpocketings of the pharynx, the pharyngeal pouches. Land vertebrates do not have gills or gill slits, but they form pharyngeal pouches (Fig. 1a), which develop into structures such as the middle ear, a tonsil, the thymus and the parathyroid glands.



**Evolution and Phylogeny of Chordates. Figure 1** (Continued)

The endostyle is a longitudinal groove in the midline of the floor of the pharynx in the primitively suspension-feeding chordates (Fig. 1b, d–g). A kind of salivary gland, it secretes food-trapping mucus and digestive enzymes for suspension feeding, but it also gathers iodine, makes thyroid hormone and is ►*homologous* to the thyroid gland of vertebrates.

The chordate tail, projecting posterior to the anus, is muscular and participates in swimming and other movements of the body.

In addition to their five main structures, all chordate groups have muscle segments along each side of the body and in most groups these segments contract in series to propel the animal by lateral undulation. In the tunicates, these segments are so small that each is just one muscle cell (see the discussion of tunicate larvae below), but in all other chordates the segments are larger blocks of muscle called myomeres (Fig. 1). The primitively aquatic chordates also have vertical ►*fins* which are related to their swimming movements.

The different groups of chordates, in which the above structures are developed to a greater or lesser degree, will be considered next [6, 7, 8, 9].

### Animals

**Vertebrates** Humans possess all the chordate structures, as best seen in a human embryo in the fifth week of development (Fig. 1a). For exploring chordate origins, however, the vertebrates are better represented by a jawless fish, a young lamprey. This is the ammocoete ►*larva* (Fig. 1b), and it is not an embryo but a life-stage that lasts several years before it metamorphoses into an adult lamprey. The ammocoete lives burrowed in the sediment of streams, is a suspension feeder and has all the chordate structures. It also has the structures that are unique to the vertebrates, including a skull, fish gills, paired lateral eyes, ear structures, an olfactory organ and a vertebrate brain that includes a telencephalon and mesencephalon as well as a diencephalon and myelencephalon. Most of these vertebrate-specific structures develop from embryonic "neural folds" [10], which are absent from the invertebrate chordates (see ►Evolution of neural crest and neurogenic placodes).

Vertebrates also have ►*vertebrae*, segmented pieces of skeleton that lie along, or mostly replace, the notochord. Such vertebral elements form when the ammocoete lamprey becomes an adult, but more significantly, they are also present in the oldest known vertebrate animal, the jawless fossil fish, ►*Haikouichthys* (Fig. 1c) [11]. *Haikouichthys* is from the Maotianshan shale of South China. This shale dates to the Early Cambrian, 520 or 530 million years ago. It was laid down in the shallow ocean and documents the first appearance of whole-body fossils of various phyla in the fossil record. Thus, *Haikouichthys* shows that the first vertebrates did possess the defining structures of the vertebrate group.

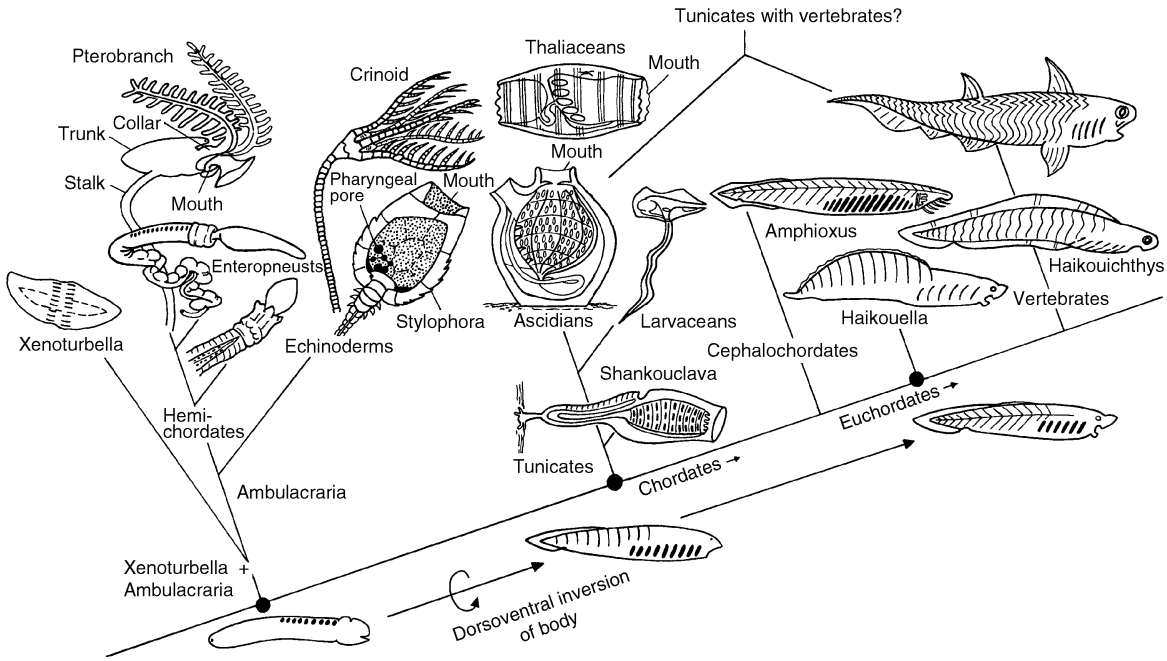
**Haikouella** Another fossil animal from the Maotianshan shale is *Haikouella lanceolatum* (Fig. 1d) [12], not to be confused with the similarly named *Haikouichthys* above. *Haikouella* is represented by many remarkably preserved specimens that reveal its anatomical structures in exceptional detail. Its well-developed head resembles that of an ammocoete lamprey. All the chordate-defining structures can be identified in *Haikouella*, plus a remarkably large brain, gills and "proto-vertebrae" that suggest vertebrae evolved early in the line to vertebrates. However, *Haikouella* lacks some features of vertebrates, such as a skull, ear and large telencephalon, so phylogenetic studies show it to be the nearest-known relative of vertebrates rather than a true vertebrate. Details of its mouth and pharynx indicate it was a suspension feeder, as are all other invertebrate chordates.

**Cephalochordates** Amphioxus (Fig. 1e) is a fish-like invertebrate that lives burrowed in coarse sands in the shallow ocean, suspension feeding on particles in the water that flows between the sand grains. Able to undulate through the sediment and to swim rapidly in the water column if dug up, amphioxus has all the chordate structures, including the locomotory myomeres, notochord and tail [6]. Its brain, head region and cranial sensory organs are much less developed than those of vertebrates. In fact, the brain is only a slightly widened part of the nerve cord and was not confirmed as a real, chordate brain until the 1990s, when ultrastructural and developmental studies showed it to consist of a diencephalon and a myelencephalon [13].

Despite some candidate fossils, cephalochordates have not been identified with certainty in the fossil record [7].

**Urochordates** Tunicates are highly specialized chordates and in many ways, the most unusual [5, 6]. They are covered by a tunic, which is a living, growing, vascularized coat of proteins and of carbohydrates that

**Evolution and Phylogeny of Chordates. Figure 1** Various chordates, with some of their larvae and relatives. Living animals are in the *left* column, and fossil animals from the Early Cambrian are in the *right* column. Redrawn from various sources. The tunicates shown in part f are ascidians, of the aplousobranchiate subgroup. In part h, *dashed lines* are used to show corresponding points on the bodies of the adult and larval hemichordates. Recent studies [1,2] confirm that the dorsoventral axis of chordates is inverted compared to that of hemichordates, so the enteropneust (h) should be flipped over for comparison with the chordates (a–g). To give some idea of sizes, all the adult animals shown here are several centimeters long in life and were drawn to roughly the same scale.



**Evolution and Phylogeny of Chordates. Figure 2** Phylogenetic tree showing the relationships among deuterostomes and chordates. This tree was derived from morphological and molecular-phylogenetic evidence [e.g., in 3, 4]. Three hypothetical, reconstructed ancestors are shown along the backbone of the tree, at the bottom and correspond to the three nodes at the large black dots. All the other animals are real except for the un-named fish at the ►*far upper right*, which is a reconstruction of the first jawed vertebrate. The bodies of all the animals are oriented with their cranial/mouth end pointing to the ►*right*, except for the ascidian tunicate, whose mouth points ►*upward*. "Euchordates" comprise the cephalochordates, ►*Haikouella*, and vertebrates; however, some recent evidence suggests instead that tunicates are closer to vertebrates (and to ►*Haikouella*) than are cephalochordates [5]. The various animals are not drawn to the same scale.

resemble plant cellulose in most tunicate groups. The group of tunicates that is most comparable to other chordates is the ascidians (Fig. 1f). Adult ascidians are sessile, not capable of real locomotion and live anchored to ocean substrates as they suspension-feed with their large pharyngeal basket. As adults (Fig. 1f, top), they have only a remnant of the brain (a cerebral ganglion and "neural gland") and no spinal cord, notochord, muscle segments or tail. As motile, swimming larvae, however, they have all these chordate structures (Fig. 1f, bottom). Furthermore, the brain of some ascidian larvae (the aplousobranchiates) is rather elaborate, with external bulges that define diencephalon and myelencephalon parts [13].

Besides ascidians, tunicates have two other subgroups, thaliaceans and larvaceans (Fig. 2).

Both of these are motile, but neither resembles other chordates as closely as ascidians do. The barrel-shaped thaliaceans (which include the salps) evolved from ascidians, as indicated by sequence data from their genes [4]. The small larvaceans are rapidly developing and short-lived in the extreme. Despite their tadpole-shape and swimming tail, their anatomy and genome are so unusual that it seems best to view larvaceans as derived and specialized animals, not as models of the ancestral chordates as some scientists have done in the past.

Recently, a convincing fossil tunicate was discovered, *Shankouclava*, from the Cambrian Maotianshan shale (Fig. 1g) [14]. Significantly, it resembles aplousobranchiate ascidians (Fig. 1f), whose bodies are longer and less pharynx-dominated than those of other ascidians. Most intriguingly, although the *Shankouclava* specimens are adults, they show segments along the dorsal body, reminiscent of myomeres (although the true nature of these segments cannot be discerned from the fossil material). Overall, *Shankouclava* suggests that tunicates evolved from an ancestor with a more elongate and more typically chordate body.

**Other Deuterostomes** Hemichordates are not chordates, but are related deuterostomes that have a few chordate structures [6, 15]. Their body is divided into three parts, which are called the proboscis, collar and trunk in the major group of hemichordates, the enteropneust worms (Fig. 1h). Enteropneusts live on the ocean bottom, many in burrows and others under shells or rocks. They are motile and can crawl; some

deep-sea species forage for food particles along the ocean floor. Enteropneusts include both suspension feeders and deposit feeders.

It is debatable whether hemichordates have a dorsal, hollow nerve cord. Their nervous system consists of a net of neurons in the epidermis over the entire body (Fig. 1h). This net includes both a dorsal and a ventral nerve cord, but these cords are solid rather than hollow. In the collar region, however, the dorsal cord folds inward to form a tubular neurocord or collar cord, suggesting it corresponds to the chordate nerve cord, which develops in the same way. Unlike the nerve cord, however, the neurocord is restricted in location and seems only to conduct signals rather than to process information. Given these differences, most authorities do not equate the hemichordate neurocord with the chordate nerve cord [15].

Hemichordates also have a notochord-like structure, the stomochord, which projects from the roof of the oral cavity into the proboscis (Fig. 1h). The notochord of chordates similarly develops from the roof of the digestive tube and its microscopic anatomy resembles that of the stomochord in considerable detail; both are collections of vacuolated cells surrounded by a sheath of connective tissue. Even so, the stomochord and notochord have different locations relative to nearby vascular and nervous structures and do not express the same genes as they deveop [2], raising doubt as to whether they are homologous structures.

Actually, these questions of homology are answered by recent studies of embryonic development of enteropneust hemichordates. These studies, by Christopher J. Lowe and others [1, 2, 9], mapped the expression domains of the genes that pattern the dorsoventral arrangement of the body (especially, of genes for bone-morphogenic proteins and for chordin). The findings revealed that the ventral side of the hemichordate body corresponds to the dorsal side of the chordate body, and vice-versa (even though the anteroposterior pattern of development defining the head and tail ends is the same in the two groups of animals). What's more, the dorsoventral pattern of the hemichordate body matches that of all other bilaterian animals, so this pattern must be ancestral, and the chordates must have turned over so that their original back surface became their belly surface. This upholds the fundamental correctness of an old and controversial idea that chordates are "upside-down" compared to arthropods and other non-chordate invertebrates (see [1] for references). All this means that the stomochord and neurocord of hemichordates are not on the same side of the body as are the notochord and nerve cord of chordates, so these structures cannot be homologous in the two groups of animals. Other implications of the apparent flip in the dorsoventral orientation of chordates will be considered later in this essay.

Hemichordates do have the chordate character of a pharynx pierced by pharyngeal slits. These slits and the pharyngeal bars between them are remarkably similar to those of cephalochordates. No iodine-binding endostyle exists in hemichordates, however.

The body musculature of enteropneusts mostly runs longitudinally and is not divided into segments. These worms move by shortening and lengthening their body and proboscis, not by undulation. Juveniles of some species have a tail behind the anus [2] but no adult enteropneust has a post-anal tail.

Besides the enteropneust worms, the other group of hemichordates is the pterobranchs ("sea angels:" Fig. 2) [6]. These are tiny animals, minimally mobile or sessile, that live in colonies in a network of cuticular tubes, mostly in the deep ocean. The body of a pterobranch resembles a bag on a stalk, with tentacled, filtering arms projecting from the collar region of the bag. The gill slits are reduced, with some pterobranchs having a single pair, others having none. Phylogenetic studies based on ribosomal rRNA genes suggest that pterobranchs evolved from one subgroup of enteropneust worms [4].

No body fossils of hemichordates are known, although the tubes of some pterobranchs are known from the Paleozoic Era about 500 to 300 million years ago and are named graptolites.

Hemichordates were long thought to be the closest relatives of chordates, but recent developmental and molecular-phylogenetic studies indicate they are closer to echinoderms instead [4, 7]. The name for this "hemichordate and echinoderm" group is Ambulacraria (Fig. 2). This grouping could mean that echinoderms evolved from enteropneust-like worms, and indeed, some fossil echinoderms from the Early Paleozoic, called Stylophora, had pharyngeal slits or pores and bodies that were more elongated and closer to bilaterally symmetrical than the bodies of later echinoderms (Fig. 2). The idea that the common ancestor of echinoderms and hemichordates was a worm is supported by the fact that *Xenoturbella,* recently found to be the closest relative of these Ambulacraria [3], is itself wormlike (Fig. 2).

## Higher Level Processes

### *Steps in the Origin of the Chordates*

Throughout most of the twentieth century, biologists focused on the facts that many of the deuterostome groups are inactive, sessile animals shaped like sacs (pterobranchs, echinoderms represented by the crinoid sea lilies and adult ascidians) and that the swimming, streamlined larvae of ascidian tunicates have all the chordate-locomotory structures that adult ascidians lack (Fig. 1f). This focus led such scientists as W. Garstang, N.J. Berrill and A.S. Romer to conclude that ►*larval* evolution was the key to the origin of the chordates and

the vertebrates [4, 8]. That is, adults of pre-chordates and early chordates were said to have been sessile "sacs" but then a swimming tunicate-larva gained the ability to reproduce (through ►*progenesis*) and thus became a swimming adult; the original, sessile adult stage was eliminated and this tunicate gave rise to the mobile cephalochordates and vertebrates. In this view, studying the evolution of the nervous system involved a straightforward exploration of how the simpler system of hemichordates could have evolved into the slightly more complex and centralized system of larval tunicates and then into the increasingly complex systems of cephalochordates and vertebrates. This approach was not very successful, however, because the nervous systems of hemichordates and chordates are too dissimilar to compare easily and because it was not yet known that tunicates and cephalochordates have true brains. Another problem with the idea that vertebrates evolved from larval tunicates is that the latter do not express certain genes needed to form the body plan of bilaterian animals, implying that tunicates could not give rise to the vertebrate body [16].

The current understanding of deuterostome interrelationships, built on molecular-phylogenetic data as well as anatomical evidence, suggests a different scenario for the origin of chordates (Fig. 2). As documented in the figure, most of the deuterostomes with sessile adults are more derived than was previously expected; that is, the pterobranchs, echinoderms and modern ascidians are high up at the end branches of the tree and do not represent basal or "primitive" animals, as was formerly believed. Instead, mobile worm-like and fish-like animals occupy these basal positions, as reconstructed at the three black dots in Fig. 2.

This leads to a simpler story of chordate and vertebrate evolution, as it occurred right before the Cambrian Period [10, 16]. At first, ancestral deuterostomes were mobile, bottom-dwelling, suspension-feeding worms with pharyngeal slits (roughly resembling enteropneusts); interestingly, at this time the ocean bottoms throughout the world were covered with a thick film or suspension of bacteria and other microorganisms (a "microbial mat") that could have supplied the food for such worms. Next, some of these early deuterostomes became more active and able to swim through the water above the ocean bottom, perhaps traveling back and forth among the most food-rich spots of the microbial mat. These swimmers were the first chordates, roughly resembling amphioxus in body form. They then gave rise to cephalochordates and the highly active vertebrates. Although the animals along the main line became progressively more active, many offshoots by contrast became less active or sessile, at least as adults: e.g., the echinoderms, pterobranchs, the sessile ascidians and even the cephalochordates when they became burrowers.

To this scenario must be added an explanation of why pre-chordates flipped their body dorsoventrally when evolving into chordates [1, 2]. This is better explained in terms of gradual adaptive changes in the life style of the lineage rather than being attributed to some abrupt, macro-evolutionary shift in developmental patterning. Three possible explanations come to mind. First, pre-chordate worms may have gone through a stage where they stopped lying and moving horizontally on the ocean floor but shifted to live only in vertical burrows. After eons of time, when the animals once again came to lie horizontally, they did so by chance on the opposite side of their body [1]. However, the special features of the chordate body do not suggest adaptation for extreme burrowing but instead for better swimming, raising a second possibility, i.e. that the first chordates, when they began swimming in the water column, swam on their backs. A modern analogy is that many branchiopod crustaceans such as fairy shrimps do swim belly-up like this. A third possibility is that in the original, worm-like deuterostomes and pre-chordates the dorsal and ventral surfaces of the body did not differ much from one another in their anatomy, so it made little difference how these animals lay on the ocean floor, whether on their bellies, backs or sides and it was only by chance that the chordate line began to orient their originally lower surface upward.

Actually, the difficult part of explaining the dorsoventral inversion of chordates involves the mouth [1, 17]. The mouths of hemichordates and most non-chordate bilaterians are on the ventral surface of their body, so the inversion should have placed the chordate mouth dorsally – but this did not happen, as the mouth of chordates is ventral. To resolve this contradiction, most workers proposed that after the body inverted the chordate mouth moved around or through the body from dorsal to ventral [1, 17], perhaps to make room for the evolving and enlarging brain, or that there was an intermediate stage with two mouths, both a dorsal and a ventral one. A simpler explanation, however, is that the original mouth of ancestral deuterostomes and pre-chordates was neither dorsal nor ventral but terminal, lying at the very anterior end of the worm's body. Only later did it migrate to the ventral location, independently in the chordates and non-chordates. This would solve the conundrum and an ancestrally terminal mouth is not impossible, given that many known worms do have terminal mouths (e.g., earthworms and nematodes).

Another thing should be noted about the scenario of chordate origins proposed here (Fig. 2). It views suspension feeding as a constant feature of all the early deuterostome and chordate groups. That is, all were suspension feeders until much later in the evolutionary radiation when advanced vertebrates and echinoderms adopted predation or other feeding modes.

## Implications of the Model

A scenario of chordate origins in which chordates evolved from hemichordate-like worms, rather than from tunicate larvae, has been presented. How does this new view affect understanding of the early evolution of chordate structures, especially of the nervous system? First, it shifts the focus from larval tunicates (old view) to amphioxus as the best proxy for the first chordate animal. Second, it implies that the nervous system of adult and larval tunicates is secondarily modified or simplified, so a straight line cannot be drawn from enteropneusts to tunicates to amphioxus in reconstructing the evolution of nervous structures.

As amphioxus moves to center stage, it is worth noting that the near-vertebrate *Haikouella* shares several body structures with amphioxus (e.g., see the "opening of atrium" in Fig. 1d, e), as well as having many vertebrate structures. This implies that amphioxus is not only a good model for the first chordates, but also for the ancestor of ►*vertebrates*. However, we must not jump to the conclusion that either one of these ancestors was exactly like amphioxus, because our scenario also implies the cephalochordate line lost some of its neural complexity when it switched from free-swimming to burrowing and living in sediment. The brain and cranial-sensory organs of amphioxus could have been secondarily reduced by an amount that is difficult to determine.

New ►*phylogenomic studies* that compare large numbers of genes across deuterostomes suggest that tunicates, although their body is highly modified, are actually more closely related to the vertebrates than is amphioxus [3, 5]. The problem is still under investigation, but if the proposed grouping of tunicates with vertebrates proves true, it will shift cephalochordates one step farther down the tree (Fig. 2) and will reinforce the current view that amphioxus resembles the earliest chordates.

Although the idea that amphioxus approximates the ancestral chordate will help to direct future research, it also reveals a disappointing gap in the available evidence. In reconstructing the initial evolution of Chordata, one is now forced to derive an amphioxus-like body from that of a (inverted) hemichordate and with no fossils to help. Although these two animals show similarities in their pharynx and in the development of their mesoderm, they differ from one another in most other organ systems (Fig. 1). These evolutionary gaps may be too wide for scientists to fill with any certainty. Most frustrating is the gap between their nervous systems: Except in very general terms it could prove too difficult to reconstruct how an extended, epidermal nerve net like that in hemichordates evolved into the highly organized and condensed central nervous system of amphioxus and other chordates.

This barrier to reconstructing the evolution of the chordate nervous system could be removed by recent findings from non-deuterostome annelid worms [18], which indicate that the common ancestor of all bilaterian animals already had a compled central nervous system (CNS), with specific neuron types shared by both chordates and annelids. This finding implies that the hemichordate line uniquely lost this CNS in favor of a secondarily simplified nerve net, making hemichordates irrelevant to the question of interest. Instead, key information on the origin of the chordate CNS could be found in the non-deuterostome invertebrates after all.

The topic of nervous-system evolution is considered further and from a different perspective in ►Evolution of the brain: at the invertebrate-vertebrate transition.

# Evolution and the Concept of Homology

Ann B. Butler
Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

Homology was originally defined by Richard Owen in 1843 as "the same organ in different animals under every variety of form and function" [1]. Its current most common usage is in the sense of phylogenetic homology, which requires presence of the phenotypic character (or trait) in the common ancestor and continuity of its expression along an evolutionary lineage and across the members of the taxon. Other definitions that focus on continuity of information, i.e., the genetic and developmental bases for a given character, are coming into use as the close relationships between evolution and embryological development are increasingly appreciated.

## Characteristics

### The Concept of Homology

While the term analogy refers to similarity of function and can be applied regardless of phylogenetic relationships, the term homology is predominantly applied to structural characters, irrespective of possible functional differences but tied, in one way or another, to the phylogenetic relationships of the animals in which they are present. Richard Owen's use of the word "same" in his pre-Darwinian, 1843 definition of homology [1], "the same organ in different animals under every variety of form and function," recently has come to be appreciated from a new perspective due to the wealth of new developmental data on gene expression patterns now available.

Consider, for example, the word "eye." This word has been applied to the paired, complexly structured ommatidial photoreceptor apparatuses on the heads of insects as well as to the paired, retinal photoreceptor apparatuses on the heads of vertebrates, which are also complexly structured but in a substantially different way. That both these sets of structures have the same name implies sameness in some manner, and, indeed, they share a number of common features including relative location on the head and similar structural components albeit differently arranged. However, while it is now known that the genetic specification at the top part of the cascade for the embryological generation of eyes is shared across vertebrates and invertebrates alike [2] (and see Evolution, of Eyes), the lack of eyes (as whole eyes) in the postulated common ancestor precludes the eyes of insects and the eyes of vertebrates as being considered homologous, at least in the historical, or phylogenetic, sense, which is by far the most common application of the concept. While the common ancestor likely had a simple, paired or unpaired, photoreceptor apparatus on the head region, consisting of one or a few receptor cells, the gain of large and complexly structured photoreceptor apparatuses – whole eyes – in insects and vertebrates occurred independently within each lineage. Thus, in the historical sense of homology, these independent gains would represent an example of homoplasy – either parallelism or convergence. These concepts will be examined, and then an alternative, conceptual approach to the issue of sameness, that of generative homology, or syngeny [3], based on the inheritance of common genetic bases, will be considered.

### Historical, or Phylogenetic, Homology

One of the more commonly cited definitions of historical homology is that of Wiley [4]: "A character of two or more taxa is homologous if this character is found in the common ancestor of these taxa, or, two characters (or a linear sequence of characters) are homologous if one is directly (or sequentially) derived from the other(s)." Historical homology thus requires that the phenotypic character was present in the common ancestor and was expressed in the phenotypes along the descendant lineage and is best applicable to characters that are reliably and consistently expressed in the phenotype. Historical homology addresses character distribution and is concerned with the reconstruction of phylogenetic relationships and the recognition of monophyletic groups.

Similarity of multiple features and to a minute degree [5] is often used to both recognize and evaluate the occurrence of historical homology. Since similarity is not a requirement, however, some instances of homology may be missed when marked variation of features has occurred. For example, two of the three middle ear bones in mammals, the malleus and incus, would not be recognizable as homologues of the articular and quadrate bones, respectively, of reptiles without the sequential evidence of change revealed by the fossil record, since their morphology and location are so different.

Most but not all historically homologous characters are produced by homologous generative systems. In a number of cases, characters that exhibit multiple points of similarity and phylogenetically congruent distributions are produced by generative systems that are different to some extent. Examples include that of Meckel's cartilage, which is induced by different tissues in different tetrapods, the columella (middle ear bone) of chicks, which is variably derived from either ectoderm or mesoderm, and development of the lens of the eye from ectoderm in the normal situation but regeneration of it from dedifferentiated iris tissue in salamanders.

## Homoplasy

The opposite of historical homology is homoplasy, which is similarity of a character in two or more taxa that is not the result of inheritance from a common ancestor. The term was coined by Lankester in 1870 to refer to the independent gain of similar characters in different taxa [1]. Homoplasy comprises three types: parallelism, reversal, and convergence. In the former two, the similarities may be multiple and minute, in some cases resulting in an incorrect hypothesis of historical homology. In the latter, similarities are usually only superficial.

### *Parallelism*

Wiley [4] defined parallelism as "the independent development of similar characters from the same plesiomorphic [i.e., precursor] character." While the presence of such a precursor character in the common ancestor is not universally considered to be essential, it is generally agreed that some basis for it, such as the genetic basis, be shared. Wake [6], for example, defined parallelism as "the production of apparently identical traits by the same generative system." The sharing of a generative basis for traits not present in a common ancestor has also been called latent homology by de Beer [7], meant to imply a "genetically based homology" for traits not expressed in the common ancestor as "visible phenotypic" traits, and a variety of terms by other authors, including deep homology, or homoiology, unique inside parallelism, and underlying synapomorphy.

### *Reversal*

Reversal refers to the reappearance, within a single lineage, of a character that was not phenotypically apparent in intermediate members of that lineage. Multiple reversals can occur along a lineage for loss, regain, loss again, regain again, and so forth of a character. The regain of a character in this manner is, as in the case of parallelism, presumably due to the same generative basis [8].

### *Convergence*

Wiley [4] defined convergence as "the development of similar characters from different preexisting characters." Wake [9] has noted that convergence may frequently be the result of design constraints. Since such characters typically are similar only to a superficial degree and occur in widely divergent taxa, it is generally agreed that convergence involves the deployment of nonhomologous generative systems.

## Specification of Homology

A crucial but sometimes neglected step in formulating a hypothesis of homology is to specify the level of the homology [10]. As discussed above, the eyes, as whole eyes, of insects are not historically homologous to those of vertebrates. The phrase "as whole eyes" specifies the level of the homology. In contrast, the eyes, as rostral head, pigmented cell structures, are homologous across all invertebrates and vertebrates, since parsimony supports that such a structure was present in the common ancestor.

Another commonly cited example is that of wings. One can state that the wings of birds and bats are not homologous. One can also state that they are. Neither of these statements makes sense, however, until they are specified. The wings of birds and bats are not homologous as wings. The wings of birds and bats are homologous as forelimbs. In a number of cases, the specification is obvious, and in these cases, it is not necessary to spell it out: for example, the dorsal lateral geniculate nucleus of birds is homologous to the dorsal lateral geniculate nucleus of mammals. Even in such cases, however, caution is advised. While the nucleus in this example can be presumed to be compared as the whole nucleus, its subdivisions, even just within mammals, are not homologous in terms of one-to-one comparison.

## Tests for Homology

Patterson [11] suggested three tests for homology that comprise a formidable methodology for evaluating hypotheses of it. The first test, that of similarity, is widely applied. The second test, that of congruence, is the methodology of cladistic analysis and also widely applied. It is the crucial test for historical homology. The third test, that of conjunction, is less commonly invoked but is highly useful in some circumstances.

### *Similarity*

Similarity is the most salient of the criteria used to assess homology. As noted above, Simpson [5] specified that most if not all homologous characters can be expected to exhibit similarity of multiple features and to a minute degree. While extensive similarity is not a required criterion, it supports hypotheses of homology where present.

### Congruence: Parsimony and Cladistical Analysis

The principle of parsimony is used in the analysis of the distribution of characters, whether they are phenotypic or generative. The hypothesis that involves the least number of changes along lineages and across taxa is formulated and then tested. Without using parsimony, more elaborate and thus less likely hypotheses could be generated. Although parsimony does not guarantee correctness of any hypothesis, the use of it in formulating hypotheses provides a reasonably efficient working methodology.

Since the nervous system leaves little trace in the fossil record, other than for its surface features in some cases, hypotheses about the neural traits of ancestral taxa must be formulated based on the distribution of characters across extant taxa. Cladistic analysis examines the distribution of a given character, such as the presence of a particular nucleus in the brain, across a phylogeny that itself is determined using multiple, unrelated, i.e., non-neural, traits. If a neural character is present in all or most members of a taxon, it is parsimonious to hypothesize that the character was also present in the common ancestor and is thus historically homologous. If, in contrast, the character is present in only one or a few members of the taxon, it is likely that it was gained independently in those members. In the latter case, a hypothesis that posits the presence of the character in the common ancestor followed by loss of it in most members would require more changes than positing its ancestral absence followed by a few instances of its subsequent gain.

### Conjunction

This criterion is rarely invoked but can be highly important in some circumstances. As Patterson [11] stated, "If two structures are supposed to be homologous, that hypothesis can be conclusively refuted by finding both structures in one organism." For example, if a particular structure in one taxon is proposed to be homologous to a structure in another taxon, identifying the former as well as the latter in the second taxon would nullify the hypothesis of homology.

## Alternative Approaches to the Concept of Sameness

A more general definition of homology than Wiley's [4] is that of Van Valen [12]: "resemblance caused by a continuity of information." As information on the generative bases for many different characters has accumulated, the concept of homology is being reevaluated.

### Biological Homology

A concept referred to as biological homology was introduced by Roth [13], who recognized that "the basis of homology in the broad sense is the sharing of pathways of development, which are controlled by genealogically-related genes." In a key insight, Roth realized that one must "tolerate some ambiguity" between [historical] homology and parallelism. Wagner [14] applied the concept of biological homology to structures that "share a set of developmental constraints, caused by locally acting self-regulatory mechanisms of organ differentiation [that] are thus developmentally individualized parts of the phenotype," and Müller and Wagner [15] more recently as "the establishment and conservation of individualized structural units in organismal evolution." Biological homology thus focuses on developmental mechanisms and addresses mechanisms of character evolution. Most biologically homologous characters are also historically homologous ones.

### Generative Homology, or Syngeny

The concept of generative homology, or syngeny (literally meaning "same genes") [3,16] focuses specifically on phenotypic (or developmental) characters produced by shared generative systems, inherited with continuity from a common ancestor. It groups characters differently than in the system of historical homology versus homoplasy. Rather, syngenous characters are all those that are produced by shared generative systems, which include (i) most historically homologous characters and cases of (ii) parallelism and (iii) reversal. An example of syngeny is that of eyes across many invertebrate taxa as well as in vertebrates, as whole eyes and to the extent that they are produced by shared patterning genes, including *Pax6* [2]. The opposite of syngeny is allogeny (literally meaning "different genes") [3]. All cases of convergence and a few cases of historical homology (such as the examples noted above) are cases of allogeny.

This concept is thus aligned with the new, evolutionary-developmental biological approach to evolution. In the same vein, Meyer [17] noted "that the biological basis for these seemingly disparate kinds of "sameness" in evolution [including all forms of homoplasy] may in some, or even most, instances not be all that different and may be based on the same principle – the long evolutionary retention of genes, gene interactions and developmental mechanisms…. Therefore, the biological basis of both [historically] homologous traits (those that are evolutionarily always expressed) and homoplasious traits (those that are not always "on," but are "reawakened" during evolution) might not be so different, and the distinction between homology and some forms of homoplasy may be somewhat artificial."

## Forms of Homology

Multiple forms of homology can be recognized. Hobart Smith [18] published succinct and clear definitions of the most commonly encountered forms, on which the following explications are based.

### Discrete Homology

Discrete homology, also referred to as one-to-one homology or strict homology, refers to specific structures that can be regarded as unitary, at least at the level of specification of the homology. The wing of a bat, specified either as a wing or as a forelimb, is an example of a discrete homology.

### Field Homology

Field homology applies to sets of structures that are derived from the same, i.e., homologous, ontogenetic source. For example, the developmental field that gives rise to the five main layers of the dorsal lateral geniculate nucleus (DLGN) in carnivores is homologous to the developmental field that gives rise to the six main layers of this nucleus in primates. The set of five main layers of the carnivore DLGN are homologous, as derivatives of that developmental field, to the set of six layers in the primate DLGN, even though the layers themselves cannot be homologized in a discrete manner. Since a developmental field may give rise to a different number of derivatives, including zero, in various taxa, this concept of homology allows the sets of derivatives to be compared. An interesting example of this involves comparing the zero (nonexistant) forelimbs of snakes to those of other tetrapods.

### Serial Homology

Serial homology is often called iterative homology or, rarely, homonomy. A commonly cited example is that of the vertebrae, either as those of one part of the spinal column or as those of the entire column: the C2 vertebra is serially homologous to the C4 vertebra, as cervical vertebrae, and to the L5 vertebra, simply as vertebrae. Some scientists, such as Wake [19] make the distinction that iteration is simply that, and iterated structures are thus not suitable material for application of the homology concept.

### Partial Homology

Partial homology is a highly controversial concept [17]. As data on patterning genes and developmental specification of morphological characters continue to accumulate, this concept gains in credibility. Wake [19] cites the system of *Hox* patterning genes in defending it, noting that "all homology among genealogical entities is partial at some level, except between the closest relatives." As discussed above, the concept of generative homology, or syngeny, is fully in accord with the concept of partial homology.

## Evolution of the Concept of Homology

The concept of homology continues to evolve as information on the generative bases for characters and their phenotypic expression increases. Concepts such as historical homology, biological homology, and generative homology often overlap and imply each other, but in some crucial aspects, they are independent. Historical homology is the most common application of Owen's original idea of sameness and is the entrenched basis for phylogenetic reconstruction based on phenotypic traits; nonetheless, some of its most strongly supported hypotheses have been overturned by genetic studies – for example, the relationships of the major groups of sauropsids to each other, with lizards and snakes alone forming the outgroup to crocodiles, birds, turtles, and the tuatara *Sphenodon* [20].

Biological homology and generative homology, in contrast, both more directly address and recognize the importance of the generative pathways for characters. While biological homology focuses the variational tendencies of characters and the mechanisms for character evolution, generative homology focuses on the evolution of the generative pathways themselves and specifies their shared usage as the basis for character classification [see 3]. The inheritance of generative systems as the basis for shared character expression is now recognized as the fundamental foundation of evolution. Whether the character is consistently (as required for historical homology) or sporadically expressed across or along a lineage is of less import than previously credited.

# Evolution and the Scala Naturae

William Hodos
Department of Psychology, University of Maryland, College Park, MD, USA

## Synonyms

Scale of nature; Phylogenetic scale; Evolutionary scale

## Definition

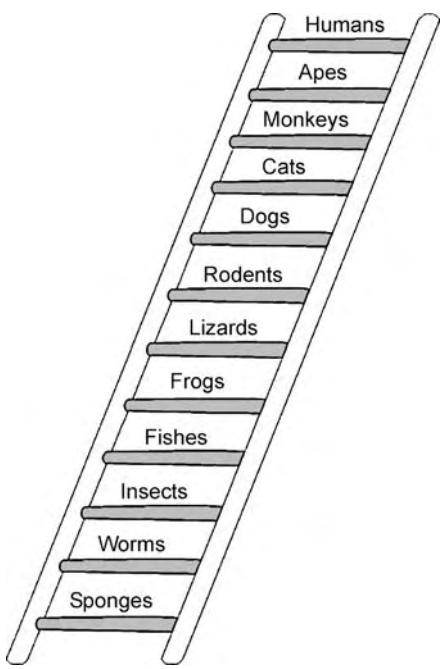
A hierarchical ranking of animals based on Aristotelian notions of perfection, with humans at the top. It has often been used incorrectly as a model for vertebrate evolution.

## Characteristics

In seeking to find order and relationship in the biological world, the Greek scientist and philosopher, Aristotle (384–322 B.C.) devised a classification scheme for animals that came to be known as the *scala naturae* in its Latin translation from Greek. In Latin, *scala* means "ladder" or "flight of steps" and *naturae* means "of nature" or "of the universe". Aristotle's idea was that living things could be assigned a hierarchical position on this metaphorical ladder that would represent their degree of perfection [1,2,3]. He placed humans on the top rung and other creatures of the known world on progressively lower rungs. He based his classification system on various biological characteristics that he could observe, such as whether the creatures were oviparous (egg bearing, such as birds or fishes) or viviparous (live bearing, such as mammals), the number of legs, etc. Although he did not produce a classification that would be useful to scientists in the post-Darwinian era, as did Carolus Linneaus (1707–1778), the creator of the system of classification of animals and plants that is used today, Aristotle's work was, nevertheless, a landmark event for its time that influenced theologians, philosophers, and scientists for many centuries to come. Its influence can still be found in some contemporary writings about brain evolution.

In the Middle Ages, and even into the nineteenth century, the *scala naturae* was a feature of religious ideas of a hierarchy of living things with the deity at the top as the most perfect being, angels next as slightly less perfect, humans still more imperfect, and then apes, monkeys, etc., down the scale to those creatures at the bottom that lacked any symmetry or regular form [4,5], Figure 1 shows a *scala naturae* of some familiar animals. It shows humans at the top of the ladder; i.e., at the pinnacle of perfection. Below them are progressively less perfect animals: apes and monkeys and then cats and dogs. Still lower down are the rodents (rats, mice, squirrels) and at the bottom of the ladder are the least perfect creatures: insects, worms, and sponges.

With the advent of the Darwinian revolution and the gradual acceptance of the concept of evolution in the second half of nineteenth century and early twentieth century, the *scala naturae,* which was already well established in the popular mind, offered a simplistic framework for evolutionary conceptualization by the



**Evolution and the Scala Naturae. Figure 1** A *scala naturae* of some familiar animals.

general public and by some scientists (including neuroscientists) who had little knowledge of the work of paleontologists on the actual lines of descent of living animals from ancestral forms. Thus, it was not uncommon to find neuroanatomists, neurophysiologists, or behaviorists reporting results from comparative studies of aggregations of animals such as monkeys, cats, and rats, and concluding that they were replicating actual historical sequences in the evolutionary history of mammals [4].

## The Phylogenetic Scale

In the post-Darwinian era, the *scala naturae* was transformed into the phylogenetic scale, which is sometimes known as the evolutionary scale or the evolutionary ladder. Although these terms sound more scientific, they are nothing more than a renaming of the *scala naturae* to suggest that it has something to do with evolution. The phylogenetic scale has nothing more to do with evolution than does the *scala naturae*. What terms such as "phylogenetic" or "evolutionary" do, however, is to add to the *scala naturae* implications about ancestor-descendent relationships that were not present in Aristotle's original formulation. The word "scale" suggests a unilinear organization in which those animals at the top of the ladder are descendents of those animals on the lower rungs and that by "climbing" this ladder, sponges and worms could somehow be transformed into humans [4,6,7].

A further disservice that the phylogenetic scale does to conceptualizations of the relationships among animals is to perpetuate the notion of higher and lower species. Those near the top of the scale are the so-called "higher" animals, which have superior characteristics and those closer to the bottom are the "lower" animals, which are more "primitive," less "advanced," and in general are expected to have inferior characteristics [4]. Closely related to the ideas of higher and lower animals is the conception that the phylogenetic scale is also a scale of complexity. This is the result of conflating the *scala naturae* with the erroneous notion that evolution always proceeds from the simple to the complex. Thus, the phylogenetic scale also connotes increasing complexity with ascent from bottom to top. This idea gained support from some early comparative studies in which the selection of a limited range of species supported the impression of a trend from simple to complex when comparing "lower" animals with "higher." While there are many examples of actual evolutionary lineages being associated with increased complexity of structures or systems from ancestors to descendents, there are also many examples of evolution resulting in increased simplification. The error was to assume that all early vertebrate ancestors were crude, primitive versions of later, descendent species. Many of the earliest vertebrates had actually adapted quite well to their environments and had evolved considerable complexity that enabled them to survive and even exploit the world around them [7,8,9,10].

## The Phylogenetic Tree

Figure 2 shows that the history of vertebrate evolution is very much more complex than a simple ladder or staircase model would suggest. A more accurate model is that of a tree with many branches radiating out from a single stem that is rooted in the ancient past. The branches of the tree are based on actual historical data, such as the geologically dated record of fossils and studies of genetic relatedness based on DNA analyses.

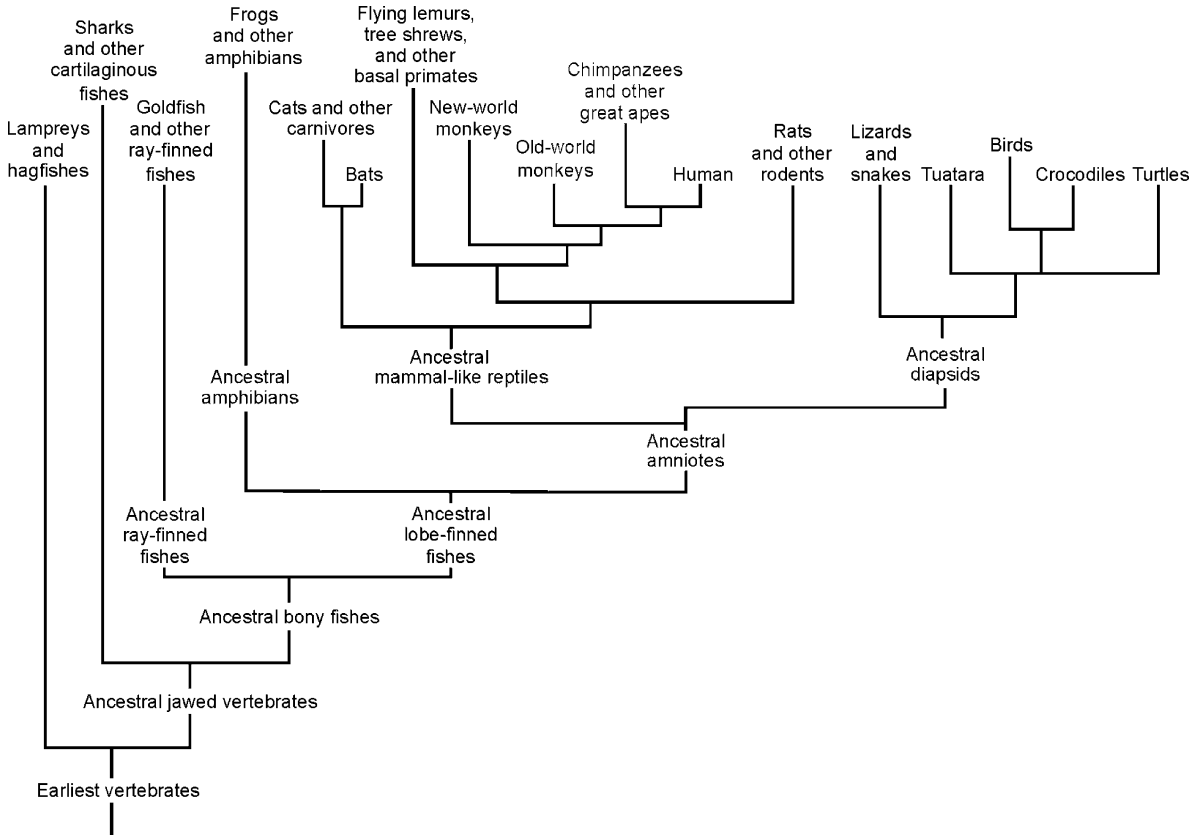
Each main branch of the tree further bifurcates into subsidiary branches as the tree advances through time until we arrive at the top of the tree, which represents those animals that are alive today. The tree shown in Fig. 2 is highly simplified for purposes of this illustration in that it shows the lineage of only a handful of well-known species. Moreover, the tree in Fig. 2 also omits the many lineages, such as the dinosaurs, that became extinct and thus did not survive to the present era, although it is now well established that birds are the living descendants of the dinosaurs. Note there is also no hierarchical arrangement of the animals within tree. They are merely descendents of different branches of the vertebrate family tree.

In contrast to the phylogentic tree, the phylogenetic scale is an entirely metaphorical concept; it has no scientific basis. You can search the evolution and classification literature and find many phylogenetic trees and detailed classification schemes, but you will search in vain for a definitive listing of the phylogenetic scale to answer questions such as: "Are dogs higher animals than cats?" or "Are bears higher animals than wolves?"

## Anagenesis

In the middle of the twentieth century, the concept of anagenesis entered the literature of comparative biology and eventually appeared in the comparative psychology literature as well. Anagenesis means a progressive improvement of a structure or system through time in a genealogical lineage [11,12]. Unlike the *scala naurae*, anagenesis was firmly based on evolutionary data, but it unfortunately was also deeply rooted in theories of the superiority of the European body type and features, especially facial features, over those of other races. Such ideas had been prevalent in Europe since at least the fifteenth century along with ideas of the superiority of European religion, culture, and social systems.

At the heart of anagenesis is the notion of "progress," which suggests an advancement from simple to complex; i.e., that the more recent forms are the more advanced. Unfortunately, the determination of what is



**Evolution and the Scala Naturae. Figure 2** A phylogentic tree that shows the genealogical relationships of the major vertebrate groups. The earliest vertebrates are at the bottom and living vertebrates are at the top. Adapted from Butler and Hodos [7] with permission of John Wiley & Sons.

progress often depends on value judgments by the observer rather than objective science [13]. Evolution is an opportunistic process, and the only determiner of success is survival of the species. If the environment changes, the same adaptation that led to increased number of individuals or increased numbers of species (some of the criteria of evolutionary success) previously could now become a handicap and start the lineage down an inexorable course towards extinction. Thus, what would be evolutionary "progress" in one environmental circumstance could prove to be a disastrous trend in another. In other words, it is the relationship between the adaptation and the environment that determines progress or efficiency rather than absolute properties of the adaptation itself.

The unit of advancement by anagenesis is the "grade," which is a stage of progressive improvement of a characteristic within a specified lineage. Although grades can be quite useful in comparative analysis to analyze the relationship between structure and function, some investigators have fallen into the *scala naturae* trap and have concluded that by merely arranging grades in a sequence of complexity, without careful reference to ancestor-descendent relationships, they have also represented an historical sequence in the evolution of the character or process being investigated [13].

# Evolution of Association Pallial Areas: In Birds

Jonas Rose, Onur Güntürkün, Janina Kirsch
Biopsychology, Institute of Cognitive Neuroscience, Ruhr-University Bochum, Bochum, Germany

## Definition

This essay describes a case of ►homoplasy of mammalian and avian brains. Both mammals and birds can organize their behavior flexibly over time. In mammals, the mental operations generating this ability are called executive functions and are associated with the prefrontal cortex. The corresponding structure in birds is the ►nidopallium caudolaterale. Anatomical, neurochemical, electrophysiological and behavioral studies show these structures to be highly similar. The avian forebrain displays no lamination that corresponds to the mammalian neocortex; hence lamination does not seem to be a requirement for higher cognitive functions. Because all other aspects of the neural architecture of the mammalian and the avian prefrontal areas are extremely comparable, the freedom to create different neural architectures that generate prefrontal functions seems to be very limited.

## Characteristics

Behavior defines the frontier along which animals interact with evolutionary selection pressures. Therefore, neural architectures are shaped during evolution to produce certain behavioral traits that are required to stand the race for fitness. If species from different lineages are faced with the same selection pressure they might react with the same solution at the behavioral level. But how many degrees of freedom are there on the neural level to achieve the same behavioral solutions? In other words, can differently organized brains implement the same set of behaviors? In the following, a case of ►homoplasy between mammals and birds will be discussed, contrasting the behavioral skills employed by both orders as well as the neural structures that enable these skills.

### Behavioral Skills of Birds and Mammals

The order of mammals is phylogenetically very successful. Mammals like humans, macaques or rats are able to adjust their behavior flexibly to changing demands. They are able to reverse-learn behavioral choices, select appropriate responses according to contextual information and withhold actions until a suitable situation occurs. In short, they optimally organize their behavior with time [1,2]. Birds represent an about equally successful vertebrate order and a vast literature testifies that birds are able to generate many of the same cognitive functions [1,2]. Pigeons, for example, are able to memorize up to 725 different visual patterns, reverse-learn contingencies, learn to categorize images as "human-made" or "natural" or rank patterns using transitive inference [3]. The evolution of these abilities is an example of ►homoplasy that enables birds and mammals to utilize a very similar repertoire of behavioral skills. These skills were not inherited from a common ancestor, however, but rather were evolved independently [3]. Furthermore, corvids in particular have developed cognitive skills to a degree that can only otherwise be found in primates. The level of corvid cognitive abilities is indicated by feats such as causal reasoning, prospection and the ability to use experience in predicting the behavior of conspecifics. Another domain in which birds stand out is the use of tools. New Caledonian crows use different types of tools for different purposes; they manufacture specific tools to standardized patterns and carry them while foraging. In the laboratory they are reported to use analogy with previous experience when using unknown materials to manufacture novel tools [4]. Another example of the vast behavioral repertoire of birds is ►episodic-like memory. Many corvids store food items and recover them often months later for consumption. In caching food items, corvids are known to show ►episodic-like memory; they remember *where* and *when* they stored *what* food item. This enables the birds to retrieve perishable food earlier, while non-perishable items can be left in storage or to recache food that might be pilfered by another bird. In sum, these abilities place corvids amongst the cognitively most developed species, finding a match only in a very few primate species [4].

### Neuroarchitecture of Birds and Mammals

A sharp contrast to the numerous similarities of mammals and birds on the behavioral level is the great evolutionary distance and therefore the substantially different organization of avian and mammalian forebrains. The lines of

birds and mammals separated about 300 million years ago. This evolutionary distance resulted in a number of crucial organizational differences on the neural level, the most notable being the lack of a laminated cortex in the avian telencephalon [1,2].

In recent years our understanding of the evolution of vertebrate brains and the homologies between avian and mammalian brains has advanced substantially. To reflect this new understanding, The Avian Brain Consortium, a group of leading experts in the field, has proposed changes to the avian brain nomenclature and renamed many avian telencephalic structures [3,5]. The classical avian brain nomenclature dated back to 1900 and was based on Edinger's model of brain evolution. According to his formulation, vertebrate brain evolution consisted of a series of additions of new brain entities, with the mammalian neocortex being the last and most advanced step. In mammals, the cortex, including neo- archi- and paleo-cortical components, together with the claustrum and lateral parts of the amygdala, constitutes the forebrain pallium. Pallium and subpallial structures, including the striatum and pallidum, make up the cerebrum. While the organization of the striatum is highly conserved among birds and mammals, pallial organization is rather different. The mammalian pallium mainly follows a laminar organization, while the avian pallium is organized in nuclei. The absence of a laminated component within the avian cerebrum led Edinger to assume that birds have virtually no pallium but an enormously hypertrophied striatum instead. Based on neurochemical, histological, behavioral, embryological and genetic studies, this view had to be rejected. Birds do indeed possess a large pallium, which consists of four main subdivisions, the hyper-, meso-, nido- and arco-pallium (Fig. 1).

The field homologies between these different subdivisions and corresponding mammalian structures are a topic of active research. For most divisions, consensus, if ever possible, has not yet been reached.

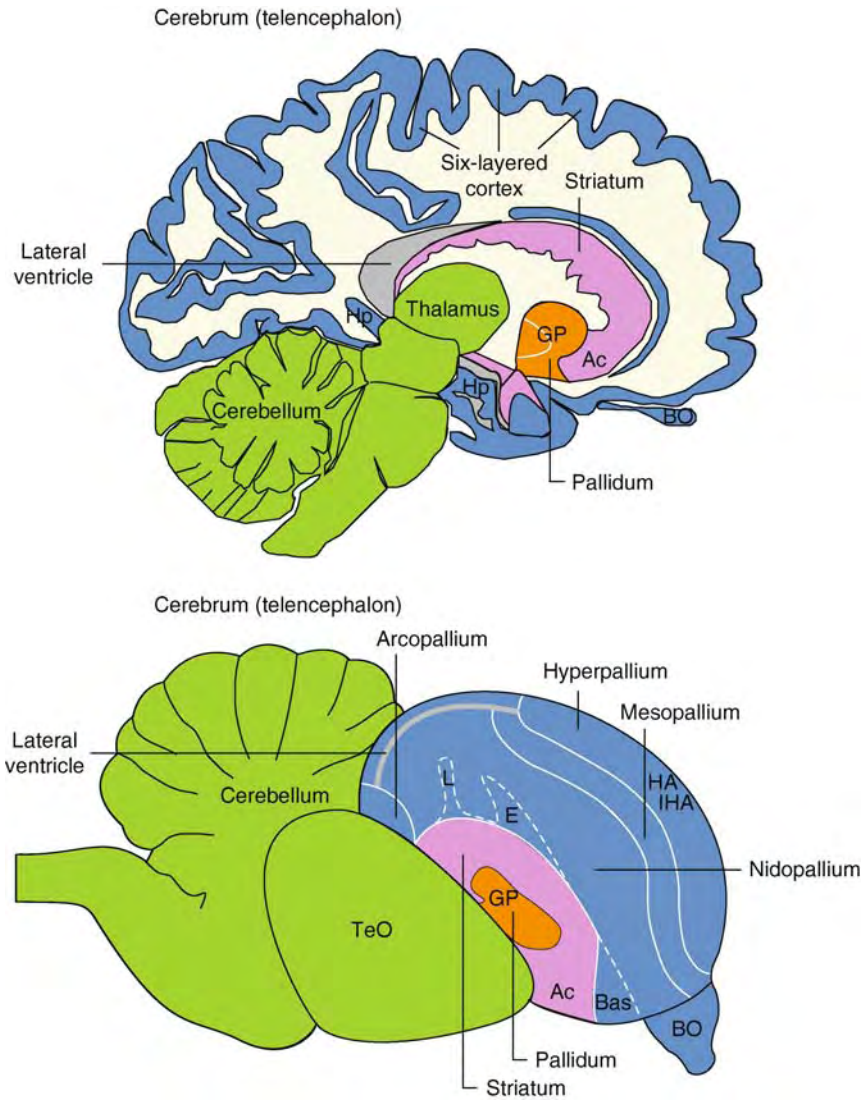
It is well known that the cognitive skills of mammals depend on their pallial association structures. These areas are organized following a general principle. Primary sensory structures project to the surrounding unimodal association areas, which in turn project to polysensory association structures. The sensory projections of the avian pallium are organized according to the same principle (Fig. 2).

Within the visual system, the afferent fibers entering the pallium project either to the visual Wulst, a subdivision of the hyperpallium or to the entopallium, a subdivision of the nidopallium. The thalamofugal (Wulst) and the tectofugal (entopallium) systems correspond to the mammalian geniculo-cortical and extrageniculate pathways, respectively. The visual Wulst shows a pseudolamination, with a primary visual layer located ventrally and a unimodal association layer located dorsally. The entopallium is organized in a primary visual core and a surrounding belt, which is a unimodal association structure called the perientopallium [6]. This organization into primary sensory core and surrounding unimodal associative belt is shared by the somatosensory Wulst, the auditory field L and the trigeminal-recipient nucleus basorostralis pallii of the nidopallium. The primary sensory areas project to the corresponding unimodal association areas that, in turn, send afferents to polysensory association structures. In birds, until now only the ►nidopallium caudolaterale (NCL) has been described as receiving polysensory input and participating in cognitive functions.

## Functions of the Avian and Mammalian "Prefrontal Cortex"

In the following the focus will be on the NCL, the functional equivalent of the mammalian prefrontal cortex (PFC) for two reasons. First, the NCL is one of the best-understood avian pallial structures and analogy to the mammalian PFC has been established satisfactorily; second, NCL and PFC are the crucial structures in mediation of many of the behaviors mentioned above [2]. The function of the PFC is commonly described with the terms "executive functions" and "►working memory." ►Working memory (WM) has been defined in parallel and rather independently in pigeons and humans. The non-human and the human definitions of ►working memory differ only with respect to the presence of a language-component in humans. Not only is WM behavior very similar between mammals and birds but the neural processes generating WM also seem to be identical in both orders. WM is based on the active maintenance and manipulation of stimulus information. These processes are mediated by neurons that show an elevated firing rate during delay periods of WM tasks. In other words, the representation of a physically absent stimulus is actively maintained over a delay. Disruption of this activation leads to a loss of the information, i.e. to forgetting. In mammals, this activation was first described in the PFC. Lesions to the PFC result in a disruption of WM. The same type of neuronal activity has been reported in the avian equivalent of the PFC, the NCL [7]. As in the case of the PFC, lesions to NCL lead to a decrease in WM-performance. In mammals, the release of ►dopamine (DA) within PFC and the subsequent activation of D1-receptors play a major role in sustained activity levels of delay cells and the animals' performance in ►working memory tasks. In pigeons, the local blockade of D1-receptors within NCL selectively disrupts ►working memory performance [2].

Apart from stimulus maintenance, the PFC takes part in the selection of behavioral goals. In reversal tasks, for instance, animals learn to associate the response to one stimulus with reward and the response to an alternative stimulus with punishment. When the animals have



**Evolution of Association Pallial Areas: In Birds. Figure 1** The new understanding of avian and mammalian brain relationships. Sagittal view of a human *(top)* and a pigeon *(bottom)* brain. established these associations, the contingencies are reversed, responses to the previously rewarded stimulus are now punished and vice versa. In order to master this task the animal has to monitor the success of its actions and reverse its behavior if the actions are unsuccessful. This flexibility in adapting to changing demands is severely disrupted in mammals with lesions to the PFC and the same holds for birds with NCL lesions or blockade of D1- [1] or NMDA-receptors in this area [8].

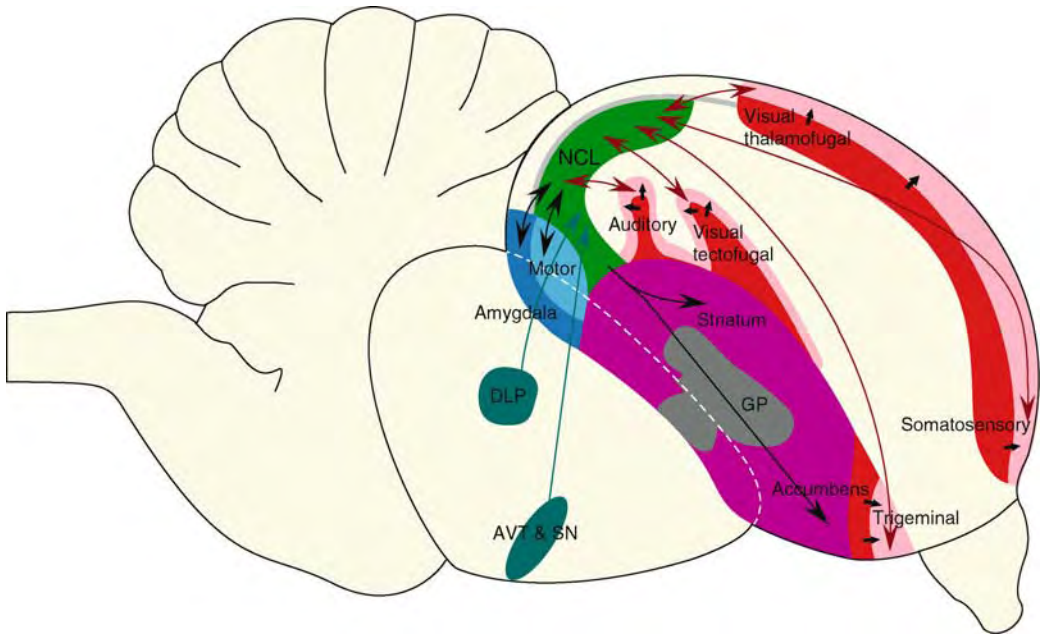
In order to plan goal-directed actions effectively and to decide between alternative strategies, it is crucial to integrate information about the costs and benefits of different actions. In other words, it is crucial to adjust the effort to obtain a reward to the value of that reward. Transient pharmacological lesions to the NCL disrupt this ability and such animals will put as much effort into obtaining a small reward as into obtaining a large reward [9]. In line with this data, a recent study showed that neurons in the NCL reflect an animal's preference for a reward, based not only on the features of the reward but also on the delay until the reward is obtained [10].

The most straightforward example of a neural correlate of executive control reported in any species thus far has recently been provided by a single-cell study in pigeons. Pigeons were trained on a WM task during which the animals were informed that



**Evolution of Association Pallial Areas: In Birds. Figure 2** Afferent and efferent connections of the ►nidopallium caudolaterale. Primary sensory areas are depicted in red, secondary and tertiary areas in pink. The primary sensory areas project to secondary and tertiary structures (*small black arrows*), which have reciprocal connections with the ncl (*red arrows*). The visual thalamofugal and tectofugal systems correspond to the geniculocortical and colliculo-pulvino-extrastriate systems of mammals, respectively. The area labeled "motor" is the arcopallium, which has descending projections to various motor and premotor structures. Thalamic afferents arise from the nucleus dorsolateralis posterior thalami. Dopaminergic afferents stem from the area ventralis tegmentalis and the substantia nigra. Abbreviations: *AVT* area ventralis tegmenti; *DLP* nucleus dorsolateralis posterior thalami; *GP* globus pallidus; *SN* substantia nigra.

remembering a stimulus was necessary in order to obtain a reward. The animals were able to use this information, memorizing only relevant stimuli. Most importantly, this selectivity was reflected in the memory-period activity of NCL neurons. The vast majority of neurons showed memory related activity when the birds chose to remember; however, this activity was suppressed as soon as the birds knew that memorizing a stimulus was not required. This decision process, controlling the neural mechanisms that govern ►working memory, is a prime example of executive functions as attributed to the mammalian PFC [11]. In spite of the great phylogenetical distance, the avian NCL and the mammalian PFC generate the same set of behaviors.

## Connectivity of the "Prefrontal Cortex"

Returning to the initial question, how many degrees of freedom are there on the neural level to generate the same set of behaviors, structural differences and similarities between PFC and NCL will now be described. The PFC of mammals is densely innervated by dopaminergic fibers from the ventral tegmental area and the substantia nigra. This dopaminergic innervation was usually taken as a characterizing element of the PFC. Ivan Divac and colleagues showed that the NCL is densely innervated by catecholaminergic fibers of probably dopaminergic nature. Subsequent studies demonstrated that NCL is indeed one of the main termination areas of dopaminergic fibers from the ventral tegmental area and the substantia nigra. The architecture of the dopaminergic terminals within the NCL closely resembles that of the PFC [1,2].

The NCL is comparable to the PFC in that it is a center of higher-order sensory integration. Sensory input reaches the NCL via a set of interconnected pathways that show a considerable overlap of different modalities (Fig. 2). The primary sensory area of each modality projects first to an adjacent area that then projects not only to the next modality-specific association area in line but also to the NCL, which in turn reciprocates by sending fibers back to the projecting area. In addition, NCL projects to most parts of the somatic and limbic striatum, as well as to motor output structures. Thus, identically to PFC, the avian NCL is a convergence zone between the ascending sensory and the descending motor systems. In addition, NCL and PFC resemble each other in terms of their

connections with the amygdala, nucleus accumbens, visceral structures and diverse chemically defined afferent systems. One difference between the connectivity of NCL and PFC is, however, the thalamic input. The mammalian PFC receives afferents from the mediodorsal (MD) nucleus of the thalamus. Thalamic afferents to the NCL arise mainly from the dorsolateral posterior nucleus, which is not homologous to MD but still seems to serve similar functions [1,2].

A comparison of the anatomical network defining NCL and PFC shows a large number of similarities with only a few differences. Like the PFC, the avian NCL is a multimodal forebrain area that is located at the convergence zone from sensation to action, is modulated by dopaminergic fibers and is tightly interrelated with structures serving limbic, visceral and memory-related functions.

## Concluding Remarks

We have shown that birds are capable of generating complex behaviors that, in some cases, outperform the skills of most mammals. Given the phylogenetic distance between birds and mammals, it can be assumed that a number of these skills have evolved independently. On the neural level, it can be said that the avian and mammalian pallium seem to be homologous with respect to their phylogenetic continuity, but this does not necessarily hold for the different pallial domains, which could also be a product of ►homoplasy. Discussion focused on the equivalence between PFC and NCL and showed that both structures generate the same set of cognitive functions using surprisingly similar systems. These structural similarities are most evident in the case of stimulus maintenance, as discussed in detail by Güntürkün [2]. Among the few obvious differences between avian and mammalian pallia is the lack of lamination, but this is evidently not a prerequisite in generating higher cognitive functions.

## Synonyms

Association = Multimodal or polymodal sensory convergence; Pallium = Dorsal part of telencephalon

## Definition

### Associative Pallium

The adult ►pallium includes areas that receive inputs from nuclei in the dorsal thalamus relaying unimodal sensory information, namely visual, auditory or somatosensory (and gustatory-viscerocceptive). In most vertebrates, intrapallial connections allow multimodal convergence in some areas that constitute the associative pallial areas. Multimodal convergence might also occur at lower levels in the *neuroaxis*. For instance, some thalamic areas receive convergent afferents from

brainstem regions processing different kinds of stimuli. The ascending projections of these thalamic multimodal areas terminate in pallial areas that should also be considered associative.

## Characteristics

### The Pallium of Reptiles

The reptilian pallium is composed of four main cortical areas plus the so-called ►dorsal ventricular ridge. The architecture of the cortex differs slightly among the different reptilian groups. Squamate reptiles (lizards and snakes) possess a three-layered cortex, with a well-organized cell layer surrounded by inner and outer plexiform (or molecular) layers, in which four areas are easily distinguished, namely the medial (MC), dorsomedial (DMC), dorsal (DC) and lateral (LC) cortices (Fig. 1). In turtles and crocodiles, the layering and the regionalization of the cortex are not so clear-cut. In squamate reptiles and turtles, the lateral aspect of the anterior dorsal cortex shows no clear boundaries with the pallial thickening, which is usually considered an additional area of the reptilian cortex (Fig. 1).

Moreover, the pallium of all reptiles (and of birds) possesses a bulge of nervous tissue that protrudes into the lateral ventricle and is therefore called the dorsal ventricular ridge (DVR). The DVR of reptiles is usually divided into an anterior (ADVR) and a posterior (PDVR) or basal portion. Although not very clear, the DVR shows a layering composed of a juxtaventricular cell-free area, a layer of cell clusters the size of which varies from medial to lateral and a deep stratum with loose, scattered cells. In the ADVR (but not in the PDVR), the layer of cell clusters shows continuity with the cell layer of the ventral lateral cortex. In addition, the ADVR shows a clear-cut separation with the subpallium due to the presence of a cell-free zona limitans [1]. The DVR derives from the lateral and ventral portions of the embryonic pallium that are ►topologically lateral to the lateral pallium, i.e. interposed between the lateral pallium and the subpallium [2,3].

A volumetric analysis of the cerebral hemispheres of the old-world lizard ►*Podarcis hispanica* indicates that the pallium constitutes about 67% of the telencephalon.

### Associative Areas of the Reptilian Cerebral Cortex

In all the studied reptiles, the main olfactory bulb, which receives a direct projection from the olfactory epithelium, projects to the LC and to portions of the superficial amygdala (Fig. 2). The accessory olfactory bulb, the vomeronasal portion of the bulb, projects to a structure of the caudal cortex that, in squamate reptiles, is called the ►nucleus sphericus. Therefore, the LC and NS represent the primary ►*olfactory and vomeronasal* cortices, respectively. In addition, studies of the afferent connections to the cerebral cortex in lizards and turtles indicate that the lateral aspect of the dorsal cortex plus the pallial thickening constitute the *visual cortex of reptiles* [4,5,6]. There is no evidence of any other unimodal input to the cerebral cortex in reptiles [7].

In contrast, the MC, DMC and most of the DC of reptiles receive a massive input from a thalamic cell group called the dorsolateral anterior thalamic nucleus (DLA) [4,5,8]. The DLA is a peculiar cell group [8] that apparently receives direct spinal and (minor) retinal inputs. In addition, DLA projection cells have long dendrites that extend out of the cytoarchitectonic boundaries of the nucleus and reach neighboring nuclei that receive retinal (lateral geniculate nucleus), auditory (medial anterior nucleus) or somatosensory afferents. The multimodal nature of the thalamic projection to the MC and DC has been demonstrated using physiological techniques [9].

In addition, the MC and DC also receive a direct input from the lateral cortex [4, 10], which, in turn, is the main target of the projections from the main olfactory bulb and of the nucleus sphericus [11,12]. Therefore, the anatomical data available in lizards indicate that the dorsal and medial cortices receive convergent sensory inputs from the chemosensory (olfactory and vomeronasal) lateral cortex and from a multimodal (visual, auditory and somatosensory) thalamic cell group (DLA).

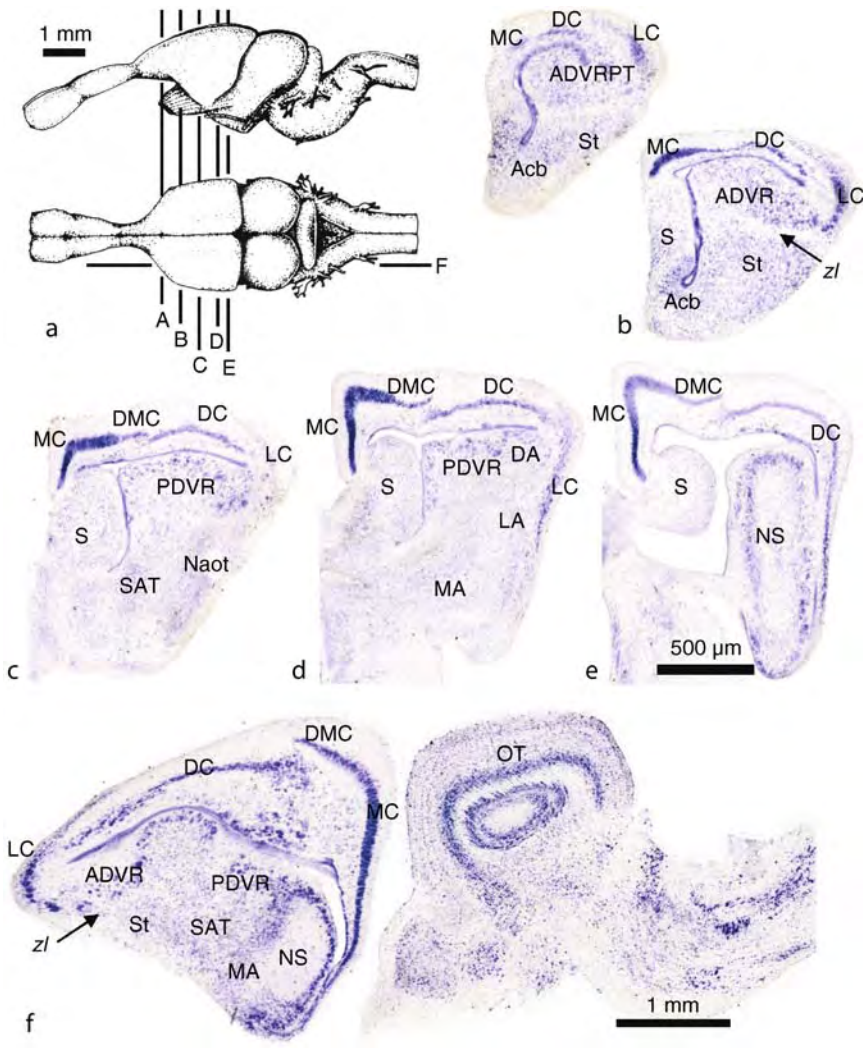
As a conclusion, the MC, DMC and DC constitute together the associative cortex of the reptilian pallium. In the lizard *Podarcis hispanica*, the MC, DMC and DC represent about 56% of the pallium and 37% of the whole cerebral hemispheres.

### Associative Areas of the DVR of Reptiles

The PDVR (Fig. 3) receives convergent projections from the medial, intermediate and lateral portions of the ADVR [1], which in turn are the targets of the three main sensory nuclei in the dorsal thalamus of reptiles [13,14], the medial anterior thalamic nucleus (auditory), the posteromedial and posterocentral nuclei (somatosensory) and the nucleus rotundus (visual, tecto-receptive).

Additional afferents to the PDVR include another multimodal thalamic cell group (the dorsomedial anterior nucleus), the ventral portion of the LC (chemosensory) and the DC [1], which is also a multimodal pallial region. Studies of the efferent projections of the ADVR [15], the dorsomedial anterior thalamic nucleus [1], the LC [16] and DC [17] indicate that all these areas also project to an ill-defined cell group in the vicinity of the PDVR named the lateral amygdala. Some of these afferents also project to another neighboring cell group called the dorsolateral amygdaloid nucleus.

These data indicate the presence of a second associative area in the pallium of reptiles, composed at least of the PDVR and the lateral and the dorsolateral

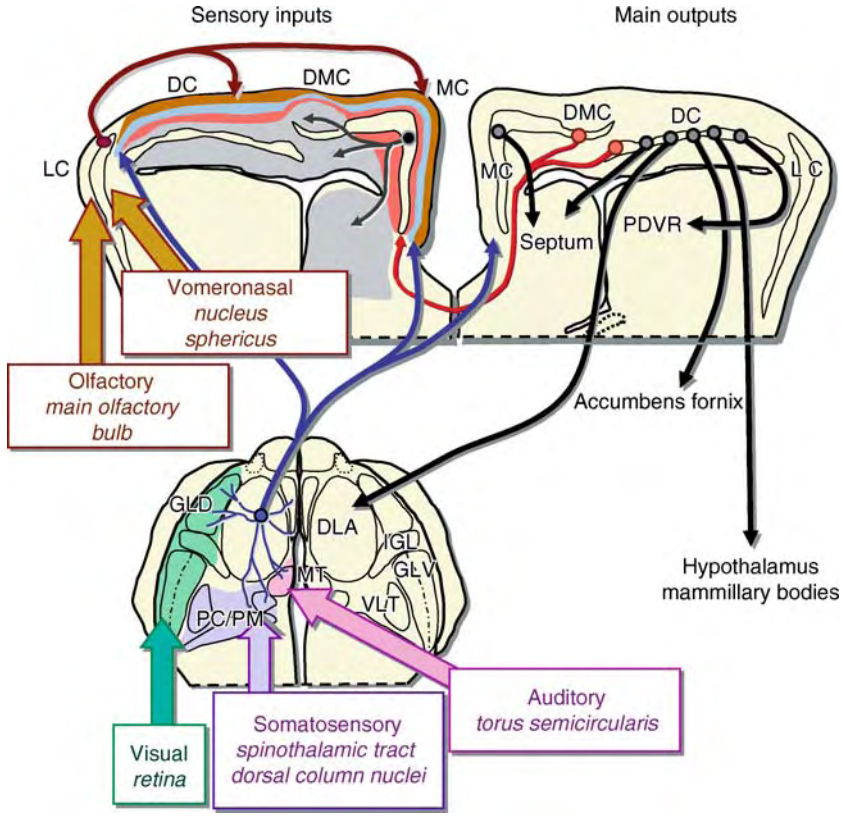


**Evolution of Association Pallial Areas: In Reptiles. Figure 1** Pallial structures in the brain of a reptile, the old world lizard *Podarcis hispanica*.The lateral (*up*) and dorsal (*down*) views of the brain of *P. hispanica* show well-developed olfactory bulbs, typical of squamate reptiles, and two medium-sized cerebral hemispheres. Frontal sections through the telencephalon (a–e) and a sagittal section of the brain (f) show a big pallium that consists of the cortex (medial, dorsomedial, dorsal and lateral areas) and the dorsal ventricular ridge (anterior and posterior parts), as well as several other adjoining structures. As a whole, the pallium constitutes 67% of the cerebral hemispheres. The subpallium is mainly composed of the septum, the striatum, and the nucleus accumbens. At the level of the anterior dorsal ventricular ridge, the pallium and subpallium are separated by a cell-free *zona limitans* (*zl*). Abbreviations (in alphabetical order): *Acb*: nucleus accumbens (ventral striatum); *ADVR*: anterior dorsal ventricular ridge; *DA*: dorsolateral amygdala; *DC*; dorsal cortex; DMC; dorsomedial cortex; LA: lateral amygdala; LC: lateral cortex; MA: medial amygdala; *MC*: medial cortex; *Naot*: nucleus of the accessory olfactory tract; *NS*: nucleus sphericus; *OT*: optic tectum (midbrain tectum); *PDVR*: posterior dorsal ventricular ridge; *PT*: pallial thickening; *S*: septum; *SAT*: striato-amygdaloid transition area; *Str*: (dorsal) striatum; *zl*: zona limitans.

amygdaloid nuclei. In *Podarcis hispanica*, these structures represent about 7.3% of the pallium and nearly 5% of the cerebral hemispheres.

## The Hippocampal Formation of Reptiles

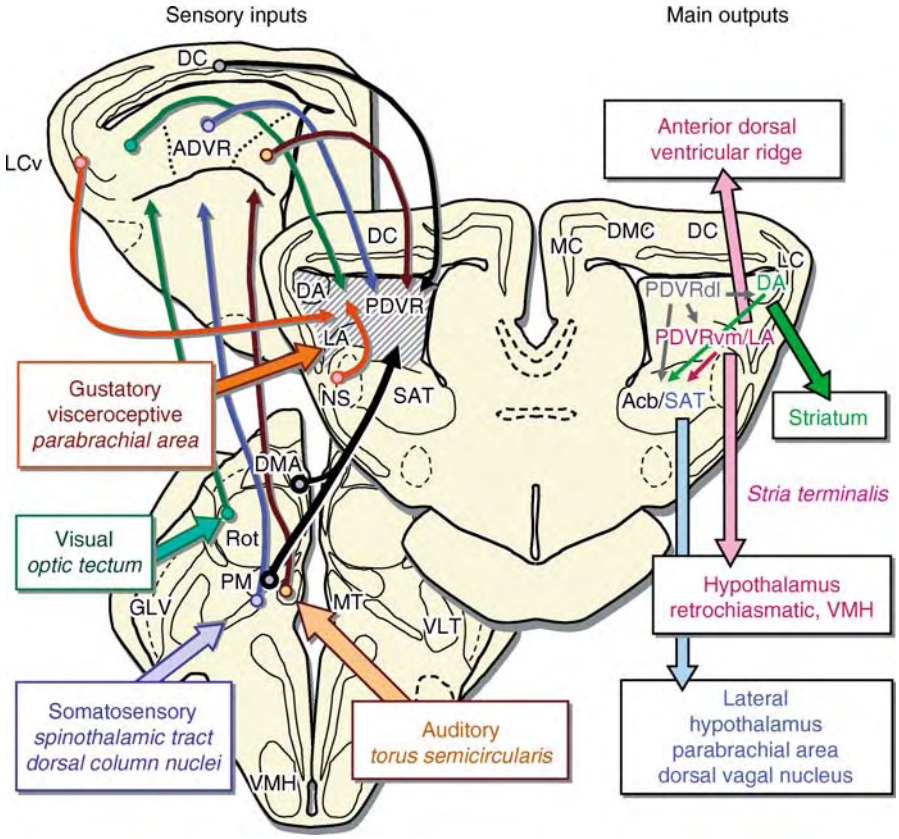
The MC, DMC and DC of reptiles not only share their inputs from the DLA and lateral cortex. The MC gives rise to massive, ►zinc-enriched projections to the DMC and DC [10]. In turn, the DMC and DC project back to the MC. This is a bilateral projection, the contralateral part of which courses through the pallial commissures [18]. In addition, both the MC and DC also give rise to a zinc-enriched, ordered projection to the (lateral) septum [10]. Finally, the dorsal cortex is the origin of a long



**Evolution of Association Pallial Areas: In Reptiles. Figure 2** The medio-dorsal cortex: an associative cortex in the reptilian cerebral hemispheres Schematic view of the cerebral cortex of reptiles with indication of the main sources of sensory inputs (*left*), as well as its main efferent pathways (*right*). In reptiles, the main thalamo-cortical pathway arises in the dorsolateral anterior nucleus of the thalamus (*DLA*) and terminates in the medial and dorsomedial cortices and most of the dorsal cortex (jointly known as medio-dorsal cortex). This is a multimodal pathway, due mainly to synaptic convergence on the long dendrites of the D*LA* projection cells, which invade adjacent sensory (visual, auditory, and somatosensory) nuclei of the dorsal thalamus. In addition, the fourth cortical area, the lateral cortex, which receives direct olfactory and indirect vomeronasal inputs, also projects onto the medial-dorsal cortex. Other intrinsic and commissural cortico-cortical projections are also illustrated. As depicted, in reptiles the main afferents of the medio-dorsal cortex terminate in a nicely layered fashion.The main efferents of the medio-dorsal cortex terminate in the PDVR (amygdala), septum, nucleus accumbens and hypothalamus. These and other features of these cortical areas strongly suggest that they constitute the hippocampal formation of the reptilian brain. Abbreviations (in alphabetic order): *DLA*: dorsolateral anterior thalamic nucleus; *GLD*: dorsal lateral geniculate nucleus; *GLV*: ventral lateral geniculate nucleus; *IGL*: intergeniculate leaflet; *MT*: anterior medial thalamic nucleus; *PC*: postero-central thalamic nucleus; *PM*: posteromedial thalamic nucleus; *VLT*: ventrolateral thalamus. For other abbreviations, see Fig. 1.

descending projection to parts of the hypothalamus through the fornix [17].

This set of connections and histochemical features, together with a topological analysis of the reptilian pallium, strongly suggests that its medial aspect including the MC, DMC and part of the DC constitutes the hippocampal formation of reptiles. This indicates that, although mammals and reptiles share a hippocampal formation that receives all kinds of chemosensory and non-chemosensory stimuli, there are important differences in the pathways providing this sensory information in the two classes of vertebrates. In mammals, an enormous isocortex that includes several primary and secondary sensory areas relays highly processed sensory information to the hippocampal cortex through the entorhinal cortex, in turn an associative area. In contrast, reptiles receive a chemosensory (olfactory and vomeronasal) input from the lateral cortex, plus a multimodal non-chemosensory thalamic afferent from the DLA. Whereas the thalamic afferents to the mammalian hippocampus, arising mainly from the nucleus reuniens, are relatively scarce, the projection from the DLA to the medial-dorsal cortex of reptiles is massive (Fig. 2).



**Evolution of Association Pallial Areas: In Reptiles. Figure 3** An additional associative area in the posterior dorsal ventricular ridge: the putative amygdala of reptiles Schematic view of the PDVR and adjoining pallial area of reptiles, with indication of the main sources of sensory inputs (*left*), as well as their main efferent pathways (*right*). The PDVR, the lateral amygdala (LA) and, to a lesser extent, the dorsolateral amygdala (DA), are the target for multimodal pathways (*thick, black arrows*) from the dorsal cortex and from two thalamic cell groups, the medial posteromedial thalamic nucleus (PM) and the dorsomedial anterior thalamic nucleus (DMA). In addition, they receive convergent projections from the auditory (*orange*), somatosensory (*bluish grey*), and visual (*green*) areas of the ADVR, which in turn, are targeted by ascending projections from the main sensory nuclei of the dorsal thalamus (*coloured arrows*). Finally, the PDVR and adjoining pallium also receives chemosensory information by means of direct afferents from the parabrachial area (which probably also conveys viceroceptive inputs), from the ventral part of the lateral cortex (olfactory), and from the nucleus sphericus (vomeronasal).The projections of the PDVR and adjoining areas are suggestive of an amygdaloid nature of this area of the reptilian pallium. Thus, the ventromedial PDVR (*PDVRvm*) and the LA display a prominent projection to the ventral and medial hypothalamus through the *stria terminalis*, whereas the DA projects to the striatum. The dorsolateral PDVR (*PDVRdl*) is mainly engaged in intrinsic projections, whereas the whole system projects to the nucleus accumbens and to the striato-amygdaloid area (SAT). The SAT gives rise to long-distance descending projections to centers of the hypothalamus and brainstem that probably are involved in the expression of fear-related behaviors. Finally, the LA projects back to the ADVR. Abbreviations (in alphabetic order): *PDVRdl*: dorsolateral part of the posterior dorsal ventricular ridge; *PDVRvm*: ventromedial part of the PDVR; *Rot*: nucleus rotundus; *VMH*: ventromedial nucleus of the hypothalamus. For other abbreviation see Figs. 1 and 2.

## The Reptilian Amygdala

Data on the connections of the PDVR and adjacent areas strongly suggest that they constitute the basolateral amygdala of reptiles [1]. Thus, like its mammalian counterpart, this multimodal area of the reptilian pallium projects to different parts of the ventromedial hypothalamus, through the ►*stria terminalis* and to the dorsal and ventral striatum. The latter projection includes a pathway targeting the caudal portion of the ventral striatum, the so-called striato-amygdaloid transition, for which a homology with the central extended amygdala has been proposed.

The amygdaloid nature of the PDVR and adjacent areas is also supported by topological data. Like the basolateral amygdala of mammals, the PDVR is a portion of the ventral pallium [3] topologically deep to

the caudal olfactory and vomeronasal cortex (nucleus sphericus).

## Functional Aspects

### *Medial, Dorsomedial and Dorsal Cortices*

Functional studies in turtles and lizards indicate that the MC-DC are involved in spatial learning [19,20]. Lesions of the medial aspect of the cortex impair the capacity to locate the goal in a maze or arena if animals need to rely on distal (extra-maze) cues (►*spatial learning*). In contrast, these lesions elicit no substantial behavioral deficits when the animals can orient themselves using local (intra-maze) cues (cue-related learning). These data suggests that the MC/DC of lizards, like the mammalian hippocampus, is involved in processing multimodal information to construct (►allocentric maps vs egocentric maps) (based on objects external to the subject) of the environment to guide navigation.

### *Role of the PDVR and Its Circuitry in Behavior*

As shown above, the PDVR seems to be part of the reptilian amygdala. Although there are few functional studies of the cerebral hemispheres of reptiles, some data indicate a role of the PDVR and adjoining areas in the expression of *fear*-related behaviors, a feature typical of the mammalian amygdala. Thus, lesions of the caudal cerebral hemispheres, including the striato-amygdaloid area or comparable areas in lizards [21] and crocodiles [22] result in a decrease in attack-retreat reactions and social interactions as well as in shortened ►tonic immobility and ►antipredator behaviours, reminiscent of the effects of amygdaloid lesions on fear reactions in mammals. In addition, electrical stimulation of the caudolateral cerebral hemispheres in freely moving crocodiles results in what resembles escape behavior, sometimes accompanied by vocalizations, respiratory changes and micturition [22].

In conclusion, the reptilian cerebral hemispheres include two different pallial associative areas that apparently comprise their hippocampal and amygdaloid formations. As in mammals, these areas seem to be involved in *spatial memory* and in the expression of emotional behaviors (e.g. fear) respectively. It is unlikely that reptiles also possess additional associative areas mediating complex functions similar to the ones found in the areas of the mammalian cortex (parietal, temporal and frontal lobes), since the rest (≈ 37%) of the pallium is mostly composed of primary sensory areas (LC, nucleus sphericus, pallial thickening and ADVR).

# Evolution of Association Pallial Areas: Parietal Association Areas in Mammals

Leah Krubitzer[1,2], Jeffrey Padberg[1]
[1]Center for Neuroscience, University of California, Davis, CA, USA
[2]Department of Psychology, University of California, Davis, CA, USA

## Definition

Posterior parietal cortex is a large region of cortex that lies between somatosensory and primary cortices. In some mammals such as primates, it contains a number of cortical fields whose functions include coding the spatial location of objects within both egocentric and extrinsic frames of reference, and in generating an internal representation of the body that contributes to a "sense of self," "body schema," or "body image." While the posterior parietal association areas are well developed in primates, likely in conjunction with specialized hand use, some of these areas may be present in a primitive form in other mammals. A similarly located region of cortex has been identified in rodents, carnivores, hedgehogs, tenrecs, and opossums.

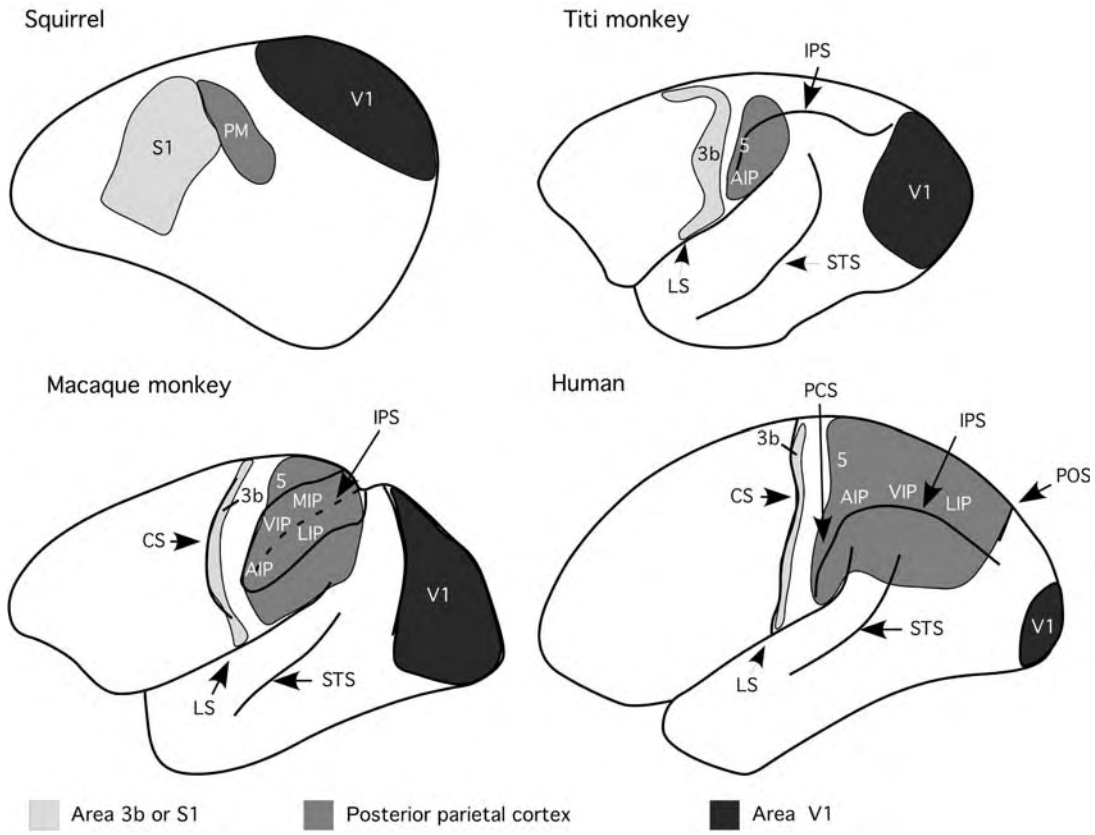
## Characteristics

All mammals actively explore their environment with specialized body parts that contain unique arrangements of various types of sensory receptors. It has been proposed that the complex motor sequences involved in exploration require an internal representation of the body, a knowledge of what constitutes the body or self, and a knowledge of what constitutes the external world, which includes animate and inanimate objects (see [1]). The region of the neocortex that is thought to generate these complex abilities is the posterior parietal association cortex, which has greatly expanded in human and nonhuman primates. Because an internal representation of the body is necessary in order to interact appropriately with the external environment, it is likely that all mammals have portions of their brain devoted to generating such an internal representation. Unfortunately, little is known about posterior parietal association cortex in mammals other than primates and whether there are fundamental features of the mammalian neocortex that give rise to this internal framework or "sense of self."

### Introduction: Posterior Parietal Cortex as an Association Area

The neocortex is a uniquely mammalian structure that comprises a large portion of the brain and is responsible for the higher order sensory, perceptual, and cognitive behaviors. In several lines of descent such as primates, cetaceans, and elephants the neocortex has disproportionately expanded compared to the rest of the brain, and much of this expansion appears to be due to an increase in the number of higher-order association areas. Traditionally the mammalian neocortex has been divided into three broad categories including motor cortex, sensory cortex, and association cortex. Association cortex, as defined by many modern text books, includes temporal, prefrontal, and posterior parietal cortex, and is hypothesized to mediate complex behaviors such as perception, attention, cognition, and other high level mental functions. The definition of what constitutes association cortex is based on the premise, which emerged from earlier mapping studies of Woolsey [2] (e.g., 1958), that the amount of cortex that could not be defined as unimodal sensory cortex in primates was relatively large compared to other mammals (Fig. 1).

Because primates are thought to have a larger repertoire of higher level or cognitive behaviors than other mammals, this expanded cortex became associated with higher mental processes and was considered a primate phenomenon.



**Evolution of Association Pallial Areas: Parietal Association Areas in Mammals. Figure 1** Illustrations of the location of posterior parietal cortex, PP (*dark grey*), in several different mammals including squirrels, non-human primates and humans. Although the relative location of PP, between S1 (*light grey*) and V1 (*black*), is maintained in the different species, the amount of cortex devoted to PP, and the number of subdivisions within PP has changed in different mammals. Further, this cortex has greatly expanded in anthropoid primates including macaque monkeys and humans.

However, the early mapping studies, which provided support for these ideas, were hampered by technical problems, which made it difficult to elicit responses from neurons in cortex other than primary and secondary sensory fields. Despite these limitations, these early studies generated several long held tenants regarding sensory and association cortex. Probably the most noteworthy was that primary fields are evolutionarily older, and that association cortex is a new evolutionary phenomenon found mainly in human and non-human primates. Thus, the expansion of association cortex was proposed to be the hallmark of human brain evolution.

The view of a hugely expanded association cortex in primates was upended by work in the early 1970s by Allman and Kaas [3] who demonstrated that much of extrastriate cortex in non-human primates that was considered to be association cortex actually contained a number of unimodal visual areas. Somewhat later, portions of parietal and temporal cortex previously thought to be association regions were similarly reassigned as unimodal somatosensory and auditory cortical fields, respectively (see [4] for review). Although we now appreciate that much of the expanded neocortex in mammals such as primates actually contains sensory areas, there are still a few regions of the neocortex that are considered to be association areas, one of which is the posterior parietal cortex.

Posterior parietal cortex appears to be involved in coding the spatial location of objects within both egocentric and extrinsic frames of reference (e.g., [5]). Much of the region traditionally defined as posterior parietal association cortex has likely evolved in primates for the generation of specialized hand use, such as manual dexterity, bimanual coordination, and visually-guided reaching and grasping. Such behavior requires an internal representation of the body that allows some species-specific effector, such as the hand in primates, to interact with objects in their surroundings. This internal coordinate system of the body contributes to what has variously been termed "sense of self," "body schema," and "body image." Currently it is unclear whether other mammals

possess neocortical areas homologous to the posterior parietal areas in primates.

## Posterior Parietal Cortex in Primates

Posterior parietal cortex in primates is located within and around the intraparietal sulcus, approximately midway between primary visual cortex (V1) and primary somatosensory cortex (3b; Fig. 1). Most work on posterior parietal areas comes from studies in macaque monkeys. In these primates, posterior parietal fields including areas 5, 7, the medial intraparietal area (MIP), the lateral intraparietal area (LIP), and the ventral intraparietal area (VIP) are thought to be involved in visuospatial processing including monitoring limb location during visually guided reaching tasks, converting sensory locations into motor coordinates for intentional movement, and perceiving the movements of the body in extrapersonal space (e.g., [5–7]). Multiunit electrophysiological studies indicate that neurons in area 5 respond to stimulation of deep receptors of the contralateral and sometimes ipsilateral body, and that area 5 is dominated by the representation of the hand and forelimb, (Fig. 3; e.g., [8]).

Some posterior parietal areas, including area 5, are more densely connected with motor cortical fields than with somatosensory or visual cortical fields. (e.g., [6,8]; Rizzolatti et al., 1998). Indeed, recent work by Stepniewska et al. [9] has shown that posterior parietal association cortex has important motor functions. Microstimulation of rostral regions of posterior parietal cortex in galagos, including area 5, evoked what the authors term "ethologically significant behaviors." These behaviors included defensive behavior, reaching, hand to mouth movements, and aggressive behaviors. It is apparent from these studies that posterior parietal areas may be specialized motor integrators that allow the internal or animal-centered states to interface with and explore the external world.

Work in posterior parietal cortex of other primates besides macaques is restricted to a few species, but most studies indicate that New World Monkeys and prosimians have significantly less posterior parietal cortex than Old World macaque monkeys (Fig. 1; [10]). Posterior parietal areas caudal to area 3b in galagos and marmosets are less extensive than those of macaques (e.g., [10,11]). Recent work in titi monkeys indicates that area 5 appears to be present, but the amount of cortex it occupies is relatively small compared to macaque monkeys [8]. One common feature of posterior parietal cortex, specifically area 5, in all primates, is an increased representation or cortical magnification of ecologically relevant effectors, such as the hand (Fig. 2).

Another feature that most primates share is dense connectivity between posterior parietal, motor, and premotor areas, and orbitofrontal cortex and the lateral posterior and lateral dorsal nuclei of the thalamus.

## Posterior Parietal Cortex in Non-Primate Mammals

Although the organization of posterior parietal cortex, defined here as cortex caudal to primary somatosensory cortex (S1) and rostral to the second visual area (V2), is not well understood in most non-primate mammals, the existing data indicate that multimodal cortex is present in the same general region as posterior parietal cortex in primates (Fig. 3).

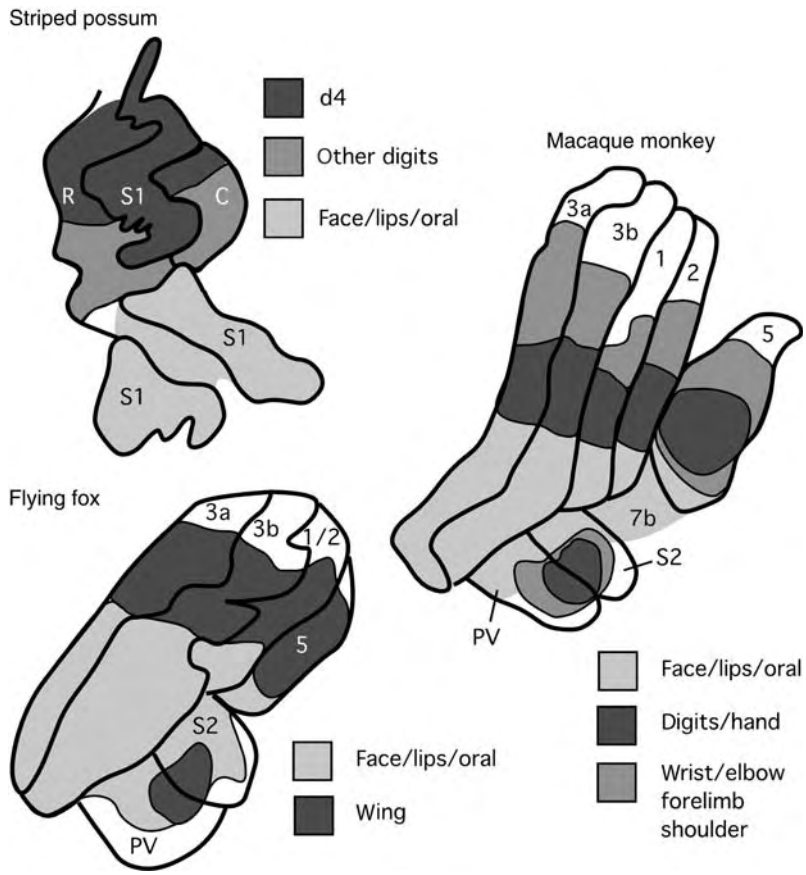
Recent studies in rodents demonstrate that they are capable of dexterous manipulations of objects (for review, Whishaw, [12] 2003). These manipulations include reaching for items in front of the animal, and using combinations of digits to hold and orient food items. It has been suggested that skilled forelimb movements may in fact be a phylogenetically old behavior that developed in early tetrapods (e.g., [12]). If this is the case, then the neural substrate for these skilled forelimb movements, which in primates appears to be posterior parietal cortex, must also be phylogenetically old, and should be observed in a wide range of mammalian species other than primates.

Studies of cortical regions in rodents that may be involved in these behaviors are limited to rats and squirrels. In rats, anatomical studies indicate that there is a posterior parietal area termed PPC (Fig. 3), and that thalamocortical connections of PPC originate from nuclei such as the lateral posterior and lateral dorsal nucleus (e.g., [13]). Homologous thalamic nuclei project to posterior parietal cortex in primates (e.g., [14]). In addition to projections from sensory areas of the neocortex, PPC in rats receives inputs from other association cortical areas such as the ventrolateral and medial orbital areas, and medial agranular cortex.

In squirrels, a region of cortex caudal to S1, termed the posterior medial (PM) area, is interconnected with S1 and contains neurons that respond to stimulation of deep receptors (Fig. 3). Further, PM/PPC is dominated by the representation of the forelimb (e.g., [15]). Based upon location, connections, and neural responsiveness, it seems likely that this region in rodents is involved in at least some of the intentional and skilled behaviors of the forepaw studied by Whishaw and colleagues.

In addition to primates and rodents, there is evidence that posterior parietal cortex has common features across all mammalian taxa (Fig. 3). For example, in carnivores such as ferrets, overlapping maps of visual and somatosensory responsiveness within a rostral posterior parietal zone have been described [16]. In cats, a zone of cortex caudal to area 3b contains neurons that respond to both deep and cutaneous somatosensory stimulation, and an area 5 similar to that observed in primates has been described (e.g., [17]).

In marsupials such as the short tailed opossum, striped possum, native cat and Virginia opossum, a small multimodal band of cortex is present between S1 and V1, and is termed C or SC (e.g., [18,19]). Likewise in



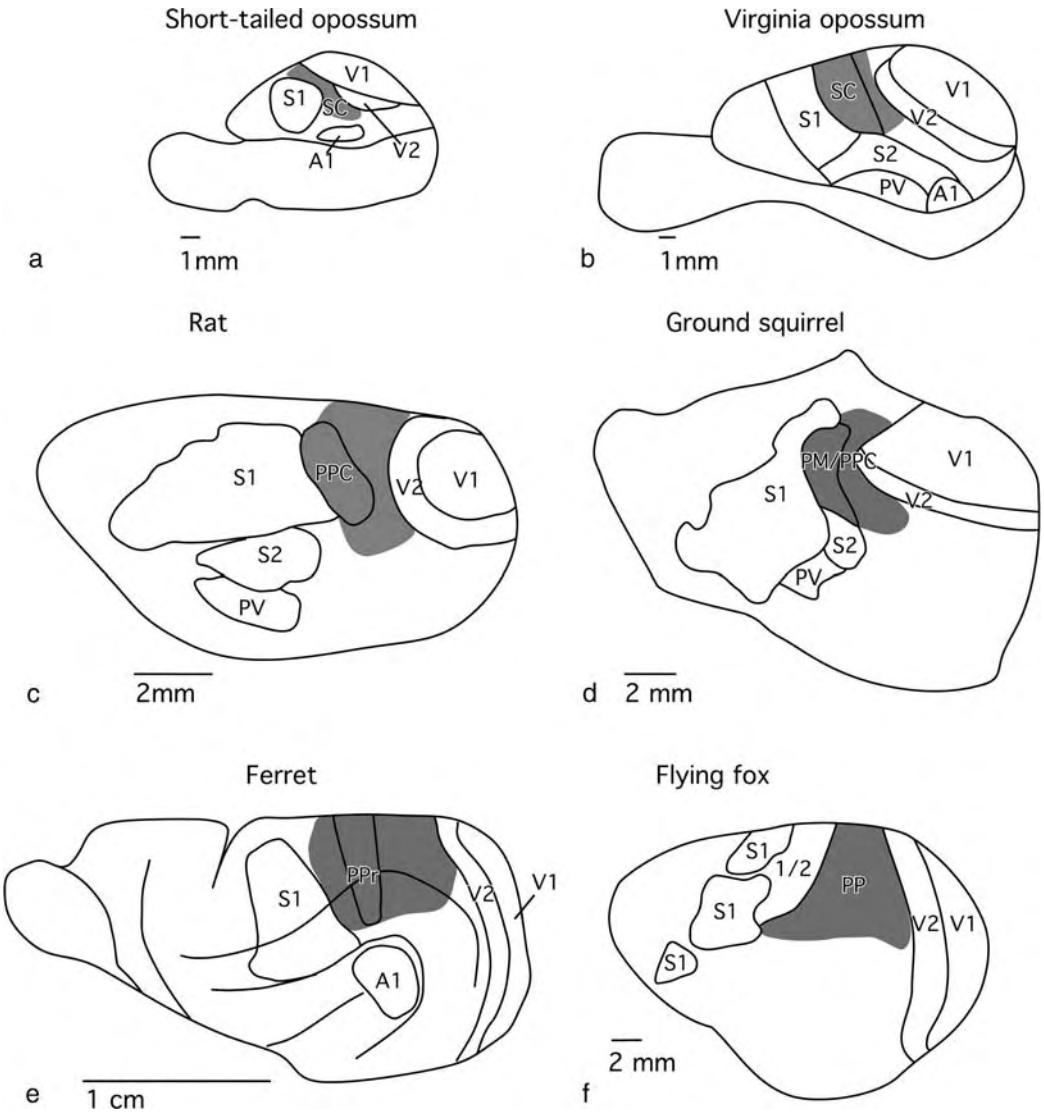
**Evolution of Association Pallial Areas: Parietal Association Areas in Mammals. Figure 2** The somatotopic organization of anterior (3a, 3b, 1 and 2) and posterior parietal area 5 in several species of mammals. Although some mammals have increased the number of somatosensory areas such as area 3a, 1 and 2 in primates, all mammals have similar features of organization of anterior and posterior parietal area. The most noteworthy feature here is an expanded representation of behaviorally relevant body structures (noted in different species by different shades of grey). These include D4 and oral structures in the striped possum, the wing and oral structures in the flying fox, and the hand, shoulder and oral structures in the macaque monkey.

hedgehogs and tenrecs, a narrow band of cortex in the location of posterior parietal cortex has been identified, and neurons in this region respond to visual and/or to auditory stimulation, to stimulation of cutaneous somatosensory receptors (i.e., deflection of quills), and/or to visual stimulation [20]. Species such as the flying fox have a cortical field termed PP, which is immediately caudal to area 1/2. Neurons in PP respond to stimulation of deep receptors as well as to visual stimulation, and PP has connections with area 1/2 (e.g., [21]).

As with area 5 in primates, electrophysiological recording studies of posterior parietal cortex in other mammals indicate that there is an extreme magnification of ecologically relevant body parts (Fig. 2). For example, in rats and squirrels, this cortex is dominated by the representation of the forepaw. In marsupials such as the striped possum, with its specialized fourth digit, this cortex contains a large representation of D4 [19]. Another feature common to PPC and area 5 is that neurons in this region of cortex respond to stimulation of deep somatic receptors and often to visual stimulation as well. Finally, as in primates, in the few studies in which the connections of PPC have been investigated in non-primates, strong connections are observed with motor cortex, orbitofrontal cortex, and the lateral posterior and lateral dorsal nuclei of the thalamus.

## The Evolution of Posterior Parietal Cortex

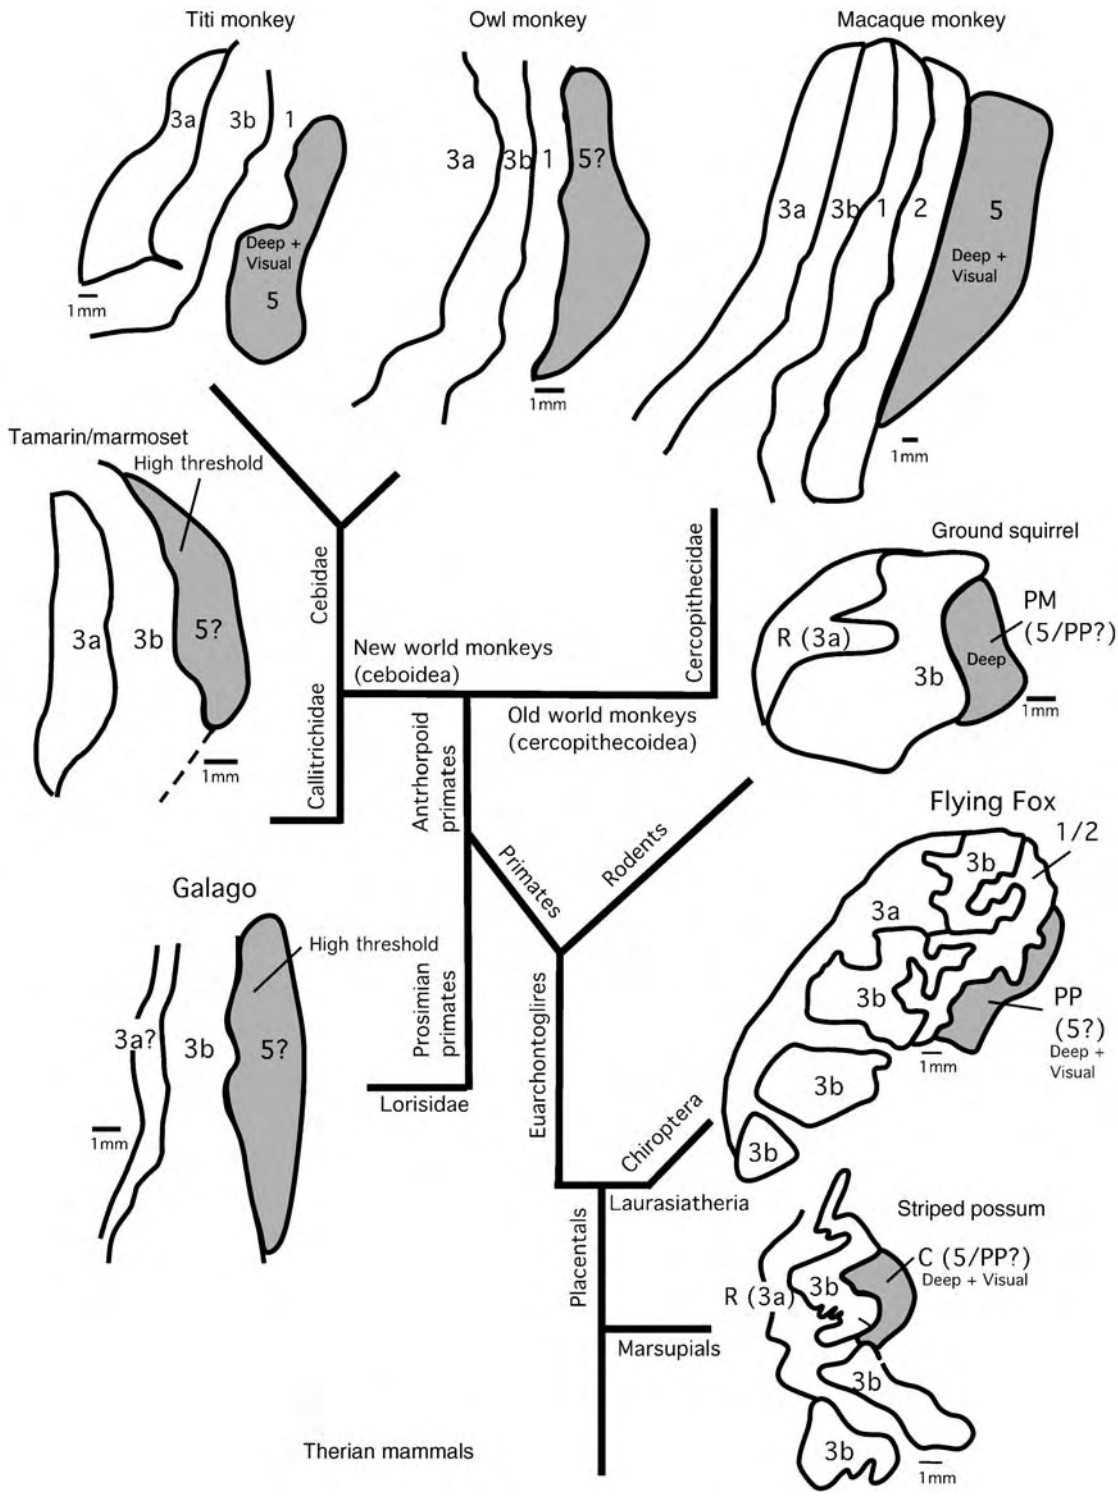
The presence of PPC in both New World and Old World monkeys, and a rudimentary form of PPC in most non-primate mammals studied suggests that this region of cortex arose early in mammalian evolution and has been retained in most or all species of this class (Fig. 4). If this is the case, then the long-held belief that PPC is a newly evolved region of cortex observed only in primates needs to be re-evaluated.



**Evolution of Association Pallial Areas: Parietal Association Areas in Mammals. Figure 3** The location of the proposed homologue of PP (*grey*) in different non-primate mammals. In marsupials such as the short-tailed opossums (a) and the *Virginia opossum* (b) a field termed SC resides between S1 and V1 and neurons here are responsive to somatic and visual stimulation. In rodents such as rats (c) and ground squirrels (d) a field termed PPC and PR respectively is located just adjacent to S1 and as in marsupials, neurons in this region are responsive to visual and somatic stimulation. Posterior parietal cortex has been less well explored in other species such as ferrets (e) and flying foxes (f), but limited data indicate that these animals also have PP. Note that in small brained animals, PP is immediately adjacent to S1 and V1, and in mammals with larger brains such as ferrets, the PP does not appear to abut primary sensory areas.

While all mammals, including primates, appear to have regions of the neocortex associated with generating an internal frame of reference, in primates, new sensory areas such as anterior parietal fields 1 and 2 (Fig. 4) have been added, new connections have formed, and existing posterior parietal cortical areas associated with visually guided hand use have been elaborated.

All of these factors may ultimately have led to the emergence of a more refined internal representation of self and increased the ways in which this internal representation interacts with objects in extra-personal space via the hands. Thus, the evolution of multiple sensory areas and an expansion of cortex devoted to hand use may be the hallmark of primate evolution. This species-specific internal representation is not a property that emerged in anthropoid primates alone but is a dynamic sensorimotor loop that all mammals possess in a derived form based on their morphological



**Evolution of Association Pallial Areas: Parietal Association Areas in Mammals. Figure 4** A cladogram depicting the phylogenetic relationship of different species and the location of posterior parietal area 5 (*grey*) relative to anterior parietal fields. Note that in New World and Old World monkeys such as titi, owl and macaque monkeys, new sensory areas have been interspersed between evolutionary older fields such as 3b (S1) and posterior parietal areas (PP or area 5).

distinctions and distribution of sensory receptors. In primates and some rodents, the morphology in question is that of the hands and the behaviors associated with the use of the hands to explore and interact with the external environment. In other mammals, exploratory behavior may involve morphological structures such as a snout, bill, or nose follicle. Regardless of the effector organ, all of these behaviors require an internal frame of reference and specialized motor programs that allow efficient interface between the effector and the external world. Studies of connections as well as electrophysiological recording data indicate that PPC does have strong interconnections with motor areas of the cortex. This suggests that the motor system plays a critical role in generating an internal frame of reference which enables all animals to distinguish self from non-self, an attribute traditionally delegated solely to association cortex in primates.

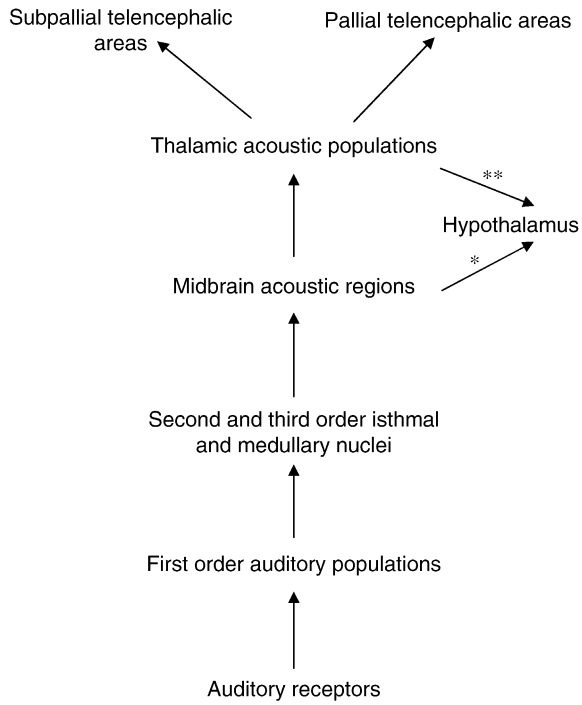
# Evolution of Auditory System in Anamniotes

Catherine A. McCormick,
Mark R. Braford Jr
Departments of Biology and Neuroscience, Oberlin College, Oberlin, Ohio, OH, USA

## Definition

The ascending auditory system comprises the receptor apparatuses, sensory ganglia and central pathways that detect and convey auditory stimuli into and through the brain. It is not known whether jawless fishes (lampreys and hagfishes) hear. Across jawed vertebrates, the auditory system exhibits diversity in its auditory receptors and central nuclei but a common pattern of organization of its central ascending pathways (Fig. 1). Jawed fishes hear using ▶otolith endorgans – the saccule, lagena and utricle – and the non-otolithic macula neglecta may



**Evolution of Auditory System in Anamniotes.**

also be auditory in some ►cartilaginous fishes [1]. Amphibians retain auditory function in the saccule and lagena and also have evolved new sound pressure receptors – the amphibian and basilar papillae [2].

The mechanosensory lateral line system, present only in anamniotes, potentially contributes to hearing in fish and those aquatic amphibians that retain it [3]. Because little is definitively known about the role of the lateral line in sound processing, it will not be discussed further. The Mauthner neuron responds to sound but does not contribute to the ascending auditory pathway [4]. Likewise, possible first-order acoustic input to the reticular formation is involved in motor activity. Other characteristics of the central auditory pathways of fish and amphibians not addressed in this chapter include (i) extensive commissural connections at many if not all levels and (ii) extensive and complex descending connections [4,5,6,7,8,9].

## Characteristics

### Ascending Auditory Pathway in Fish

#### *Brainstem Auditory Structures*

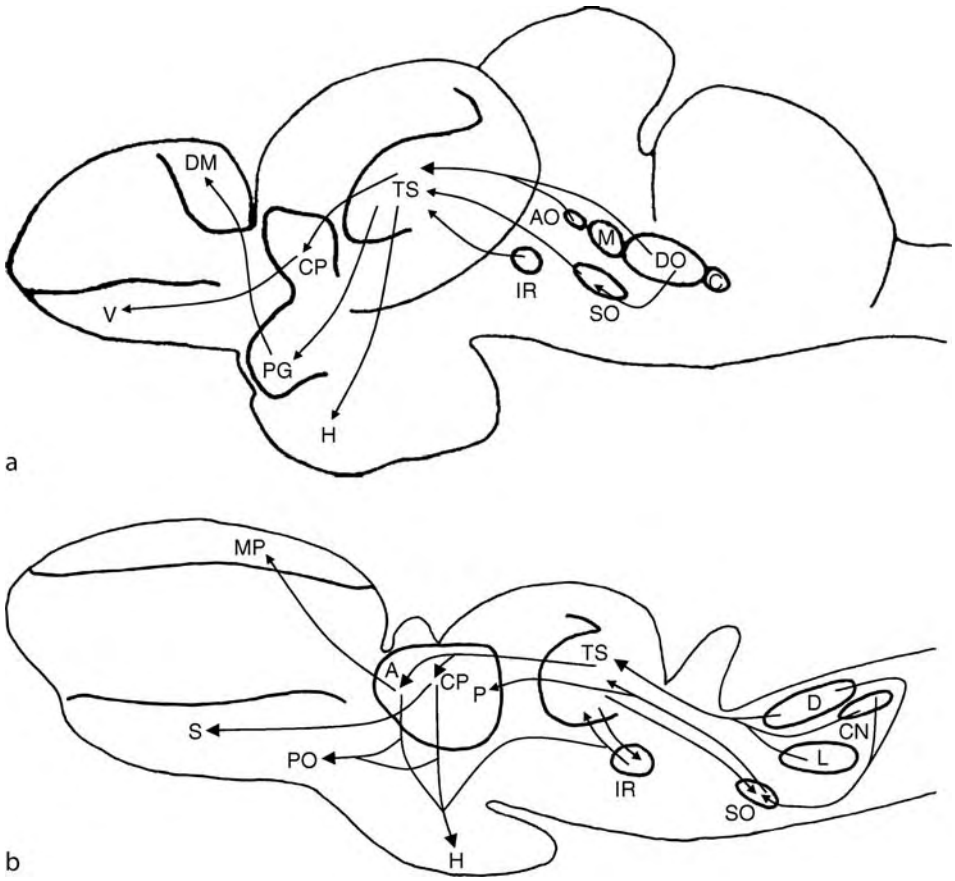
The three otolith endorgans in bony and cartilaginous (jawed) fish may function both as hearing and as gravistatic organs [1]. Each endorgan thus gives rise to a branch of the statoacoustic nerve that may have auditory and vestibular components. The central auditory pathways have been studied in relatively few species; among the ►bony fishes information is available for only the ray-finned fishes (actinopterygians). Auditory fibers segregate from otolith endorgan vestibular fibers and supply auditory regions within functionally mixed (auditory-vestibular) first-order octaval nuclei [4]. In certain cartilaginous fish auditory macula neglecta fibers also terminate in these regions [4].

Four first-order nuclei receive inner ear input in cartilaginous and the ray-finned bony fishes, the anterior, descending, magnocellular and posterior octaval nuclei (Fig. 2a). ►Teleost fish, which comprise the majority of bony fish, have an additional nucleus tangentialis. The dorsal division of the descending nucleus is the major first-order auditory center and contributes the majority of input to the auditory midbrain and other higher-order brainstem auditory structures [4]. The dorsal division of the less prominent anterior nucleus provides input to the auditory midbrain in some, but not all, species [4,10].

Within the auditory division of the descending and anterior nuclei, the otolith endorgans and, in cartilaginous fish the macula neglecta, have partially overlapping terminal zones. Fibers from the saccule, lagena and utricle usually terminate in medial to lateral locations respectively [4].

The auditory portion of the descending nucleus varies in size and morphology among fishes. Although it is largest in bony fish species specialized for sound pressure detection, there is an incomplete understanding of the functional significance of the three morphological variations that have been described [4]. The saccule in certain teleosts is specialized for sound pressure detection [1] and in these species the saccule has a very prominent, medially located terminal zone in the dorsal descending nucleus [4,8,11]. In clupeids, a teleost group in which a portion of the utricle is specialized for sound pressure detection, it is the utricular projection that prominently supplies the most medial terminal zone in the descending nucleus [4]. These comparative data suggest that in bony fish specialized for sound pressure detection, the medial portion of the dorsal descending nucleus processes the pressure component of sound and that other auditory areas of the nucleus process the particle motion component of sound.

Information about auditory processing in the anterior nucleus is lacking, but there is further information about the descending nucleus. Anatomical data from two distantly related species suggest that initial computations underlying sound localization potentially occur in the descending nucleus [12,13]. In the sonic batrachoidid teleosts, a region of the descending nucleus



**Evolution of Auditory System in Anamniotes. Figure 2** Lateral view of the brain of a goldfish and b frog schematically showing major components of the ascending auditory pathway. (along with adjacent second-order neurons) may be a vocal-acoustic integration site [10].

The auditory divisions of the descending and in some species, the anterior nuclei give rise to the lateral lemniscus (Fig. 2a). This fiber bundle has a major output to the auditory midbrain bilaterally, usually with contralateral predominance [4,8,10,11]. In bony fish the auditory midbrain comprises the nucleus centralis of the torus semicircularis (TSc; or mediodorsal nucleus of mormyrids). In some species a medial pretoral nucleus is closely allied and interconnected with the TS and other auditory structures in the diencephalon and brainstem [4,8,10]. The medioventral nucleus of the lateral mesencephalic complex in cartilaginous fish is the possible homologue of the TSc [4]. The TS as a whole also includes lateral line and probably somatosensory subdivisions and is classically considered to be homologous to the mammalian inferior colliculus. Functional studies in various teleost species implicate the TS in sound localization and recognition of species-typical vocalization, relying heavily on temporal rather that spectral cues [14]. A loose tonotopic organization has been reported in two teleost species [14].

Other brainstem components of the ascending auditory pathway are best known in bony fishes; their functional roles are unknown. In the medulla, a secondary octaval population (Fig. 2a) composed of two or three distinct divisions receives input from the dorsal descending nucleus and projects bilaterally to the TSc [4,8,10,11] and in ▶otophysan teleosts to the medial pretoral nucleus [8]. In cartilaginous fish, the relatively unstudied cell

plates C1–C3 may include a group comparable to the secondary octaval population [4]. Populations associated with the lateral lemniscus also project to the TSc. Among these, the paralemniscular/paralemniscal nucleus and possibly the isthmoreticular nucleus (Fig. 2a) receive input from the secondary octaval nucleus in ►otophysan teleosts [8].

## Ascending Auditory Pathway in Fish: Forebrain

Anatomical information on forebrain auditory pathways is limited in bony fish and absent in cartilaginous fish. Auditory structures and patterns of connectivity appear to vary among bony fish taxa [4]. Connectional differences have even been reported among closely related species. Combining data across species, it can be generally stated that nuclei in each of four regions of the diencephalon receive input from the acoustic midbrain as well as from other sensory systems in some or all species studied to date [4]. Thus, sound is processed in (i) the central posterior nucleus of the dorsal thalamus, (ii) the ventromedial nucleus of the ventral thalamus, (iii) one or more of the nuclei within the preglomerular complex of the posterior tuberculum and (iv) the anterior tuberal nucleus or other regions of the hypothalamus. Some of the mostly unimodal neurons in the central posterior nucleus of the goldfish (an otophysan teleost) are auditory [15]. Most anterior tuberal neurons in goldfish are multimodal; units responding to sound can also respond to light, to hydrodynamic (lateral line) stimuli or to both [15].

Neurophysiological analyses of the area dorsalis of the telencephalon (the pallium) have identified an auditory population within the dorsomedial area (DM) [4,16]. Anatomical studies have revealed that the bulk of the auditory input to DM arises from one or more nuclei, variously named in different species, within the preglomerular complex [4,6,9,17]. DM gets only a minor input from the central posterior and anterior tuberal nuclei and has strong descending connections to the latter [4,6,18]. DM has been hypothesized to be homologous to the pallial amygdala [6,18] or alternatively to the auditory isocortex [9]. Anatomical studies also suggest the presence of one or more auditory regions in the area ventralis (subpallium) based on input from the central posterior nucleus [4,19].

## Amphibian Ascending Auditory Brainstem Pathways

### *Overview of the Auditory Periphery*

Amphibians retain the otolith endorgans, the lagena and in particular the saccule are auditory [2]. Amphibians also have one or two endorgans with hair cells that are covered by a membrane or tectorium, the ubiquitous amphibian papilla and the variably present basilar papilla. ►Urodeles, ►apodans and certain ►anurans lack a tympanic membrane and thus seismic stimuli may be the dominant acoustic signal. Most anurans have a tympanic membrane, are thus very sensitive to airborne sound in addition to substrate vibrations and have all four acoustic organs [2].

### *Brainstem Auditory Structures*

In all amphibians studied to date, acoustic fibers from the conserved otolith endorgans and the newly evolved papillar organs converge in presumed acoustic populations in the dorsal portions of mixed auditory-vestibular nuclei. This pattern of organization thus resembles that of fishes. Homologies between these mixed-modality nuclei in fish and amphibians have been suggested but are not established [20]. Little is known about the function of these populations, but in anurans the lateral vestibular and caudal/medial vestibular nuclei project directly to one or more higher-order auditory areas [20]. Anurans have in addition evolved a first-order nucleus dedicated to auditory processing, the dorsolateral nucleus or dorsal medullary nucleus. It is tonotopically organized with a high frequency dorsomedial zone that receives basilar papilla input and a lateral zone that receives the lower frequency amphibian papilla input [7]. The lagena and saccule, both low frequency receptors, project respectively to the lateral zone of the dorsolateral nucleus [4] and to a neuropil ventrally adjacent to the dorsolateral nucleus [4,7,20].

Connections beyond the first-order level are known primarily from studies on anurans. As in fish, the lateral lemniscus conveys auditory input from lower levels of the neuraxis to the midbrain torus semicircularis (TS), a structure thought to be homologous to the mammalian inferior colliculus (Fig. 2b). The TS has a complex nuclear organization that is interpreted variously in the literature. Five toral subdivisions are generally recognized in ranid anurans, three of which are involved in sound processing, the magnocellular nucleus/ventral zone, laminar nucleus and principal nucleus [7]. The TS in the clawed toad *Xenopus* is hypertrophied and differently organized, probably due to the presence of a lateral line mechanosensory area [21]. Nevertheless, a common theme in the TS of both groups of anurans is the presence of (a) a main acoustic recipient zone – in ►ranids the ventral toral zone/magnocellular nucleus and in Xenopus the laminar nucleus – and (b) mixed modality zones. The anuran TS also receives a somatosensory projection, contains multimodal sensory areas and sends fibers to the deep layers of the optic tectum [7].

In anurans, the dorsolateral nucleus projects bilaterally to the TS (Fig. 2b) [7]. The superior olive (SO), located in the medulla, receives bilateral input from the dorsolateral nucleus and from the mixed-modality caudal/medial vestibular nucleus and projects bilaterally to the acoustic midbrain – the torus semicircularis (Fig. 2b) [7,20]. Like the dorsolateral nucleus, the SO and TS are tonotopically

organized [14]. All three structures additionally contain some neurons that are sensitive to interaural time and intensity differences [14]. The superficial reticular nucleus, located in the isthmus, receives contralateral input from the dorsolateral nucleus and ipsilateral input from the SO and projects bilaterally to the TS (Fig. 2b) [7]. In ranids, the main auditory area in the TS is reciprocally connected to the secondary isthmal nucleus/nucleus of the lateral lemniscus [7]. Because the secondary isthmal nucleus also projects to the ventral hypothalamus along with some of the acoustic thalamic nuclei, it may be involved in circuitry that links vocalizations and reproductive behavior [5].

### Forebrain Auditory Structures

As is the case in fish, the anuran TS has widespread connections to the diencephalon. Many of these nuclei are multimodal, and not all are auditory. Two dorsal thalamic nuclei – the caudal portion of the central posterior nucleus and the posterior thalamic nucleus (Fig. 2b) – appear to contain subpopulations that are exclusively or largely focused on auditory processing [5]. The anterior nucleus (Fig. 2b) is an acoustically responsive multimodal region of the dorsal thalamus that also receives visual and somatosensory input [5].

The central posterior nucleus is reciprocally connected with the main auditory toral region, the ventral zone/magnocellular nucleus (Fig. 2b) [5]. The posterior thalamic nucleus receives input from the SO, the central posterior nucleus and the TS ventral zone [5]. The central posterior and posterior thalamic nuclei may be components of parallel circuits that process temporal and spectral components of sound respectively [4]. Both of these nuclei project to the striatum (Fig. 2b) [4,5].

The central posterior nucleus and the anterior nucleus additionally provide input to acoustically responsive areas in the preoptic area and ventral hypothalamus (Fig. 2b); acoustic input potentially influences vocalization and the hormonal control of reproductive behavior via this pathway [5]. The anterior thalamic nucleus receives a small direct input from the TS and a larger indirect toral input via the pretectal gray in addition to visual and somatosensory inputs [5]. Acoustic responses have been recorded from one of its telencephalic targets, the medial pallium (Fig. 2b) [5]. The medial pallium may contain homologues of the hippocampus and non-olfactory sensory cortices [22].

### Evolutionary Overview

The ascending auditory pathways of fish and amphibians share a common pattern of information flow – a multisynaptic, ascending system that begins in the medulla and terminates in the forebrain (Fig. 1). At each level of this circuit, various taxa have evolved unique specializations. For example, among fish, the organization of otolith endorgan inputs into the acoustic region of the main auditory nucleus varies. Among amphibians, anurans uniquely evolved a dedicated auditory processing nucleus but also have mixed auditory-vestibular nuclei present in other amphibians and fish. Anurans and at least some groups of fish have significant inputs of the auditory system to the hypothalamus, but the circuits are organized differently. Forebrain auditory pathways are particularly variable. It is noteworthy that the general pattern of auditory information flow in fish and amphibians is also present in ►amniotes. This may reflect conservation of a primitive pattern established at least as early as the evolution of the first jawed vertebrates, if not earlier [4]. Whereas the ascending auditory pathway in mammals terminates mainly in auditory isocortex with smaller inputs to the striatum and amygdala, in fish and amphibians this pathway terminates in the striatum and in pallial areas of uncertain homology.

# Evolution of Brain: At Invertebrate–Vertebrate Transition

Ann B. Butler
Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

Evolution of the brain in the earliest vertebrates from their invertebrate chordate ancestor.

## Characteristics

### Phylogenetic Relationships

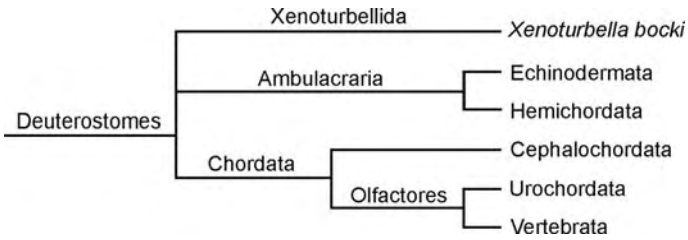
The earliest vertebrates evolved from ancestral, invertebrate chordates. Vertebrates (= craniates) are defined here as including among their extant members the jawless vertebrates (agnathans) – both hagfishes and lampreys – and jawed vertebrates (gnathostomes). The latter comprise cartilaginous fishes (Chondrichthyes) and the bony fish (Osteichthyes) radiation. Osteichthyes includes ray-finned fishes (actinopterygians) and the sarcopterygian radiation of lungfishes, crossopterygians, and tetrapods (amphibians, mammals, reptiles, and birds). Vertebrates have long been classified as one of three groups of chordates, which also include cephalochordates (the lancelets, i.e., amphioxus, or *Branchiostoma*) and urochordates (tunicates, or sea squirts). The hemichordates (acorn worms) have long been recognized as the sister group to the chordates, with echinoderms (starfishes, sea urchins, etc.) being the outgroup to the group of both hemichordates and chordates. The echinoderms, hemichordates, and chordates comprise the extant deuterostomes, which are distinguished from protostomes (most invertebrate taxa) by embryological differences early in development.

Recent molecular evidence [1–3] has prompted a revision of the cladogram for deuterostomes such that it now contains four phyla (Fig. 1) – Xenoturbellida (which comprises the single species *Xenoturbella bocki*), Ambulacraria (which comprise both the echinoderms and the hemichordates), Cephalochordata (the lancelets), and Olfactores (the urochordates and vertebrates). This new phylogeny includes a displacement of cephalochordates, long regarded as the sister group of vertebrates, to the sister group of the Olfactores, with urochordates (tunicates) being the closest extant lineage to vertebrates (see ►Evolution and Phylogeny of Chordates).

Recent hypotheses on how the brains and heads of the earliest vertebrates evolved have been based on the previous phylogenetic hypothesis that placed lancelets as the sister group. The tenets of these hypotheses are nonetheless well supported in light of the new phylogenetic interpretation, because additional recent findings about the nervous system in ascidian larvae reveal that it is much more similar to that of lancelets and vertebrates then previously realized.

### New Head Hypothesis of Northcutt and Gans

In 1983, Northcutt and Gans [4] published a major breakthrough for our understanding of vertebrate evolution with their New Head Hypothesis. Among its several new insights was the realization that tissues derived from neural crest (cells that arise next to the neural tube and give rise to multiple tissues, including some neurons) and neurogenic placodes (neighboring neurogenic epithelial regions) accounted for most of the features that uniquely occur in vertebrates, and thus the



**Evolution of Brain: At Invertebrate–Vertebrate Transition. Figure 1** Dendrogram showing the relationships of the deuterostomes, based primarily on Bourlat et al. [1] and other references as cited in the text.

E

origin and elaboration of these tissues had played a crucial role in their evolution. Neurogenic placodes contribute sensory neurons to many of the cranial nerve sensory ganglia as does neural crest, while the latter also gives rise to a host of other tissues, including structural components of the gill arches, dermal skull, teeth, and pigment cells. Some indication of the presence of neural crest derivatives and placodes has been found in the invertebrate chordates, particularly in ascidians (urochordates), as discussed by Holland and Holland [5] and Northcutt [6], and Jeffery [7] has recently bolstered his assertion that neural crest-like cells that give rise to pigment cells are present in numerous ascidians. Nevertheless, the main point of Northcutt and Gans's insight stands in that the elaboration, if not the completely novel evolutionary gain, of these two tissues was one of the most significant and catapulting events in the evolutionary origin of the vertebrate subphylum.

Northcutt [6] recently reassessed the New Head Hypothesis. As noted above, its recognition of substantial elaboration of neural crest and neurogenic placodes in the earliest vertebrates (even if these tissues are not unique to vertebrates) has been supported. A second claim of the New Head Hypothesis, that the elaboration of the neural crest and placodes allowed a shift from filter feeding to active predation is likewise supported by the accumulated data, as will be discussed further below.

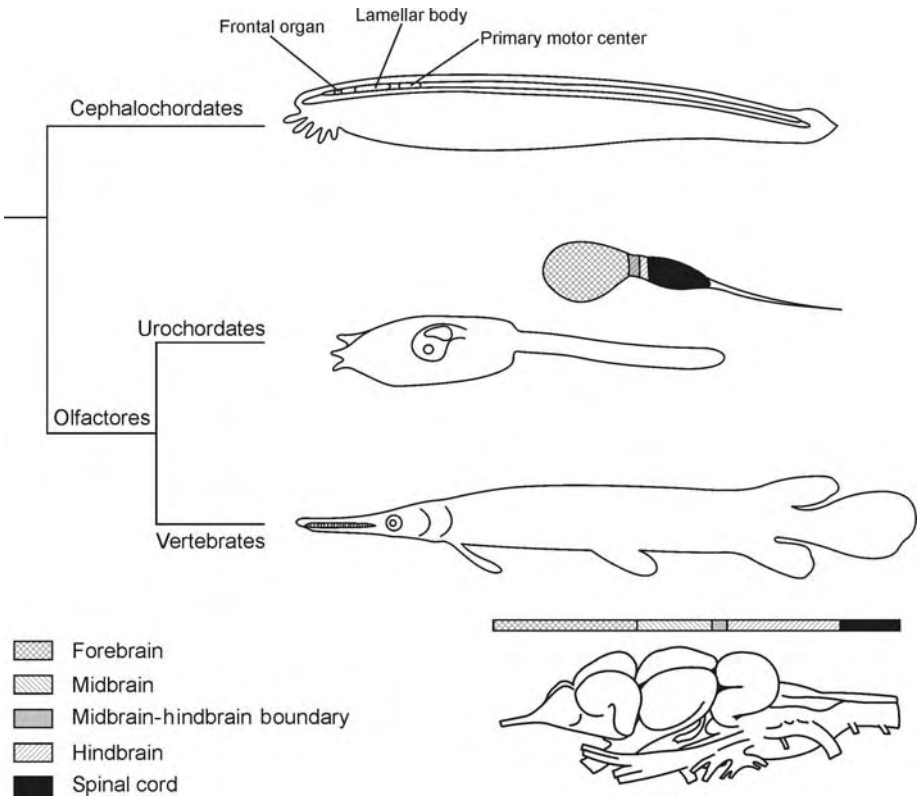
## The Nervous Systems of Cephalochordates and Urochordates

In a seminal series of papers, Lacalli and his co-workers [8–10] illuminated the details of the rostral part of the central nervous system (CNS) of cephalochordates, as studied in the larval lancelet, *Branchiostoma* (amphioxus), by doing meticulous 3D reconstructions from serial sections at the level of the electron microscope. Using this methodology, they definitively demonstrated for the first time that a brain with distinct subdivisions and several recognizable homologues of vertebrate CNS structures is present in the cephalochordates (Fig. 2). Among the vertebrate homologues is a rostrally located pigment spot and associated neurons that likely comprise a homologue of the paired eyes of vertebrates, a structure called the lamellar body, which is thought to be homologous to the vertebrate pineal, and a so-called balance organ that actually is a homologue of at least part of the vertebrate hypothalamus. Farther caudally is a collection of motor neurons, called the primary motor center, that is regarded as the rostral-most population of hindbrain motor neuron pools.

Recent work also has provided new insights into the structure of the rostral part of the neural tube in urochordates, as studied in the larval tadpole form of *Ciona*. These animals have a sensory vesicle that is separated by a so-called neck region from a visceral, or trunk, ganglion, which contains motor neurons, in the trunk, as well as a caudally extending nerve cord. The sensory vesicle contains two pigment spots, an otolith and a more dorsocaudally situated ocellus, the latter possibly associated with photoreceptor cells [12]. Homeobox gene expression data support the morphological comparisons for urochordates (Fig. 2). Based on the work of Dufour et al. [11] and Imai and Meinertzhagen [11], the picture now emerging is that, as is likely also the case in amphioxus, the brain in ascidian larvae lacks a midbrain region. Rather, they have a clearly identifiable forebrain region that is divided from a rather small hindbrain by a midbrain-hindbrain boundary, the latter also identifiable in vertebrate brains. These components all lie within the sensory vesicle, while the trunk ganglion comprises the neuronal populations that correspond to the spinal cord.

## Vertebrate Eye Evolution Considered

In considering the New Head Hypothesis, the question arose as to whether the full elaboration of all sensory systems, brain, and the vertebrate head could have occurred as essentially simultaneous events or whether a sequential scenario might account for the transition to the earliest definitive vertebrates [13,14; and see 15,16]. If the neural crest and neurogenic placodal sensory systems of the head, i.e., the peripheral senses – the olfactory, trigeminal, facial, lateral line, auditory, vestibular, glossopharyngeal, and vagal – had elaborated before the brain also elaborated, they would not be



**Evolution of Brain: At Invertebrate–Vertebrate Transition. Figure 2** Drawings, from top to bottom, of a cephalochordate (lancelet), a urochordate (represented here by larval *Ciona intestinalis*), and a vertebrate (gar), with the brains drawn separately and offset to the right for the latter two. Rostrocaudal regions, from left to right and indicated by colors, of the urochordate brain (sensory vesicle) and their correspondence to regions of the vertebrate brain are based on the interpretation of Dufour et al. [11]. Similarly, for the lancelet brain, the frontal organ and lamellar body are components of the forebrain, while the region of the primary motor center most likely corresponds to the midbrain-hindbrain boundary and/or hindbrain.

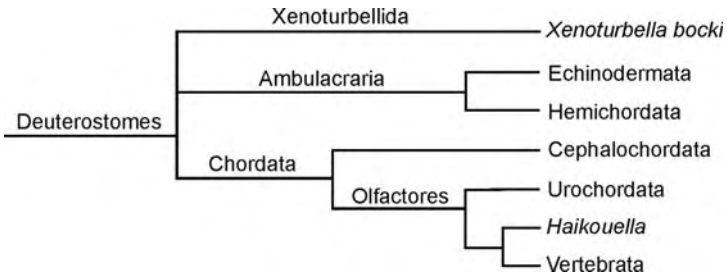
potentially adaptive without the brain circuitry to take advantage of their sensory inputs.

In contrast, if the brain had undergone elaboration first, including the gain of the paired vertebrate eyes as an elaborated part of the diencephalon, such an event would be advantageous, due to the enhanced visual input, even without the elaboration of the neural crest and neurogenic placodal tissues. Their subsequent elaboration would be adaptive, however, since their inputs could be processed and utilized by the already elaborated brain. Further elaboration of both the peripheral senses and of the brain, including the visual system, would then quite rapidly follow. While the brain and paired eyes elaborated in the earliest vertebrates, the telencephalon would not have appeared until the subsequent elaboration of the olfactory system. This idea is called the "Cephalate" or the "Serial Transformation" Hypothesis [13,14,16].

## Fossil Evidence: Answers From *Haikouella*

The discovery of a wealth of fossil material in part of Haikou, China has provided numerous data that support the key tenets of the New Head Hypothesis, as well as the Serial Transformation Hypothesis that the paired eyes and an elaborated brainstem, including the diencephalon, were gained before much of the elaboration of the neural crest and all or most placodal sensory systems. Recent cladistic analysis by Mallatt and Chen [17] indicates that this extinct species, *Haikouella lanceolatum*, is the closest known sister group of vertebrates (Fig. 3). If this interpretation is correct, it provides an unusually clear picture of vertebrate origins.

In 1996, from analysis of the then available evidence on living and fossil fishes, Mallatt [18] had proposed that the basal vertebrate ancestor would have been a true vertebrate (craniate) with a skull, as well as with many of the neural features predicted by the New Head Hypothesis, including the presence of at least some peripheral sensory systems, such as the olfactory and auditory/vestibular systems, and a telencephalon in addition to the rest of the brain. The external features of *Haikouella*'s head and body are remarkably like Mallatt's [18] prediction, including the presence of



**Evolution of Brain: At Invertebrate–Vertebrate Transition. Figure 3** Dendrogram showing the relationships of the deuterostomes, based primarily on Bourlat et al. [1] and other references as cited in the text, with the addition of *Haikouella* as the sister group of vertebrates, based on Mallatt and Chen [17].

branchial bars (to which neural crest substantially contributes), a circular mouth surrounded by an oral ring and tentacles, lips, and a premandibular oral cavity. Present on the body are myomeres and a series of bands on the notochord, which may be indicative of protovertebrae. *Haikouella* also has paired eyes, as predicted by both Mallatt [18] and Butler [13,14,16], but, also as Butler predicted, *Haikouella* fossils do not indicate the presence of most peripheral sensory systems, including the ear and/or a lateral line system, derived from neural crest and neurogenic placodes. The fossil material is ambiguous as to the presence of nostrils, but, while the paired eyes are clearly evident, the rostral part of the brain appears to comprise only a diencephalon, with a telencephalic region mostly or completely absent. Nonetheless, the brain-body ratio appears to be comparable to that of extent lampreys, indicating substantial elaboration of the brain in comparison to lancelets, let alone urochordates.

## Summary and Conclusions

The evidence now available from *Haikouella* [17], in conjunction with the previous predictions and other evidence, indicates that the earliest vertebrates arose because of some neural crest elaboration that resulted in the gain of branchial bars and the crucial switch from filter feeding to active predation, as predicted by Northcutt and Gans [4] in their New Head Hypothesis, as well as the gain of at least some components of the vertebrate skull, also mostly a neural crest derivative, as also predicted by Mallatt [17,18]. Possibly like *Haikouella*, these earliest vertebrates may have had mesodermally-derived protovertebrae, consistent with their increased mobility for active predation. Also, these earliest vertebrates would have had paired eyes and an elaborated brainstem, including the diencephalon, as consistent with the Serial Transformation Hypothesis [13,14]. That step was followed by substantial further elaboration of the neural crest and neurogenic placodes for the gain of most of the peripheral sensory systems, as also predicted by the New Head Hypothesis [4], if not necessarily as effectively simultaneous acquisitions. Among the latter, the olfactory system was elaborated (or further elaborated), and in conjunction with it, the telencephalon also was elaborated. At this stage, the definitive taxon of vertebrates, with a new head and the shared, basic divisions of the brain – a prosencephalon, or forebrain, comprising telencephalon rostrally and diencephalon caudally, including paired eyes; a definitive mesencephalon, or midbrain; and a rhombencephalon, or hindbrain, comprising the metencephalon rostrally (pons and cerebellum of mammals, for example) and myelencephalon caudally (medulla oblongata) – as well as the basal set of peripheral cranial nerves, was established.

# Evolution of Cerebellum

William Hodos
Department of Psychology, University of Maryland, College Park, MD, USA

## Definition

The cerebellum is a major subdivision of the hindbrain that is involved in various sensory-motor functions, especially those involving the vestibular and somatosensory systems, and electroreception in certain ray-finned fishes. It has also been reported to play a role in certain cognitive processes.

## Characteristics

The cerebellum is a major feature of the vertebrate hindbrain. It varies widely in its shape and in its size relative to other major brain components such as the cerebrum [1,2]. In shape, it most often is roughly spherical, but it also can be a flattened sphere or even a flat plate. Typically, the cerebellum is smaller than the cerebrum; hence its name, which means "little brain" in Latin. In some fishes, however, such as the Mormyrid fishes, which have an exquisitely developed system of ►electroreception, the cerebellum assumes gigantic proportions and can be as large or larger than the rest of the brain [3]. This may be seen in Fig. 1 which is a simplified ►cladogram of vertebrate evolution with figurines representing the brains of each of the animals shown.

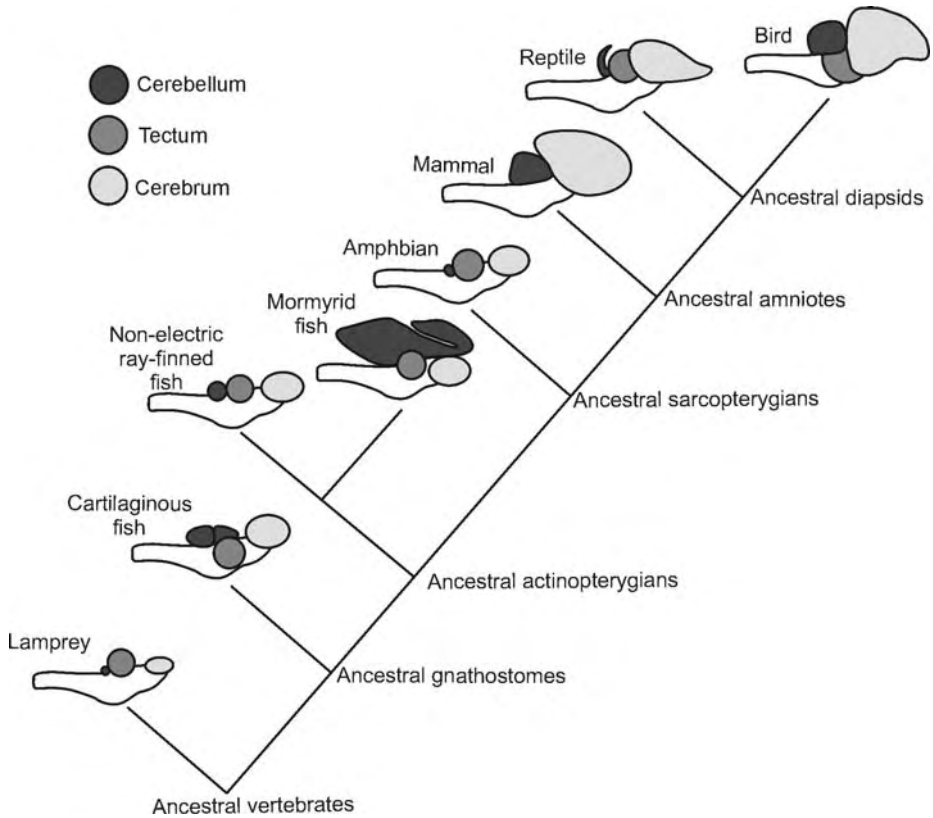
The brains have all been scaled to have the same size brain stem; i.e., the brain stem of a relatively small ray-finned fish, such as a trout or a carp is shown as the same size as that of a human or sheep. Thus, in the Fig. 1, the size of the cerebellum relative to the size of other major brain regions, such as the cerebral hemisphere, can be seen. The majority of ►ray-finned fishes (which lack electroreception), as well as lampreys and amphibians, have cerebella that are relatively small in comparison to the total size of the brain or to the cerebrum. Among the amniotes (mammals, reptiles, and birds), reptiles also have a relatively small cerebellum, which is in the form of a flat plate that often is curved [4,5]. Apart from the electroreceptive fishes, mammals and birds have the largest cerebellum relative to the rest of the brain [1,2].

The major components of the cerebellum that can be found in most vertebrates are the corpus cerebelli (the main body of the cerebellum) and the cerebellar auricle ("little ear"), which is also known as the flocculus in ►tetrapod vertebrates [1,2]. Although some cerebellar folding is present in the cerebellum of many vertebrate taxa (and extreme cerebellar folding occurs in the cerebella of the electroreceptive Mormyrid fishes, the surface of the cerebellum tends to be relatively smooth. In birds and mammals, however, the cerebellum becomes quite ►foliated [1,2]. In addition, in mammals, the corpus cerebelli becomes compressed into a narrow, worm-like midline structure called the vermins ("worm" in Latin) and a large, foliated, hemispheric extension called the neocerebellum appears on both sides of the vermis. Rather than being a new addition to the cerebellum, as its name implies, the neocerebellum appears instead to be merely a lateral expansion of the corpus cerebelli. An additional cerebellar structure, the valvula cerebelli, is unique to ray-finned fishes [6].

Figure 2 shows schematic illustrations of the cerebellum in a number of vertebrates. The corpus cerebelli and auricle are shown in each. Hagfishes lack any trace of a cerebellum, and in lampreys, the cerebellum is small and rudimentary. It's relationship to the corpus cerebelli of the other vertebrates is not clear at the present time. In contrast, all jawed vertebrates have a clearly discernable corpus cerebelli and auricle. The narrow midline structure in the mammal's cerebellum is the vermis and the so-called neocerebellum is shown on either side of it.

## Pre-Cerebellar Nuclei

The neuronal groups that supply input to the cerebellum are sometimes known as the precerebellar nuclei. In addition to its ►somatosensory and ►vestibular inputs, the cerebellum receives important projections



**Evolution of Cerebellum. Figure 1** A cladogram of vertebrate evolution showing the changes in the size and shape of the cerebellum in various classes of vertebrates. All of the representations of brains have been scaled to the same size to facilitate relative size comparisons. Also shown are the cerebrum and optic tectum. Reproduced from Butler and Hodos [1] with permission of John Wiley and Sons.

from other precerebellar neuronal groups [7]. These include nuclei of the ►reticular formation, the ►inferior olivary nucleus [8], which is present in all vertebrates with a cerebellum and varies in size with the size of the cerebellum, and the ►pontine nuclei, which are present in birds and mammals [1,2]. In addition, ray-finned fishes have a nucleus lateralis valvulae, which is very well developed in electrosensory fishes with a gigantic cerebellum, and many species also have a nucleus paracommisuralis [1,2].

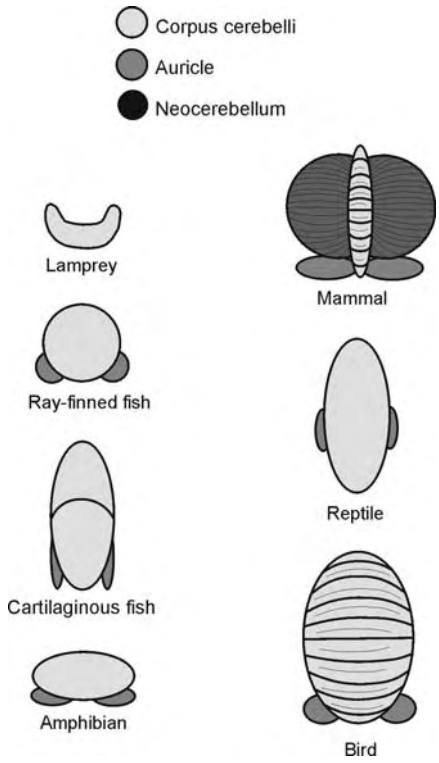
## Cerebellar Cortex

The corpus cerebelli and the auricle are covered by a layer of neurons known as the cerebellar cortex [1,2,7]. It has an organization that bears some similarities to the cerebral cortex, but with different cell types and a different organization. The most superficial layer is the molecular layer and the deepest layer is the cerebellar white matter. Between these two are the layer of densely packed granule cells and the layer of Purkinje cells.

Although there are important differences in the cerebellar cortex among the various vertebrate classes, there also are many similarities. In general, the two main types of cells of the cerebellar cortex are the Purkinje cells and the granule cells. Granule cells are remarkably similar in appearance across vertebrate classes. They are very small cells with relatively few dendrites. The dendrites are characterized by claw-like or knob-like endings. These cells are the most numerous and most densely packed of any cells in the central nervous system.

In contrast to the granule cells, the Purkinje cells are quite variable in their form across vertebrate taxa. They can however, easily be recognized in most cases by their large cell bodies, which are located along the margin of the granule cell layer and from which emerge a large, candelabra-shaped dendritic tree oriented towards the surface of the cortex. The Purkinje cell bodies are quite large and often are arranged in a layer that is only one cell body thick.

The outermost layer of the cortex is the molecular layer, which contains a variety of small inhibitory neurons that exert negative feedback over the granule cells and Purkinje cells. The Purkinje cell dendrites rise into the molecular layer and spread out like the branches of a tree. The axons of the granule cells also



**Evolution of Cerebellum. Figure 2** Schematic diagrams of the major components of the cerebellum in various groups of vertebrates. The brains have been scaled to the same size to facilitate relative size comparisons. Adapted from Butler and Hodos [1] with permission of John Wiley and Sons.

ascend into the molecular layer, form a T-shaped junction and pass through the Purkinje cell dendrites like telephone wires passing through the branches of a tree. These granule cell axons in the molecular layer are known as parallel fibers [9].

The deepest layer of the cortex is the white matter, which consists of the axons of neurons entering the cortex and those of the Purkinje cells leaving the cortex. Embedded within the white matter are one or more deep cerebellar nuclei, which are the destination of the axons of the Purkinje cells. The deep nucleus or nuclei send their axons to multiple targets, including the red nucleus in the midbrain tegmentum and the dorsal thalamus (e.g., its ventral lateral nucleus in mammals). A notable exception to this pattern are the Purkinje cells of ray-finned fishes, which differ from typical vertebrate Purkinje cells in several ways: first, they may be scattered throughout the molecular layer in parts of the cerebellum, and second, they do not terminate in a deep cerebellar nucleus. Instead their terminations are intrinsic to the cortex. The cortical efferents are carried instead by eurydendroid cells [1,2], not to a deep cerebellar nucleus, which they lack, but directly to neuron groups in the brain stem and spinal cord that affect movement or other processes.

## Connections of the Cerebellum

The connections of the cerebellum to other brain regions are roughly the same in all vertebrate classes [1,2,7]. In general, the cerebellum has major connections with parts of the brain that are involved in balance and movement or other responses of the body, such as the generation of electric discharges in fishes that are electroreceptive. The cerebellum also receives major inputs from the somatosensory system of the spinal cord and from the vestibular system of the hindbrain as well as from the visual system and other senses. The afferents to the cerebellum are of two sorts: climbing fibers, which climb the Purkinje cell dendrites like a vine climbing the branches of a tree and originate in the inferior olivary nucleus, and mossy fibers, which arise in the other sources of cerebellar input. In birds and mammals, the major source of mossy fibers is the pontine nuclei.

Efferents of the cerebellum are via the deep cerebellar nuclei in most taxa, as noted above, and typically are to the vestibular nuclei, reticular formation, pontine nuclei, and inferior olivary nucleus of the pons region of the hindbrain as well as to the red nucleus of the midbrain and, in amniotes, the dorsal thalamus. Although some cerebellar efferents pass directly to the spinal cord, the cerebellum mainly controls movement via pathways to the spinal cord from the red nucleus, vestibular nuclei, and the reticular formation.

## Cerebelloid Structures

A number of brain structures of non-tetrapods that traditionally have been regarded as separate entities have an organization that resembles that of the cerebellar cortex. Among these are:

1. The crista cerebellaris (cerebellar crest), which is continuous with the molecular layer of the cortex and indeed resembles it. It is present in cartilaginous as well as ray-finned fishes. It contains parallel fibers from nearby granule cells and dendrites from nearby Purkinje-like cells [1,2].
2. The torus longitudinalis, which is located on the roof the cerebral ventricle in the depths of the optic tectum of ray-finned fishes. It is continuous with the granule cell layer of the cerebellum [1,2,10].
3. The electrosensory lateral line lobe of electrosensory fishes that consists of a molecular layer, a granule cell layer, and a series of additional layers. It receives its input from electrosensory receptor organs on the skin and from the inferior olive, which is also a major source of input to the cerebellum [1,2,11].

In addition to these structures found in fishes, the dorsal cochlear nucleus of mammals, which is

one of the neuronal groups that receives the incoming axons of the auditory nerve, also has a structure very similar to that of the cerebellar cortex complete with granule cells that form parallel fibers, efferent cells that send their dendrites into the layer of parallel fibers and many other characteristics of the cerebellum [1,12].

### Evolution of the Cerebellum

Although there are some striking differences between and even within vertebrate classes, the cerebellum generally has remained relatively conservative in its evolution. Some of the major changes in the cerebellum that accompanied the transition to land have been the appearance of new types of inhibitory cells, the development of multiple deep cerebellar nuclei, and the elaboration and expansion of the corpus cerebelli in mammals and birds [1,2].

## Evolution of Eyes

Russell D. Fernald
Department of Biology, Stanford University, Stanford, CA, USA

### Synonyms

Eye evolution; Phototransduction; Lens evolution; Opsin evolution

### Definition

Eye evolution is the process through which eyes evolved in the animal kingdom. Eyes are organs that compare light from different directions to produce an image. Information carried by light is transduced by specialized photoreceptor cells in the eye into neural information to be used by the brain. Many eyes have lenses that serve to collect and focus light, and these proteins have an independent evolutionary history.

### Characteristics

Light has been exploited by organisms for energy via photosynthesis and information through the evolution

of photoreceptors and ultimately eyes in animals. Darwin first wondered how such a remarkable organ as the eye could have evolved. We now know that the many adaptations of different eye types among widely different organisms concealed some interesting constraints on eye evolution. Morphological comparisons of differences in eye structures first suggested eyes are polyphyletic, evolving possibly 40–60 times, but studies of eye development identified some molecules used to build eyes in many species, suggesting eyes are monophyletic. Most studies compared eyes using ciliary photoreceptors found primarily in vertebrates with eyes using microvillar photoreceptors found primarily in invertebrates. Each eye type uses different members of the rhodopsin (type 2) protein for phototransduction and have remarkably different molecular cascades that convert photons into information. Recently, this controversy has been resolved with evidence that both primary eye types existed in ancestral bilaterians, and both are present in extant vertebrates and invertebrates. This means that at least these two eye types and probably many more were present in the urbilateria, prior to the Cambrian explosive speciation. Moreover, the novel functional photodetection system, the cryptochromes that exist widely in both plants and animals is as ancient. Thus, the eyes we know are certainly polyphyletic in origin and more surprises await us.

## Constraints on Eye Evolution from Physical Laws

Although there seems to be a large variety of eyes in the animal kingdom, physical laws have constrained solutions for collecting and focusing light to just eight types of eye optics [1].

Animal eyes are not simply photon detectors but organs that produce an image by comparing light from different directions using pinholes, lenses or mirrors to focus an image on photoreceptors. Light travels in straight lines and information is carried by wavelength, intensity and/or polarization, setting limits on eye dimensions and detection systems. Of ca. 33 animal phyla, about one-third have no specialized organ for detecting light, one-third have light sensitive organs, and the rest are animals with what we would consider eyes. Image-forming eyes appeared in six of the 33 extant metazoan phyla (*Cnidaria, Mollusca, Annelida, Onychophora, Arthropoda, and Chordata*), and these six contribute about 96% of the known species alive today.

Since earliest evolution occurred in water which transmits only a limited range of wavelengths, the mechanisms for photon response converged on biochemical solutions that set the course for subsequent evolution [1]. The evolution of eyes very likely proceeded in stages. First were eye-spots, found in nearly all major animal groups, with a small number of receptors in an open cup of screening pigment. Eye-spots are able to distinguish light from dark but cannot represent complex light patterns. Second, invagination of this eyespot into a pit adds the capacity to detect the direction of incident light. Third, increasing the number of receptors, either by adding them in an existing pit or duplicating the pit in its entirety, probably led in two directions: adding receptors may have led to a chambered eye, while duplication of receptors may have led to a compound eye [1]. Fourth, adding an optical system that increases light collection and produces an image significantly increases the usefulness of an eye. Early in the Cambrian period (570–500 million years ago), very simple eyespots, useful for detecting light but not for processing directional information, were present. Explosive speciation, or the "Big Bang" of animal evolution, happened during the Cambrian period, and existing eye types improved radically, coincident with the appearance of carnivory and predation. Whereas primitive eyes can inform about light intensity and direction, more advanced eyes deliver more sophisticated information about wavelength, contrast and polarity.

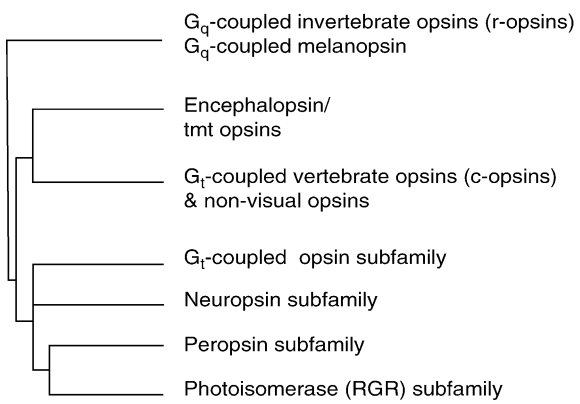
## Other Photodetection Systems

In addition, a second family of photodetection is found in archaea and eukaryotic microbes based on an independently evolved family of rhodopsin molecules (rhodopsin 1). Evolution produced this solution for harvesting light for energy, guiding phototaxis and serving other yet undiscovered functions. Genetic sequencing of organisms in large water samples has increased the number of known type 1 opsins (>800). Despite remarkable convergence in molecular details of their function, there is no phylogenetic relationship between the gene sequences of opsin types 1 and 2. Nonetheless, both are seven transmembrane domain proteins, both use an associated retinal moiety to capture light and, in both, retinal is attached in a Schiff base linkage via a lysine residue in the seventh helix. However, type 1 opsins function within the membrane to pump ions or signal other integral membrane proteins as opposed to signaling via intracellular G proteins. Finally, the two retinal molecules are photoisomerized quite differently. Progenitors of the type 1 opsins probably existed in earliest evolution before the divergence of archaea, eubacteria and eukaryotes, meaning that a light driven ion transport mechanism for deriving energy used in association with opsin 1 preceded the evolution of photosynthesis as a means for using the sun's energy. These photodetection systems can trigger movement in response to light direction and intensity and thus might be considered "proto-eyes." Comparing these two opsin systems reveals the power of natural selection to generate independent inventions which, when coupled with strong functional constraints, yield complex, convergent biological systems.

## Capturing Photons

The transduction of photons into neural signals uses seven-transmembrane opsin proteins (30–50 kDa) combined with a photon sensitive vitamin A-derived non-protein retinal chromophore attached via a specialized binding pocket. These opsin proteins, or visual pigments, which control sensitivity to light of different wavelengths, appeared before eyes and evolved into seven or eight distinct families, diverging from an ancestral type before fish split from other vertebrates (Fig. 1). It is now clear that all animals have multiple opsin types, and opsin was present before deuterostomes split from protostomes suggesting that a common ancestor had multiple opsin genes, a surmise recently verified. Multiple new opsin genes, as well as new genes for other photo transduction specific families (e.g., G proteins, nucleotide-gated channels etc.) arose early in vertebrate evolution during extensive chromosome duplications and very likely facilitated retinal specializations, providing the raw material for natural selection. For example, opsin gene duplication was responsible for the independent evolution of three color (trichromatic) vision in both Old and New World primates, and opsin gene duplications in lepidoptera (butterflies) followed by increased rate of evolution produced a diversity of pigments sensitive to visual spectra important for specific species. Photoreceptor wavelength absorption spectra are exquisitely modulated by a small collection of amino acid side groups adjacent to the chromophore binding site in the seventh transmembrane domain of opsins where the effects of natural selection are now most evident.

An example of how color vision shapes cone opsin evolution is in the visual systems of cichlid fishes in the East African lakes. In one riverine species, ancestral to the lake species, seven cone opsin genes are present due to gene duplications. Though only four cone opsins are found in the adult retina and hence can contribute to wavelength discrimination by the animal, the rest are expressed variously during ontogeny. This preservation of opsin genes may offer a substrate for rapid selection of different visual chromatic sensitivities in response to selective pressures.

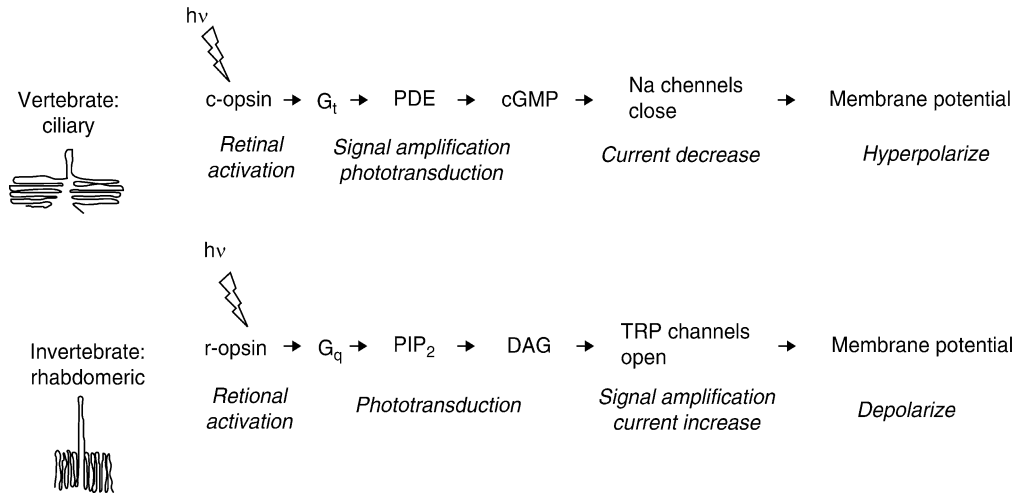


**Evolution of Eyes. Figure 1** A schematic molecular phylogenetic tree inferred by the neighbor-joining method showing the seven known opsin subfamilies [Simplified from Terakita A. (2005) The opsins. Genome Biology 6:213.1–213.9].

The two best known photoreceptor types use distinct families of opsins packed in quite different membrane specializations and, importantly, use different mechanisms of transduction (Fig. 2).

Vertebrate photoreceptors use members of the ciliary opsin (c-opsin) family named because they are incorporated into specialized cilia, while invertebrate photoreceptors use members of the rhabdomeric opsins (r-opsin) that are typically formed into structures called rhabdoms. Each receptor type uses different heterotrimeric guanine nucleotide–binding proteins (G protein), named transducin in vertebrates, and the Gq family in invertebrates. Vertebrate photoreceptors produce hyperpolarizing potentials via a phosphodiesterase cascade while invertebrate photoreceptors are depolarizing and use a phospholipase C cascade. The site of biochemical signal amplification is quite different between these receptor types, as are the mechanisms for terminating the response. Moreover, opsins in invertebrates are fixed to their membranes, allowing polarization detection while those in vertebrates are not. It is clear that these photoreceptor types arose independently and co-existed in urbilateria before bilateria arose.

Eyes have evolved to extract information about the environment exploiting the same properties of light: intensity differences produce contrast, and wavelength differences produce hue. However, no unique neural solutions exist for extracting this information, and specializations that evolved to process intensity and wavelength differ among species, reflecting how natural selection can solve similar problems via diverse mechanisms. For example, mammals and bees use long wavelength photoreceptors for intensity and color vision, while flies and birds have evolved separate sets of photoreceptors for these two purposes. Similarly, blowfly and monkey photoreceptors are equally effective in compressing a wide range of light intensities and in converting detected intensity variations into useful visual contrast using vastly different mechanisms. Thus, blowfly and monkey photoreceptors evolved independently, use different molecular mechanisms, signal processing and other physiological steps, yet essential information about the world delivered to the nervous system is nearly identical. These few examples reveal the different routes natural selection has taken during the evolution of eyes in response to the information available in light.



**Evolution of Eyes. Figure 2** Schematic illustration showing the key differences between a simplified representation of: (TOP) canonical vertebrate ciliary phototransduction and: (BOTTOM) invertebrate rhabdomeric phototransduction where hv represents incident photon energy. The two different opsin types (c-opsin and r-opsin) are contained in distinctly different membrane types, ciliary and rhabdomeric. The opsins are coupled to different families of G proteins that act via different types of transduction cascades. Ampification occurs during phototransduction in ciliary receptors and during channel opening in rhabdomeric receptors. These cascades produce signals of different sign. Gt, transducin; PDE, phosphodiesterase; cGMP, cyclic guanosylmophosphate; Gq, guanine nucleotide binding protein α15; PIP2, phosphatidylinositol-4,5-biphosphate; DAG, diacylglycerol.

## Lenses

Eye lenses collect and focus light, leading to increased sensitivity and allowing information to be spatially resolved. More advanced eyes collect light through an aperture and focus it with a lens onto a layer of photoreceptor cells. Lenses are made from proteins, so could their phylogenetic relationships provide insight into eye evolution?

Vertebrate lenses contain high concentrations of soluble proteins called crystallins because they maintain transparency while lens proteins of most invertebrate eyes are secreted by specialized cells. Three major gene families of crystallins are widely expressed in vertebrate lenses and account for most of the protein in aquatic and terrestrial vertebrates: α-crystallins [2–3], β-crystallins (6+) and γ-crystallins [2–16]. Though it was once thought that these proteins had uniquely evolved to function as lenses, some are found expressed in heart, brain and other tissues of the eye. The remaining vertebrate lens proteins are a diverse, non-conserved group, several of which serve as enzymes elsewhere in the body having been co-opted from other functions, such as enzymes, and typically the same gene encodes both the enzyme and lens protein. This molecular opportunism has also occurred both in cephalopods (octopus, cuttlefishes, etc.) and in *Drosophila* [1]. The common strategy of assembling lenses from diverse proteins seems to be a convergent evolutionary solution that has occurred independently many times in vertebrates with the source of protein quite variable.

Functionally, the exquisite gradient of refractive index necessary to allow spherical lenses to focus light [2] is a convergent solution that has evolved in water-dwelling vertebrates and invertebrates alike. What remains unknown is how genetic programs assemble differing amounts of diverse proteins to preserve the essential functional properties of lenses and whether there is any rhyme or reason to which specific proteins are used in different taxa.

## Origins of Eyes

In the past 100 years, ideas about whether eyes evolved from many origins (polyphyletic) to one origin (monophyletic) have switched back and forth. Originally, it was thought that there could have been many origins of eyes, but when it was discovered that opsin proteins were central to phototransduction in all eyes, a monophyletic origin was posited. Subsequent morphological comparisons suggested that eyes evolved 40 or more times independently based on, among other things, the distinct ontogenetic origins of eyes in different species. For example, the vertebrate retina arises from neural ectoderm and induces head ectoderm to form the lens, while cephalopod retinas result from invaginations of lateral head ectoderm, ultimately producing an eye without a cornea. These observations and many others suggested eyes had multiple origins

that converged onto a limited number of forms dictated by the physics of light.

Multiple origins were also supported by the apparent ease of eye evolution, shown by an elegant simulation model [3]. Starting from a patch of light-sensitive epithelium, the simulation, under selection for improved visual acuity, produced a focused camera-type eye in less than $4 \times 10^5$ generations. For animals with generation times less than a year, this would be less than a half million years.

The idea that eyes arose multiple times independently was challenged by the discovery that a single developmental gene, *pax6*, could initiate eye construction in diverse species. However, subsequent work has shown that *pax6* does not act alone, but that building an eye requires many interacting genes. Nonetheless, discussion about eye origins was invigorated by the discovery that homologous genes can trigger construction of paralogous systems for photodetection, just as homologous *hox* genes do for paralogous body parts across phyla.

Eye development proceeds via morphological transformations of newly generated tissue that are regulated by multiple genes with expression patterns that overlap in time and space. Identifying clear control pathways is difficult because gene products are tightly regulated, and many are used repeatedly. Functions for at least 15 transcription factors and several signaling molecules have been described for human and mouse eye development, many of which are also widely expressed in other tissues. For *Drosophila* photoreceptor arrays, it is now known that seven genes, encoding transcription factors and two signaling molecules, collaborate. These genes [(*eyeless (ey), twin of eyeless (toy*) (both of which are *pax6* homologs), *sine oculus (so), eyes absent (eya), dachshund (dac), eye gone (eyg) and optix)*] and signaling systems, including the Notch and receptor tyrosine kinase pathways, act via a complex regulatory network. Deletion of any one of these genes causes radical reduction or complete loss of the *Drosophila* eye. Yet in collaboration with certain signaling molecules, any one of these genes, except *sine oculus,* can also cause ectopic expression of an eye. Like other developmental cascades, a network of genes is required for organogenesis. Notably, *Six1*, *Dach* and *Eya* are important in the formation of the kidney, muscle, and inner ear, as well as eyes, suggesting that this suite of genetically interacting gene products may have been recruited repeatedly during evolution for organogenesis of other structures.

It seems highly probable that photodetection systems came first in evolution. Appearance of photodetection probably happened many, possibly hundreds of times until selection produced at the very least the two independent, main types of photoreceptor types known today – ciliary and rhabdomeric (e.g., Fig. 2). Clearly, though, the other opsin families also have photodetection capacities mediated by unknown structures for functions also unknown. Although these two main photoreceptor types were thought to be strictly segregated in vertebrate animals (ciliary) and invertebrate animals (rhabdomeric), recent studies show that elements of both photoreceptor types probably co-exist in most organisms.

An overlooked hint about the existence of multiple photodetection systems came from the discovery of both depolarizing and hyperpolarizing responses to light stimuli from cells located in different layers of a scallop retina (*Pecten irradians*). Depolarizing potentials, characteristic of invertebrate photoreception, arise from the proximal layer, and hyperpolarizing potentials, characteristic of vertebrate photoreception, arise from the distal layer. In 2004, Arendt and colleagues found that the polychete ragworm (*Platynereis dumerilii*) had ciliary photoreceptors in the brain in addition to rhabdomeric photoreceptors in its eyes [4]. The canonical opsins associated with each photoreceptor type were localized only with its type (e.g., vertebrate c-opsin with ciliary receptors in the brain and invertebrate r-opsin with rhabdomeric receptors in the eye). Thus both main types of "eyes" exist in a worm. Correspondingly, in vertebrates, Berson and colleagues [5] had found a small population of intrinsically photosensitive retinal ganglion cells (the neural output of the retina), use melanopsin, a member of the r-opsin family. Melanopsin in these neurons, functions via transduction pathways like those in invertebrates and signals presence or absence of light in parallel to and collaboration with the well known image-forming visual system.

Arendt and colleagues also proposed that rhabdomeric photoreceptors might be the evolutionary ancestors of vertebrate ganglion cells based on use of r-opsin and the expression of a constellation of transcription factors including pax6, Math5, Brn3 and BarH. Further, they suggested that other retinal processing neurons, horizontal and amacrine cells, might also share in this rhabdomeric photoreceptor ancestry but have lost photosensitivity. Taken together, these data show that at least two kinds of photoreception existed in the Urbilateria, before the split into three Bilateria branches at the Cambrian. Moreover, each branch of the family tree still carries versions of both of these photoreceptor types, along with other opsin dependent photo detection systems yet to be fully described. In the course of evolution, vertebrate vision favored ciliary photodetection for the pathway that delivers images, while invertebrates favored rhabdomeric photodetection for their main eyes, although why this might be remains unknown. Along both evolutionary paths, secondary photodetection systems remained to give additional information about light, possibly to instruct circadian

rhythms, phototaxis or other light dependent behaviors. But, if vertebrates are an example, these two photodetection systems functioned together rather than remaining separate. Although the remaining five families of opsins have not been fully characterized, it seems probable that they also respond to light, and organisms use the information they provide. Understanding whether and how they extract information from light and how animals use that information is now a major challenge.

## Synonyms

Evolution of corticospinal motor systems; Evolution of reticospinal motor systems; Evolution of rubrospinal motor systems; Evolution of vestibulospinal motor systems

## Definition

The descending pathways from the forebrain and brainstem to the spinal cord represent the instruments by which the central nervous system (CNS) steers movements of the trunk, the tail and the extremities. All vertebrates have a certain repertoire of descending brainstem pathways in common [1-3]. ►Reticulospinal projections form the most ancestral descending motor system by which the vertebrate brain exerts control over movements in all classes from cyclostomes to mammals. ►Vestibulospinal projections were also present early in evolution for control of equilibrium and postural activities. With the appearance of extremities, the development of an adequate neural control system for the steering of limb movements became apparent. It is likely that the ►rubrospinal tract plays an important role in this mechanism [4]. Goal-directed limb movements are controlled mainly by the rubrospinal tract, and in mammals also by the corticospinal tract.

## Characteristics

### Reticulospinal Projections

The ancestral vertebrate motor system included myomeric axial musculature, spinal motoneurons, a spinal network composed of at least two types of interneurons (excitatory interneurons and inhibitory commissural interneurons) and reticulospinal neurons to activate the spinal networks [5]. Throughout vertebrates, reticulospinal neurons are large. Their coarse axons conduct rapidly and make direct contact with spinal motoneurons and interneurons [6]. For rapid escape movements, a pair of specialized very large cells in the brainstem, the Mauthner cells, has been formed. These features of the early motor system were retained in living anamniotes. Major changes occur among amniotes such as the break-up of the myomeres into a large number of discrete axial

muscles, the development of paired fins and limbs with associated muscles and the development of a topographic map of the motor column onto the embryonic myotome. Tract-tracing studies have shown that a basic pattern in the organization of descending pathways is present throughout vertebrates, with a dominant role for reticulospinal projections (Fig. 1).

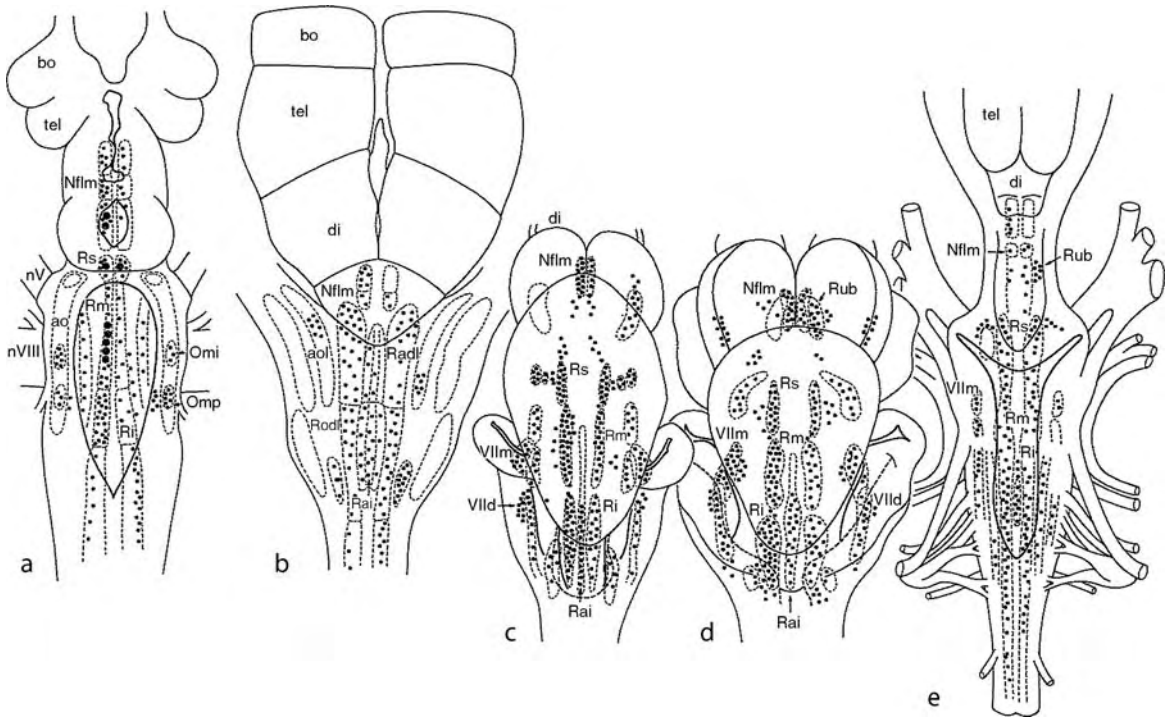
Reticulospinal projections arise from the mesencephalon (the nucleus of the fasciculus longitudinalis medialis, giving rise to the interstitiospinal tract) and throughout the rhombencephalic reticular formation. Moreover, serotonergic raphe-spinal and noradrenergic coeruleospinal projections are common to all vertebrates. Locomotor activity can be initiated by stimulation of reticulospinal pathways, as elegantly shown in for instance lampreys [7].

The likely ancestors of the land vertebrates, i.e. the lobe-finned rhipidistian crossopterygians, presumably used their paired fins to "walk" on the bottom as the modern lungfish do. For locomotion on land an increased efficiency of the limbs was necessary. Limb-moving generators were developed in the spinal cord, one for each limb. These central pattern generators (CPGs) are driven from a brainstem locomotor region in the caudal part of the mesencephalon [8, 9]. Reticulospinal neurons serve as a final common supraspinal pathway for locomotion.

## Vestibulospinal Projections

Vestibulospinal projections arise from the vestibular nuclear complex in the medulla oblongata and are involved in the control of equilibrium and postural activities. With the reticulospinal formation, vestibulospinal or octavomotor neurons give rise to the bulk of the descending motor pathways in anamniotes (Fig. 1). Ipsilateral vestibulospinal projections arise in the large-celled lateral vestibular nucleus or its equivalent, whereas contralateral vestibulospinal projections arise in other vestibular nuclei.

Tract-tracing data from amphibians, reptiles, birds and mammals show that throughout terrestrial vertebrate's



**Evolution of Motor Systems: Corticospinal, Reticulospinal, Rubrospinal and Vestibulospinal Systems.**

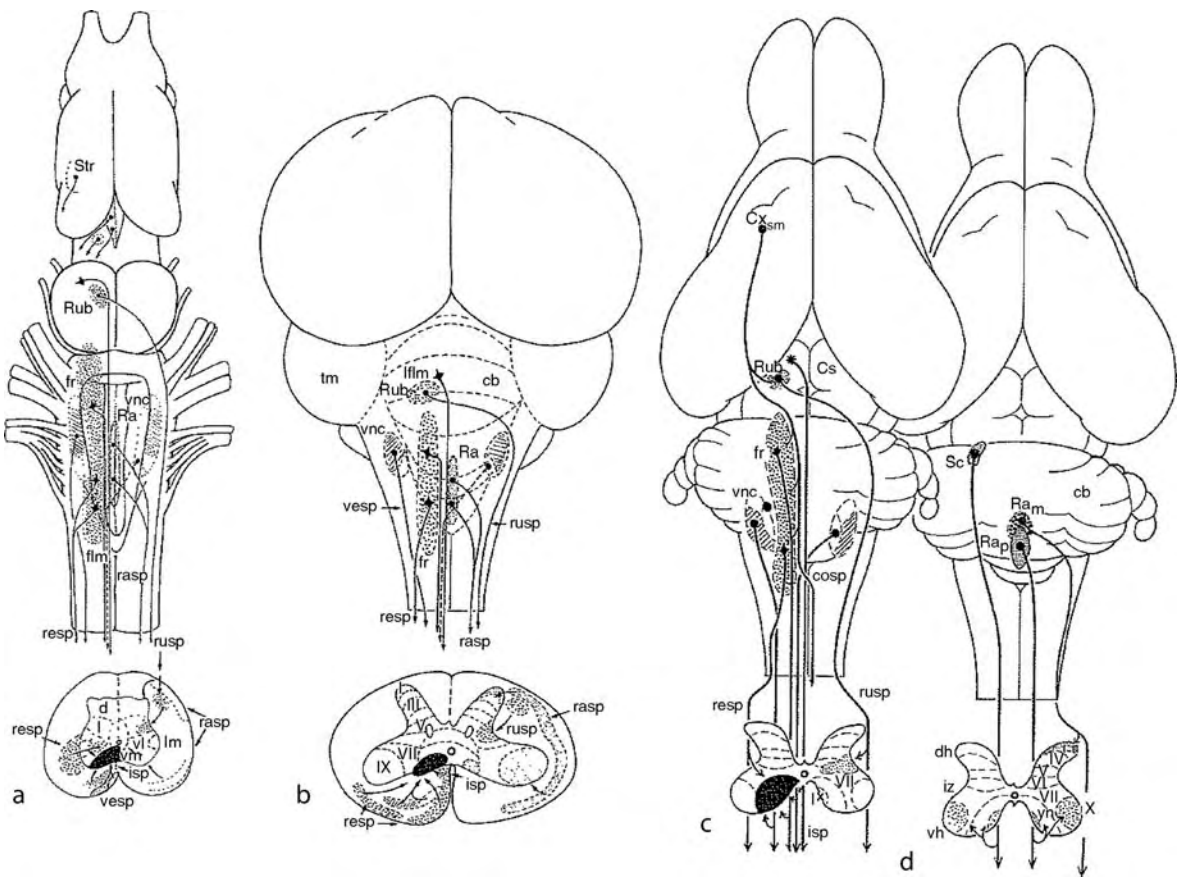
►medial and ►lateral systems of descending brainstem pathways as advocated by Kuypers [10] can be distinguished. Interstitiospinal, reticulospinal and vestibulospinal pathways pass via the ventral funiculus and the ventral part of the lateral funiculus and terminate in the mediodorsal part of the ventral horn and in the adjacent parts of the intermediate zone (Fig. 2).

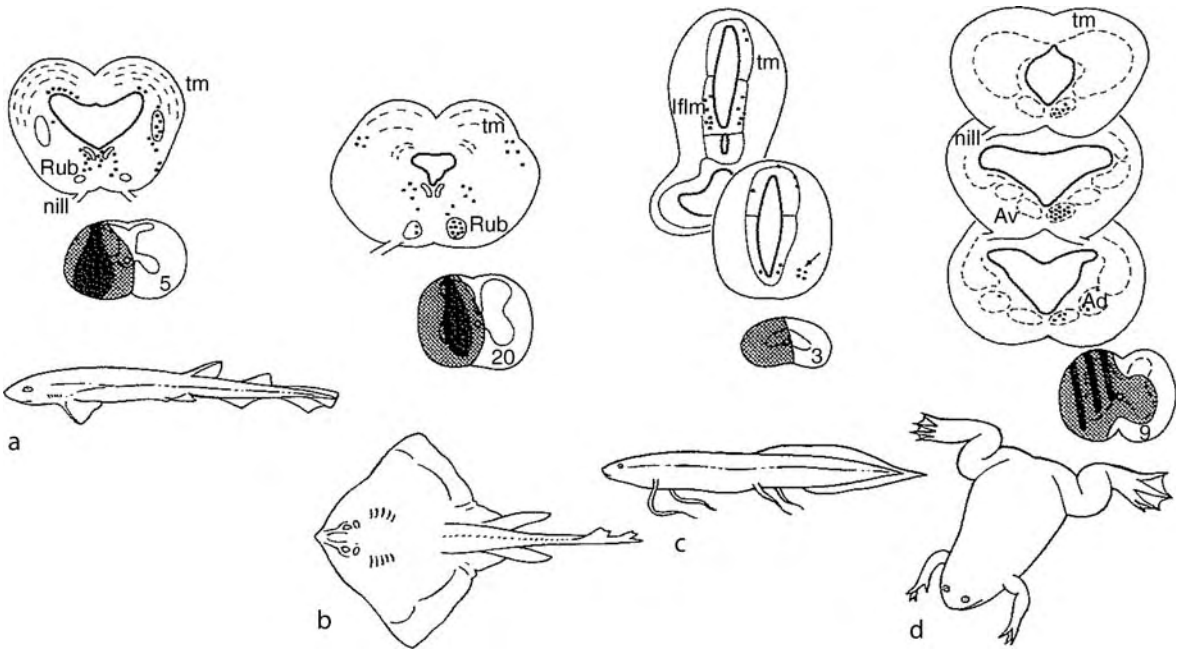
This ►medial system is functionally related to postural activities and progression and constitutes a basic system by which the brainstem exerts control over movements. The ►lateral system consists of fibers occupying a lateral position in the lower brainstem and descending into the lateral funiculus of the spinal cord. This system is mainly composed of rubrospinal fibers that terminate in lateral and dorsal parts of the intermediate zone.

## Rubrospinal Projections

In anamniotes, a red nucleus (or nucleus ruber) is indistinct or cannot be identified cytoarchitectonically. In gnathostomes, a small, unspecialized red nucleus may possibly have originated with paired appendages. Apparently, some of its connections were lost again in some fish species. Criteria used to identify a structure as a (primordial) red nucleus are, apart from its relative position in the midbrain tegmentum, the mesencephalic site of termination of the brachium conjunctivum and its contralateral spinal projection [4]. Based on such criteria, a crossed rubrospinal tract could be unequivocally identified in the thornback ray, *Raja clavata*, in the common goldfish, *Carassius auratus*, in the African lungfish, *Protopterus amphibians* and in amphibians with limbs (Fig. 3).



**Evolution of Motor Systems: Corticospinal, Reticulospinal, Rubrospinal and Vestibulospinal Systems.**
**Figure 2** Summary of experimental data on descending supraspinal pathways a the clawed toad, *Xenopus laevis* b the pigeon, *Columba livia*, c, d the North American opossum, *Didelphis virginiana* (after ten Donkelaar [2]). Abbreviations: *cb*, cerebellum; *cosp*, corticospinal tract; *Cs*, colliculus superior; $Cx_{sm}$, somatomotor cortex; *d, l, lm, vl, vm*, dorsal, lateral, lateral motor, ventrolateral and ventromedial fields of spinal grey matter; *dh*, dorsal horn; *flm*, fasciculus longitudinalis medialis; *fr*, formatio reticularis; *Iflm*, interstitial nucleus of the *flm*; *isp*, interstitiospinal tract; *iz*, intermediate zone; *Ra*, raphe nucleus; $Ra_m$, nucleus raphes magnus; $Ra_p$, nucleus raphes pallidus; *rasp*, raphespinal projections; *resp*, reticulospinal projections; *Rub*, nucleus ruber; *rusp*, rubrospinal tract; *Sc*, subcoeruleus area; *Str*, striatum; tm, tectum mesencephali; *vesp*, vestibulospinal projections; *vh*, ventral horn; *vnc*, vestibular nuclear complex; *I-X*, laminar subdivision of spinal grey matter.



**Evolution of Motor Systems: Corticospinal, Reticulospinal, Rubrospinal and Vestibulospinal Systems.**
**Figure 3** The distribution of retrogradely labeled neurons in the mesencephalon at the level of the oculomotor nerve after horseradish peroxidase injections into the spinal cord. (a) a shark, the spotted dogfish *Scyliorhinus canicula.* (b) the thornback ray, *Raja clavata.* (c) the African lungfish, *Protopterus amphibians.* (d) the clawed toad, *Xenopus laevis* (after ten Donkelaar [4]). Abbreviations: *Ad, Av*, anterodorsal and anteroventral tegmental nuclei; *lflm*, interstitial nucleus of fasciculus longitudinalis medialis; *nIII*, oculomotor nerve; *Rub*, nucleus ruber; *tm*, tectum mesencephali. Numbers refer to spinal segments.

No rubrospinal tract could be identified in a shark or in a limbless amphibian, the apodan *Ichthyophis kohtaoensis*. These data suggested that the presence of a rubrospinal tract is related to the presence of paired appendages. The thornback ray uses its enlarged pectoral fins for locomotion. In teleosts, paired fins are used for postural stability and steering control but also to maneuver and propel the body at low speed. In a more recent study in the gymnophionan *Dermophis mexicanus*, Sánchez-Camacho et al. [11] identified a loosely arranged mesencephalic cell group that projects to the contralateral spinal cord and identified it as the caecilian red nucleus.

In reptiles, in general a well-developed red nucleus is found. In freshwater pond turtles, Houk and co-workers extensively studied the functional role of a cerebellorubrospinal circuit in goal-directed limb movements [12, 13]. The red nucleus, cerebellum, and their extensive interconnections form a premotor network for controlling limb movements. Snakes have presumably lost their rubrospinal tract secondarily, since in boid snakes no rubrospinal tract could be demonstrated [14]. They retain a nucleus ruber with a distinct rubrobulbar projection however, which is presumably involved in the neural control of mastication. Birds and mammals have a well-developed red nucleus, the magnocellular part of which gives rise to the rubrospinal tract. The parvocellular part of the red nucleus in amniotes innervates the ipsilateral inferior olive and is involved in a cerebellar loop. In monkeys, neurons of the magnocellular red nucleus are preferentially related to movements of the hand and fingers [15]. Particularly in anthropoid primates such as the gibbon, the magnocellular part is much reduced [16]. In humans, the rubrospinal tract is very small. Only a few fibers reach the spinal cord and these do not usually extend beyond the upper cervical segments [17].

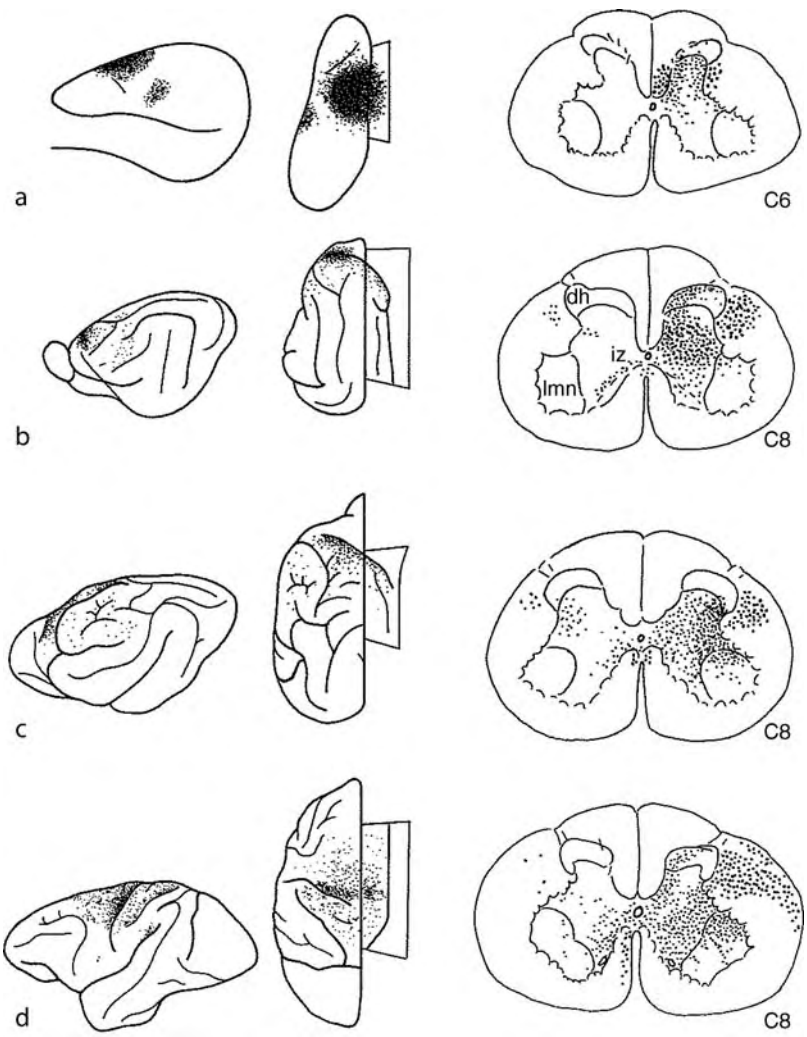
## Corticospinal Projections

Although minor telencephalospinal projections are found in some sharks and birds, a ►corticospinal tract is a derived feature of mammals. Its emergence appears to be associated with the acquisition of dexterous motor skills [10]. For prehensile extremities and tails, corticospinal projections are essential. The sensorimotor capacities of the hand for exploring the visible world develop best in primates. Direct ►corticomotoneuronal connections from the sensorimotor cortex to motoneurons innervating hand, finger, foot or tail muscles are found only in primates and a few specialized carnivores such as raccoons, which are capable of some form of precision grip. In birds, a unique sensorimotor circuit is present that is related to the handling or ´mandibulation´

of food [18]. Its anatomical organization is analogous to that of the sensorimotor pathways controlling the forelimbs of mammals.

The corticospinal tract arises invariably from layer V pyramidal cells, particularly from rostral, frontal parts of the cerebral cortex. Both motor and somatosensory cortices give rise to corticospinal projections. The somatosensory cortex innervates the dorsal horn of the spinal cord and the dorsal column nuclei. The corticospinal projection is predominantly contralateral, but in many insectivores such as moles largely ipsilateral. Moles have dense corticospinal projections from the forelimb presentation of the somatosensory and motor cortices that may reflect sensorimotor specializations related to digging [19]. With regard to the terminal distribution of corticospinal fibers, the various mammals tend to fall into four groups that show an increasingly wider distribution area of corticospinal fibers in the spinal grey matter (Fig. 4).

By ranking the motor skill of the hands of 69 different mammals from one to seven, Heffner and Masterton [20] concluded that the extent and the site of termination of the corticospinal tract most closely correspond with dexterity. Direct corticomotoneuronal connections to motoneurons innervating hand and finger muscles are only found in primates and a few

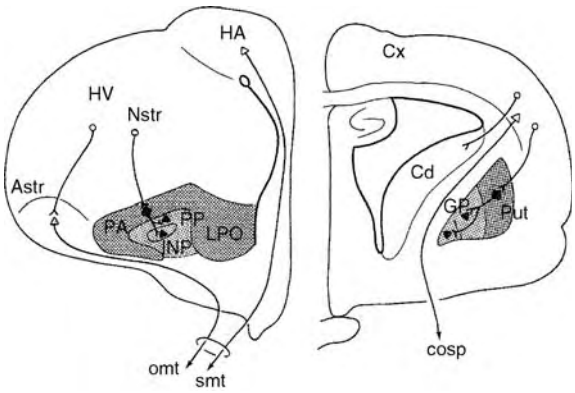


**Evolution of Motor Systems: Corticospinal, Reticulospinal, Rubrospinal and Vestibulospinal Systems.**
**Figure 4** The distribution of the cells of origin of the corticospinal tract shown in lateral and dorsal views of the brain. (a) the North American opossum, *Didephis virginiana*. (b) the domestic cat, *Felis catus*. (c) the raccoon, *Procyon lotor*. (d) the rhesus monkey, *Macaca mulatta*. Also shown are the sites of termination of the corticospinal tract in the cervical enlargement of the spinal cord (based on various sources, after ten Donkelaar [2]). Abbreviations: *dh*, dorsal horn; *iz*, intermediate zone; *lmn*, lateral motoneuron column.

carnivores such as raccoons and kinkajous [10]. This suggests that the presence of direct corticomotoneuronal connections is a derived characteristic that has evolved independently, along with manual dexterity, in both primates and carnivores [20]. Direct corticomotoneuronal projections are not restricted to forelimb motoneurons however. In many monkeys, the motor cortex also projects to hind limb motoneurons, and in spider (*Ateles*) and woolly (*Lagothrix*) monkeys even to motoneurons innervating the muscles of the prehensile tail [21].

Telencephalic projections to the spinal cord are not restricted to mammals. Minor telencephalospinal projections were found in the nurse shark, *Ginglymostoma cirratum* [22]. Using intracranial electrical microstimulation mapping and simultaneous recording of the evoked body movements in goldfish, Salas and co-workers [23] showed that a primary somatomotor pallial area is present in the most caudal part of the telencephalon, reminiscent of the somatosensory cortex in mammals. This motor pallium innervates premotor centers in the reticular formation of the brainstem. Early, rather crude electrical stimulation studies in reptiles in search of a motor pallial area suggested the presence of a "motor cortex" in turtles [24]. Later studies, however, showed that the motor responses reported after cortical stimulation in turtles and also in alligators probably resulted from current spread to underlying, striatal structures [25]. The evidence for one or more pallial areas in reptiles that elicit movements of restricted body parts following electrical stimulation is therefore not convincing.

In birds, at least three descending pallial efferent systems have access to the brainstem [26]. Birds use their beaks for the manipulation of the environment. The beak functions in reaching, grasping and manipulation analogously with the forelimb of mammals and the primate hand [18]. The sensorimotor circuit involved includes tactile information from mechanoreceptors in the beak passed via the trigeminal system to the nucleus basorostralis pallii (formerly known as nucleus basalis), which forms part of the dorsal ventricular ridge (DVR). The DVR, a large intraventricular protrusion, and the Wulst, a swelling present on the dorsal surface of the avian telencephalon, contain cell groups that may be homologous to those in the mammalian neocortex [27, 28], although the hypothesis of the neocortical homology of the DVR is currently under debate (See: ►Evolution of the Forebrain: Embryological Development and Evolution of the Telencephalon: in Amniotes.). Both of these pallial structures, including their association areas, comprise end stations of ascending systems and telencephalic motor output areas. Via a relay in the hyperstriatum ventrale, the nucleus basalis innervates the rostral part



**Evolution of Motor Systems: Corticospinal, Reticulospinal, Rubrospinal and Vestibulospinal Systems. Figure 5** Origins of somatomotor projections in birds (left panel) and mammals (right panel). The corresponding parts of the basal ganglia are shown by shading (after Karten and Dubbeldam [27]). Abbreviations: *Astr*, archistriatum (rostral part); *Cd*, caudate nucleus; *cosp*, corticospinal tract; *Cx*, cerebral cortex; *GP*, globus pallidus; *HA*, hyperstriatum accessorium (part of Wulst); *HV*, hyperstriatum ventrale (part of dorsal ventricular ridge); *INP*, interpeduncular nucleus; *LPO*, lobus parolfactorius; *Nstr*, neostriatum; *omt*, occipitomesencephalic tract; *PA*, paleostriatum augmentatum; *PP*, paleostriatum primitivum; *Put*, putamen; *smt*, septomesencephalic tract.

of the archistriatum (Fig. 5) which gives rise to the ►occipitomesencephalic tract.

This major pallial efferent pathway projects to various brainstem nuclei including premotor groups in the reticular formation that innervate the motor nucleus of the jaw muscles [29, 18]. In pigeons and ducks, the occipitomesencephalic tract extends to the rostral part of the spinal cord [29]. This tract represents the telencephalic output channel for the trigeminal feeding circuit and resembles the corticobulbar tract found in mammals.

In birds, another corticobulbar pathway, the ►septomesencephalic tract, arises from the Wulst. The caudal, visual part of the Wulst plays a role in modulating the activity of tectal projections to premotor structures in the brainstem reticular formation. The rostral, somatosensory part of the avian Wulst innervates the red nucleus, pontine nuclei, dorsal column nuclei and rostral spinal cord [30]. In parrots, which possess brains with the most highly developed telencephala among birds, the basal branch of the septomesencephalic tract reaches the cervical cord. In zebra and green finches, rather extensive projections to the cervical spinal cord are present [30]. In other prehensile birds such as cockatoos and rosellas however, no telencephalospinal projections have been found. Therefore, in birds there is no general direct palliospinal control of refined motor skills of the extremities.

# Evolution of Motor Systems: Vocal and Song Systems of Birds

David J. Perkel
Departments of Biology & Otolaryngology, University of Washington, Seattle, WA

## Definition

Vocal learning, the ability to mimic sounds made by other individuals, is a very common feature of birds. It has arisen independently in three avian taxa, the oscine songbirds, the parrots and the hummingbirds, together comprising more than half of all extant bird species. In oscine songbirds, song learning is essential for territory defense and mate attraction, and thus probably for reproductive success. The brain circuit underlying oscine vocal learning consists of discrete,

interconnected forebrain nuclei forming a descending motor pathway and a basal ganglia pathway essential for learning. These structures share properties with their surrounding brain regions, and thus could have evolved via relatively minor specializations of pre-existing circuits.

## Characteristics

### Avian Vocal Behavior (Calls and Songs)

There are approximately 9,000 extant species of birds (class *Aves*). Birds produce a wide variety of vocalizations that are used for communication. In general, these vocalizations can be classified into two broad categories: calls and songs. All bird species generate calls. Although there are exceptions, calls tend to be relatively simple and unlearned. They can carry a variety of meanings, from desire for food (e.g. begging calls) to expression of danger (e.g. alarm calls). The meaning of some calls is unknown. In contrast, songs tend to be more complex, and are used for courtship, territory defense, mate selection and mate recognition. In temperate regions, males are the predominant or exclusive singers, while in tropical species, duetting is more common.

### Vocal Learning in Three Bird Taxa

Current evidence supports vocal learning in three taxa of birds. Vocal learning, as used here, means the production of sounds heard through experience. In the vast majority of natural cases, this involves learning to produce sounds produced by other individuals of the same species. The largest group of vocal learners is the oscine songbirds (Order *Passeriformes*), which make up approximately half of bird species. Behavioral studies have shown that song learning in oscines occurs in two main phases. During a sensitive period early in life, a bird hears and memorizes the song(s) of another bird, often called the tutor. This is called the sensory phase of song learning. Later, through practice involving a large number of trials, he gradually learns to produce sounds that are a good match to the memorized song(s). This is termed the sensorimotor phase of learning, because it requires that the bird be able to hear himself vocalize while practicing. When he can sing a good copy of the tutor song, the song becomes highly stereotyped, and the bird has a much-reduced ability to memorize songs of other birds.

This basic pattern holds across the oscine songbirds, but there is also substantial variation in aspects of this process [1]. For example, some species learn a single, relatively simple song, while others learn large repertoires comprising hundreds of songs. Some species learn only once during juvenile development, while others relearn parts of their repertoire seasonally or continuously through adulthood. This diversity provides experimentalists a wide variety of study species with different capabilities. It also highlights an important aspect of the evolution of vocal learning, namely that it is plastic, while maintaining a core set of behavioral features.

In addition, parrots and parakeets (Order *Psittaciformes*) are also well-known vocal mimics, and some of these species are able to produce sounds closely resembling those of human speech. In addition, some hummingbirds (Family *Trochilidae*) have been found to exhibit learning abilities. Far less is known about the behavioral aspects of song learning in parrots and hummingbirds than in songbirds. Nonetheless, given how rare vocal learning is in mammals, it is an interesting and fundamental question how three avian taxa have evolved the capacity for learned vocalizations.

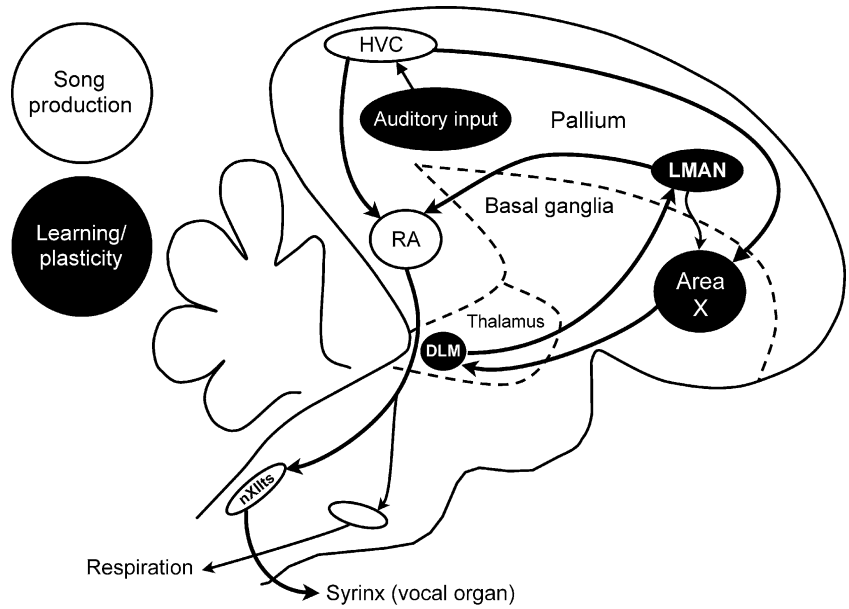
In contrast to the thousands of avian species exhibiting vocal learning, this capacity has been demonstrated in only one species of primates, *Homo sapiens*, in some marine mammals and may occur in some bats.

### Song System of Oscine Songbirds

The variety of vocal learning and performance capabilities of birds, and their appearance in three bird taxa, raise the question of how song learning arose and whether there are similarities in mechanism among the three clades. Answers to such questions in general depend on comparative analyses of a variety of species, including representatives of outgroups of the taxa of interest. In addition, the fossil record could be consulted for intermediate stages to help determine when specific features arose. In this case however, in which vocal learning likely reflects changes solely within the central nervous system, which leaves essentially no fossil evidence, we are left only with comparative analysis of the brains of extant species, which we can examine using neuroanatomical and neurophysiological techniques [2].

The neural substrates of avian vocal learning an production have been best studied in oscine songbirds [3]. Examination of their brains reveals a set of discrete clusters of neuronal cell bodies that stand out from the surrounding tissue by virtue of their larger cell bodies, denser packing or other cellular features [4]. These clusters, known as nuclei, are found in oscine songbirds, but not in non-oscine species. A variety of studies have implicated these nuclei in the control, learning and perception of song, and they have come to be known collectively as the song system. Neural tracing studies have delineated interconnections among these nuclei. A simplified schematic diagram of these structures is shown in (Fig. 1).

Studies involving localized brain lesions, electrophysiological recording, examination of gene expression and electrical stimulation have provided evidence for different functional roles for different portions of this circuit. For example, the pathway from nucleus



**Evolution of Motor Systems: Vocal and Song Systems of Birds. Figure 1** Simplified schematic diagram of the oscine song system. The descending motor system includes nucleus HVC (used as the proper name), which projects to nucleus RA (robust nucleus of the arcopallium) which projects to the tracheosyringeal portion of the hypoglossal motor nucleus (nXIIts) and to respiratory premotor nuclei in the medulla. HVC receives auditory input and projects to Area X, a large nucleus in the basal ganglia. Area X projects to the medial portion of the dorsolateral nucleus of the thalamus (DLM), which projects to the lateral magnocellular nucleus of the anterior nidopallium (LMAN). LMAN projects to RA, and sends axon collaterals to Area X.

HVC (see figure legend for descriptions of names) to nucleus RA to the hypoglossal motor nucleus is an obligatory descending motor pathway essential for song production. An indirect connection from HVC to RA, known as the anterior forebrain pathway (AFP), travels by way of Area X in the basal ganglia, the thalamic nucleus DLM and the pallial nucleus LMAN to RA. The AFP is not essential for song production, although this pathway can contribute somewhat to trial-to-trial song variability. The AFP is crucial for song learning, however; lesions to LMAN or Area X, even after song memorization has occurred, dramatically disrupt song learning. In addition, lesions to LMAN prevent some forms of adult song plasticity that have been examined. Precisely how the AFP contributes to learning is currently a question being actively investigated.

Non-oscine birds do not show evidence for such song nuclei.

## Vocal Control Systems in Parrots and Hummingbirds

### *Parrot Nuclei and Tracing*

Examination of the parrot brain reveals nuclei in the forebrain in locations roughly corresponding to the song system of oscine songbirds. It was thus initially thought that these nuclei might have existed in a common ancestor of oscines and psittacines. Indeed, two posterior forebrain nuclei appear to form a descending motor pathway, and two anterior nuclei are important for song plasticity. However, careful analysis of the connections among the vocal control nuclei in parakeets has shown important differences from the oscine song system [5]. It seems very difficult to reconcile current data with a common origin of vocal learning in these two taxa.

### *Immediate Early Genes in Parrots and Hummingbirds*

When they are highly active, many neurons transiently increase the expression of certain genes, known as immediate early genes (IEGs). Examining expression of IEGs in the 30–60 min after bouts of intense vocal production has revealed increased IEG levels in several song nuclei in oscine songbirds [6]. Use of the same technique in psittacines and hummingbirds has also revealed the presence of nuclei with increased levels of IEGs in more-or-less comparable locations as in songbirds [7,8]. This similarity of nucleus location suggests that similar networks of vocal-control nuclei might underlie vocal learning an production in these three taxa, and could be used to support the hypothesis that song learning evolved once in an ancestral lineage common to songbirds, parrots and hummingbirds, and has since been lost in intervening taxa.

While this possibility is intriguing, and while it remains impossible to eliminate firmly the hypothesis of shared evolution of avian vocal-control nuclei, it seems most plausible at this time to hypothesize three independent evolutionary events in which vocal learning arose.

### Similarities with Mammals

Although early comparative neuroanatomists thought that most of the avian forebrain resembled the basal ganglia (deep grey matter) of mammalian brains, it is now clear that the forebrains of birds and mammals share similar architecture, though there are clearly some important differences [9,10]. In both birds and mammals, the ventral approximately two thirds of the forebrain consists of basal ganglia, while the dorsal one third arises from pallial origin, and includes such structures as the hippocampus and parts of the amygdala. In mammals, the pallium also includes the cortex. Birds do not possess cortex *per se*, but their pallial tissue arises from the same developmental precursor. The oscine songbird nucleus Area X lies within the basal ganglia. The neurons of Area X, as well as surrounding basal ganglia exhibit strong similarities in cellular electrophysiological and morphological properties to their counterparts in mammalian basal ganglia [11,12]. Moreover, the basal ganglia of a non-oscine bird, the domestic chicken, has neurons with very similar properties [13]. Together, these results suggest that the AFP arose as a specialization from pre-existing basal ganglia circuits shared by all birds and indeed by mammals as well.

### Hypothesized Evolutionary Steps to Explain Both Similarities and Differences Among Birds

All birds that have been tested can use sensory feedback to guide the learning of subsequent motor acts. It seems that a relatively simple set of steps can account for the evolution of vocal-control systems. First, a descending motor system must arise or come to be in place to control the vocal and respiratory musculature, but since there is abundant evidence in even non-vocal learning species for descending, topographic forebrain control of body musculature in general, this requires only access to vocal and respiratory musculature. In addition, circuitry must be present to compare the bird's own vocalizations with that of a target song. Initially, that target need not have been memorized, but could have been an innate program for a species-typical vocalization. Finally, some means is needed to convey the output of that comparison to the motor system to allow for changes in subsequent songs. All of these elements are common to, or easily obtained through, small modifications of the typical vertebrate forebrain-wiring diagram.

The general architectural similarities between bird and mammal brain organization, combined with the conservation of cellular properties in the basal ganglia, suggests a way to reconcile the similarities among the nuclei identified in all three avian taxa that exhibit vocal learning with independent evolution of this process in those taxa. If each "invention" of vocal learning involved pre-existing basal ganglia circuits, perhaps with slightly different ways in which those circuits connected to the motor system, then the three resulting neural circuits for vocal learning could have deep similarities. These similarities would be due to homologies among these circuits as basal ganglia circuits rather than as vocal learning circuits [14]. In this way, then, it is even possible that vocal learning circuits in humans could resemble those in songbirds in fundamental ways, without them necessarily being evolutionarily homologous as vocal learning circuits.

# Evolution of Nucleus Isthmi

Elizabeth Dudkin[1], Edward Gruberg[2]
[1]Penn State University, Media, PA, USA
[2]Biology Department, Temple University, Philadelphia, PA, USA

## Definition

The nucleus isthmi is a nucleus that lies within the region of the midbrain-hindbrain junction of many vertebrates. It is reciprocally connected with the ipsilateral optic tectum. The nucleus isthmus has a high ►acetylcholinesterase activity.

## Characteristics

### Location of Nucleus Isthmi

The isthmic region of vertebrates connects the hindbrain to the midbrain. In this region is a visually driven bilateral cell group called the nucleus isthmi. The nucleus isthmi is found in bony fish, amphibians, mammals, reptiles and birds. In mammals it is called the ►parabigeminal nucleus. For economy, this cell group will be referred to as "n. isthmi" except in the case of mammals.

### Reciprocal Isthmotectal Connections

The common characteristic of the n. isthmi in all species studied so far is their strong reciprocal connections with the much larger ipsilateral midbrain structure, the optic tectum (homologous with the mammalian superior colliculus). This tecto-isthmo-tectal connection is a feedback loop for the tectum and thus the n. isthmi can influence tectal function. The optic tectum is an important target of retinal ganglion cells. Retinotectal fibers terminate in superficial layers of the tectum where they form a ►visuotopic map, i.e. adjacent points in visual space are represented at adjacent points in laminae of the optic tectum. Isthmotectal fibers tend to terminate in the same layers or adjacent layers of the tectum as retinotectal fibers. The isthmotectal fibers also form a visuotopic map and usually it is in alignment with the retinotectal visuotopic map [1–3]. The nucleus isthmi should not be confused with another isthmic nucleus, the ►isthmo-optic nucleus, which is found in reptiles and birds. The isthmo-optic nucleus receives input from the optic tectum and projects to the retina.

### Other Inputs

Depending on the species, the n. isthmi may also receive input, with fewer fibers, from non-tectal areas of the brain. In some frog species (anurans) but not others, there are scattered cells in the tegmental anterodorsal nucleus that project to the contralateral n. isthmi. In the ray-finned fish, ►*Navodon modestus,* the diencephalic nucleus pretectalis (= the magnocellular superficial pretectal nucleus) projects to the ipsilateral n. isthmi [4]. In the weakly electric fish ►*Apteronotus*, the dorsal torus semicircularis, an electrosensitive area, makes reciprocal connections with the n. isthmi [5].

### Histochemical Character

The nucleus isthmus is further characterized by having high acetylcholinesterase (AChE) activity, (the enzyme that hydrolyzes acetylcholine). Most isthmotectal fibers have been shown to be cholinergic and their tectal terminal zones have high AChE activity and high ►choline acetyltransferase (ChAT) activity (the enzyme that synthesizes acetylcholine). The frog n. isthmi also contains high ChAT activity not only in perikarya but also in adjacent neuropil [6]. This suggests that tectoisthmal fibers, at least in frogs, may be cholinergic also.

### One, Several Nuclei Isthmi

While a single n. isthmi on each side of the midline is recognizable in amphibians, mammals and fish, birds have evolved several distinct n. isthmi, all with reciprocal connections with the tectum and each with high AChE activity. These nuclei are nucleus isthmi pars parvocellularis (Ipc), nucleus isthmi pars magnocellularis (Imc) and nucleus semilunaris (SLu) [7]. Ipc and SLu make precise reciprocal topographic maps with the optic tectum; both Ipc-tectal fibers and SLu-tectal fibers are cholinergic and terminate in both retinoreceptive layers and deeper layers. Imc-tectal fibers use γ-amino butyric acid (GABA) as their neurotransmitter and form a more diffuse map restricted to the deeper layers of the tectum. Other neurons in Imc project widely to Ipc and SLu without any obvious topography. Turtles have both an Ipc (called "Imc" in turtle) and an Imc (called "Imc" in turtle) with tectal connectivity similar to that in birds [8]. As in birds, turtle Imc projects to Ipc nontopographically. Lizards have two isthmic structures that make reciprocal connections with the ipsilateral tectum, the Imc and nucleus profundus mesencephali (NPM), which may respectively correspond to the Imc and Imp of turtles [9].

## Appearance of Nucleus Isthmi

In many species, the n. isthmi can be recognized in ►Nissl stained material. In mammals, the parabigeminal nucleus is clearly identifiable as a dense cluster of cells located on the lateral superficial wall of the isthmic region [2]. In birds, all three isthmic nuclei are recognizable [7]. In anurans, the nucleus stands out as a discrete area with a high density of cortical cells demarcating much of the outer edge of the nucleus and a lower density of cells in a core medullary area [3,10]. In urodele amphibians, the nucleus is not clearly distinguishable from adjacent tegmental tissue. In ray-finned fish, the n. isthmi is distinguishable by having a cortical layer of cells and a non-cellular medullary region.

## Morphology of Isthmi Cells

The nucleus isthmi in frogs is made up of several neuronal cell types [11]. In the cortex, there are mostly piriform cells with a single large apical dendrite, either straight or curved, from which several secondary dendrites begin. The axon originates from the primary dendrite or the soma. Both cortical and medullary cells have no basal processes. In the medulla there are several different types of cells; most common are cells that have several dendrites arising from the soma. Roughly speaking, the size of dendritic spread as a proportion of the size of nucleus is greater in frog species with poorer vision (fewer optic nerve fibers). In ray-finned fish, single apical dendrites of n. isthmi cells extend from the outer shell into the noncellular core where they branch. The axons arise from the cell bodies that possess many spiny processes [12]. In birds, Ipc and SLu soma are round, have relatively uniform diameter and emit multiple dendrites. Bird Imc soma are quite variable in both size and shape and are multipolar. The size of dendritic spread is variable [13].

## Feed-Forward Connections

In addition to the reciprocal connections between n. isthmi and ipsilateral tectum, the n. isthmi projects in topographic order to the contralateral tectum in amphibians [3,10] and mammals [2]. In urodele amphibians, n. isthmi cells project to both tecta. There are apparently no significant n. isthmi projections to the contralateral tectum in reptiles, birds or bony fish.

The projection from eye to tectum is almost entirely crossed in most anurans, yet information from the ipsilateral eye reaches the optic tectum. For example, the pathway that originates in the left eye and eventually reaches the left tectum is from the left eye to the right tectum to the right nucleus isthmi to the left tectum (the pathway from the right eye to the right tectum being mirror symmetrical) [3]. ►Ablation of the right nucleus isthmi eliminates the response in the left tectum to left eye visual stimulation [14]. The isthmotectal fibers projecting to the contralateral tectum follow a remarkable rostral route from the n. isthmi along the lateral wall of the ipsilateral midbrain and diencephalon [3]. Depending on the species, the contralaterally projecting isthmotectal fibers cross the midline ventrally, either in the caudal part of the optic chiasm or immediately posterior in the postoptic commissure. The fibers then course dorsocaudally to the tectum. A similar path and crossing pattern is seen in mammals [2].

## Map Anomalies

The isthmotectal visuotopic map and the retinotectal visuotopic map are not necessarily in register throughout the tectum. Almost all animals have a frontal part of the visual field seen by both eyes (the binocular visual field) and left and right lateral areas of the visual field seen exclusively by left and right eyes, respectively (the monocular visual fields).

In anurans, the visual projection from, e.g. the left eye onto the right tectum encompasses the binocular field and the monocular field of the left eye. This visual projection covers the entire surface of the right tectum. Those two fields are also represented in the right n. isthmi. In turn, the right n. isthmi projects back to the right tectum, where the isthmic and tectal maps are in register. However, the right n. isthmi also projects to the left tectum. The left tectum receives a direct visual projection from the right eye encompassing the binocular region and also the monocular field of the right eye across the entire surface of the left tectum [10]. The binocular region of each tectum thus consists of two binocular maps that are in register, one from each eye, one direct and one indirect via the nucleus isthmi. In the monocular region of the tectum, there are also two visual maps of monocular visual space. However, these maps are the superimposed fields of left eye and right eye monocular visual space. These maps cannot be in register but rather each point in this part of the tectum corresponds to mirror image locations in monocular visual space of the two eyes [15].

## Other Centrifugal Connections of Nucleus Isthmi

In mammals, the parabigeminal nucleus projects to the dorsal lateral geniculate nucleus [2]. Depending on the species, this projection is ipsilateral (primates), bilateral (cats) or contralateral (rodents, gophers, tree shrews and marsupials). In birds, the SLu subdivision of n. isthmi projects to the nucleus rotundus and the lateral spiriform nucleus, both of which lie within the dorsal thalamus [16]. Neither of the latter two nuclei is homologous to the dorsal lateral geniculate nucleus of mammals, however.

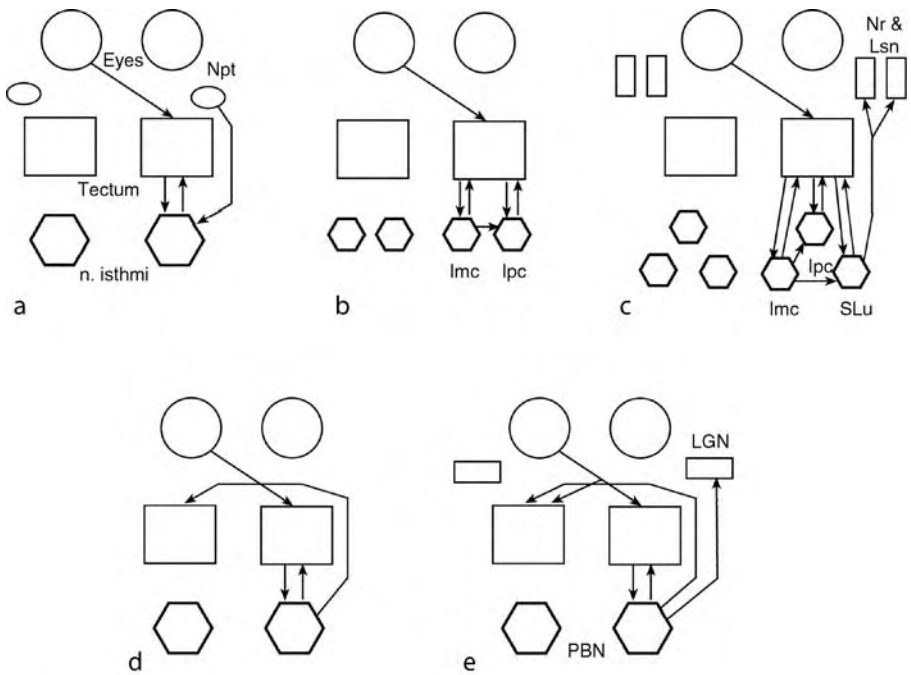
Electrical recording in the n. isthmi is generally consistent with the topographic tectoisthmal projection. A recording microelectrode systematically moved to different locations in the nucleus will record electrical responses to stimuli placed in anatomically determined

visual field locations. This is true in mammals, amphibians and birds. However, in the bony fish, sunfish and goldfish, electrical responses are evoked at any n. isthmi location wherever the stimulus is placed in the visual field [17]. Thus, there is no apparent physiological correlate to the neuroanatomically determined visuotopy in the n. isthmi of at least some fishes. This apparent lack of visuotopy could be due to electrical coupling between cells of n. isthmi, since it is known that fish n. isthmi cells are interconnected via gap junctions.

## Isthmotectal Physiology

In amphibians and reptiles, most tectal neurons are excited by isthmic electrical stimulation whereas a minority of tectal cells are inhibited by isthmic stimulation [18]. In birds, there is a complex interaction between Ipc, Imc and the tectum. Tectal bipolar "shepherd crook" cells (so called because of the characteristic 180° bend of their axons as they emerge from their cells) have narrow dendritic spread and project visuotopically to Ipc cells. In turn, Ipc neurons project back to the same visuotopic locations with excitatory cholinergic axonal terminations ("paintbrush" terminals) as part of a narrowly spread axonal tree extending in a radial column over many superficial tectal layers [19]. Imc receives a coarser visuotopic input from tectal bipolar cells. In turn, Imc cells project to both Ipc and to tectum with GABAergic inhibitory terminals in a heterotopic manner. Their projections spread widely but not to the visual location in Ipc and tectum from which the Imc cells receive their input from the tectum. The effect is perhaps to provide an excitatory center and inhibitory surround to tectal cells. In other avian studies, it has been shown that blocking activity in Imc reduces the firing rate of tectal cells after visual stimulation. Conversely, Ipc appears to have an inhibitory effect on most tectal cells and a brief excitatory effect on other tectal cells followed by inhibition. The inhibition is apparently contributed directly by GABAergic Ipc cells and by excitation of tectal interneurons that are in turn GABAergic.

In frogs, cholinergic isthmotectal fibers have a modulatory effect on frog retinotectal fibers that express acetylcholine receptors on their surface [20]. Calcium uptake (and indirectly, release of neurotransmitter) into retinotectal fibers is significantly enhanced when there is near simultaneous electrical input from retina and ipsilateral n. isthmi compared to input from retina alone.



**Evolution of Nucleus Isthmi. Figure 1** Basic connections of right n isthmi in (a) bony fish, (b) reptiles, (c) birds, (d) amphibians and (e) mammals. In all these animals there are reciprocal connections between the tectum and ipsilateral nucleus isthmi. With the exception of mammals, the projection from the eye to the tectum is mostly crossed. Amphibians and mammals also have a crossed projection from nucleus isthmi to the tectum. The fibers of this projection cross the midline in or near the optic chiasm. Reptiles and birds have more than one nucleus isthmi. Abbreviations: *Imc* nucleus isthmi pars magnocellularis; *Ipc* nucleus isthmi pars parvocellularis; *LGN* lateral geniculate nucleus; *Lsn* lateral spiriform nucleus; *Npt* nucleus pretectalis; *Nr* nucleus rotundus; *PBN* parabigeminal nucleus; *SLu* nucleus semilunaris.

Electrical input from n. isthmi alone has no effect on calcium uptake into retinotectal fibers.

There are reports that the n. isthmi has a respiratory function. Injection of lidocaine or kainic acid solutions into frog n. isthmi results in changes in breathing rate [21]. The results are problematic given that the volumes injected are large enough to spread over much of the isthmic region and so could affect other isthmic structures. Also, there is no obvious anatomical connection between n. isthmi and known brainstem respiratory areas.

## Behavior

The superior colliculus plays a role in directed eye and head movements in mammals, and this is reflected in parabigeminal function. In awake cats trained to move their eyes to fixate points on moving targets, the level of response of parabigeminal cells is a function of how far the center of gaze is away from the target. The parabigeminal nucleus thus provides error signals to the superior colliculus [1].

In frogs, unilateral ablation of n. isthmi results in a ►scotoma to prey and looming stimuli in the contralateral monocular visual field. The scotoma has the quality of "visual neglect" [14]. That is, within the scotoma zone, the animal is not completely unresponsive to visual stimuli, but the likelihood of response is very low. Partial ablation of the nucleus isthmi causes a smaller scotoma in the same monocular visual field region, but the scotomas always include the temporal most part of the contralateral field. Thus, the scotomas are not isomorphic with the part of the visual field map that has been ablated. In contrast, partial ablation of the optic tectum results in a scotoma commensurate with the tectal visual representation [15]. Another consequence of ablation of frog n. isthmi is an increase in the size of visually evoked multiunit receptive fields recorded from the tectum [14]. Thus, the visuotopic map degrades as if retinotectal axonal terminals are less stabilized in the absence of isthmotectal input.

## Functional Role

In fish, given the non-topographic responsiveness of n. isthmi, it may play a role as a sentinel, alerting the system that something is moving in the visual field rather than directing the animal to a particular object or to a particular point in space. In amphibians and birds, the system could act as a "winner-take-all" module, selecting a particular object for attention [7,15,22]. In mammals, the parabigeminal nucleus mediates visuomotor tracking by computing error signals [1].

The tectum serves the visual needs of particular species in different ways such as tracking visual objects, discriminating between different classes of objects, selecting (or attending to) one of several objects, and directing movement of eye or head or body. The nucleus isthmi appears to be an important modulator and facilitator of tectal function (Fig. 1) [23].

# Evolution of Oculomotor System

Bernd Fritzsch
Department of Biomedical Sciences, Omaha, NE, USA; Department of Biology, University of Iowa, Iowa City, USA

## Synonyms

Eye movement system; Vestibular-ocular reflex system; Oculomotor systems

## Definition

The oculomotor system consists in mammals of three functionally interconnected motorneuron populations, the oculomotor, trochlear and abducens motornuclei. These three motorneuron populations innervate all six ocular muscles such that the oculomotor nerve (cranial nerve III) innervates four ocular muscles (superior rectus, inferior rectus, medial rectus, inferior oblique) the trochlearis nerve (cranial nerve IV) innervates one muscle (superior oblique) and the abducens nerve innervates one muscle (lateral rectus) and, if present, the retractor bulbi. In mammals, the oculomotor nerve also innervates the levator palpebrae muscle that lifts the upper eyelid. All jawed vertebrates have a parasympathetic component of the oculomotor nerve (the Eddinger-Westphal nucleus) that innervates the ciliary ganglion. The ciliary ganglion, together with the sympathetic fibers from the superior cervical ganglion, innervates the internal eye muscles for pupillary control and accommodation.

In its basic form, the oculomotor system is driven by information from the vestibular system to keep the eye on target through any and all head movements. For this, the ocular motoneurons receive input from the vestibular nuclei, which in turn receive information from the inner ear about head movements through the vestibular neurons of the ear.

This chapter will analyze how each of the components of this three neuron reflex arc (vestibular hair cell, vestibular neuron, vestibular nucleus neuron, ocular motoneuron, ocular muscle) evolved and how they achieved their functional interactions as described above for mammals.

## Characteristics

Six ocular muscles move the eye in the orbit. Ocular muscle fibers are unique in several respects; they have both fast twitch fibers for rapid eye movements and slow, tonic fibers to maintain position without fatigue. Ocular muscles have very small motor units. This feature evolved early and was largely maintained [1]. Several vertebrates have seven eye muscles, one of which retracts the eye into the orbit and/or moves a membrane across the cornea and/or closes the eyelids. However, some vertebrates have no ocular muscles and some have lost and/or transformed individual muscles to generate weak electric signals.

Ocular motoneurons have been referred to as "somatic motoneurons" as they are under conscious control. However, neither the molecular basis of their development [2] nor their overall evolution [3] fits this assumption. It is possible that trochlear and oculomotoneurons co-evolved with the mid/hindbrain barrier as they depend critically on molecules necessary for the formation of this barrier [4,5].

Four to five vestibular nuclei have been characterized in vertebrates [6,7]. Each nucleus receives a unique complement of input from the ear and other senses and relates the processed information to higher centers such as the ocular motoneurons [7]. Additional vestibular information processing is in the cerebellum, which modifies the vestibular output. In addition, brainstem and midbrain centers for horizontal and vertical gaze control exist and can be activated by higher centers such as the midbrain tectum or the cortex.

The ear has two different sets of sensors, the canals with their associated sensory epithelia to measure rotation and gravistatic sensors with associated otoconia/otoliths to measure position in space [8]. The information from the ear is related to the vestibular nuclei and the cerebellum in discrete but partially overlapping vestibular afferent fiber tracts [9].

## Description of the Process

Evolution has changed ocular muscle patterns, innervation of ocular muscles, connection of vestibular nuclei to ocular motoneurons, input of the ear to the vestibular nuclei and the ear. We will describe the process, starting from the ocular muscles and finishing with the ear.

Hagfish have no ocular muscles and a reduced eye. This condition may be primitive as vertebrate outgroups have no eyes or ocular muscles. Lampreys, which together with hagfish form the taxon agnatha, or jawless fish, have six ocular muscles. However, ocular muscles are oriented differently in the orbit of lampreys and have a unique pattern of innervation [10]; two muscles are innervated by the abducens, one by the trochlearis and three by the oculomotor. In jawed vertebrates there are two patterns of six to seven eye muscles and their innervation. Four muscles are innervated by the oculomotor, one by the trochlear, one by the abducens and the seventh muscle (if present) is also innervated by the abducens. Sharks and other elasmobranches have an innervation of the nasal rectus by an oculomotor branch that passes dorsally around the optic nerve. In contrast, all bony fish and land vertebrates have an oculomotor twig to the medial rectus muscle that passes ventrally around the optic nerve. How the new nasal/medial rectus muscle relates to the oculomotor nerve innervated ocular muscles of lampreys is unknown. Most interesting is the seventh ocular muscle. This muscle can be used to retract the eye into the orbit (retractor bulbi), can retract the eye and move a nictitating membrane across the cornea, can close the eyelid or is completely detached from the eye. In the last case this muscle may function as a retractor for a tentacle [11] or may move a mobile anterior part of the skull [12]. In many mammals, including man, the retractor bulbi is lost and facial nerve innervated muscles close the eyelids.

Hagfish have no ocular motoneurons. Lampreys have ocular motoneurons but they are peculiar in several respect. The trochlear motoneurons are in the cerebellum [10] apparently through migration away from their site of origin [13]. Abducens motoneurons exit not as a ventral motor root but rather with the trigeminal motoneurons [3]. Abducens motoneurons extend from rhombomere 6 through 5 and into the caudal half of 4, thus are next to the most caudal trigeminal motoneurons [3,6,14]. Some variation of abducens position occurs in jawed vertebrates with the most notable change being the restriction to only rhombomere 5 in mammals whereas birds have abducens motoneurons in both rhombomeres 5 and 6 [15,16,7].

Much less is known of the evolution of vestibular projections to ocular motoneurons, which appears to be highly conserved across vertebrates with only minor changes [17,6,7].

The ear shows two canals for vertical rotation detection in hagfish and lampreys and three canals in jawed vertebrates [8]. Since canal input is the main input into ocular motoneurons, evolution of the ear should allow understanding of the sensory input that controls the motor output. Jawed vertebrates evolved a third canal, the horizontal or lateral canal, apparently through incorporation of at least two new genes into ear development, Foxg1 for the formation of the horizontal canal sensory epithelium and Otx1 for the formation of the horizontal canal [18]. Whether changes in ear development preceded evolution of eye muscle arrangements and their innervation as previously proposed [6] remains unknown.

## Regulation of the Process

The general assumption for evolution is that mutations cause alterations in gene expression (promoter mutations) or gene function and thus alterations in development. How a complex interconnected system evolves is still a matter of conjecture. For the vestibulo-ocular reflex system, it appears that alterations in the ear (formation of vertical canals, formation of the horizontal canal) precede changes in the eye muscle innervation. Whether evolution of a horizontal canal is upstream to eye muscle geometry and innervation changes or whether both changes are driven by changes in the same unrelated developmental event (evolution of jaws and appendages) remains to be resolved, once the latter changes are mechanically understood in terms of sequence of genetic changes.

## Function

The vestibular-ocular system functions to stabilize gaze on target. The reflex can be supplemented by several higher order inputs to provide control of eye movements beyond simple reflexes.

## Pathology

Strabismus is a pathological misalignment of eyes that can result in amblyopia. Numerous pathologies of eye muscles, summarized as congenital cranial dysinnervation disorders, are known. An atypical consequence of the congenital absence of proper innervation is fibrotic muscle degeneration, known as congenital fibrosis of the extraocular muscles [19]. Several genes have been identified which in humans and in mouse mutants cause strabismus or congenital fibrosis syndrome [4,20]. Many of these genes (Phox2a, Hoxa1, Krox20) are known to be essential for some ocular motoneuron population development and were probably important for ocular motor axis evolution.

# Evolution of Olfactory and Vomeronasal Systems

Alino Martínez-Marcos, Mimi Halpern
Facultad de Medicina and Centro Regional de Investigaciones Biomédicas (CRIB) Universidad de Castilla-La Mancha, Albacete, Spain

## Synonyms

Vomeronasal organ; Vomeronasal system (Accessory Olfactory system); Accessory olfactory system

## Definition

The olfactory and ►vomeronasal systems (Accessory olfactory system) are the main nasal chemosensory systems in vertebrates. Both are composed of chemosensory epithelia, olfactory bulbs and olfactory- and ►vomeronasal-recipient (Vomeronasal-amygdala) structures in the basal telencephalon. The ►olfactory system is present in virtually all major groups of vertebrates, whereas the vomeronasal system is thought to first appear in amphibians.

## Characteristics

### Structure of the Olfactory and Vomeronasal Systems

The olfactory and vomeronasal systems are the primary nasal chemosensory systems in vertebrates. The olfactory system is sensitive to volatile airborne odorants, whereas the vomeronasal system is primarily sensitive to non-volatile molecules or volatile molecules bound to carrier (usually protein) molecules such as ►pheromones [1,2,3].

Among vertebrates, the olfactory and vomeronasal systems are remarkably conserved, having similar structures and functions in virtually all groups. The olfactory system is present in all vertebrates (except some cetacean mammals), whereas the vomeronasal system appears in amphibians, some, but not all, reptiles and mammals [4]. The olfactory system consists of a peripherally located ►olfactory epithelium lining portions of the nasal cavity, a ►main olfactory bulb, located in the most anterior (rostral) portion of the brain and several ►olfactory-recipient structures more centrally located in the brain, which serve as neural networks controlling responses to olfactory information [1,2] (Fig. 1).

The vomeronasal system, structurally similar to the olfactory system, is composed of a ►vomeronasal organ (Jacobson's organ) that contains a ►vomeronasal epithelium, an ►accessory olfactory bulb that is located rostrally in the brain (usually posterior to the main olfactory bulb) and several more caudally situated brain

vomeronasal-recipient structures involved in orchestrating the behavioral and endocrinological responses to vomeronasal stimuli [3] (Fig. 1).

## Olfactory Epithelium and Vomeronasal Organ

The olfactory epithelium of most vertebrates consists of a relatively thin layer of cells surmounted by a mucous layer. Three types of cells are found in the epithelium – basal, receptor and supporting cells (Fig. 2). The receptor cells are bipolar neurons whose axons leave the epithelium and terminate in the main olfactory bulb. Receptor cell dendrites reach the apical surface of the epithelium and contain enlargements, called olfactory vesicles, from which cilia emanate. It is on these cilia that the receptor proteins that bind odorants are located. Supporting cells are situated adjacent to the receptor cells. They are thought to be involved in removal of substances from the epithelial surface and perhaps contribute to the mucous layer. Basal cells are stem cells that periodically undergo mitosis and are the source of new receptor cells during the periodic turnover of the epithelial constituents [5].

The vomeronasal epithelium is located in the vomeronasal organ, which in many, but not all, vertebrates is located at the base of the nasal septum. In different vertebrates, the organ opens into the nasal cavity (e.g., salamanders and frogs), the oral cavity (e.g., snakes and lizards) or both (e.g., many mammals) (Fig. 1). No separate vomeronasal organ is present in agnathans (jawless fishes), gnathostomes (jawed fishes), turtles, crocodiles, the tuatara *Sphenodon*, birds, cetaceans and sirenians (dugongs and manatees) [4]. As in the olfactory epithelium, the vomeronasal sensory epithelium consists of three types of cells – supporting, receptor and basal

**Evolution of Olfactory and Vomeronasal Systems. Figure 2** Schematic diagrams showing the cellular organization of the olfactory and vomeronasal epithelia.

cells (Fig. 2). The vomeronasal receptor cells (with a few exceptions) differ from those of the olfactory epithelium in lacking cilia on their dendritic surfaces, which are covered instead with microvilli. The receptor proteins that bind vomeronasal stimuli are presumably located on these microvilli. As in the olfactory epithelium but less frequently, basal cells periodically undergo mitosis and generate new receptor cells to replace receptor cells that are dying or have died. Again as in the olfactory epithelium, the function of supporting cells is unclear [3].

## Evolution of Chemosensory Receptors

Little was known about chemosensory receptors prior to 1991 when a multigene family encoding mammalian olfactory receptors (OR) was identified [6]. This discovery provided a molecular basis for olfactory recognition and it was awarded the Nobel Prize in 2004. The olfactory receptor family includes about 1,000 genes that encode 7-transmembrane domain G-protein coupled receptors expressed in the membrane of olfactory cilia. Subsequently, two different families of vomeronasal receptors (V1R and V2R) were cloned [3]. These gene families (about 100 genes each) also encoded 7-transmembrane domain G-protein coupled receptors, but are only distantly related to each other and to the olfactory receptor family. The V1R and V2R families are expressed in the microvilli of apically and basally located vomeronasal receptor cells respectively (Fig. 2). They also have different molecular structures indicating that they could recognize different vomeronasal stimuli.

Apart from OR, V1R and V2R, two additional families of mammalian taste receptors (T1R and T2R) have been cloned. All of these five families belong to a superfamily of G-protein coupled chemosensory receptors. A group of V1Rs is distantly related to T2Rs, suggesting that all these genes could have evolved from a common ancestor possessing cells detecting water-soluble substances. In fact, in fishes – where a single chemosensory epithelium exists – two different gene families encoding chemosensory receptors have been found. One is similar to mammalian ORs, whereas the other is similar to mammalian V2Rs [7]. All of these data support the hypothesis that the separate olfactory and vomeronasal epithelia of terrestrial vertebrates arose in evolution by segregation of distinct classes of neurons that were already present in the olfactory epithelium of an aquatic vertebrate precursor [3].

## Signal Transduction in Chemosensory Receptor Cells

Signal transduction refers to a process whereby a physical stimulus (e.g., light, sound, odor, hormone) is transformed into a cellular signal. In chemosensory neurons, signal transduction occurs when chemical stimuli bind to specific cell-surface receptors, which then transmit the information that they have bound the chemical signal to intracellular or membrane-bound proteins that initiate processes that eventually result in membrane voltage changes.

In the cilia of olfactory receptor neurons, odor binding to a G-protein coupled receptor (typically $G_{olf}$) results in activation of the enzyme adenylyl cyclase, which in turn stimulates the production adenosine 3′,5′-cyclic monophosphate (cAMP). cAMP targets cyclic nucleotide calcium-permeable channels in the cell membrane resulting in calcium influx into the cell and depolarization of the cell membrane. In addition to this second messenger system, odorant binding to G-protein coupled receptors linked to the enzyme phospholipase C has been reported to increase intracellular concentrations of inositol-1,4,5-trisphosphate

($IP_3$). $IP_3$ targets $IP_3$-gated channels that in turn allow calcium entry into the cell with a consequent depolarization of the cell membrane. This latter mechanism is less common in olfactory system transduction [1,2].

In the microvilli of vomeronasal receptor neurons, stimulus binding to G-protein coupled receptors activates phospholipase C, which in turn stimulates the production of $IP_3$ and diacylglycerol (DAG). In mammals, current evidence suggests that $IP_3$ and DAG target $IP_3$- and DAG-gated transient receptor protein channels (TRPC2) in the microvillar membrane, resulting in increases in intracellular calcium and membrane depolarization. In snakes, the data indicate that increases in intracellular $IP_3$ result in both influx of extracellular calcium and release of calcium from intracellular stores, the combined effect of which is to produce membrane depolarization [3].

## Primary Olfactory and Vomeronasal Projections

In contrast to some other sensory systems, olfactory and vomeronasal receptor cells are true neurons that generate action potentials that are transmitted along the entire length of their axons in response to chemical stimuli. Axons group into olfactory and vomeronasal nerves that terminate in the main and accessory olfactory bulbs respectively.

In fishes, extrabulbar projections from the olfactory epithelium to telencephalic and diencephalic targets other than the olfactory bulb have been reported. Ciliated and microvillous receptor cells differentially project to the olfactory bulb. In salamanders, vomeronasal axons run separately along the lateral edge of the olfactory nerve. In frogs, the vomeronasal nerve is located first medial to and then ventral to the olfactory nerve prior to reaching the cranial cavity. In all reptiles, olfactory axons pierce the cribiform plate of the ethmoid bone; in lizards and snakes vomeronasal axons form the vomeronasal nerve, which is located along the nasal septum and also penetrates the cribiform plate. In mammals, both olfactory and vomeronasal axons cross the cribiform plate, the latter occupying a more medial position. Olfactory receptor cells express four different types of olfactory receptors that project specifically to given glomeruli of the main olfactory bulb [8]. Vomeronasal receptor neurons located apically and basally in the epithelium express different vomeronasal receptors (V1R and V2R) and G proteins ($G_{i2\alpha}$ and $G_{o\alpha}$) and project to the anterior and posterior portions of the accessory olfactory bulb respectively [3,8].

## Main and Accessory Olfactory Bulbs

The olfactory bulbs are located in the most rostral portion of the brain in most vertebrates, except in some groups such as primates where the frontal cortex has expanded more rostrally and cetaceans in which the bulbs are absent. In amphibians, the accessory olfactory bulb is located caudo-lateral to the main olfactory bulb, in lizards and snakes it is caudal to the main olfactory bulb and in mammals it is located dorso-caudal to the main olfactory bulb [1,2,9] (Fig. 1).

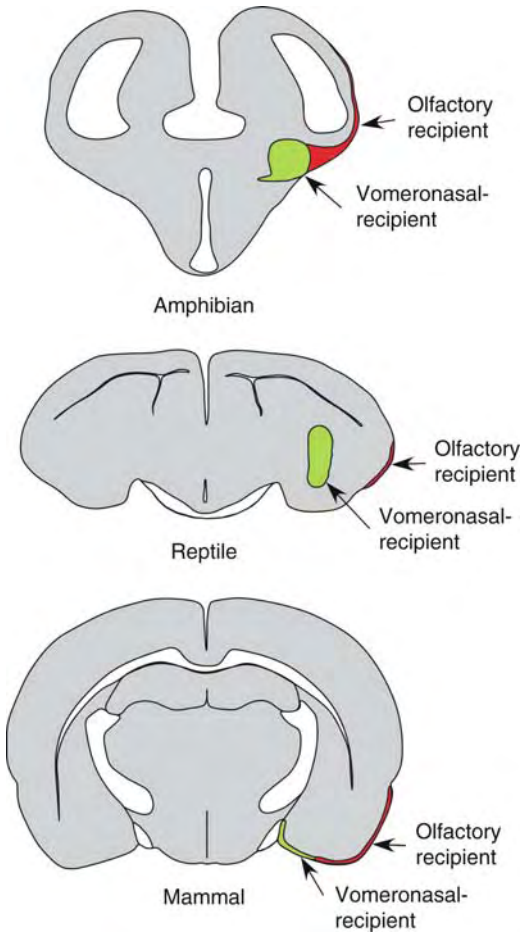
Relative to brain size, the olfactory bulbs constitute an important portion of the telencephalon of fishes, amphibians and reptiles; they are more reduced in many mammals and comparatively insignificant in birds and primates. The relative size of the main and accessory olfactory bulbs also varies across taxa and species. The accessory olfactory bulb is more than twice as large as the main olfactory bulb in snakes, it varies considerably among lizards and it is smaller than the main olfactory bulb in amphibians. In mammals, the accessory olfactory bulb is in general much smaller than the main olfactory bulb [1,2,3,9] (Fig. 1).

In vertebrates, the main and accessory olfactory bulbs are laminated structures with similar structural features. The most external layer is composed of the axons of receptor neurons, forming the nerve layer. The axons terminate in the adjacent, more internal, glomerular layer. Below the glomerular layer are located, in order from superficial to deep, external plexiform, mitral (or mitral/tufted) cell, internal plexiform and granule cell layers. The neural circuitry of the bulbs involves synaptic terminations of receptor cell axons onto mitral (mitral/tufted) cell dendrites and reciprocal synapses between the dendrites of mitral cells and the dendrites of granule cells. Periglomerular cells and short axon cells are also involved in modulation of this basic pattern. The axons of mitral (mitral/tufted) cells project out of the bulbs to targets in the forebrain [1,2,3].

## Projections from the Main and Accessory Olfactory Bulbs

In vertebrates, axons from mitral cells form a main bundle, the lateral olfactory tract, which reaches olfactory-recipient cortical areas of the telencephalon. In some groups, a comparatively minor medial olfactory tract is present. In tetrapods that have the vomeronasal system, axons from mitral/tufted cells form the accessory olfactory tract that terminates in vomeronasal-recipient structures. Olfactory and vomeronasal-recipient areas of the telencephalon are adjacent structures with minor overlap between them [3,10].

In fishes, the axons of mitral cells form the lateral olfactory tract, which terminates in the ventral telencephalon. In amphibians, the lateral olfactory tract ends in the lateral pallium, whereas the accessory olfactory tract travels to the medial amygdala. In reptiles, the lateral olfactory tract projects to the lateral cortex and olfactory amygdala; additionally in lizards and snakes, the accessory olfactory tract projects to the nucleus sphericus, a conspicuous structure of the vomeronasal amygdala. In mammals, the lateral olfactory tract carries



**Evolution of Olfactory and Vomeronasal Systems. Figure 3** Schematic diagrams showing the olfactory- (*red*) and vomeronasal-recipient (*green*) areas of the telencephalon of amphibians, reptiles (lizards and snakes) and mammals.

axons to a number of cortical structures, including the olfactory amygdala, piriform cortex and a portion of the entorhinal cortex. The accessory olfactory tract also ends in vomeronasal cortical structures such as the medial and posteromedial cortical nuclei [1,2,3,9,10] (Fig. 3).

## Plasticity in the Olfactory and Vomeronasal Systems

The olfactory and vomeronasal systems are plastic mainly at two levels, the epithelium and the bulb. In the olfactory and vomeronasal epithelia, receptor neurons become apoptotic and die periodically. Basal stem cells divide, migrate and mature to become neurons and replace senescent cells. How axons of these new cells reach appropriate glomeruli in the bulb is not fully understood [3,5]. In addition, there is a portion of the telencephalic ventricular wall (anterior subventricular zone) that generates stem cells that migrate rostrally (rostral migratory stream) to the main and accessory bulbs. There, these cells differentiate into granule and periglomerular cells. What the function of these new cells is or how they are incorporated into the circuitry of the bulbs are matters yet to be resolved [3].

## Functions of the Olfactory and Vomeronasal Systems

It is critically important for animals to respond to their chemical environments for safety (avoidance of predators or fire), nourishment (identification of life-sustaining nutrients) and reproduction (selection of sexually appropriate mates). Both olfactory and vomeronasal systems participate in these chemically mediated behaviors. In addition, in macrosmatic animals (those with well developed olfactory systems), individual recognition and identification of conspecifics is frequently mediated by the nasal chemical senses [1,3,9].

In general, the behavioral purview of the olfactory system is to identify and respond appropriately to airborne odorants. Potential prey will, upon sensing the odor of a predator, become restless and eventually seek cover. The successful predator remains "down wind" from his prey to avoid detection. Prey without a functional olfactory system will be unable to detect the proximity of a predator and therefore risk capture.

For many animals, odor, as well as taste, dictates the choice of nutrients. In those cases where odor is a major source of information about the location of suitable food, the olfactory system is essential for its identification and localization. In animals where carrion represents the main diet component, the smell of rotting flesh is the cue to its presence; conversely, the same odor may result in the avoidance of the same food by animals for whom consumption of rotting meat is a health risk. In humans, the odor of food serves as a motivational stimulus, both positive and negative. Whereas in most animals identification and consumption of foods is associated with gustatory and olfactory functions, in snakes (and perhaps lizards) identification of prey and their consumption is primarily a vomeronasal function [3,9].

Reproductive behavior is a complex set of responses to multiple external and internal signals, only some of which are mediated by the nasal chemical senses. Chemical signals secreted or excreted by one animal and responded to by another animal of the same species are usually termed "pheromones." Over the years it has been common to associate pheromonal communication with the vomeronasal system, since pheromone molecules are typically large complex molecules or small volatiles bound to larger molecules such as proteins. Interestingly, detection of the pheromones that subserve individual recognition, at least in hamsters, appears to depend on a functional olfactory system and not a

functional vomeronasal system. Many, but not all, of the chemical signals that signal reproductive state are mediated by the vomeronasal system. Thus, the nipple-search pheromone used by nursing rabbit pups to attach to the maternal nipple is detected by the olfactory system. Similarly, response of female pigs to androstenone, a pheromone in boar saliva, is detected by the olfactory and not by the vomeronasal system. Rodent pheromones that mediate induction of estrus, male-induced acceleration of puberty and strange male-induced implantation failure among others, all depend on a functional vomeronasal system. The female snake sex pheromone to which males respond with avid courtship is also detected by the vomeronasal organ. It is therefore important to remember that although the vomeronasal system detects and responds to many pheromones, it is a misnomer to consider it as the only pheromone detecting system [1,3,9].

### Origins of the Olfactory and Vomeronasal Systems

Attraction (food sources) or repulsion (toxins) by chemical substances (chemotropisms) is one of the oldest and more conserved behaviors present in all groups of animals – even in bacteria. Among vertebrates, the olfactory system is present in all groups and the vomeronasal system in some tetrapods.

The olfactory epithelium of some fishes contains ciliated as well as microvillar receptor cells. These latter cells could be evolutionary precursors of vomeronasal receptors neurons. They express G-proteins and receptor genes similar to mammalian vomeronasal receptor genes. These microvillar cells tend to group separately from the ciliated ones and project differentially to the bulb. This evidence suggests that the aquatic ancestor of tetrapods possessed both cell populations and that thereafter they segregated into separate olfactory and vomeronasal epithelia and distinct chambers. This idea is supported by the observation that the vomeronasal system is well developed in fully aquatic amphibians and also by the fact that the vomeronasal organ of terrestrial vertebrates is fluid-filled and responds to non-volatile odors, frequently in a liquid state. This thesis argues against the idea of the vomeronasal system as an adaptation to terrestrial life. The presence of the olfactory system in most vertebrates and the vomeronasal system in most tetrapods suggest that these systems were lost during the past history of some groups or species that no longer possess olfactory and/or vomeronasal systems [4].

## Synonyms

Septal nuclei; Septum; Septal region; Septal complex

## Definition

The septal nuclei constitute a subcortical (i.e. subpallial) telencephalic structure that lies at the base of a dorsally extending wall ("septum") in the midline that separates the lateral ventricles of the two cerebral hemispheres and is known as the septum pellucidum or septum lucidum (Figs. 1–3). The latter structure is mostly composed of glial cells. The septal nuclei are an evolutionarily well-conserved part of the limbic system, present in all vertebrate groups. Among their most conserved features are a massive excitatory input from the hippocampus and major interconnections with the hypothalamus.

## Characteristics

Septal nuclei or their homologues may be present in all or most vertebrates. A septal region or septal nuclei have been identified in ray-finned and cartilaginous fishes and tentatively in hagfishes. However, little information is yet available on the details of the connections and neurochemistry of these nuclei in fishes, so this essay focuses mainly on the septal nuclei in tetrapods.

### The Septal Nuclei in Tetrapod Vertebrates

The septal region has long been thought to be a subcortical structure of the limbic system deeply interconnected with the hippocampus and the hypothalamus. However, recent data on the expression of homeotic genes during development indicate that, in both mammals and non-mammalian tetrapods, pallial, striatal and pallidal divisions can be distinguished within the septal complex [1], with the striatal and pallidal divisions being the major structures of the septal region. In fact, Swanson and Risold (see [2]) consider that the septal region constitutes the medial division of the striato-pallidal complex in the cerebral hemispheres.

#### *Pallial, Striatal and Pallidal Territories in the Septal Region*

The identity of the pallial division of the septum is currently a matter of debate. During some embryonic developmental stages, a small dorsally located area of the medial wall of the cerebral hemispheres shows expression of pallial genetic markers such as pax-6, tbr-1 and emx-1 (at least in mice and chicks [1]). In the adult however, these markers are no longer expressed and the pallio-subpallial boundary has no obvious landmark within the septal region (Figs. 1–3). Therefore the location and extent of the pallial septum is still an open issue.

The striatal division is characterized by a strong expression of the striatal marker Dlx-2 [1,3]. It corresponds to what is usually named lateral septal complex (Figs. 1a–c, 2a–c, 3a–c), with the possible exception of its dorsal most part, which may be a pallial derivative. In all tetrapod vertebrates the lateral septal complex receives a dense and topographically organized zinc-enriched excitatory input (Figs. 1d–e, 3d) from the hippocampal formation, gives rise to topographical projections to the pallidal septum and has extensive bidirectional connections with the hypothalamus (Fig. 3i).

The pallidal division corresponds to the complex formed by the medial septum (called in reptiles the nucleus of the medial forebrain bundle) and the diagonal band. It is characterized by the expression of Nkx 2.1 [1], receives a substantial topographically organized input from the several nuclei of the lateral septal complex and gives rise to a projection back to the hippocampal formation that partially arises from cholinergic cells (Figs. 1f, 2f, g, 3e). Therefore, the main circuitry of the septo-hippocampal complex includes a pallio-striato-pallido-pallial loop, with glutamatergic pallio-striatal projections, GABAergic striato-pallidal projections and cholinergic pallido-pallial projections [4].

#### *Neurochemistry and Hodology of the Septal Divisions*

The patterns of gene expression during embryonic development, together with recent data on neurochemistry and ►hodology in the adult allow detailed comparisons of subdivisions of the septal complex among rodents [5], birds [6,7,8], reptiles [9,10,11] and amphibians [12,13,14] (see Table 1 and Figs. 1–3). In teleost fishes, the septal nuclei are considered to be represented by the ventral nucleus of the ventral telencephalon, but subdivisions similar to those present in the tetrapod septum have not been recognized [15].

As discussed above, the lateral septal complex is a well-conserved structure that has been described in the four classes of tetrapod vertebrates. It consists of two major groups of nuclei, the lateral septum and the posterior septum (Figs. 1–3; [5]; Table 1), the latter being a set of cell groups apparently associated with the

hippocampal (pallial) commissure and the fornix (the main hippocampofugal tract). In mammals, the lateral septum is characterized by a massive and topographically organized glutamatergic afferent from the hippocampal formation (Ammon's horn and subiculum) that is enriched in zinc (Fig. 1d, e). In addition, it receives ascending projections from peptidergic (Fig. 1g) and monoaminergic (Fig. 1h, i) cell groups in the hypothalamus (mainly from mammillary levels), tegmentum and brainstem, as well as from the midline thalamus. Whereas the hippocampal input gives rise to synapses on dendritic spines of the septal cells, the ascending afferents from the hypothalamus and brainstem display terminal axonal arborizations that form nests around septal cell bodies and proximal dendritic shafts ([5]; see Fig. 1g–i). This kind of afferent innervation includes a vasopressinergic projection that mainly arises from the amygdala and parts of the bed nucleus of the stria terminalis and that terminates in a specific region of the lateral septal complex [16]. This amygdalo-septal projection is sexually dimorphic and sensitive to sexual steroids. Other afferents, either identified with specific markers or by means of anterograde tracing techniques, also show a great specificity for distinct regions of the lateral septum.

The main efferent projections of the mammalian lateral septum innervate the medial septal complex and the hypothalamus and ventral midbrain. These projections arise from spiny stellate cells (Fig. 1j) that use GABA as a neurotransmitter. Therefore, the principal cell of the striatal septum is an inhibitory medium-sized spiny neuron, following the same pattern of organization found in other striatal regions [4,5].

The pattern of afferent and efferent connections of the mammalian lateral septum described above is similar to the one observed in amphibians [12,14], reptiles (Fig. 3; [10,11]) and birds (Fig. 2; [6,8,17]). As can be observed in Figs. 2 and 3, the lateral septum of non-mammalian amniotes also receives a zinc-enriched glutamatergic afferent input (Fig. 3d) from the hippocampal formation and ascending projections that terminate in pericellular nests arising from peptidergic (e.g. CGRPergic, Figs. 2d, 3f) and monoaminergic (e.g. dopaminergic, Figs. 2e, 3g) cell groups located in the hypothalamus, tegmentum and brainstem. These anatomical data suggest that the lateral septum has undergone a conservative evolution and therefore, it very likely plays a key role in the control of the physiology and behavior across tetrapods (see below).

Based on chemoarchitectonic information, Goodson et al. [7] have suggested that the dorsal zone of the caudal part of the lateral septum of birds and mammals (Figs. 1a–c, 2a–c) are comparable structures that apparently correspond to the pallial septum. However, the neurochemical properties of topographically equivalent structures in the septum of reptiles (Sdl, Fig. 3a–c; [9]) and amphibians (Sld, [13]) only partially coincide with those of mammals and birds. Therefore, further evidence is needed to confirm or discard the pallial origin of these structures.

In contrast to the lateral septum, the connections of the nuclei that compose the posterior septum are poorly studied. In the four classes of tetrapods, its main output reaches the epithalamus (amphibians [12], reptiles [11], birds [8], mammals [5]). The main afferents of the posterior septum have been studied in amphibians [14] and reptiles [10]. In these animals it receives non-topographical afferents from the hippocampal (medio-dorsal) cortex. At least in reptiles this projection is poor in zinc [9]. In addition, like the lateral septum, the posterior septum seems to receive ascending thalamic and hypothalamic inputs.

The pallidal division of the septal region, the medial septal complex, has not been studied as extensively as the lateral septal complex (at least in non-mammalian vertebrates). It is composed of the medial septal nucleus (or nucleus of the medial forebrain bundle in reptiles) and the diagonal band in the four classes of tetrapod vertebrates. One of its defining features is the presence of cholinergic cells (Figs. 1d, 2f–g, 3f) projecting to the hippocampal cortex. Although present in all the studied vertebrates, the size of this cell population shows a substantial variability even within a single class (see [7] and references therein). Another significant characteristic of the pallidal septum is an important population of GABAergic cells that gives rise to ascending projections to the hippocampal formation (and other pallial areas) as well as to descending projections to the hypothalamus and brainstem [5]. In addition, the medial septum-diagonal band complex is innervated by a dense plexus of substance P-positive fibers (Figs. 2h, 3h). As can be observed in Figs. 2 and 3, the pallidal septum in birds and reptiles is not in a medial position, but it is located ventral to the lateral septum, adjacent to the diagonal band mainly at rostral (precommissural) levels. Regarding its afferents, the massive projections of the medial septal complex to the

posterior hypothalamus and the brainstem are bidirectional. Moreover, the medial septal complex is also characterized by a topographical projection from the lateral septum [5].

## Evolution of the Septal Function

The analysis of the connectivity and chemical neuroanatomy of the septal region described above reveals that it is composed of three major divisions (lateral, medial and posterior septum) that can be recognized in the four classes of tetrapod vertebrates, where they show remarkable similarities. It is therefore reasonable to suggest that the function of the septal region should also be conserved and consequently the septum is probably implicated in neural mechanisms that are essential for the survival and reproduction of the animals. It is not known, however, whether the three major divisions of the septum are involved in a unitary function. From the anatomical point of view, the lateral and medial septal divisions are strongly interconnected (Fig. 4; [5]), and therefore it is likely that the structures are functionally interdependent. In contrast, the posterior septum is only moderately interconnected with the rest of the septal regions. Although earlier studies based on lesion data suggested that the posterior septum played a role in water intake, it seems that this function is actually carried out by the subfornical organ [11], which is located next to the posterior septum. In fact, the role of the posterior septum in water balance appears inconsistent with its main differential feature, the efferent projection to the habenula, a structure that has been recently shown to be functionally related to the hippocampus and the nucleus accumbens in mediating higher cognitive functions [18].

### *Functional Organization of the Lateral Septum and the Medial Septal Complex*

Data derived from lesion studies and pharmacological manipulations have demonstrated that the lateral septum is involved in social memory, parental behavior, intraspecific aggression, dominant-subordinate relationships and territoriality (see [2]). Therefore, the lateral septum is usually considered a key node of the ►social behavior network [19,20] and its main connections can be interpreted in this context.

The efferent projections of the lateral septum (directly and indirectly through the medial septal complex) target the social behavior network in the hypothalamus and brainstem, which control both reproductive and

defensive/►agonistic behaviors [21] (Fig. 4). The reproductive network includes the medial preoptic nucleus and parts of the ventromedial tuberal hypothalamus, together with the ventral premammillary and tubermammillary nuclei. On the other hand, the defensive network includes the anterior hypothalamus, parts of the ventromedial hypothalamus, the dorsal premammillary nucleus and periaqueductal grey. Additional projections to the midline thalamus and reticular formation might subserve attentional processes common to both kinds of social behaviors.

The main afferent input to the lateral septum, which arises from the hippocampal formation (Fig. 4), provides contextual information (including spatial and non-spatial cues). Therefore, the lateral and medial septal divisions should play a key role in initiating the appropriate reproductive/defensive/aggressive behavior as a function of the contextual situation of the animal [11,20], thus constituting a pivotal center for ►territorial motivation. A crucial aspect of the context is the animal's location in its territory or in a competitor's territory. In fact, the behavioral response of an animal to a conspecific may vary from aggressive (when the animal is located within its own territory) to defensive/submissive (when it is located outside its territory). In rodents, and in many other territorial species where chemical signals are used for territorial marking, olfactory and vomeronasal information relayed to the septum might reveal the presence of competitors and give information on its sexual identity and social status. There are two possible neural pathways. On the one hand, the hippocampus receives its main input from the entorhinal cortex, which in turn is directly targeted by the efferent projections from the main olfactory bulbs (Fig. 4). On the other hand, the ventral part of the lateral septum receives a direct projection from the amygdala and the bed nucleus of the stria terminalis that probably conveys both olfactory and vomeronasal information (Fig. 4). Therefore it is reasonable that the lateral septum be involved in social recognition and social memory (see [2]). In conclusion, the great variety of behaviors elicited by electrical stimulation of the lateral septum, as well as the inconsistent effects that lesioning this structure has in behavioral tests in the laboratory, may be explained by the role of the lateral septum as distributor of behaviors as a function of variables such as territoriality and social context, which are difficult to control in the laboratory.

Although the medial septum has not been implicated in social behavior, it is deeply interconnected and thus functionally interdependent with the lateral septum and hippocampus (Fig. 4). In fact, in mammals the medial septum is known to function as a pacemaker that synchronizes the neural activity of hippocampal (and entorhinal) cells by means of its GABAergic and cholinergic projections (see [2]), giving rise to the generation of the theta rhythm. Although the function of the theta rhythm is not clear, it is expressed during exploratory behavior and voluntary motor activity (as well as REM sleep) and the activity of place cells is in phase with the theta rhythm [22]. This suggests a role of the medial septum in sensory processing by the hippocampus that would, in turn, have a strong influence on the hippocampo-septal pathways controlling the social behavior network. In this respect, the functional interdependence of the medial and lateral septal divisions is further indicated by the important projections from the caudal aspect of the lateral septum onto the supramammillary nucleus [5], which is the main interface between the brainstem reticular formation and the medial septum. Therefore, the influence of the lateral septum on the activity of medial septal cells (both by direct projections and indirect modulation through the supramammillary nucleus) provides anatomical evidence of a joint role of the medial and lateral septum on attentional processes related to acquisition of spatial memory during exploration of the territory. Consequently, it is not surprising that lesions of the medial complex in mammals result in complex deficits in behavioral paradigms requiring attention and memory [2,5]. In conclusion, the septum is a key node in the social behavior network that initiates the appropriate reproductive/defensive/aggressive responses as a function of the territorial motivation.

# Evolution of Subpallial Cholinergic Cell Groups

Alice Schade Powers
Department of Psychology, St. John's University, Jamaica, NY, USA

## Synonyms

Nucleus basalis; diagonal band; medial septum; Ch1; Ch2; Ch3; Ch4

## Definition

Cells that make *acetylcholine* and are located primarily in the basal forebrain.

## Characteristics

Cells that make *acetylcholine* have been found in the basal forebrain throughout tetrapod phylogeny. In cyclostomes and fishes, cholinergic cell groups have also been identified, but the equivalence of those cell groups to the cell groups found in tetrapods is not always clear. These issues are reviewed below.

Cholinergic cells can be identified by immunohistochemistry using an antibody against *choline acetyltransferase* (ChAT). The alternative method of identifying cells that contain *acetylcholinesterase* (AChE) is not accurate because AChE is known to be located in non-cholinergic cells as well as cholinergic ones [e.g., 1]. The studies to be reviewed below all used ChAT immunohistochemistry to identify cholinergic cells.

## Mammals

In placental mammals, three broad groups of cholinergic cells can be recognized in the basal forebrain, the *medial septum*, the *diagonal band of Broca* and the *nucleus basalis of Meynert*, which lies within the *substantia innominata* and is called the *nucleus basalis magnocellularis* in many nonprimate species. These cells, which have also been called Ch1 (*medial septum*), Ch2 and Ch3 (vertical and horizontal limb of the *diagonal band of Broca*) and Ch4 (*nucleus basalis of Meynert*), form a continuous band from rostromedial to caudolateral in the basal forebrain [1]. Cholinergic interneurons are also found in the dorsal striatum or caudate-putamen of mammals, but these cells will not be treated in detail here because they are considered to be components of the basal ganglia. In addition to this group of nuclei, cholinergic cells are seen in the nucleus accumbens and olfactory tubercle. In some mammalian species, cholinergic cells can also be identified in the *lateral septum* [2], medial nucleus of the amygdala and bed nucleus of the stria terminalis, but these are not consistently seen.

The cells in the *medial septum* project to the hippocampus. Cells in the diagonal band project to

the hippocampus, hypothalamus, olfactory bulb and cortex. Cells in the nucleus basalis project to the cerebral cortex and amygdala [1].

In a study of the monotremes platypus (*Ornithorhynchus anatinus*) and echidna (*Tachyglossus aculeatus*) [3], cholinergic cells were described in the nucleus basalis and ventral pallidum and in the *medial septum*, but not in the diagonal band. Cholinergic cells were also found in nucleus accumbens. A few cells were described in the amygdala, but the area in which they were located was not clear.

## Fishes

In cyclostomes, few cholinergic cells are found in the forebrain. A few cells have been seen in the area thought to be the striatum of *Petromyzon marinus*, the sea lamprey [4], but none in *Lampetra fluviatilis*, the river lamprey [4].

Similarly, in the dogfish *Scyliorhinus canicula,* a member of the class Chondrichthyes or cartilaginous fishes, no cholinergic cells were found in the basal forebrain [5]. In this species, however, a large number of small cholinergic cells were found in the superficial dorsal pallium [5]. This finding of *acetylcholine* cells in the pallium is rare among vertebrates and, because no other species of Chondrichthyes has been studied, whether it is characteristic of this class or unique to the dogfish is unknown.

In the class Osteichthyes, or bony fishes, representatives of two superorders within the subclass actinopterygians, Acipenseriformes and Teleostii, have been studied. Like the dogfish, the sturgeon ►*Acipenser baeri*, a member of the Acipenseriformes, does not have cholinergic cells in the telencephalon [6]. The first consistent evidence of cholinergic cells in the basal forebrain appears in the teleosts [7]. The fish that have been studied are the midshipman ►*Porichthys notatus* [8], two species of trout (*Oncorhynchus mykiss* and *Salmo trutta fario*) [9], the cyprinids *Danio rerio* and *Tinca tinca* [10,11] and the European minnow *Phoxinus phoxinus* [12]. The cholinergic cells found in the telencephalons of these fish are located in different subdivisions. *Phoxinus* has small ChAT-positive neurons in the area ventralis lateralis (Vl) and nowhere else in the telencephalon [12]. This area may be equivalent to the olfactory tubercle [12,13,14]. Cholinergic cells in Vl were also found in two species of trout [9]. Although they reported no ChAT-positive cells in the telencephalon in one study of the cyprinid *Danio rerio* [10], Clemente et al. [11] later found cholinergic cells in the "lateralmost area of the central nucleus within the ventral telencephalic area" in both *Danio rerio* and *Tinca tinca.* This region again appears to be Vl. In contrast, Brantley and Bass [8] described cholinergic neurons in the ventral zone of area ventralis (Vv) in the teleost fish *Porichthys notatus*, the midshipman. The Vv has been thought to be equivalent to the septal area or perhaps to a broader basal forebrain region of tetrapods, including the septum, nucleus accumbens and the *nucleus basalis magnocellularis* [13]. Brantley and Bass [8] saw no cholinergic cells in the lateral zone of the area ventralis (Vl), where cholinergic cells have been found in other teleost species. Thus, the basal forebrain of teleost fish clearly contains cholinergic cells, but these cells are not always found in the same location, and their homologues in tetrapods are not clear.

## Amphibians

In amphibians, a consistent pattern similar to that seen in mammals can be discerned. Representatives of all three orders of amphibians have been studied, anurans (the frogs *Rana perezi* and *Xenopus laevis* [15,16] and the fire-bellied toad *Bombina orientalis* [17]), pleurodires (the Iberian ribbed newt *Pleurodeles waltl* [16]), and gymnophionans (the Mexican caecilian *Dermophis mexicanus* [18]). In all three orders, cholinergic cells are found in the basal forebrain, but some differences have been found. In anurans, cholinergic cells are found in the *medial septum* but not the *lateral septum* (a few cells were reported in the rostral *lateral septum* of *Rana perezi* [15]). No ChAT-positive cells were found in the septum of the single urodele that has been studied and in the only gymnophionan, such cells were seen in the lateral but not the *medial septum*. Anurans have been shown to have cells in the *diagonal band of Broca*, but these cells were not seen in either the urodele or the gymnophionan species. In the ventral pallidum however, all three groups have cholinergic cells. These cells have been variously identified as being in the lateral amygdala or medial amygdala, but Sanchez-Camacho et al. [16], using the newer nomenclature of Marin et al. [15], found ChAT-positive cells in the ventral pallidum and medial amygdala of *Rana*. In urodeles, cells are found in the same region, which is probably equivalent to the ventral pallidum and medial amygdala, but the terminology has not been revised for this group. Similarly, in the gymnophionan *Dermophis,* cells are seen in the basal forebrain and in a region called the amygdala, pars lateralis, but the true equivalence of the latter to areas in other groups is not known.

## Reptiles

In reptiles, studies have been done on the cholinergic cells in the forebrain of the turtles *Chrysemys picta* and *Pseudemys scripta* [19], the lizards *Gallotia galloti* [20] and *Gekko gecko* [21] and the crocodilian *Caiman crocodilus* [22]. All show cholinergic cells in the basal forebrain, in the characteristic mammalian pattern of cells extending from the septum to the diagonal band to the ventral pallidum. Turtles and caiman have cholinergic cells in all three subdivisions; the lizards *Gallotia galloti* and *Gekko gecko* were reported not to have

cholinergic cells in the *medial septum*, but the medial wall of the hemisphere in *Gallotia galloti* did contain cholinergic cells. Cholinergic cells were seen in the nucleus accumbens in all reptiles. Some cells were also seen in the bed nucleus of the stria terminalis in the lizard *Gallotia* and in the amygdala in turtles.

### Birds

A similar pattern is seen in birds. Studies have been done of the pigeon *Columba livia* [23] and budgerigar *Melopsittacus undulatus* [24,25] and of the septal area of songbirds [26]. All birds studied have cholinergic cells in the ventral pallidum, which was recently renamed the *nucleus basalis magnocellularis*, and the diagonal band. The *medial septum* in the budgerigar *Melopsittacus undulatus* is reported not to contain cholinergic cells, but the *medial septum* of pigeons and songbirds does contain such cells. The nucleus taeniae, thought to be the homologue of the medial amygdala, contains cholinergic cells in pigeons [Reiner A, 2006, personal communication] and parrots. The bed nucleus of the stria terminalis in pigeons and the nucleus accumbens in both pigeons and parrots have also been reported to contain cholinergic cells.

In addition, the cholinergic system has been studied in the song control nuclei of zebra finches [27,28,29] and budgerigars [24]. Cholinergic perikarya are found in area X of zebra finches and the equivalent magnocellular nucleus of the medial striatum (MStm—formerly LPOm) of budgerigars. No other song-control nucleus contains somata labeled by ChAT-immunohistochemistry. Other song control nuclei in both groups, the higher vocal center (HVC) of zebra finches and the equivalent NLC (central nucleus of the lateral nidopallium) of budgerigars, are innervated by cholinergic fibers and these projections were shown in the zebra finch to originate in the ventral pallidum [27], as do projections to the robust nucleus of the arcopallium (RA).

### Comparative Aspects Across Vertebrates

Thus cholinergic areas in the basal forebrain are found consistently in amniotes and the forerunners of such cholinergic areas are found in amphibians. Cholinergic cells are found in the basal forebrain of fish, but the exact homologues of these areas with those of amniotes are not clear. Inconsistencies are found among amniote groups only in whether cholinergic cells are found in the *medial septum* (a few groups do not have them), the *lateral septum* (the common pattern is that cholinergic cells are not found, but a few groups have them), and in whether the amygdala, nucleus accumbens and bed nucleus of the stria terminalis contain cholinergic cells.

Semba [3] has suggested that the cholinergic neurons of the basal forebrain may have changed their function over the course of evolution, beginning as part of the olfactory system, but moving caudally in the brain to supply *acetylcholine* to the pallium (the hippocampus and cerebral cortex in mammals) and to function in learning, memory and attention. Although evidence for their early function in olfaction is weak, the evidence for their function in cognitive tasks is strong in mammals and they have been shown to have this function in at least one group of reptiles, the turtles [30].

# Evolution of the Amygdala: Tetrapods

Agustín González, Nerea Moreno
Dept. Biología Celular, Fac. Biología, Univ. Complutense, Madrid, Spain

## Synonyms

Amygdaloid complex; Extended amygdala; Tetrapods

## Definition

In mammals, the amygdaloid complex is a group of nuclei topographically situated in the ventrolateral caudal telencephalic region. It has four major divisions, two of which are mostly pallial and receive major inputs from the olfactory system, one of which is likewise pallial, receives sensory inputs and is highly interconnected with other pallial areas and the fourth of which is subpallial and closely interconnected with the autonomic nervous system. The amygdala is present across tetrapods, with a variety of shapes, sizes and component parts depending on the tetrapod studied.

## Characteristics

### Overview of the Amygdala in Tetrapods

The amygdala was first identified by Burdach in the early nineteenth century as an almond shaped mass of gray matter through the temporal pole of the human cerebral hemispheres. Subsequently, with the progressive achievement of new technical approaches, it was observed that the amygdala of diverse mammalian species is a complicated structure consisting of an extended continuum of nuclei and the term "amygdaloid complex" was commonly used. This complex is located within the basal telencephalon and extends rostrally to reach the caudal tip of the shell portion of the nucleus accumbens. Diverse studies have demonstrated that the distinct divisions of the amygdala in all tetrapods (amphibians, reptiles, birds and mammals) show a common histochemical and hodological organization that includes an intricate set of intra-amygdaloid connections and a common embryological origin, supporting the idea of a highly conserved structure in the telencephalon of vertebrates [1,2]. However, there are differences due to specific features in the brain of each vertebrate class, such as is the case for birds, which possess a huge dorsal ventricular ridge of uncertain comparative significance, a poorly developed olfactory system and a virtual lack of the vomeronasal system [3].

Nevertheless, there are several key features of amygdaloid complex organization shared by most of the studied tetrapods. These are (i) its location in the ventrolateral caudal telencephalic hemispheres, (ii) a common embryological origin with components from lateral and ventral pallial territories (the latter organized into cortical and deep amygdaloid components) and components embryologically derived from the lateral and medial ganglionic eminences of the subpallium (Fig. 1), (iii) strong vomeronasal (with the exception of birds) and olfactory inputs that are mainly relayed to the hypothalamus and autonomic centers, thus defining different functional systems in the amygdaloid complex, vomeronasal, olfactory, autonomic and multimodal, all four strongly related by an intricate intra-amygdaloid network, (iv) the presence of a main output center involved in the autonomic system and therefore influencing the behavioral final response of the animal, (v) the ►*stria terminalis* as the main fiber tract connecting the amygdaloid complex with basal telencephalic populations and with the hypothalamus, (vi) abundant local circuit neurons within the amygdaloid nuclei, (vii) important and distinct inputs from dorsal thalamic multisensorial areas (Fig. 2) and (viii) a strong peptidergic input from hypothalamic and midbrain centers. Due to its close relation to different sensory systems, the amygdaloid complex changes in distinct vertebrate groups with individual environmental adaptations, e.g. snakes possess a highly developed vomeronasal system and a ►vomeronasal amygdala, strikingly larger than in other reptiles, whereas in birds the absence of a vomeronasal system has reduced this amygdaloid area [4].

### Description of the Structure

Among tetrapods, the expression pattern of different homeotic genes during development and in the adult supports a new interpretation of the ►homology between different amygdaloid territories [1,5,6] (Fig. 1). The current view of the amygdaloid complex of tetrapods considers pallial and subpallial components based on their distinct ontogenetic origin. Derivatives of the lateral and ventral pallial regions form the "►*pallial amygdala*," whereas derivatives of the lateral and medial ganglionic eminences (origin of the striatum and the pallidum, respectively) constitute the "►*subpallial amygdala*" (Fig. 1). In addition, the amygdala in amniotes is formed by two kinds of pallial structures, (i) the *cortical amygdala* that shows a laminar organization, a superficial position and is dominated by massive inputs from the olfactory bulbs [7] and (ii) those pallial derivatives deep in the cortical amygdala that constitute the *basolateral amygdala*, are in general indirectly related to the olfactory system and constitute an important relay center for the multisensorial thalamic information [4,7]. In contrast, the amphibian pallial amygdala does not posses cortical structures [1] and is formed by the putative homologues of the amniote deep pallial amygdaloid components [2]. However, the subpallial amygdala in all tetrapods is composed of the *centromedial amygdaloid* area, represented by the central nucleus of the amygdala, which is a striatal derivative and the main component of the autonomic amygdaloid subdivision and the *medial*

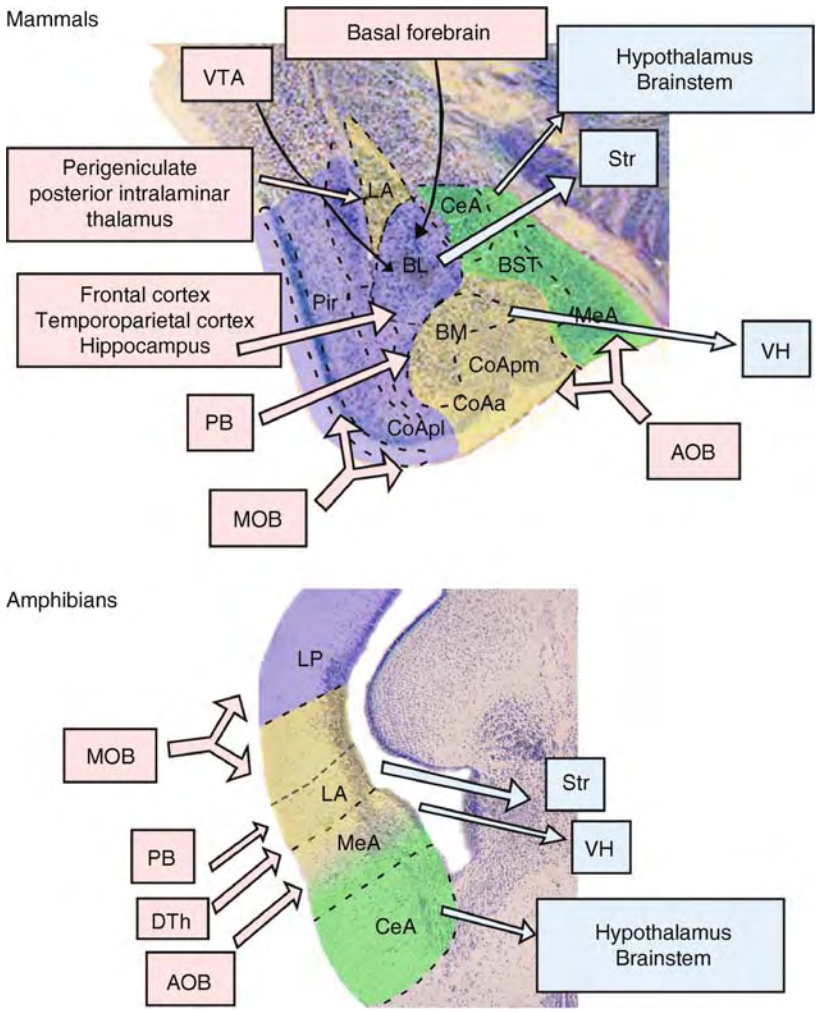
*amygdala,* which is an important secondary vomeronasal center [1]. Thus, in general, the amygdala seems to be formed by areas acquired at different moments in evolution, with the subpallial components being the most conserved areas, present in all tetrapods with the same basic features. In contrast, the cortical amygdala seems to be a newly evolved area, originating during the anamniote-amniote transition.

## Evolution of the Tetrapod Amygdala

In amniotes, the different subdivisions of the amygdaloid complex were identified on the basis of their distinct connectivity, i.e. those with long descending projections, those receiving olfactory information, those that do not receive direct olfactory information but project to the hypothalamus and those receiving ascending thalamic information [4]. Significantly differently in amphibians (anamniotes), a single ventropallial structure receives direct olfactory information and projects massively to the ventral hypothalamus through the *stria terminalis* [1]. It seems that during the transition from water living to earth living animals, the brain of ancestral tetrapods developed an elaborated amygdaloid complex in response to the new requirements.



**Evolution of the Amygdala: Tetrapods. Figure 2** Schematic drawings over representative transverse sections of the mouse and anuran telencephalon illustrating the embryological origin of the different amygdaloid nuclei and their main hodological (and thus functional) relationships. For abbreviations see Fig. 1.

The basic organization of this brain system is still recognizable in all extant tetrapods. During the evolution of tetrapods, the pallium was enormously expanded in amniotes and thus the medial, dorsal, lateral and ventral areas dramatically increased in size (Fig. 1). As a consequence of the acquisition of large new superficial areas, the current spatial arrangement of the mammalian amygdaloid complex reflects a re-localization of the central, medial (autonomic, vomeronasal) and basolateral (multisensory) nuclei, which in the ancestral condition could occupy a superficial ventrolateral position in the caudal telencephalon, as is still the condition in living anurans (Figs. 1 and 2). The "new evolutionary nuclei" (cortical regions) could have pushed the "more conserved nuclei" medially, explaining why in mammals the central and medial nuclei occupy the most medial position, followed by the basolateral complex, whereas the cortical amygdaloid nuclei occupy the most lateral position. Thus, the mammalian amygdala may be composed of evolutionarily old centromedial and basolateral regions and new cortical regions, the latter being missing in the anuran brain. The evolutionarily old brain structures have been conserved through evolution, maintaining a pattern of organization shared by all tetrapods. The developmental, hodological and neurochemical features common to the amygdaloid complex of all tetrapods are those needed to fulfill its multiple vital functions (such as survival and reproduction), which have been conserved over the course of evolution.

## Higher Level

The ►forebrain, in general, shows a relative diversity among tetrapods, more so than the brainstem or the spinal cord which appear much more conserved. However, indications of the existence of a basic plan, "bauplan," in the origin, regionalization and organization of the

forebrain in tetrapods are increasing, as for example in the amygdaloid complex and the basal ganglia.

## Function

On the basis of its heterogeneous origin, chemoarchitecture and hodology, the amygdaloid complex represents a number of different, unrelated anatomical structures, with pallial and subpallial derivatives belonging to different functional systems, the olfactory, vomeronasal, autonomic and the frontotemporal cortical systems [7]. The summation of all these systems by means of an intricate intraamygdaloid network allows the multimodal integration that occurs in the amygdaloid complex, which is the basis for the acquisition of "emotional memory." This has as its final response "emotional behavior," i.e. responses that occur to promote the survival of individuals and their species as, for instance, in defense against danger, in the interaction with sexual partners or in fighting with an enemy [8]. It allows the association of different stimuli – olfactory/vomeronasal, acoustic, painful, pleasant and so on – that are important in terms of survival and reproduction with the emotions that occur at the same time, thus resulting in an emotional labeling of these stimuli with important somatosensory and autonomic components.

The vomeronasal system, also known as the accessory olfactory system, plays a crucial role in the detection of chemical molecules, i.e. pheromones, and is therefore crucial in co-specific recognition and reproductive processes in most terrestrial vertebrates. This system is present in representatives of amphibians, reptiles and mammals, but is absent in birds. In turn, the olfactory system is present in almost all tetrapods and detects volatile chemical molecules. The olfactory/vomeronasal information passes via the olfactory bulbs to the "olfactory" and "vomeronasal amygdala" [7]. This olfactory/multimodal amygdaloid system consists of distinct cortical and deep amygdaloid areas in amniotes but only the deep portion is present in amphibians [1]. All parts of the vomeronasal amygdala receive direct information via the accessory olfactory bulb (Fig. 2), whereas cortical structures of the ►olfactory amygdala receive direct inputs from the olfactory bulb. The deep pallial components receive indirect information through the intricate intraamygdaloid network [7]. In addition, a variety of sensory inputs reach a major integrative center of the amygdala (mainly from the dorsal thalamic nuclei), which, after integration of these diverse inputs, conveys sensory information to other amygdaloid nuclei for further processing. This system of connections comprises an important component of the multimodal amygdala which is strongly implicated in emotional behavior.

Abundant behavioral studies indicate that the amygdala profoundly influences numerous responses, as well as the expression of instinctive and conditioned behaviors with motivational and/or emotional components, which could be mediated, at least in part, by projections to the hypothalamus. Given its importance, there have been many studies of the amygdalo-hypothalamic projection and it is of particular interest in an evolutionary perspective since it seems to be extremely conserved across tetrapods [9]. Actually, the major similarities among the amygdala in amniotes are highlighted when analyzing their hypothalamic projections via the *stria terminalis*. The *stria terminalis* (or a homologous amygdalo-hypothalamic fiber tract) is a prominent fiber bundle found in all tetrapods which interconnects the amygdala with the rostromedial forebrain and the hypothalamus. Physiological evidence indicates that the amygdala also influences a variety of visceromotor responses that could be mediated, at least in part, by projections from the amygdala to the lower brainstem. Thus, in all tetrapods a striatal component can be detected which is strongly related to the autonomic system [5]. It constitutes the main output nucleus of the amygdaloid complex, which receives convergent information from several other amygdaloid regions and generates behavioral responses that presumably reflect the sum of neuronal activity produced by different amygdaloid nuclei [10]. Hence it is considered to be the main integrative center in the amygdaloid complex and, due to its connections with autonomic brainstem centers and with forebrain limbic regions (and according to physiological data), it is involved in the modulation of autonomic, somatic and endocrine functions [7]. Furthermore, it has been related to the integration of emotional and motor components of behavior and to the mediation of conditioning oriented responses, behavioral responses to nociceptive and conditioned aversive stimuli and to the visceral and behavioral responses to stressful stimuli.

# Evolution of the Auditory System

Susanne J. Sterbing-D'Angelo
Department of Psychology, Vanderbilt University, Nashville, TN, USA

## Definition

Sensory systems are inevitably the adaptive products of natural selection. In some mammalian species certain specializations of the auditory periphery can be correlated with ecological niches. Examples of niches that require special adaptations of the auditory system would be underwater hearing (e.g., whales and dolphins), ►echolocation (bats), or orientation in underground environment (e.g., mole rats). In addition to ecologically driven adaptations, physical constraints (e.g., limitations of the size of the tympanic membrane) and ►phylogenetic precondition, as well as non-auditory factors like body or head size have to be considered. While the special adaptations to environmental parameters are quite obvious for the auditory periphery, such adaptations are less obvious in the central auditory system. Here, adaptations are manifested in more general parameters like relative volume/size of auditory structures versus overall brain size, relative size of individual auditory nuclei that are specialized for the processing of different sound parameters, or differentiation/number of auditory cortical fields and their connectivity [1].

## Characteristics

The evolution of the auditory system has been traditionally regarded as a gradual process of change from a "primitive" amphibian to the "advanced" mammalian auditory system driven by the transition from life in water to life on land. In congruence with this idea, auditory brain structures between e.g., sauropsids (reptiles and birds) and mammals were homologized based on location and connections. However, more recent paleozoological research revealed that, e.g., middle ear structures of modern amphibians, sauropsids, and mammals developed independently. Also long-accepted homology between nuclei of the auditory pathway, e.g., the homology between the nucleus laminaris of sauropsids and the mammalian medial superior olive, recently have been questioned because of differences in potassium channel distribution and differences in inhibitory inputs [2]. However, both structures are involved in sound localization, specifically in the coding of interaural time differences, which are the differences in arrival time of sound waves between the two ears for lateralized sound sources. While there are many similarities in the function of ►auditory brainstem nuclei of sauropsids and mammals, there are also distinct differences. In contrast to amphibians and sauropsids, most non-aquatic and non-subterranean mammals possess a "pinna." The pinna, the visible part of the external ear, is typically complex in shape and can be quite mobile. The angle of sound incidence upon the ridges and folds of the pinna causes certain frequencies to be amplified while others are attenuated. Therefore, these pinna cues provide information about the location of sound in space, which distinguishes the localization ability of mammals from nonmammalian vertebrates. Also, adaptations of the middle ear and inner ear anatomy reflect the different environmental pressure imposed on specialized species of mammals. For example, the middle ear cavity is enlarged to a "bulla tympanica" in some small mammals that are specialized for low frequencies (e.g., chinchilla, guinea pig [3]). Another example is the anatomical specialization of the cochlea of bats, which allows the perception of very high frequencies, enabling bats to echolocate, i.e., to actively use the auditory system for obstacle avoidance and prey detection during flight in complete darkness.

To shed light on the questions of the evolution of the mammalian auditory system, it is worthwhile to look at the paleozoological findings [4,5]. About 190 million years ago, during the age of dinosaurs, the first primitive mammals (prototheria) evolved from mammal-like amniotes. The first true mammals were probably represented by the genera Hadrocodium, Repenomamus and Gobiconodon, which filled an intermediate position between the basal mammal Morganucodon and the earliest therian (marsupial and placental mammals), such as Triconodon [6]. Triconodon was about the size of a Virginia opossum. Unfortunately, the fossils cannot provide much information about the function of the auditory system, because soft tissues are not preserved [4]. Fortunately, the primitive mammals still have living

descendants in the monotremes, i.e., the egg-laying duckbilled platypus and the spiny anteater of Australia. Studying the extant monotremes, which are regarded as inhabiting an intermediate position between therapsid amniotes and therian mammals, might therefore provide key insight into the evolution of the auditory system. In many primitive mammals, like the monotremes and some insectivores, the middle ear cavities are not bony, but are in part covered by cartilage and connective tissue. Physiological data are quite sparse and were mostly obtained from the auditory periphery via cochlear microphonic potentials, cochlear ►distortion product otoacoustic emissions, or auditory brainstem potentials (ABR) [7,8]. Although some anatomical aspects of the peripheral hearing system in monotremes appear bird-like or reptile-like, e.g., the relatively short, demilunar shape of the cochlea and the ►columella-like stapes, the functional properties of the cochlea and the ABR are comparable to those of advanced mammals, albeit with a compressed frequency range. Monotremes also have the mammalian neocortex (see below), although it is not differentiated into as many areas. Furthermore, the corpus callosum, the massive bundle of fibers that connects the two cortical hemispheres in placentals, is absent. At this time, behavioral data on hearing are lacking for monotremes.

About 135 million years ago, marsupials (metatheria) branched off from true placental mammals (eutheria). An extensive comparison of the morphometry of the central auditory system across 53 mammalian species (marsupials and placentals) has been published by Glendenning and Masterton [9]. The smallest species studied was the mole, the largest species the human. While the absolute size of the auditory system varies more than 139-fold among the species, the logarithmic volume of the auditory system is closely correlated to the logarithmic brain weight ($r = 0.903$). However, compared to rather primitive mammals like the marmosa opossum, the kangaroo rat, and bats, humans have the smallest auditory system relative to brain size. A detailed analysis of similarity for the entire ascending auditory pathway resulted in a rank order of species from "least deviant" to "most deviant" to the average auditory system. Surprisingly, species from the same taxonomic group could show up at either end of this spectrum. For example, marsupials: the ring-tail possum has the least deviant auditory system in the tested group of 53 mammals, while the Virginia opossum has one of the ten most deviant. The same holds for the rodents: while the prairie dog has one of the least deviant systems, the mouse has the most deviant of the tested mammals. However, if only a subsystem that is involved in a specific hearing task was compared, the rank orders looked substantially different. One example is the nuclei of the superior olivary complex (SOC), which are involved in sound localization. The least deviant group of mammals in regards to the SOC comprised mostly marsupials, insectivores, bats and rodents. The most deviant group contained mostly primates and predators. The conclusion of the authors is that the overall form of the subcortical auditory system has been relatively unchanged for 135 million years, while some subsystems might have developed into different directions in adaptation to the ecological niches of each species [10].

So far, only the evolutionary aspects of the auditory periphery and the auditory brainstem nuclei have been discussed. How did the auditory cortex evolve? The origin of the mammalian neocortex, in which the auditory cortex is located, has been discussed controversially. For quite some time part of the neocortex was regarded as a ►homologue of the reptilian "dorsal ventricular ridge," which receives auditory and visual inputs from the thalamus. In contrast, more recent studies suggest that all of the mammalian neocortex evolved from the "dorsal pallium" of reptiles, which is mainly a visual and somatosensory structure. This new insight is supported by molecular and developmental evidence [11]. Consequently, the mammalian neocortex would be a "new" target – in an evolutionary sense - for projections from the auditory thalamus. The evolution of the neocortex is paralleled by a gradual general expansion of the brain. This is evident from fossil skull endocasts (molds) of early mammals, e.g., Hadrocodium and Morganucodon. The enlargement of the neocortex has also been associated with the evolution of a "modern" middle ear, which makes sound transmission more effective. Whether these two structures dependently coevolved is questionable. While most early mammals with an enlarged neocortex indeed had a fully evolved middle ear, the reverse is not true. Not every mammal with a "modern" middle ear also has an enlarged neocortex. This makes inconclusive the theory that the enlargement of the neocortex was caused chiefly by more demand for sound processing.

In sauropsids, particularly birds, the auditory part of the pallium has subdivisions with complex interconnections for auditory processing (see ►Evolution, of the Auditory System: in Reptiles and Birds), as is also the case in most mammals. However, the auditory cortex of placental mammals offers even more neural substrates for processing. An evolutionarily "new" neuronal substrate that placentals have is the presence of additional thalamic inputs that bypass the primary auditory cortex (A1) but target certain secondary cortical areas. In primates for example, the caudomedial area of the belt region of the auditory cortex is serially activated by the primary auditory cortex. However, it receives additional extralemniscal and possibly also additional ►lemniscal projections from parts of the auditory thalamus other than the ventral medial geniculate body (MGv), which is the primary projection to A1. Such additional inputs (e.g., MGd) might indicate

a specialization of this area for the processing of certain sound attributes.

Another evolutionary new layer of neuronal processing would be provided the connection between the cortical hemispheres via the corpus callosum. Monotremes and marsupials lack the corpus callosum. Their interhemispheric connections run through the ventrally located anterior commissure, and hence have to cross over a long distance. However, large-brained marsupials like the kangaroo developed interhemispheric cortical fibers ("fasciculus aberrans"), which descend from the subcortical white matter along the internal capsule and then reach the anterior commissure, thus significantly shortening the traveling distance [12]. Nevertheless, the corpus callosum of the placental mammals allows information to travel much more efficiently between the hemispheres, especially between higher-order cortical areas.

To summarize, the relative contribution of different areas of the auditory cortex has not been studied in enough species to clearly reveal an evolutionary trend of specialization for certain sound parameters. However, all mammalian species studied so far (e.g., carnivores, rodents, bats and primates) have in common that the auditory cortex can be divided into a core region of two or three areas and a belt region with additional areas. This seems to be the basic organization retained from a common ancestor. The number of areas varies remarkably across species. Furthermore their relative location and their connections vary. Finally, different physiological properties, especially in highly specialized bat species [13], make it likely that the complex cortical processing system has developed in a quite independent fashion across mammalian taxa. The evolution of the mammalian auditory system in general seems to be driven by ecological needs independent of taxon and common ancestry.

# Evolution of the Auditory System: In Reptiles and Birds

Catherine Carr[1],
Jakob Christensen-Dalsgaard[2]
[1]Department of Biology, University of Maryland, College Park, MD, USA
[2]Institute of Biology, University of Southern Denmark, Odense, Denmark

## Definition

The anatomical organization of the central auditory system is similar across the Reptilia (turtles, lizards, snakes, crocodiles and birds) and physiological studies reveal similar responses to sound. Tonotopic organization, emergence of binaural comparisons, feature detection, convergence of sensory modalities and descending modulation all characterize the reptilian auditory system and are probably ancestral properties. The central auditory systems of both modern reptiles and mammals show

examples of parallel solutions to similar problems of neural coding.

## Characteristics

Whereas the animals traditionally identified as "reptiles" form a paraphyletic or invalid group, Reptilia is a valid clade that includes the snakes and lizards (Lepidosauria), turtles (Testudines), crocodiles (Crocodilia) and birds (Aves) and their most recent ancestors [1]. In Reptilia, the birds, crocodiles and the extinct dinosaurs belong to the group Archosauria and the turtles are a sister group to the archosaurs [2]. The modern consensus is that birds descend from theropod dinosaurs and Aves is therefore a subgroup within Dinosauria. Most extant archosaurs are vocal and birds have provided a major model for studies of complex sound processing and vocal communication. Sensitive, well-developed ears are, however, also found in non-vocal reptilians such as the lizards.

Tympanic ears appear to have evolved independently at least five times in the lines leading to mammals, lepidosaurs, archosaurs, probably turtles and amphibians [3]. The ancestral, atympanic ear would have responded to sound, but the evolution of the tympanic ear increased the sensitivity and high-frequency response of the ears to airborne sound [4]. The emergence of this increased sensitivity to airborne sound would have influenced the organization of ascending auditory information in the central nervous system. The central auditory system is organized similarly in all vertebrates, presumably because it evolved from an ancestral sensory system sensitive to vibration or gravistatic stimuli.

## Auditory Endorgans

Reptilians usually have an external ear and tympanum and one middle ear bone, the columella, which connects the tympanum and the oval window. The eardrums are connected through the interaural canal or mouth cavity and thus can act as pressure gradient receivers. The strongest acoustical coupling of the eardrums is found in lizards and probably reflects the condition of the ancestral tympanic ear [4,5]. Acoustical coupling allows sounds from each ear to interact at the tympanum and leads to the strongly directional responses of the lizard eardrum [5, 6]. Since binaural interaction is already found at the tympanum, every neuron of the auditory system, including the auditory nerve, is binaural. The reduced acoustical coupling found in some birds and all mammals is the result of increasing isolation of the middle ear. Middle ear isolation appears to be a derived feature and profoundly changes the operation of the system. Since the ears are now independent and non-directional, direction must be computed by the central auditory system based on binaural cues generated by neural interaction.

The reptilian ear has a new feature, the elongate basilar membrane. The stereotypical papilla of modern amniotes appears to have begun with the stem amniotes [7]. The papilla is a strip of membrane populated by tonotopically-organized hair cells. Salient features in papilla evolution include lengthening and curvature of the sensory epithelia; features thought to both enhance sensitivity and extend the audible frequency range. Lizards also display a varied and unique population of freestanding hair cells not associated with a tectorial membrane. These freestanding hair cells are thought to be an adaptation that enables lizards to respond to higher frequencies. The low-frequency population of hair cells in lizards is generally similar to that of other amniotes and is probably ancestral [7].

Variation in hair cell type characterize both mammals and archosaurs. The avian and crocodilian basilar membranes do not contain the two types of hair cells found in mammals but instead have hair cells that change continuously in length from short to tall across the papilla. Tall hair cells on the neural edge receive the major afferent innervation [7]. Birds hear higher frequencies than turtles, snakes and lizards [8]. Most birds hear up to 5–6 kHz, while the barn owl has exceptional high frequency hearing, with characteristic frequencies of 9–10 kHz in the auditory nerve, probably as a consequence of specialization for localization of high-frequency sound.

## Central Auditory Pathway Overview

In Reptilia, the auditory nerve enters the brain and divides into two to project to a column of first order auditory nuclei. These projections are tonotopically organized and mediate the emergence of coding for different aspects of the auditory stimulus, such as sound timing and level in birds [9]. The ascending branch of the nerve largely terminates in the nucleus angularis and the descending branch in the nucleus magnocellularis. The nucleus magnocellularis projects to the nucleus laminaris, which in turn projects to the superior olive, to the lemniscal nuclei and to the central nucleus of the auditory midbrain, termed the torus semicircularis or the inferior colliculus. The nucleus angularis projects to the superior olive, to the lemniscal nuclei and to the central nucleus of the auditory midbrain. Thus, the first order nucleus projections contribute to two ascending streams, one binaural combining information from the two ears and the other monaural. The binaural stream is formed when projections from the ipsi- and contralateral nuclei converge on second-order nucleus laminaris that project in parallel with the monaural nuclei to the midbrain. The auditory midbrain receives ascending inputs from both monaural and binaural hindbrain nuclei and physiological studies have revealed the emergence of complex response properties there. The midbrain projects to the thalamus, which in turn projects to auditory structures in the telencephalon. The organization of the telencephalon is structurally and

functionally diverse. In all vertebrate clades, the telencephalon exhibits large changes associated with the increased use of sound for communication. In addition to these ascending pathways, the central auditory system is characterized by multiple descending projections.

## Anatomical Components and Their Physiological Responses in the Central Auditory System

Tonotopic organization is a key feature of the reptilian central auditory system, probably reflecting the tonotopic organization of the auditory papillae. Each point on the basilar membrane projects to an iso-frequency plane across the extent of the first order auditory nuclei. Thus, the cochlear place representation is expanded into a second dimension in the brain, unlike the visual and somatosensory systems, which are point-to-point.

The first order auditory nuclei process parallel ascending streams of auditory information, which will be described starting from the primary auditory nuclei (reviews in [9,10]). In archosaurs, the nucleus magnocellularis is the origin of a neural pathway that processes timing information, while a parallel pathway for processing sound level information originates with the nucleus angularis. Auditory responses in the nucleus angularis in the barn owl include primary-like, onset, chopper and complex type IV responses. Recordings in the chicken cochlear nuclei have found a similar but less clear segregation of function. The similarities between the owl and the chicken suggest that the functional separation of time and level coding is a common feature of the avian auditory system. The anatomical divisions into angular and magnocellular nuclei characterize turtles, lizards and archosaurs [9]. In lizards as in the anurans, the available data suggest that time and level information is not processed in separate streams, maybe due to the strong, but frequency-dependent directional input generated by the acoustically coupled ears [6].

The auditory system uses phase-locked spikes (firing at a certain phase of the stimulus) to encode the temporal parameters of sound. All vertebrate auditory nerve fibers phase-lock to low-frequency stimuli, but the upper frequency limit of phase locking varies from approximately 1–2 kHz in lizards to 9 kHz in the barn owl. The preservation of the phase-locking information in the CNS mediates accurate detection of temporal information. The specialized endbulb terminal in the nucleus magnocellularis, termed an endbulb of Held, has been documented in mammals, birds and lizards and conveys the phase-locked discharge of the auditory nerve fibers to its postsynaptic targets in the nucleus magnocellularis [11]. AMPA-type glutamate receptors contribute to the rapid response of the postsynaptic cell by virtue of their rapid desensitization kinetics [12,11]. In birds, the nucleus magnocellularis projects to the nucleus laminaris, where sensitivity to interaural time differences (ITDs) emerges.

ITD is the principal cue for auditory azimuth representation in birds. There are two stages to ITD computation. It begins with binaural interactions in the nucleus laminaris. There, neurons generate interaural phase difference (IPD) selectivity by coincidence detection between binaural excitatory inputs and encode IPD in a place map according to the Jeffress model [13]. IPDs are an ambiguous coding of ITD, since ITDs that vary by integer multiples of cycle time have identical IPDs. The second stage of ITD computation occurs in the inferior colliculus, where across-frequency integration filters phase-ambiguous side peaks, forming neurons that respond mainly to the true ITD [14]. ITD computations are modulated inhibitory feedback via the superior olive. Both the nucleus laminaris and the nucleus angularis project to the superior olive, the lemniscal nuclei and the inferior colliculus. The superior olive projects to the inferior colliculus and also provides inhibitory GABAergic feedback to the nucleus magnocellularis, the nucleus laminaris, and the nucleus angularis. This olivary input appears to provide tonic inhibition, in contrast to the inhibitory projections of the mammalian MSO that provide phase locked inhibition [13]. The GABAergic input in birds appears to maintain the coincidence detector in the optimal range of operation.

The interaural level difference pathway begins with the nucleus angularis, whose neurons respond to changing sound level over about a 30 dB range. The nucleus angularis sends an excitatory projection to the contralateral dorsal lemniscal nucleus, which also receives an inhibitory projection from the opposite dorsal lemniscal nucleus. In the barn owl, this dorsal lemniscal nucleus (also called VLVp) mediates detection of interaural level differences. Sensitivity to interaural level differences emerges through the interaction between the excitatory and inhibitory inputs to neurons of the dorsal lemniscal nucleus. These neurons do not encode elevation unambiguously and are therefore described as sensitive to interaural level difference. More selective responses arise in the auditory midbrain [14]. There are two identified lemniscal nuclei in lizards and turtles (dorsal and ventral) and three in birds (dorsal, intermediate and ventral). They receive input from the first order auditory nuclei and from the nucleus laminaris and project to midbrain, thalamic and telencephalic targets [9].

The reptilian auditory midbrain is termed the torus semicircularis or inferior colliculus and is homologous to similarly named structures in all other vertebrates. It receives ascending input and projects to the thalamus. In birds the auditory midbrain is surrounded rostrally and laterally by an intercollicular area that receives descending input from the forebrain arcopallium [15]. The inferior colliculus is a major center for auditory processing, while the intercollicular area appears to mediate vocalization and other auditory-motor

behaviors. The inferior colliculus is divided into an external nucleus and a central nucleus that receives ascending projections from the nucleus angularis, the lemniscal nuclei and the nucleus laminaris [15]. Interaural time difference and interaural level difference signals are combined and the combinations conveyed to the external nucleus, which in the barn owl contains a map of auditory space [14]. Studies of the owl auditory midbrain have shown that most neurons are binaural, excited by inputs from the contralateral ear and inhibited by the ipsilateral ear, although bilateral excitation and contralateral excitation are also present. Many neurons are sensitive to changes in interaural level and time difference. The tonotopic organization in birds is consistent with that observed in lizards and crocodiles, with low best frequencies being represented dorsally.

Recordings from the midbrain in barn owls and songbirds show the emergence of biologically relevant responses. Barn owls are nocturnal predators with excellent sound localization ability [16] and their midbrain responses are dominated by computations directed to localization. Most barn owl inferior colliculus neurons are binaural and many are sensitive to changes in interaural level and time differences. Physiological properties are subdivision specific and reflect the inputs to each subdivision. The central nucleus projects to both the auditory thalamus and the external nucleus. Space-specific responses emerge in the external nucleus [14,16]. The external nucleus projects topographically to the optic tectum, which contains aligned maps of visual and auditory space. Activity in the tectum directs the rapid head movements made by the owl in response to auditory and visual stimuli [17]. In the zebra finch midbrain, recordings show strong onset responses and encoding of temporally modulated signals and it appears that selectivity for specific song-related spectrotemporal properties emerges in the midbrain [15].

The central nucleus of the auditory midbrain projects bilaterally to a dorsal thalamic region made up of a central nucleus surrounded by a shell [10]. The core and shell receive ascending input from the central nucleus and from the lemniscal nuclei, respectively. In both birds and crocodilians, the core and shell thalamic regions project to separate, non-overlapping regions of the telencephalon, suggesting a basic division of auditory input to the telencephalon into two separate streams. Although the connections and dorsal thalamic locations are consistent throughout amniote phylogeny, suggesting that these structures are homologous, the anatomical terminology differs. The dorsal thalamus is called nucleus reuniens in turtles, nucleus medialis in lizards and crocodilians and nucleus ovoidalis in birds. The nucleus ovoidalis is tonotopically organized, with high best frequencies located dorsally and low best frequencies ventrally. In the barn owl, all divisions of the central nucleus project to the nucleus ovoidalis and the physiological responses in the ovoidalis reflect this diverse array of inputs. Most neurons respond to interaural time difference and/or interaural level difference at stimulus frequencies similar to those found in the midbrain. In contrast to the mapping found in the midbrain however, the nucleus ovoidalis contains no systematic representation of sound localization cues. Nevertheless, sound localization and gaze control are mediated in parallel in the midbrain and forebrain of the barn owl [14].

In birds, Field L is the principal telencephalic target of ascending input from ovoidalis [18]. It is a component of the nidopallium and is divided into three parallel layers, L1, L2 and L3. Auditory units in L2 generally have narrow tuning curves with inhibitory sidebands, which might be expected from their direct input from the dorsal thalamus, while the cells of L1 and L3 exhibit more complex responses in the guinea fowl. The general avian pattern is that Field L projects to the adjacent nidopallium and to other nuclei of the caudal nidopallium. Auditory targets of Field L (direct and indirect) include dorsal nidopallium in the pigeon, HVC in songbirds and ventrolateral nidopallium in budgerigars. These nidopallial nuclei project to the auditory areas of the arcopallium (AIVM, RA), which project back down to the auditory thalamus and midbrain [9].

## Forebrain and Birdsong

Song systems have evolved in parallel in songbirds, parrots and hummingbirds. In all groups, the dependence on auditory learning has led to changes in telencephalic structures that have been related to song learning and production. In oscine songbirds the song system is composed of an anterior and a posterior pathway. The posterior pathway is required throughout life for song production and is composed of a circuit from HVC (the higher vocal center) to the robust nucleus of the arcopallium and then down to the motor nuclei that control the syrinx and respiration. The anterior forebrain pathway is a basal ganglia-forebrain circuit critical for both song learning and adult modification of vocal output. It projects to the posterior pathway and provides a guiding influence on the developing vocal motor program. A revision of the avian anatomical nomenclature has provided a common language for studying the function of the cortical-basal-ganglia-cortical loop, enabling neuroscientists to take advantage of the specialization of basal ganglia areas in various birds [19]. In both birds and mammals, the basal ganglia contain similar cell types, which project to the midbrain substantia nigra and globus pallidus and receive a major glutamatergic input from the overlying pallium, dopaminergic input from midbrain and a lesser glutamatergic input from thalamus. These two types of striatal projection neurons, a substantia nigra and a globus pallidus are present in all jawed vertebrates, supporting the idea that the basal

ganglia performs a fundamental role in telencephalic function [20]. Studies of the role of the anterior pathway in auditory learning are illuminating the interaction between sensory, motor and reward signals in the basal ganglia and the function of these signals in task learning and execution.

# Evolution of the Brain in Mammals

Jon H. Kaas
Department of Psychology, Vanderbilt University, Nashville, TN, USA

## Definition

The brain is the part of the central nervous system that is inside the skull. Major parts include the hindbrain, midbrain, and forebrain. In mammals, the neocortex comprises the largest portion of the rostral part of the forebrain, the telencephalon, and, with its distinctive six layers and particular cytoarchitecture, is the hallmark of the mammalian brain. Other parts of the mammalian brain, including the diencephalon and cerebellum, are also enlarged and elaborated in comparison to the brains of most other vertebrate groups. In contrast, the more basal parts of the midbrain and hindbrain have been more conservative in their evolution.

## Characteristics

The brain is the part of the nervous system that is enlarged and elaborated in mammals compared to other amniotes. This enlargement and elaboration is especially great in some lines of mammalian evolution, and the enlargement mostly involves the forebrain, especially the neocortex. Thus, the neocortex is a part of the brain that varies greatly in size across mammals. In addition, the neocortex is subdivided into a number of functionally distinct regions called areas. Mammals with the smallest brains have an estimated 15–20 cortical areas, while humans have as many as 150. While the mammalian brain has evolved in many other ways, the most dramatic changes have involved a disproportionate enlargement of the forebrain,

especially neocortex, and a ten-fold increase in number of functionally distinct areas.

## The Brains of Early Mammals

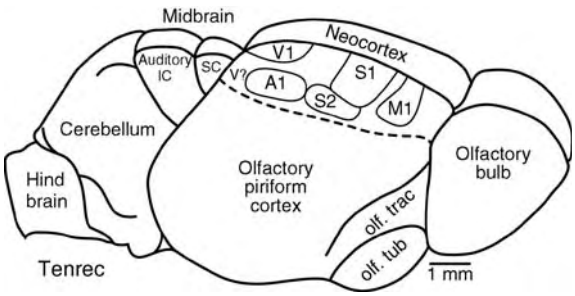
Early mammals, some 150–200 million years ago (mya) were generally small, cat-to-mouse sized, and nocturnal. Their brains were small, as brain size scales with body size, but their brains were especially small for mammals [1]. Over the course of over 200 million years of mammalian evolution, a common trend has been toward an increase in brain size relative to body size. In some lines of evolution, the increase has been dramatic, while in a few lines of evolution the brain appears to have enlarged little, if at all. What we know about the sizes of the brains of early mammals comes from the fossil record, as the internal shape of the skull, that is the brain case, closely reflects the size and shape of the brain in mammals [2]. However, as the soft tissue of the brain itself is not preserved in the fossil record, internal organizations of the brains of early mammals cannot be known directly, but only inferred from the brain features present in the species of mammals that exist today. In practice, the brains of those species of mammals that have retained a small brain, much like the brains of early mammals in size, appear to provide the closest picture of the internal organizations of early mammal brains. The accepted formal approach in evaluating this assumption is called a cladistic character analysis in which brain features or characters are compared across a group of related species to estimate which of the features have been retained from an early, common ancestor [3,4].

The brain of a small tenrec, a nocturnally active insectivore-like mammal from the island of Madagascar in the superorder Afrotheria, serves as a model of the brain of an early mammal (Fig. 1).

In this dorsolateral view of the brain, the peripheral nerves and spinal cord have been removed so that the main parts of the brain can be more easily appreciated. Only the caudal part of the brainstem (where it was separated from the spinal cord), that is, the hindbrain, and the roof (tectum) of the midbrain are apparent, as the cerebellum covers much of the lower brainstem (hindbrain). The tectum of the midbrain includes the sensory processing stations, the inferior colliculus for auditory processing and the superior colliculus for visual processing. The midbrain is adjoined rostrally by the diencephalon, which includes the thalamus and the basal ganglia, which are within the ventral part of the telencephalon and are covered by the cortex, and thus, cannot be seen in this external view. The rostral end of the brain is formed by the olfactory bulbs.

Because the proportions of brain parts and the size of the brain relative to body size in tenrecs closely compare to those estimated from the fossils of early mammals, many of which were also nocturnal or crepuscular, some general conclusions about the brains of early mammals are justified. Most notably, early mammals devoted much of their brain to processing olfactory information. Thus, the olfactory bulb and the more caudal olfactory (piriform) cortex are very large in proportion to the rest of the brain. Olfaction was and remains important for many mammals [6] particularly in the nocturnal environment, for being able to find food and mates, while detecting predators and competitors.

In addition, neocortex was a proportionately small part of the brain in early mammals. This is especially relevant because primates in general, and humans in particular, have devoted a huge proportion of their brains to neocortex [7]. Neocortex is a multilayered sheet of tissue that evolved from a simpler structure in stem amniotes that is homologous, at least in part, to the dorsal cortex of reptiles, to become the most variable part of the brain in mammals [8]. In all mammals, neocortex is divided into functionally distinct regions, the cortical areas. Comparative studies of extant mammals indicate that some of these areas, 15–20, were present in early mammals. These areas include the primary and secondary visual areas, V1 and V2, primary and secondary somatosensory areas,



**Evolution of the Brain in Mammals.**

**Figure 1** A dorsolateral view of the brain of a Madagascar tenrec (*Echinops telfairi*) a small Afrotherian mammal. In this mammal, the forebrain is dominated by a large olfactory bulb and a large (relative to the rest of the brain) olfactory (piriform) cortex. Note also the olfactory (olf.) tract and tubercle (tub.). Piriform cortex is capped by a small expanse of neocortex, which contains several functionally distinct areas, including primary visual cortex, V1, the second visual area, V2, a primary somatosensory area, S1, a second somatosensory area, S2, a primary motor area, M1, and a primary auditory area, A1. There are other, less well-identified areas; perhaps 15 areas exist in this mammal. As the neocortex is small, it does not extend caudally to cover the midbrain, as it does in most mammals, so the inferior colliculus (IC) and superior colliculus (SC) of the tectum (roof) of the midbrain can be seen. The cerebellum covers the mid portion of the brainstem. Based on Krubitzer et al. [5].

S1 and S2, and at least one auditory area, A1. Although these areas, as well as subdivisions of cingulate cortex and orbital frontal cortex, existed, they were not well differentiated into layers and specialized cell types, suggesting little functional specialization. Surprisingly, a primary motor cortex apparently was not present and did not appear until the evolution of placental (Eutherian) mammals [9]. The dorsal thalamus, which is directly interconnected with neocortex, providing the sensory activation of neocortex, was also less extensively differentiated. Thus, early mammals did not depend much on neocortex, which was devoted to rather simple sensory-perceptual functions. The minor role that neocortex had in motor control was mediated through somatosensory areas.

Other parts of the brains of early mammals were small but not remarkably so in relation to body size. The brainstem, especially, is often used as an index for the disproportionate growth of other parts of the brain. This is because it maintains a roughly similar size in proportion to the size of the mammal in evolution, although structural modifications have occurred. The midbrain size varies, with an emphasis on the size of the inferior colliculus in mammals relying most on hearing, as in echolocating bats, and an emphasis on the size of the superior colliculus in some visually dependent mammals, such as squirrels where the superior colliculus is ten times larger than expected for their body size. However, major changes in the proportions of the midbrain are unusual. The cerebellum, with functional ties to the neocortex varies in size with neocortex. Although, as they both increase in size, the size of the cerebellum increases less than that of the neocortex. However, the small sizes of the microneurons (granule cells) of the cerebellum, allows the number of neurons in the cerebellum and neocortex to remain roughly proportional with increases in cortical size. This is because mammals with larger brains have greater increases the sizes of cortical neurons than cerebellar neurons [10].

## How Brains have Evolved in the Great Mammalian Radiation

Over the last 200 million years or so, mammals have differentiated into six major superorders [11], and approximately 4,500 extant species. The fossil record indicates that over much of their early history, mammals did not change very much. While forming the body plans of the major divisions (monotremes, marsupials, and placentals), the brains did not enlarge or specialize in many ways. However, with the extinction of the "ruling reptiles," 65 mya, many environments became open to mammals, allowing for rapid diversification, as modifications in their brains, especially in neocortex, allowed them to exploit the many new opportunities.

Many of the changes involved specializations of sensory systems that involved only modest overall increases in brain size. Thus, echolocating bats became successful as their auditory system evolved to become sensitive to echo frequencies, and specialized cortical areas emerged to analyze the information obtained from these echoes. Many other mammals exploited the information obtained from bending hairs on the surface of the body, and used long vibrissal hairs on the face, or on other parts of the body to detect objects at short distances. They used this information via computations in specialized somatosensory systems to guide prey capture, as in cats, or environmental exploration, as in rats. The nose was modified in the line leading to the star-nosed mole to produce 22 fleshy and mobile appendages covered with specialized receptors, Eimer's organs, that activate a highly specialized sensorimotor system used to detect and capture small prey [12]. The strange Australian mammal, the platypus, which is a monotreme, evolved receptors for electroreception on its bill-like snout, and modified the somatosensory system and cortex for electroreception to find prey in murky streams [13]. Likewise, the other genus of monotremes, echidnas, also has electroreceptors on their snouts [14]. Tarsiers, survivors of an early branch of primate evolution, depend on extremely large eyes to see in dim light, and a highly differentiated and proportionately large primary visual cortex to mediate its unique primate roll as a visual predator of small invertebrates and vertebrates [15].

In these and other examples, specializations within a system and their related neocortical components have occurred, rather than global changes in the brain. The specializations include enlargements of the behaviorally relevant parts of the systems, and structural differentiations of the relevant parts so that neuron types, modules of neurons and classes of layers emerge to expand and vary functions of the systems. In addition, new connections, new cortical areas, and subcortical nuclei, may be added to the systems.

In other instances, brain changes have been more global, as brains evolved to permit behavior that is more flexible. The larger brains of primates are characterized by a proportionately larger neocortex, especially in humans and other highly social primates [7]. This suggests that much of neocortex in these primates is not just processing sensory information for immediate action, and programming the skillful movements needed in the actions, but is involved in calculating the benefits of various alternative behaviors in a complex social environment. Many types of information have to be extracted from the ongoing behaviors of others and related to past behaviors. Primates seem to have accomplished this by greatly expanding some parts of the brain, mainly by adding a great number of processing areas, thereby increasing the steps in serial

processing sequences, and increasing the number of pathways through variously specialized processing systems (areas and nuclei). The number of cortical areas devoted to processing mainly visual information increased from 4–5 in early mammals, to 15–20 in prosimian primates, to 30–40 in macaque monkeys, and to over 50 or so in humans [16]. Especially in social primates, the frontal lobe expanded and subdivided, allowing for planning for the future [17]. The frontal motor system became enlarged and more complex with the addition of premotor and cingulate motor areas, fields were added to somatosensory cortex, and posterior parietal cortex became large and subdivided into motor planning areas, especially those for using the valuable visual information that guides the social behavior of primates [18]. To some extent, similar changes took place in other social mammals, such as wolves, but they were less extensive.

## Conclusions

In summary, the brains of mammals have differentiated from those of early mammal ancestors in many ways. Various brain parts have selectively enlarged, and whole brain regions have enlarged. Parts have differentiated by the gain of new neuron types and aggregates of interconnected neuron modules and layers enabling specialized subfunctions. New areas and nuclei have been added to systems, most probably by differentiation from existing structures. Connections between structures have changed, sometimes via losses [19] and sometimes by invading other parts of the brain. While the local modifications in brain organization are the most notable, these changes imply widespread alterations in brain structure and function. As sensory-perceptual systems become more sophisticated, the use of the additional information requires modification in memory systems, motor control, motor programs, and decision-making circuits. The less changed brainstem circuits are likely to be altered along with the more modified cortex, as both brain regions contribute to the integrated systems guiding behavior.

# Evolution of the Brain in Reptiles

Laura L. Bruce
Department of Biomedical Sciences, School of Medicine, Creighton University, Omaha, NE, USA

## Definition

The brain consists of a forebrain, midbrain, and hindbrain. Among reptiles, the degree to which the forebrain, particularly its upper part, the pallium, is elaborated varies. Turtles, the tuatara *Sphenodon*, and some lizards have relatively modest pallial specializations; snakes and other lizards have a greater degree; and crocodiles exhibit the most specialized pallium. The roof of the midbrain, the tectum, is well developed

in all reptiles, whereas the roof of the hindbrain, the cerebellum, is much more modestly developed than it is in mammals and birds.

## Characteristics

The major regions of the brain are the hindbrain, midbrain, and forebrain; the latter is composed of the diencephalon and telencephalon (Fig. 1).

These regions are present in all tetrapods and probably in all vertebrates, although interspecies comparisons reveal anatomic and physiologic diversity. Among tetrapods, there has been an evolutionary trend of increased size and complexity in thalamic and telencephalic regions since the transition of amphibians to stem amniotes. As a result, hypotheses about the homologues of thalamic and pallial regions in amphibians, reptiles, and birds are in general agreement, but comparisons with mammalian regions have proven more difficult and more controversial. This difficulty comparing homologous forebrain regions between mammals and other tetrapods may be related to their divergent evolutionary history. The anapsid line of stem amniotes gave rise to two independent lineages, first the synapsid line to mammals and later the diapsid reptilian line, which gave rise to all living reptiles and birds (see ►Evolution, and ►Phylogeny of Amniotes). The following paragraphs describe some of the characteristics of reptilian brains and their relationships to other vertebrates.

### Hindbrain

The organization of the reptilian hindbrain is fairly similar to that of amphibians, birds, and mammals. The same major components, including sensory and motor cranial nerve nuclei and reticular nuclei, are found in all tetrapods. The nuclei vary, however, in their size and rostral to caudal spread. For example, the rostral limit of each motor nucleus is similar, but the caudal limit may differ by one or more rhombomeres. Comparisons of motor nuclei suggest that the trigeminal (V), facial (VII), and octavolateral efferents (VIII) are particularly variable (see ►Evolution, ►of the Hindbrain, ►Evolution, of the Cranial Nerves).

One notable brainstem specialization is unique to infrared-detecting snakes [1]. In pythons and rattlesnakes infrared is detected by pit organs near the mouth, which are innervated by branches of the trigeminal nerve. This infrared information reaches a unique brainstem region, nucleus caloris, which evolved as a specialized region of the brainstem reticular formation.

### Midbrain

In reptiles the roof, or tectum, of the midbrain (Fig. 2) includes three regions that integrate sensory information: the optic tectum (with visual information superficially and somatosensory information in deeper layers), the somatosensory subdivision of torus semicircularis, and the auditory subdivision of torus semicircularis. Homologues of all three regions have been identified in amphibians, birds, and mammals.

The reptilian optic tectum is homologous to the mammalian superior colliculus. The superficial neurons receive a direct retinal projection and are exclusively visual. The deeper neurons integrate visual information with somatosensory, and probably auditory and limbic, information. In rattlesnakes, the optic tectum contains neurons that respond to infrared stimuli, related to their infrared-detecting specializations [1]. Stimulation of the optic tectum elicits directional head movements, indicating that it contains a motor map in addition to the sensory maps. The reptilian optic tectum sends sensory information to two thalamic nuclei, a minor projection to nucleus dorsolateralis and a robust projection to nucleus rotundus (Figs. 2, 3b) [2,3,4,5]. The auditory and

somatosensory parts of torus semicircularis also project to two thalamic targets. The auditory torus projects sparsely to the nucleus dorsolateralis and robustly to nucleus medialis (Figs. 2, 3a), and the somatosensory part of torus projects to nucleus dorsolateralis and nucleus medialis posterior (Figs. 2, 3c) 2,3,4,5].

## Diencephalon

The reptilian diencephalon consists of the epithalamus, dorsal thalamus (sometimes called thalamus), ventral thalamus, and hypothalamus. This section focuses on the hypothalamus and dorsal thalamus, which have been studied extensively.

### *Hypothalamus*

The reptilian hypothalamus contains multiple neuronal groups with diverse functions. It is crucial for regulating behaviors and involuntary functions that are essential for survival. These functions include feeding, temperature regulation, body fluid homeostasis, diurnal rhythms,

autonomic responses, and reproductive behaviors. The same major functional and anatomical regions identified in the reptilian hypothalamus are also present in birds and mammals, as are the histochemical expression patterns and the interconnections with other parts of the brain, notably the amygdala, septum, and brainstem. These critical hypothalamic systems apparently evolved in earlier vertebrates and then were largely conserved through subsequent evolutionary stages (see ►Evolution, of the Hypothalamus: in Amniotes, ►Evolution, of the Hypothalamus: in Anamniotes).

### *Dorsal Thalamus*

The dorsal thalamus consists of nuclei that are connected with the telencephalon (Figs. 3, 4).

Their homologues in amphibians and birds are commonly agreed upon, but the mammalian homologues are more controversial. There are two main hypotheses of dorsal thalamic evolution (Table 1), which are based mainly on divergent interpretations of some of the telencephalic targets of two major sensory thalamic groups in reptiles and mammals. Hypothesis A compares the reptilian dorsal cortex to some sensory and all limbic cortical regions in mammals, and the DVR to the mammalian lateral sensory cortical areas [6,7]. Hypothesis B considers the reptilian dorsal cortex to be the homologue of all mammalian cortical areas except the hippocampus and olfactory cortices, and the reptilian dorsal ventricular ridge (DVR) the homologue of the mammalian pallial amygdala [8,9]. The identification of thalamic homologues is consistent with the telencephalic homologues proposed by each hypothesis.

General organization of the thalamus. The reptilian dorsal thalamus consists of three major groups, as well as several smaller groups. The three major groups can be characterized by their connections [2,4,5,8,10] as follows (Figs. 2, 3 and 4).

(1) A visual nucleus that receives a direct retinal projection and projects to the dorsal cortex, called the dorsal lateral geniculate nucleus.
(2) Nuclei that predominantly receive projections directly from the spinal cord, dorsal columns, trigeminal nuclei, and hypothalamus, as well as sparse projections from the midbrain tectum and torus semicircularis, and in turn project mainly to the dorsal cortex in the pallium. The nucleus dorsolateralis is the main component of this group in reptiles.
(3) Nuclei that receive robust visual, somatosensory, and auditory projections from the midbrain roof (tectum and torus semicircularis) and in turn project mainly to the striatum and dorsal ventricular ridge in the pallium. Nuclei rotundus, medialis posterior, and medialis (called reuniens in turtles and crocodiles) are the main components of this group in reptiles.

Evolutionary considerations of thalamic homologies. Most comparative neurologists consider the dorsal lateral geniculate (LGD, group 1) to be homologous to the mammalian dorsal lateral geniculate [10]. There are, however, two divergent hypotheses about the mammalian homologies of thalamic groups 2 and 3 (Table 1). These are based mainly on the interpretations of some of the telencephalic targets of two major sensory thalamic groups in reptiles and mammals.

Hypothesis A, proposed by Butler [6,7], compares the reptilian cortex to all motor and limbic cortical regions and to only the primary sensory visual and

somatosensory cortical areas of mammals, and compares the DVR to the primary sensory auditory area and to visual, somatosensory, and auditory association areas of the mammalian cortex, plus the mammalian pallial amygdala. Thus, Butler includes both the reptilian nucleus dorsolateralis (thalamic group 2) and nucleus dorsomedialis in the same thalamic group and compares them to the mammalian anterior, ventral, and medial thalamic nuclei. Along with the LGD, she names these the "lemnothalamic nuclei" because they receive mainly direct sensory and limbic projections. Butler also compares the predominantly tectal and toral recipient nuclei (thalamic group 3) to the mammalian lateral posterior, posterior, medial geniculate, and amygdalar-projecting (perigeniculate) thalamic areas. She names these the "collothalamic nuclei" because of their predominant input from the midbrain colliculus (tectum).

Hypothesis B, originally proposed by Bruce and Neary [8,9], considers the reptilian cortex to be comparable to all mammalian cortical areas, and the reptilian dorsal ventricular ridge (DVR) to be comparable to the mammalian pallial amygdala. This hypothesis proposes that the reptilian nucleus dorsolateralis (thalamic group 2) is homologous to the mammalian anterior, ventral posterior, lateral posterior, and posterior, plus the parts of the medial geniculate that project to the cortex (Table 1).

Furthermore, the predominantly tectal and toral-recipient thalamic nuclei (rotundus, medialis, and medialis posterior; thalamic group 3) are comparable to the mammalian perigeniculate sensory thalamic groups that project to the pallial amygdala. Further studies of the development of thalamic regions and their connections are required in order to resolve which of these two hypotheses is correct.

## Telencephalon

The reptilian telencephalon is composed of pallial and subpallial regions; the latter includes striatal and pallidal components. The major components of the pallium include the medial cortex, dorsal cortex, lateral cortex, and dorsal ventricular ridge.

### *Subpallium*

The subpallial telencephalon includes the striatal area and the pallidum laterally and the septal nuclei medially. The striatal area contains homologues of

the mammalian striatum and central amygdaloid nucleus, and the pallidum includes homologues of the mammalian globus pallidus and ventral pallidum. The reptilian striatum and globus pallidus are organized similarly to those of birds and mammals. They have similar connectional, developmental, and histochemical characteristics in all amniotes [11]. However, they are much larger than in the amphibian condition, suggesting that they increased dramatically in size from their anamniote ancestral condition. The septal nuclei are largely comparable across amniotes and other vertebrates (see ►Evolution, ►of Septal Nuclei).

### *Pallium*

The medial, dorsal, and lateral cortices are comparable to the mammalian hippocampus, general cortex (including part or all of neocortex), and olfactory cortex, respectively. Although the dorsal cortex of reptiles lacks the discrete lamination pattern seen in mammalian neocortex, it is the target of ascending auditory, visual, and somatosensory pathways (Fig. 3) and has similar connectional, developmental, and neurochemical expression patterns as neocortex. The reptilian dorsal cortex is the homologue of the avian Wulst plus the adjacent dorsolateral corticoid area. The dorsal cortex receives visual, somatomotor, auditory, and limbic inputs from the thalamus (Fig. 3, 4). The reptilian DVR contains auditory, visual, and somatosensory regions, as well as a region that projects to the ventromedial hypothalamus, and another that projects to the lateral hypothalamus [2,4,5,9]. The dorsal ventricular ridge (DVR) of reptiles is clearly homologous to the ventral part of the lateral pallium in amphibians and to the nidopallium in birds [8,9,12,13], but its relationship to the mammalian brain remains controversial.

Two distinct patterns of neural organization occur in the DVR of living reptiles [2,5]. The ancestral type is characterized by a plate of neurons adjacent to the ventricle and a central core with few neurons, typical of most turtles, rhynchocephalians (tuatara), and some lizards, including geckos, lacertids, anguids, and skinks. In the derived type, neurons are scattered throughout, and there is no distinct cell plate. This condition occurs in iguanas, chameleons, varanids, snakes, and crocodilians and also in birds; it thus evolved independently in at least two lineages, one lineage leading to crocodilians and birds, the thecodonts, and another, within squamates, to some lizards and snakes.

Evolutionary considerations of pallial homologies. The reptilian dorsal cortex is considered to be homologous to some or all of the mammalian neocortex by most comparative neurologists. However the mammalian homologues of the reptilian dorsal ventricular ridge (DVR) are highly controversial. There are three distinct hypotheses that are widely discussed by comparative neurologists: the cortical layer hypothesis, the lateral cortex hypothesis, and the amygdalar hypothesis.

The cortical layer hypothesis, first proposed by Karten in 1969 [14], suggests that large groups of neurons within the DVR are homologous to neurons located in particular layers of the mammalian cortex. Thus, neurons in the DVR that receive thalamic projections resemble those of mammalian cortical layer IV, neurons in the rostral DVR that receive inputs from the latter and project to the posterior DVR resemble intercortical neurons of mammalian cortical layers II-III, and the latter in turn project to neurons in the posterior DVR that project to the thalamus and brainstem and therefore resemble those in mammalian cortical layers V and VI. The lateral cortex hypothesis, first proposed by Butler [7,15], contends that the DVR is homologous to the developmentally lateral parts of neocortex. These include auditory, extrastriate visual, and association insular cortices, which are the predominant targets of the tectal-recipient thalamic nuclei, as well as parts of the pallial amygdala. The DVR-pallial amygdala hypothesis, first proposed by Bruce and Neary [8,9,12,13], argues that the parts of the DVR receiving sensory thalamic input are homologous to the mammalian lateral amygdaloid nucleus, which also receives sensory thalamic input, whereas the parts of the DVR projecting to diencephalon and brainstem are homologous to the basomedial and basolateral amygdaloid nuclei. This hypothesis is based on the numerous connectional, neurochemical, gene expression, and topological similarities between the reptilian and avian DVR and the mammalian pallial amygdaloid nuclei. Further comparative studies using a combination developmental, genetic, and neurochemical approaches are needed to determine the evolutionary history of the reptilian pallium.

# Evolution of the Brain in Amphibians

Walter Wilczynski
Center for Behavioral Neuroscience and Department of Psychology, Georgia State University, Atlanta, GA, USA

## Synonyms

Amphibians; Brain evolution

## Definition

The general structure and functional organization of the amphibian brain includes several apparently primitive features (such as a small size and relatively little cell migration and areal differentiation, these being less severe in ►anurans than in other amphibians) as well as the standard major brain areas and basic connectional patterns found in all vertebrates. Evolutionary specializations are also apparent, especially in anurans where expanded visual and auditory midbrain areas are present. The forebrain contains many of the basic vertebrate systems and general organization of connections, but the functional organization of sensory systems is quite different from the familiar pattern seen in mammals, birds and reptiles.

## Characteristics

Modern day amphibians are represented by three groups, the anurans, i.e., the frogs and toads, the ►urodeles, i.e., the tailed amphibians including salamanders and newts and the ►apodans or ►gymnophiones, an unusual and relatively small group of legless amphibians [1]. The groups are similar in having (at least) two distinct life stages including an early aquatic tadpole stage followed by metamorphosis into a radically different adult form. As adults the three amphibian groups have quite different body forms and behavioral ecology characteristics that are, no doubt, reflected in neural specializations. For example, all anurans with the exception of the most primitive have their adult social behavior driven by acoustic signals, while urodele social interactions are guided by olfactory and visual communication. Locomotion is highly specialized in anurans and the burrowing, fossorial apodans. Despite specialized features, common structural characteristics mark all amphibian brains, including a small brain to body ratio as well as less cell migration in most brain divisions and less differentiation into distinct structural and functional divisions than in larger brained vertebrates. Interestingly, amphibians share these characteristics with the lobe-finned lungfish and the most primitive ray-finned bony fish and sharks. Because of this, and because of the amphibians' position as living representatives of the ancestral vertebrates giving rise to reptiles, birds and mammals, amphibian brains have often been used as surrogates for the primitive condition from which the more advanced brains of amniotes evolved. In broad anatomical terms, there is probably some validity to this. In terms of the fine structure and the physiological and functional organization that go with it, such assumptions are riskier. Both the anurans and the apodans are highly derived vertebrate groups and therefore considering any particular brain character found in either as primitive should be done with extreme caution.

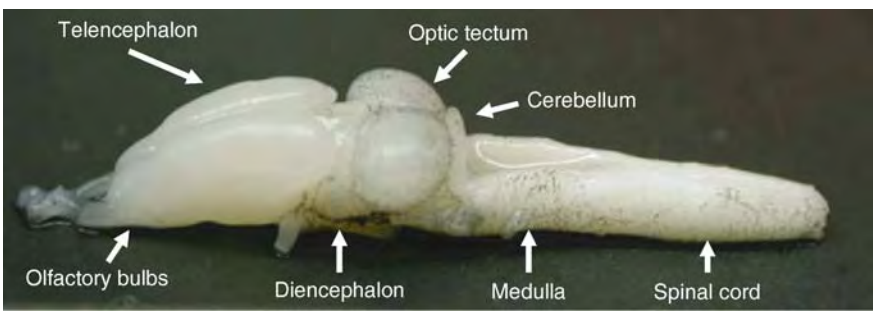
### Brain Size and General Structure

Overall brain size (relative to body size) in amphibians is small compared to that of mammals and birds, falling within the range of other anamniotes such as fish [2]. Salamanders and newts have exceptionally small brains even for amphibians and seem to have undergone

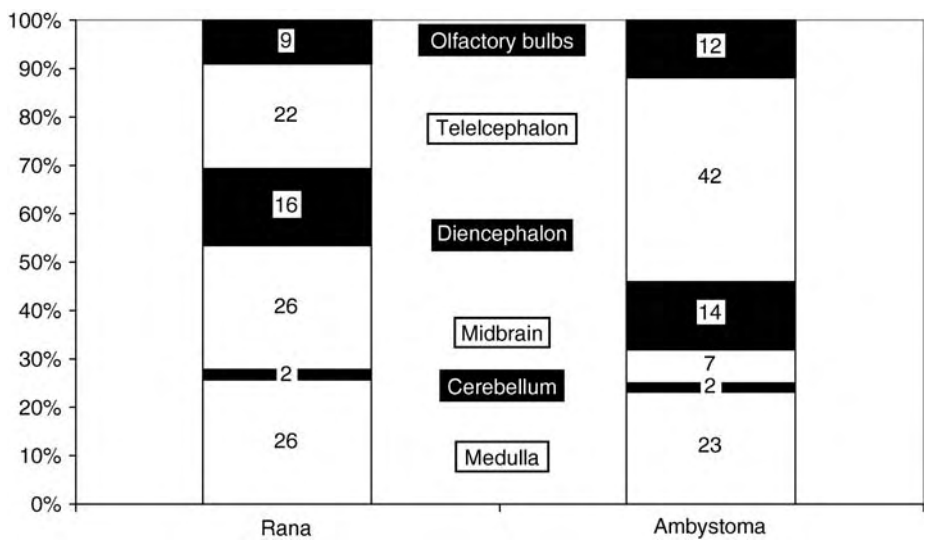
an evolutionary reduction in brain size [2]. The amphibian brain has an elongated appearance in which the major vertebrate brain divisions are clearly visible (Fig. 1).

The medulla lies caudally and has the usual complement of motor and sensory areas. The cerebellum is apparent between the medulla and midbrain. It is curiously small in all amphibians. It is not clear whether this is a primitive trait or the result of a secondary reduction. These brain areas are relatively conserved across amphibian groups in their size and general appearance. The midbrain is large in anurans relative to the other amphibian groups due to an expanded optic tectum and torus semicircularis, which are homologous to the mammalian superior and inferior colliculus respectively. The forebrain, with diencephalic and telencephalic divisions, occupies the most rostral portion of the brain. The telencephalic hemispheres appear as elongated cylinders with prominent ventricles, extending rostrally to terminate in main and accessory olfactory bulbs. Although older texts often present amphibian brains as being dominated by the midbrain with a small olfactory telencephalon, the forebrain (telencephalon and diencephalon, excluding olfactory bulbs) in fact represents about 40% of the total brain volume in anurans and about 56% in urodeles (Fig. 2).

Olfactory input into telencephalic areas is indeed extensive, but amphibians have the normal complement of vertebrate sensory systems, all of which make connections to diencephalic nuclei and ultimately the telencephalon. It is true that the functional organization may be quite different in amphibians compared to other tetrapods (see below), but the basic pattern of multiple sensory inputs – vision, hearing, somatosensory – reaching the forebrain along with olfaction is now recognized as common to all vertebrates.



**Evolution of the Brain in Amphibians. Figure 1** Photograph of an anuran brain (the green treefrog, *Hyla cinerea*). Major brain divisions are indicated.



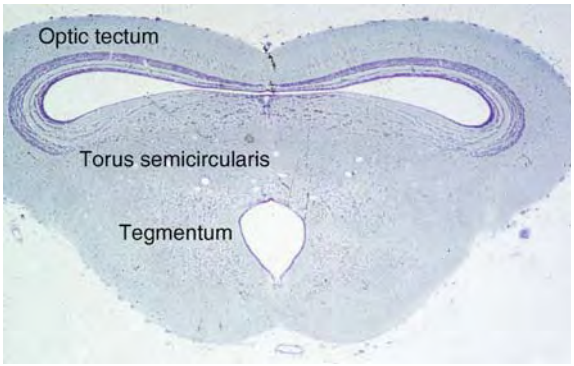
**Evolution of the Brain in Amphibians. Figure 2** Relative sizes of brain divisions in an advanced anuran (the bullfrog, *Rana catesbeiana*) and a urodele (*Ambystoma sp.*). Percent of total brain volume is indicated by the numbers in the boxes. Data from Northcutt et al. [3].

The general structure of the forebrain is, at a gross level, so clearly organized into the fundamental divisions familiar to all neuroanatomists that it has often been viewed as a representation of a primitive vertebrate ►bauplan. The diencephalon is composed of four divisions oriented dorsal to ventral along a prominent, midline third ventricle. The clearly defined habenula comprises the epithalamus at the dorsal apex of the diencephalon. Beneath that is a dorsal thalamic division that is indirectly [4, 5] in receipt of ascending sensory input. Next is a ventral thalamic division with a mixture of ascending and descending outputs. The hypothalamus forms the floor of the diencephalon, with various divisions containing neurosecretory neurons and associated centers important in a variety of visceral, endocrine and behavioral functions. These are adult divisions; see Puelles et al. [6] for a discussion of their complex embryological origins.

A complex transition zone joins the diencephalon to the telencephalic hemispheres. Each hemisphere can be bisected into a dorsal pallial and a ventral subpallial zone, each in turn with lateral and medial components, resulting in four basic quadrants to the amphibian telencephalon. The lateral subpallium or striatum is embryologically, connectionally and histochemically similar to the basal ganglia of mammals, while the medial subpallium is equivalent to the septal area and related secondary olfactory nuclei. The lateral quadrant of the pallium has two divisions. The lateral pallium is dominated by olfactory input and as such is similar to the various olfactory cortices of mammals. A dorsal pallium above it has been considered the likeliest site of homologies to mammalian neocortical areas. The medial pallial area is similar to the hippocampus and associated limbic cortices. See Butler and Hodos [7] for a more thorough discussion.

The majority of neurons throughout the brain are situated close to the ventricles, with fiber tracts and terminal fields occupying the areas peripheral to them. As cell proliferation zones are located around the ventricles, this suggests less cell migration during development than is seen in reptiles and birds or mammals or even teleost fish and advanced sharks. Furthermore, differentiation of cell populations into discrete nuclei is less apparent in amphibians, especially urodeles, than in these other vertebrates [2, 7, 8]. There are some exceptions in anurans. The midbrain roof contains a complexly laminated optic tectum and an auditory torus semicircularis with several nuclei (Fig. 3).

Secondly, the anuran diencephalon is clearly divisible into multiple nuclei within three of its four divisions, the epithalamus, dorsal thalamus and ventral thalamus. Most hypothalamic cells remain very close to the ventricles. Thirdly, the medial halves of the telencephalic hemispheres are more expanded and differentiated than the lateral halves and the subpallial portion contains several distinct, migrated nuclei. In all three areas, urodeles and apodans have far less differentiated brains, with nearly all neurons occupying periventricular positions.



**Evolution of the Brain in Amphibians. Figure 3** Cross section through the midbrain of a bullfrog (*Rana catesbeiana*) showing the multilaminated optic tectum and the torus semicircularis beneath the tectal ventricle. The relatively undifferentiated reticular nuclei of the tegmentum can also be seen. Note that even in this expanded region of anurans, cell density is low and most neurons remain clustered near ventricles.

## Brainstem Areas and Cranial Nerves

The organization of the cranial nerves is highly conserved across all vertebrates, including amphibians. In addition to the standard tetrapod twelve identified pairs and their motor and sensory nuclei, lateral line nerves and nuclei such as those in aquatic vertebrates are present in tadpole stages and in the adult stages of those amphibian species that retain an aquatic life style following metamorphosis. The cranial nerves of amphibians that are also present in amniotes include the so-called special senses such as taste, hearing and vestibular systems as well as the general somatic sensory systems mediated by the trigeminal nerve and its three brainstem nuclei. All contribute to ascending sensory pathways that reach the diencephalon along with ascending somatosensory pathways from the spinal cord in a pattern recognizable in all vertebrates. Individual nuclei can be quite difficult to recognize, but overall what has been seen in the amphibian brainstem suggests that this area of the brain follows a conserved and probably primitive vertebrate plan.

The major exception to the simplicity and relatively undifferentiated structure of the brainstem is the midbrain roof of anuran amphibians (Fig. 3). There the optic tectum expands to form paired multilaminated dorsal lobes. This large and complex structure represents an important visual processing structure in the anuran brain related to the specialized visual predation characterizing frogs and toads. Some urodeles share this specialized feature [9].

The second expanded structure of the midbrain roof is the torus semicircularis. It lies caudal to the optic tectum in primitive frogs such as the pipids but is folded beneath the optic tectum in advanced frogs and toads as the increased expansion of both the tectum and torus rotates it underneath the tectal ventricle. The multiple nuclei of the torus serve as points of convergence for ascending auditory pathways, as well as an important motor interface between ascending auditory and descending forebrain inputs and outputs to various motor centers associated with vocal production [10]. The toral expansion in anurans coincides with this group's specialization of the auditory system for use in reproductive social behavior [11].

## Forebrain Organization

Virtually all of the detailed connectional anatomy of the amphibian forebrain has been done in anurans, although enough is known in urodeles to suggest that the basic anuran organization represents a general amphibian condition. The expansion and differentiation of diencephalic areas and medial parts of the telencephalic hemispheres are derived conditions in anurans however, as they are not shared by the other amphibian groups.

All ascending sensory pathways that have been investigated in any detail have been shown to reach thalamic nuclei. This includes visual input, both directly from the retina and from the optic tectum, auditory input from the torus semicircularis and somatosensory input from the spinal cord, dorsal column area and trigeminal nuclei. All have extensive connections to a variety of thalamic nuclei. There is very little if any olfactory representation in dorsal or ventral thalamic areas.

In terms of the input it receives therefore, the amphibian thalamus is similar in some respects to that seen in other tetrapods. One difference however, is that none of the thalamic nuclei are clearly dedicated to a single sensory modality, with the possible exception of the retinal recipient targets that lie along the lateral margins of the thalamus embedded within the optic tracts, the nucleus of Bellonci and the corpus geniculatum, both of which are ventral thalamic nuclei. A second difference concerns the pattern of termination of the direct retinal and somatosensory projections; while in fish and in amniotes these projections terminate within the anterior part of the dorsal thalamus (nucleus anterior), in amphibians they terminate within ventral thalamic nuclei, which then in turn project to the anterior part of the dorsal thalamus [4,5].

Dorsal and ventral thalamic nuclei are major relay centers sending their output to the telencephalon, hypothalamus and midbrain areas. Telencephalic connections from the middle and posterior portions of the thalamus terminate heavily in the basal ganglia region termed the striatum. The thalamo-striatal pathway is the predominant ascending thalamic connection to the amphibian telencephalon. Anterior portions of the thalamus target instead telencephalic limbic regions, the medial pallium and septal nuclei. At least a small component of these connections reaches the dorsal part of the pallial division.

From these connections it can be seen that all sensory systems not just olfaction reach large areas of the telencephalon. In this general way, amphibians are similar to other tetrapods, notwithstanding that the inputs are dominated by a very heavy middle thalamic input to the striatum. The details however, reveal a quite different functional organization from that which might be expected [10]. The telencephalic targets of ascending sensory pathways are all multimodal. There is no evidence for separate representations for each sensory system, no indication of a topographically preserved projection from any thalamic nucleus to any telencephalic area and no physiological evidence for a sensory (or for that matter motor) map. In essence, there is no evidence for the distinct, unimodal, mapped sensory representations that are so prominent in the mammalian cortex. A possible exception may be the core olfactory-recipient region of the lateral pallium. That is not to say that there is or is not a homologue of mammalian neocortex within the amphibian telencephalon, but there are certainly no functional equivalents for the well-mapped, pure sensory zones that are so prominent in mammals and are significant telencephalic components in reptiles and birds.

A major question in vertebrate evolution is what happened at the transition from anamniotes to the true land vertebrates. Crucial to understanding this is deciding whether the structural and functional organization of the anuran telencephalon represents the primitive tetrapod condition or reflects the specialized functions of vision and hearing in these vertebrates. It is not easy to resolve this without extensive investigations in other primitive vertebrates.

# Evolution of the Brain: At the Reptile-Bird Transition

Mihaly Kalman
1st Department of Anatomy, Semmelweis University, School of Medicine, Budapest, Hungary

## Definition

Enlargement and elaboration of many brain features occurred independently in the diapsid line leading to modern reptiles and birds and separately in the synapsid line leading to modern mammals. Within the diapsid line, birds, which arose from the archosaur line that includes crocodiles, show the most elaboration of a number of their brain structures. They have the greatest number of distinct thalamic nuclei, particularly for the visual and somatomotor systems, correspondingly expanded areas of the telencephalic pallium for sensory, motor, and associative areas; elaborated cerebellar and basal ganglia circuitry for motor control; and the "astrocytic" glial system. All of these features are also present in mammalian brains, independently gained.

## Characteristics

### Evolutionary Relations

The amniotes form three major groups: ►Anapsida, Synapsida, and Diapsida. Mammals are synapsids, whereas birds are diapsids, as well as the extant reptiles. Turtles were regarded formerly as anapsids, i.e. closest extant relatives of the ancestral, stock amniotes. Recent studies suggest, however, that the turtles are also diapsids (see [1]). Major diapsid groups are the Archosauria (crocodiles, ►pterosaurs, dinosaurs, birds, and probably turtles) and Lepidosauria (Squamata: lizards and snakes). The closest extant relatives of birds are the crocodilians.

### External Morphology

Like in other tetrapods, the telencephalon consists of paired, evaginated hemispheres and an unevaginated telencephalon impar. In most reptiles the telencephalon is elongated, but rather rounded in the crocodiles and birds, and in the birds there is a rostromedial eminence ("Wulst," Fig. 1).

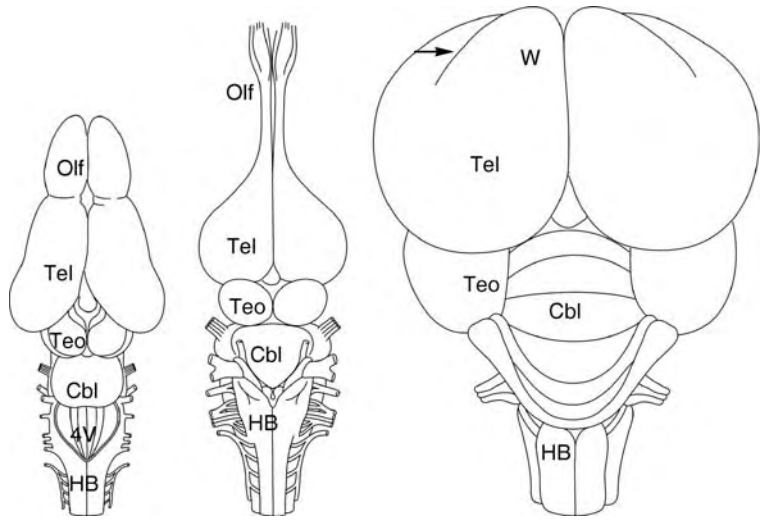
The hemispheres cover the olfactory tracts in turtles, and, frequently, even the olfactory bulbs in birds. The major reptile/bird difference lies within the cerebellum. In the birds it is similar to that of mammals in size and foliation, but there are no distinct vermis and hemispheres. The optic lobes are pushed down, into dorsolateral or even ventrolateral position by the large cerebellum. The crocodile cerebellum has a fissura prima and a fissura secunda; therefore, anterior, middle, and posterior lobes are separated. Otherwise the cerebellum is only a lamina, which curves backward in turtles but forward in lizards [2,3].

The birds have brain weights 6–10 times larger than reptiles (as related to the body weight) (see ►Evolution, and Brain-Body Allometry). One might suppose that these larger brains are necessary for a well-coordinated flight, but the cranial volume of pterosaurs was within the reptilian range (although near the upper border). The fossil bird, *Archaeopteryx*, from the late ►Jurassic already had a brain weight in the border range between birds and reptiles. The intense brain enlargement probably occurred before the late Eocene, as calculated from skull endocasts [1–3].

### Inner Structure and Cytoarchitectonics

In the spinal cord a characteristic structure of birds is the so-called lumbosacral sinus, which is filled with the jelly-like glycoid body. In the brainstem the reticular formation in crocodiles is more complex than in the other reptiles but less complex than in birds. In the cerebellum, despite the difference in size, the basic neuronal network is similar, except that basket cells are more numerous in birds than in reptiles. Reptiles have two deep cerebellar nuclei, whereas birds also have a third one [1,2].

The layering of the optic tectum in birds is more crispy demarcated than in reptiles, although its neuronal types are similar. Fifteen layers of the optic tectum are generally recognized in birds. The extra layer is recognized within the layers 2–8, whereas in reptiles only six layers, 8–13, constitute the same part of the tectum. (Note that, by convention, the layers of the avian tectum are numbered from superficial to deep, but in



**Evolution of the Brain: At the Reptile-Bird Transition. Figure 1** Comparative sketches of turtle (a), crocodilian (b), and bird (c) brains. Note the conspicuous differences: Size and position of olfactory (Olf) tract and bulb; Size and shape of cerebellum (Cbl); The position of the optic tectum (TeO); *HB* hindbrain; *Tel* telencephalon; *W* "Wulst," arrow points to the vallecule, i.e. the furrow bordering laterally, *4V* fourth ventricle.

reptiles in the opposite way. When comparing the avian and reptilian tecta, a disparity exists in the placement of the boundary between the superficial and central zones). In reptiles the torus semicircularis is clearly distinct, whereas in birds it is not conspicuous, and hence named as nucleus mesencephali lateralis. A comparison of reptilian and avian diencephalic nuclei will be discussed below [1,2].

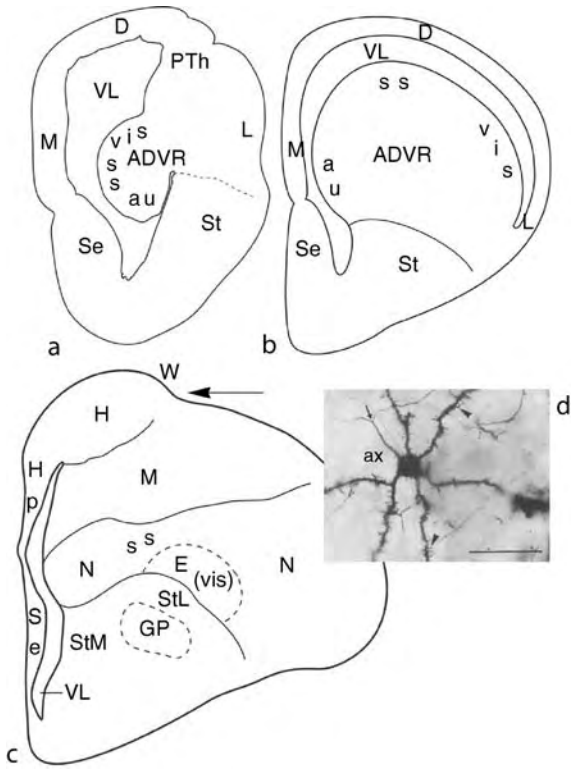
In both groups the telencephalic hemispheres consist of pallium and subpallium; the latter comprises the septum (discussed below with the limbic system) and the striato-pallidal complexes (Fig. 2).

In the subpallium magnocellular and parvocellular areas, corresponding to the pallidum and striatum, can be distinguished in reptiles. In birds, the striatum is more differentiated, with lateral and medial subdivisions of the dorsal striatum that are clearly distinct [1,2].

The pallium consists of medial, dorsal and lateral pallia, and the dorsal ventricular ridge (DVR), which bulges into the ventricle (Fig. 2). The DVR is characteristic of the brains of both reptiles and birds. Anterior and posterior parts are distinguished (ADVR, PDVR), and this structure is now known to be pallial rather than striatal, as previously believed. However, there is no general consensus as to whether it derives from the lateral or dorsal pallium or from the recently described ventral pallium [4]. The avian forebrain is reminiscent of that of reptiles, but three areas evolved substantially: the dorsal pallium, the DVR, and the medial pallium.

The dorsal (general) cortex of reptiles consists of the three main layers, deep and superficial cell-poor plexiform layers, and a middle neuron-rich layer. Dorsolaterally a pallial thickening is found (Fig. 2a). In birds the layered arrangement dissolved into an irregularly scattered but markedly expanded neuronal population. In the rostormedial part of the dorsal pallium a thickening, the hyperpallium or Wulst (German for "hump," Figs. 1c and 2c) evolved. Cytoarchitectonically it comprises three perpendiculary arranged areas: hyperpallium apicale, intercalatum, and densocellulare. The "intercalatum" contains small granular cells, not yet found in reptiles [1,2]. Note that the new revised terminology of the avian brain (based on the recommendations of the Avian Brain Nomenclature Forum) is followed here, as in numerous recent publications, but not in the previous literature.

In turtles ADVR is separated from the dorsal pallium and the striatum by the dorsal and medial ventricular sulci (Fig. 2a). In the other groups the ADVR expanded (and the ventricle narrowened) to the point where it is difficult to recognize boundaries. In the crocodiles the ADVR lies immediately dorsal to the striatum (Fig. 2b), and in birds, is closely juxtaposed to the dorsal pallium, so only the medullary laminae (dorsal and superior frontal) mark the borders (Fig. 2c). In reptiles, there are only less distinct areas (dorsolateral and intermediolateral in the pallium, whereas the ventrolateral area corresponds to the striatum). In birds the ADVR comprises the so-called meso-, and nidopallium; within the latter there are further areas such as entopallium, Field L, and nucleus basorostralis. PDVR is also less distinct in birds; here the arcopallium and amygdalar complex are found, although their correspondence to the PDVR regions in reptiles is not yet resolved [1,2].



**Evolution of the Brain: At the Reptile-Bird Transition.**
**Figure 2** Comparative sketches of telencephalic coronary sections (a,b,c – as in Fig. 1). Note the differences in the size, inner structure of DVR, and its connection to the other parts of the telencephalon. The continuous *thin lines* inside the drawings represent medullary laminae, while the *dashed lines* are cytoarchitectonical borders. (d) "Spiny" neuron from chicken entopallium. *Ax* axon (arrow points to branching), *arrowheads* – "spines"(small dendritic protrusions to receive synapsizing axons). Bar 50 μm. (Photomicrograph of T. Tömböl.) *ADVR* anterior dorsal ventricular ridge; *au* auditory area; *D* dorsal pallium; *E* entopallium; *GP* pallidum dorsalis része (globus pallidus), *H* hyperpallium (its emergence forms the "Wulst," W, arrow points to the vallecule, see also in Fig. 1c), *Hp* hippocampus; *L* lateral pallium; *M* medial pallium in (a) and (b), but mesopallium in (c), *N* nidopallium; *S* septum; *ss* somatosensory area; *St*, *StL*, *StM* striatum, mediale and laterale; *PTh* pallial thickening; *vis* visual area; *VL* lateral ventricle. In birds (c), the auditory area (field L) is caudo-medial to the somatosensory area (ss), i.e. it is not in the plane of section.

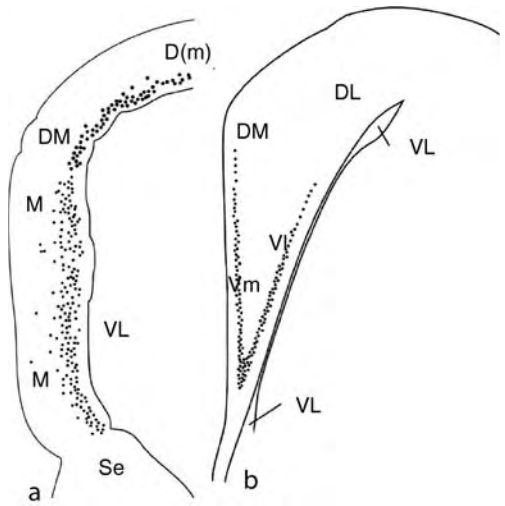
The reptilian ADVR has two basic cytoarchitectonic patterns, based on the distribution of neurons – type I or type II [5]. Type I occurs in the tuatara, turtles, and some lizards, whereas type II occurs in other lizards, snakes, and crocodiles, as well as in birds. The type I ADVR configuration has three relatively distinct zones: an outer, narrow cell-poor zone, with periventricular neurons, their dendrites extending concentrically with the ventricular surface; the second zone has a relative large number of clustered neurons; whereas in the third zone there are scattered neurons, occasional clusters. The neurons are spiny or non-spiny, and the axons are radially arranged in the latter two layers. The more distributed type II configuration lacks zonal organization; instead it contains scattered clusters of neurons, which are almost all spiny (Fig. 2d) [1,2].

The medial pallium of reptiles (Fig. 3a) has also a three-layered cortical lamina, divided into medial and dorsomedial parts. Due to their cytoarchitectonics and connections, the medial cortex has been compared with the dentate gyrus and the dorsomedial cortex with Ammon's horn. The medial part of the dorsal cortex may correspond to the limbic parts bordering the Ammon's horn (subiculum, entorhinal cortex). The topological order of these parts is similar in mammals and reptiles [1].

In birds, the relationships of parts of the medial pallium to those in reptiles have been controversial (Fig. 3b). The avian medial pallium ends in a V-shape that contains two layers of neurons – ventromedial (Vm) and ventrolateral (Vl) – collectively referred to as hippocampus, and a region of scattered neurons called parahippocampal area. Five different regions within the hippocampal formation have been recognized. The hippocampus has subdivisions Vl and Vm, and the parahippocampal area has dorsolateral (DL), dorsal dorsomedial (DMd), and ventral dorsomedial (DMv) ones. Vl and Vm have been argued to represent the Ammon's-horn, and DL, DMd and DMv the dentate gyrus, subiculum and entorhinal cortex, respectively [1,6]. However, more recent work [7] has illuminated in the intrinsic connections and established homology of the V-shaped Vm and Vl regions with the dentate gyrus of mammals and of DM to Ammon's horn. The septal areas are similar in reptiles and birds. The main difference is that a direct septal-interpeduncular connection is missing from birds, but present in reptiles [1,2].

## Sensory Systems

There are two types of pathways to the corresponding thalamic relay nuclei: directly (so-called lemnothalamic pathways, referring to the direct sensory pathway as ribbon-like, as the word lemniscus means, or through the tectum (collothalamic, referring to the colliculi of the mammalian tectum). In the optic tectum, the superficial layers belong to the visual system (completely contralateral from the retina in birds, but with an ipsilateral component in some reptiles), whereas the deeper layers are multisensory, mainly somatosensory. The auditory pathway is represented in the torus semicircularis in reptiles, and the nucleus mesencephali lateralis in birds; only a collothalamic pathway has been reported for this system [1,2,8].



**Evolution of the Brain: At the Reptile-Bird Transition.**
**Figure 3** Turtle (a) and avian (b) hippocampal formations. Note the varied subdivisions, and the position of the layer of large cells: DM in (a), V in (b). *D (m)* dorsal pallium, medial part; *DM* dorsomedial pallium in (a), the dorsomedial part of the hippocampal formation in (b); *DL* the dorsolateral part of the hippocampal formation; *M* medial pallium; *S* septum; *Vm,l* ventral medial and lateral areas of the hippocampal formation.

The collothalamic nuclei of reptiles are: nucleus rotundus (visual), nucleus medialis (auditory, called nucleus reuniens in crocodiles and turtles), and for the somatosensory sensory system a nucleus termed nucleus caudalis in turtles, nucleus medialis posterior in lizards, or as the medialis complex in crocodiles, where via the nucleus reuniens pars diffusa a secondary pathway also emerges. In birds, the nucleus triangularis is mentioned beside the rotundus in the visual representation, the somatosensory nuclei comprise nuclei dorsolateralis posterior pars caudalis and semilunaris parovoidalis (in some species: ovoidalis pars ventralis); the nucleus ovoidalis is auditory [1,2,8].

The lemnothalamic nuclei of reptiles are: the geniculatum laterale pars dorsalis (visual), and the dorsolateralis anterior and dorsomedialis (so-called perirotundal nuclei). These latter two are multi- rather than only somatosensory, having connections (mainly the dorsomedial) with viscerosensory, limbic, motor, etc. systems. In birds, the visual nucleus (opticus principalis thalami) is a complex of small nuclei, now called the dorsal lateral geniculate nucleus (DLGN). Somatosensory input is received by several nuclei: the dorsalis intermedius ventralis anterior (DIVA), the area ventralis intermedia (VIA), and a set of nuclei called the dorsal thalamic zone (DTZ), which have different functions. The latter two nuclei communicate with the motor and limbic systems, respectively. Comparing the thalamic systems across sauropsids, the main difference seems to be that in birds more discrete nuclei are present, so that the different functions belong to specialized nuclei rather than multifunctional ones [1,2,8].

The thalamic sensory relay nuclei project to both the striatum and pallium, mainly ipsilaterally. The collothalamic pathways terminate in turtles in three neighboring areas (dorsal visual, medial somatosensory, ventral acoustic) which fill almost completely the AVDR, leaving free only the central area, for the incoming axons of the lateral forebrain bundle (Fig. 2a). In crocodiles the arrangement is less tight (Fig. 2b). In birds, the target areas are also derivatives of DVR: entopallium (visual, Fig. 2c), field L (acoustic), intermediate part of the nidopallium (somatosensory, Fig. 2c), which, however, leave large areas of DVR free. The lemnothalamic pathways project to the dorsal pallium (this area is called "lemnopallium"): in reptiles to the pallial thickening. In the avian dorsal pallium, the hyperpallium (also known as the Wulst, Figs. 1c and 2c) emerged to receive the somatosensory projections (from DIVA) and visual projections from DLGN, in distinct areas. Within the hyperpallium cytoarchitectonic "pseudolayers" (hyperpallium apicale, intercalatum, and densocellulare, see above) enhance the analysis. The thalamic and pallial representations are somatotopic (retino-, tonotopic) in birds, but, as for reptiles, this is only found in the somatosensory lemnothalamic pathway of crocodiles, more or less. In the hyperpallium the representations are bilateral, allowing for stereoscopic vision [1,2,8].

There is an especially important somatosensory system for the head, the trigeminal. It collects information from the oral and nasal regions, by which the animals can explore the environment actively. In reptiles, the somatosensory representation of head region is related to a lemnothalamic pathway that originates from both trigeminal sensory nuclei (principal and spinal), and projects to the nucleus dorsolateralis anterior thalami, which also receives the somatosensory input from the body. In birds, the head representation is rather separate from that of body. Whether it is comparable to the lemnothalamic trigeminal pathways in reptiles is yet to be determined. The pathway, the quintofrontal tract, originates in the principal trigeminal nucleus of the pons, lacks relay in either the midbrain or the thalamus, and terminates within the nucleus basorostalis pallii, in the nidopallium (i.e. in a collopallial area). Its evolution is not clear, though a relationship to the reptilian nucleus tractus olfactorii lateralis has been mentioned. The terminals of the basorostral pallial nucleus reach two areas of the nidopallium: frontale pars trigeminalis and caudale pars trigeminalis. The basorostral nucleus contains somatotopic representations [1,2,8].

Both the isthmo-optic, and isthmo-tectal nuclei, which help the early analysis of visual information, and the pretectal and other systems organizing the

oculomotor responses (mainly the nucleus lentiformis mesencephali) are more evolved, and have more extended connections in birds, than in reptiles [1].

The parietal eye (►Parietal organ) occurs in lizards (except for some equatorial species) but it was lost from most of snakes, most of turtles, crocodiles (which have not even pineal gland), and birds. The ►vomeronasal organ and the accessory olfactory bulb are also found in squamatae but were lost in other reptiles and birds. Occurrence of accessory olfactory bulb is accompanied by its sensory center, the nucleus sphericus in the PDVR of squamatae [1,2,8].

## Motor Systems

The reptile-bird transition involved a number of modifications in the motor control of limbs and head. Instead of the "wriggling" movement inherited from amphibians (such as Urodela) and used by squamate reptiles, walking with a limb-supported body evolved in dinosaurs and birds, with crocodiles representing more or less an intermediate stage. Evolving flight in birds (as well as in certain mammals and reptiles) separated the coordination between the anterior and posterior limbs.

Both in reptiles and birds the main motor pathways descend to the motoneurons from the deep layers of the tectum, the nucleus ruber, and the reticular formation. Notably, in birds the tectum has no direct connection to the spinal cord, only *via* the reticular formation. These systems in reptiles are controlled mainly by the striatum, *via*: (i) pretectum (mainly the nucleus of the posterior commissure), and (ii) the substantia nigra. Apart from a minor corticotectal projection, projections from the pallium to the striatum, rather than to the brainstem have been demonstrated. The cerebellum receives spinal, vestibular, and retinal inputs (via the pretectal nucleus of posterior commissure); its output targets are mainly the vestibular nuclei and, to a lesser extent, the nucleus interstitialis fascicules longitudinalis medialis, nucleus ruber, and the thalamic subpeduncular nucleus. In reptiles, there is an apparent absence of striato-thalamo-cortico-striatal loops and of similar thalamic loops involving the cerebellum [1,2,9].

In birds the motor system consists mainly of (i) pallial efferents (ii) feedback loops involving the thalamus, and (iii) the additional elaboration of a cerebellar feedback loop. Concerning the pallial efferents, the somatosensory/motor part of the Wulst projects to the red nucleus and the reticular formation, the tectum, and presumably (at least in several species) to the contralateral spinal cord, resembling the pyramidal tract, but usually extending only to the cervical segments [10]. Another pathway, the occipitomesencephalic tract descends from the temporoparieto-occipital pallium, the anterior part of the arcopallium. This tract terminates, among others, on the tectum, the tegmentum, the lateral reticular formation, and the rostral spinal cord. The pathway is related to the ascending pathway from the trigeminal system to the nucleus basorostralis palii: some efferents of the latter nucleus terminate in a region of the arcopallium, which in turn gives rise to descending projections to the spinal nucleus of trigeminal nerve [1,2,11]. From the striatum and pallidum, there are thalamic feedback systems by VIA to the Wulst, and by DTZ to the nidopallium and in turn to the arcopallium. The cerebellum receives new inputs, mainly from the pallium: from the Wulst *via* the pontine nuclei and the inferior olive and from the arcopallium *via* the lateral pontine nuclei and the pretectal nucleus spiriformis medialis. A new acquisition is also the cerebellothalamic connection, through VIA [1,8]. Specialized thalamic nuclei of these functions cannot be recognized in reptiles, although parts of other thalamic nuclei (perirotundal nuclei, area ventralis) may have similar functions, mainly in crocodiles, which have also a pretectal input to the cerebellum [1].

Relatively little research has been done on the vocal control mechanism of reptiles. In the general case for birds the telencephalic auditory center, Field L, and the nucleus dorsomedialis posterior pars caudalis have efferents to the arcopallium pars ventralis, from which the vocal-respiratory pathway originates, which supplies the oral, respiratory, and larynx muscles. In songbirds the pathways involved in the regulation of vocal behavior are more complex. The ►syrinx is controlled by the tracheosyringeal division of the hypoglossal nucleus (nucleus XIIts). The nucleus basorostralis also participates in these regulatory processes [1].

## Higher Cerebral Functions, Behavior

Numerous behavioral phenomena indicate a high evolutionary level of the avian brain, in some respects comparable, or even superior to that of most mammals (for reviews see [12,13]). Such key elements are visual acuity, color and stereoscopic vision, cognitive and learning abilities, elaborate vocalization, communication, imitation, advanced social behavior, nesting and nursing, prolonged family partnership, migration and homing, colony formation, ►food-storing. In reptiles, similar phenomena are absent, or rather unfrequent and less elaborate (crocodilians: vocal signals, nesting and nursing, pelagic turtles: homing to the nesting shore).

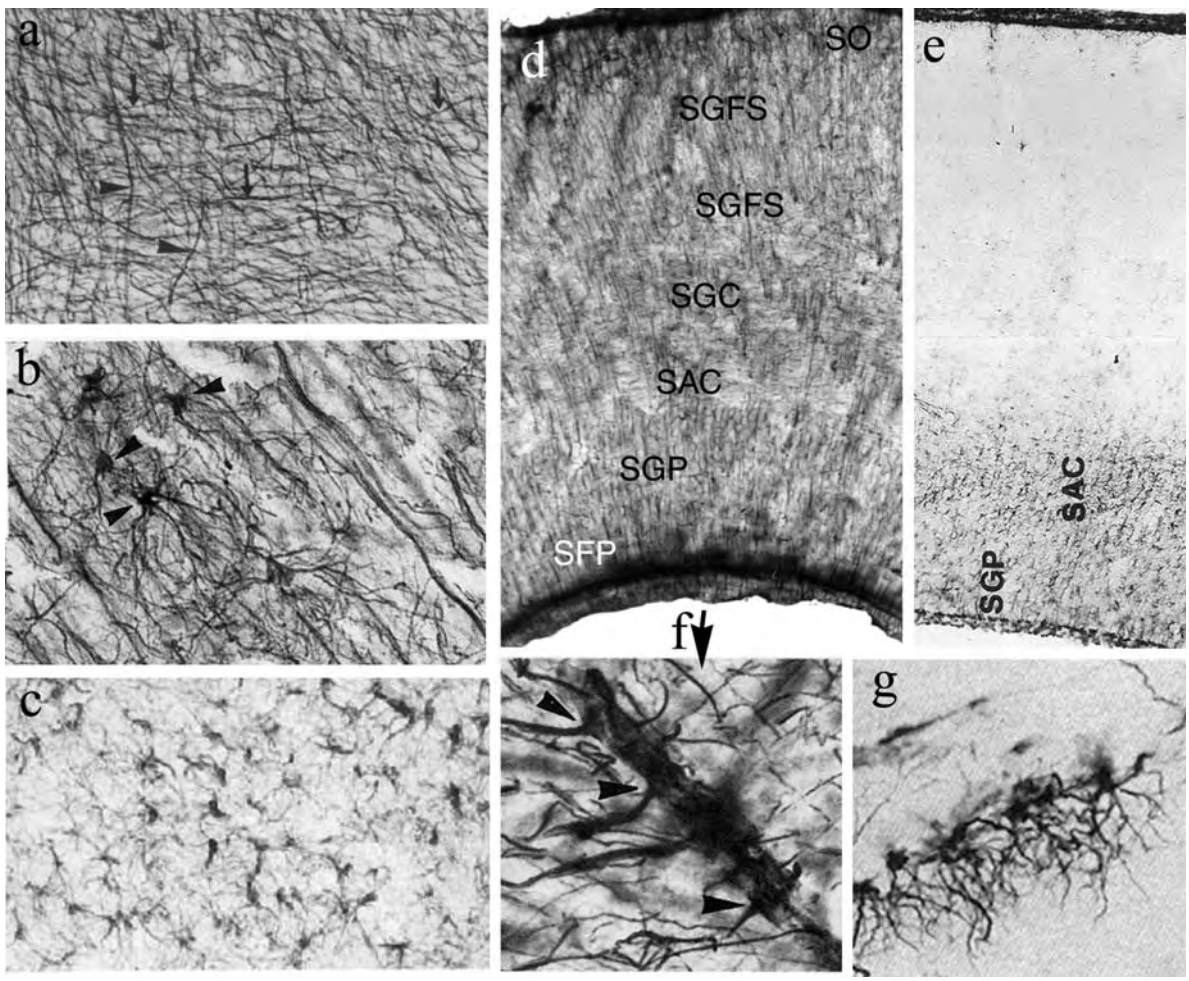
The behavioral advances of birds can be attributed to the facts that large pallial areas remain free between the primary sensory and motor areas for associative tasks. In consequence, the intrapallial connections are also more extended (e.g. the fronto-arcopallial tract). The nidopallium caudolaterale has been proposed to be responsible for cognitive abilities, similar to those of the prefrontal cortex of mammals [14]. The temporo-occipital and lateral corticoid areas are also candidates of behavioral regulation [5]. The hippocampal

formation has more distinct subdivisions in birds (see Fig. 3), and distinct thalamic nuclei in the DTZ have become specialized for communication with the limbic system.

## The Glial System

Whereas brain structure, cytoarchitectonics and hodology are rather similar in reptiles and birds, most strikingly, their glial architecture is completely different (Figs. 4a, b, d, f vs. c, e, g). Birds share with mammals the general features of glial architecture and ►GFAP distribution. These are: (i) predominance of astrocytes (stellate-shape cells, Figs. 4c and g), (ii) absent or limited GFAP-immunopositivity of several brain areas (Fig. 4e), and (iii) a distinct glial architecture of several brain areas. Radial fibers in the mature avian brain are found only along the telencephalic medullary laminae, in the hippocampus, and hypothalamus [1,14,15].

In reptiles, radially arranged ►ependymoglia is the predominant glial element, like in amphibia and fishes. Radial processes form the submeningeal ►glia limitans and the end-feet on the blood vessels (Figs. 4f and g).



**Evolution of the Brain: At the Reptile-Bird Transition. Figure 4** Comparison of reptilian and avian glial system (immunohistochemical staining of GFAP). (a) Turtle; the radial processes (*arrowheads*) are almost completely masked by other processes (*small arrows*). (b) Caiman, between the radial cells astrocytes are also occur as complementary elements (*arrows*). (c) Chicken, the predominant elements are astrocytes. (d) Turtle tectum. Almost evenly distributed, immunopositive radial glia. *SAC* stratum album centrale; *SFP* stratum fibrosum periventriculare; *SGFS* stratum griseum et fibrosum superficiale; *SGC* stratum griseum centrale; *SGP* stratum griseum periventriculare; *SO* stratum opticum. (e) Chicken tectum: astrocytes, but immunopositive only in the deeper layers (therefore layers are only here recognizable). (f) Caiman, perivascular endfeet at the end of a long process (*arrowhead*). (g) Bird, perivascular astrocytes. (Photomicrophotographs of M. Kalman.)

The radial glia are interwoven with a number of fine non-radial processes. Except for some major tracts, no brain area is devoid of GFAP-immunopositivity. A comparison of the glial structures of the reptilian and avian tectal walls demonstrates the differences (Figs. 4d and e). Astrocytes have also been demonstrated in certain areas in snakes and lizards but not in turtles (Figs. 4a and b). In crocodiles, astrocytes are found in every major brain part but nowhere as a predominant glial element. No ►astrocyte was found in a perivascular or subpial position. Only in crocodiles were some nuclei (e.g. magnocellularis cochlearis) recognizable by their glial structure [15–17]). Oligodendrocytes, myelin sheaths, satellite glial cells, and microglia are similar in both groups.

## Lesion and Regeneration

The avian brain responds to lesions like the mammalian brain: after a critical stage of development no axonal regeneration is observed, and ►glial reaction is formed [18]. Neurogenesis in the adults is confined to some special areas, mainly those responsible for song-learning [19]. The glial reactivity and regenerative capability of reptiles has not been estimated with certainity, although there are data on post-lesion glial reaction (at least an intense GFAP expression), neuron production, and axonal regeneration. The latter phenomena may be attributed to the persistence of radially oriented ependymoglia, which preserves the original axonal pathways and may produce neurons, at least according to the recent data [17,20].

## Divergent Evolution of Squamates

Here only those features are summarized in brief, which were acquired (or lost) by snakes and/or lizards probably after their divergence from other reptiles. Their ancient features were mentioned above. In the visual system there were two tendencies. In the ►dracomorph lizards the visual system surpassed that of other reptiles, both in the tectum, which became ►iguanid (type) from the most common ►lacertid (type), and in the extended visual area of ADVR. The other tendency is a moderate reduction of the visual system, in most snakes (e.g. ►ophiid (type) of tectum, poor pretectal nuclei), and a progressive reduction in ►burrowing lizards and snakes (►amphisbenid (type) of tectum, disappearance of some visual nuclei and pathways). In some snakes (Boidae and ►Crotalidae) a thermosensitive "►pit organ" evolved. This organ is innervated by the trigeminal nerve, and in these snakes the tectum is well-developed, like in most reptiles [1,2].

In snakes the motor system also has specific features. The spinal cord has no intumescentiae. To help the horizontal movement of the trunk, a separate vestibular nucleus evolved. ►Pythons (but not the snakes in general, see e.g. ►Colubridae) lack the rubrospinal tract [1,2].

## Interspecies Avian Differences

There are particular modifications associated with behavioral adaptation within the various clades. Songbirds (oscine perching birds) surpass the other birds in several fields. The food-storing songbirds have a high capability of memory based on a well-developed medial pallium. All songbirds have an elaborate vocal control system, organized around the higher vocal center (HVC). A part of this system, Area X, occurs only in males. In the HVC there is a seasonal reproduction and reorganization of neurons. Parrots have also high capability of cognition and learning and elaborate vocal control (note their imitation activity), but these abilities are based on a different neural organization [1].

The birds of prey have a large and well-developed visual hyperpallium and a descending system related specifically to the motor control of the talons. In owls it is accompanied with an elaborated spatial representation of auditory space. An expansion of the nucleus basalis is associated with the use of the beak as a tactile organ in wading birds. The neurobiological basis of the capability of homing has not yet been found, but olfactory, magnetic field sensitivity, and visual functions are supposed to play a role [1].

## Conclusion: Convergent Evolution with Mammals

Summarizing the advanced cerebral features of birds – the separation of functions in distinct nuclei, distinct and somatotopically organized thalamic and pallial sensory representations, stereoscopic and colored vision, the extended functions of telencephalon, its direct effects on the lower motor centers, the pallio-ponto-cerebellar connection, the striato-pallido-thalamo-pallio-striatal circuitry, the highly enlarged cerebellum, the extended associative pallial areas, and the "astrocytic" glial system – are also characteristic of mammals. These features evolved independently, despite the long-separated phylogeny, fundamentally different lifestyles, and rather different pallial morphogenesis and cytoarchitectonics of birds and mammals.

## Dinosaur Evolution or Reptile/Bird Transition?

Recent data suggest that many of the avian behavioral features were most probably also shown by some dinosaurs. Since birds' ancestors were within the dinosaur clade, the question arises as to whether the avian behavioral features and cerebral structures that are advanced in comparison to those of reptiles evolved in dinosaurs or only in their avian descendants. Skull endocasts demonstrate, however, that most dinosaur brains were within the range of reptilian brains (as related to the body weight), except for some small ostrich-like, carnivorous dinosaurs (*Stenonychosaurus* and *Dromiceiominus*). These latter ones appear to have had remarkably large brains falling into the range of

birds' brains. Such highly advanced dinosaurs, however, including those (mainly hadrosaurs) that left fossil marks of "bird-like" behavior, are recorded to the upper ►Cretaceous, whereas the bird-dinosaur divergence is supposed to have taken place in the (upper?) Jurassic. Therefore, the avian brain represents its own evolutionary line [1,2].

# Evolution of the Brain in Birds

M. Fabiana Kubke, J. Martin Wild
Department of Anatomy with Radiology, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

## Definition

Birds share large brain–body ratios with mammals, although enlargement of their forebrain is more variable across species, and innovations in various parts of the brainstem have also occurred. The diencephalon and telencephalon both show enlargement and elaboration as compared with reptiles, particularly including the dorsal ventricular ridge (DVR) and Wulst regions of the pallium. The latter occupies much more of the telencephalic territory than previously realized. While possible homologies with mammalian brain structures are unresolved, the avian pallium similarly is in receipt of the major ascending sensory pathways, gives rise to descending corticospinal-like pathways, and is involved in motor control circuits with the basal ganglia and cerebellum. Further, avian brains exhibit considerable lability, as evidenced by the presence of novel nuclei for the vocalization (e.g., song) system.

## Characteristics

### Origin and Evolution of Avian Brains

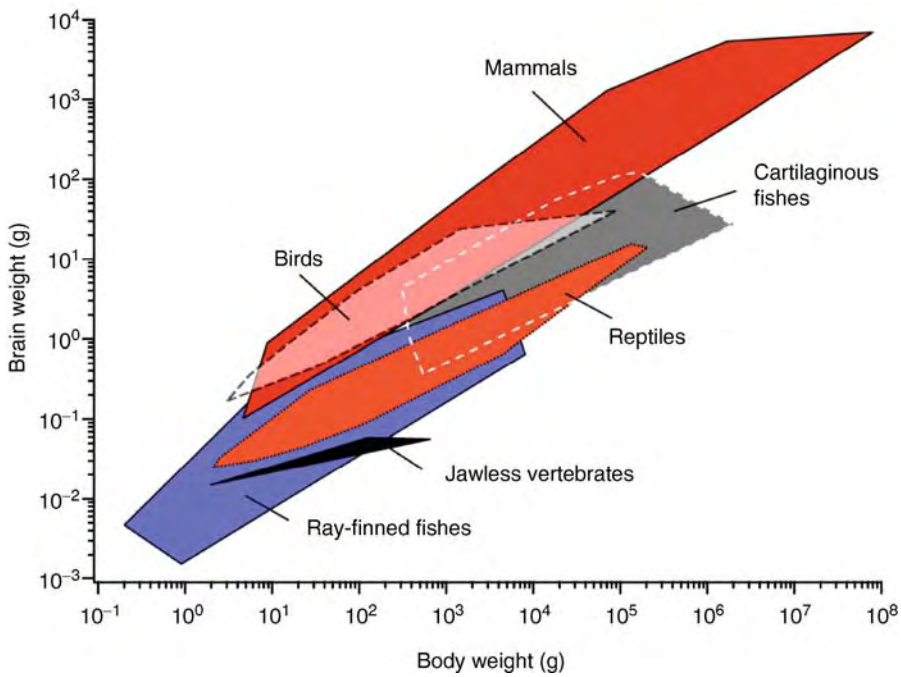
The prevailing view of the evolutionary origins of birds (Aves) is that they are derived from small theropod dinosaurs of the Middle to Late Jurassic, roughly 150 mya. However, our knowledge of the structure and function of the brains of modern birds has accumulated only within the last 100 years or so and predominantly in the last 35, due to the rise of contemporary techniques for the analysis of neuronal connections, gene expression, cladistic relationships, immunohistochemistry, and electrophysiology. From the evolutionary point of view, birds in general are considered to be flying

reptiles with a brain similar to that of modern, and presumably also to that of ancient, crocodilians (Archosaurs). The little we know about the brains of pre-Tertiary birds derives from studies of cranial endocasts, which suggest that *Archaeopteryx* exhibited a "bird-like" brain that was probably adapted for flight. Modern comparative neuroanatomy has, however, more frequently sought to compare avian and mammalian brains, rather than avian and reptilian brains, probably because of the disproportionate wealth of knowledge of the brains of mammals and the relatively modern view that birds and reptiles constitute a monophyletic group (Sauropsids).

## Quantitative Description

A classic approach to quantifying variation in brains is to look at how their size (or the size of brain regions) varies in relation to body weight. Principally, brain size varies with body size in a way that can be described by the allometric function: brain weight = $a \times$ body weight$^b$ [1], where a is the normalization constant and b is the scaling exponent. Differences in brain size are thought to result from two contributing factors – those changes in size directly related to differences in body size and increases in size due to encephalization [1]. Despite the close phylogenetic relationship between birds and reptiles, the brains of birds are significantly larger than those of their close relatives and instead are more similar in size to the brains of mammals of similar body size. This suggests a strong evolutionary drive toward increasing brain size in the avian lineage, similar to that seen in mammals (Fig. 1).

Changes in brain size are the result of two types of brain evolution, which have been referred to as passive (easy) and active (difficult) modes [2]. The passive mode refers to global increases in brain size, whereas the active mode refers to enlargement of specific cell groups that are not accompanied by a concomitant enlargement of their containing structure. Variations in the relative sizes of brains and of brain regions have been extensively reported in the literature, for both birds and mammals. Despite the similarity in the relative brain size seen in birds and mammals, there are two important differences in the regulation of brain size in these two groups. First, the final brain size of adult birds depends on the developmental mode of the species under study (see later). Second, increases in brain size appear to be more homogeneous in birds than in mammals. While enlargement in the brain size of mammals is associated with a relatively greater enlargement of the forebrain, this is less pronounced in birds, and preferential enlargement of the forebrain may not



**Evolution of the Brain in Birds. Figure 1** Brain to body scaling in major vertebrate groups. Minimum convex polygon plots for mammals, birds, reptiles, and fishes. Despite the close phylogenetic relationship between birds and reptiles, the brain to body size relationship is more similar to that of mammals (Reproduced with permission from Georg Striedter, University of California, Irvine [2]).

be common to all birds, and may indeed be quite variable even within given orders. This suggests that the increase in total brain size in birds, unlike that in mammals, does not necessarily result from a predominant increase in the size of the telencephalon.

Enlargement of brain size (or brain regions) in mammals can be accounted for by protracted neurogenesis, that is, larger structures are achieved by delaying the birth date of constituent neurons, which may lead to an exponential increase in the number of progenitor cells [2]. It has been argued that increases in the size of specific mammalian brain regions occur at the expense of accompanying increases in size of related structures, but recent studies suggest that components of functional systems can also evolve together and independently of size changes in the rest of the brain (mosaic evolution or active mode) [2]. Evidence for mosaic evolution in birds has also been recently shown by several authors. Bennett and Harvey failed to see a correlation between specific brain structures and the specific niche occupied by the species and concluded that there appears to be no correlation between, for example, the size of the optic tectum (OT) and diurnal versus nocturnal habits. In contrast, Cobb showed variation in the ratio of the sizes of the optic tectum to auditory midbrain in different species, suggesting that in birds, too, variation in the size of separate functional structures can occur in the absence of global increases in the size of the brain (or the brainstem in this case). It has been suggested, for example, that auditory structures are enlarged in auditory specialists such as owls and that visual areas (e.g., the OT) are reduced in the nocturnal kiwi [3]. Thus, mosaic evolution can occur in avian brains; that is, variation in the relative size of the neuronal assemblies can occur in the absence of a parallel variation in relative size of the entire structure. Yet, although mosaic evolution may be evident in some individual species, i.e., at the level at which natural selection acts, it may not be a general trend in birds.

The variation seen in the relative number of neurons in the auditory nuclei of auditory specialists may also be dependent on body size. Since larger birds have larger brains, overall increases in brain regions may be achieved by simply scaling to body size. Relative increases, however, must by definition be the result of mosaic evolution. The relative enlargement (hyperplasia) of auditory areas may be less pronounced in auditory specialists of larger body size. We can propose that if a given neuronal computation requires a minimum number of neurons, larger birds may achieve sufficiently large nuclei simply as a result of the scaling of the brain to body size. Smaller sized birds may have limits on brain weight and may therefore require a relative increase in cell number (hyperplasia) in order to acquire an equally enlarged brain region.

Size changes in the avian hippocampus have been reported in relation to spatial orienting behavior and in oscine song nuclei in relation to vocal repertoire [2]. Since these nuclei are subject to adult neurogenesis, variation in size may result from changes in adult neuron survival rather than from changes in developmental programs.

Thus, mechanisms other than those that underlie the general increases in brain size can operate to produce hyper- or hypoplasia of brain regions, and mosaic evolution can also be seen within functional units in the brains of birds.

## Description of the Structural Diversity of Avian Brains

### *Structural Diversity in the Avian Brainstem*

Although the structure of the brainstem of birds may at first glance appear constant and surprisingly reminiscent of that of a mammal, rather than that of a reptile [4], there is sufficient evidence that innovation in the avian brainstem can indeed occur. For example, the auditory nucleus laminaris, which appears to have evolved in the Archosauria and may not be present in other reptiles, exhibits morphological variation between bird species at both the histological and ▶cytoarchitectonic levels, whereas the morphology of other auditory structures (with the exception perhaps of the nucleus angularis) appears to be quite conserved. The nucleus angularis in ratites and chickens has a medial region that extends dorsally toward the midline, which is absent in all other bird lineages examined (parrots, songbirds, pigeons). Since this medial region of nucleus angularis is seen in reptiles as well, it probably represents the plesiomorphic (ancestral) condition. Brainstems in the avian lineage also appear to lack a cerebellar-like structure (such as the dorsal cochlear nucleus of mammals or the dorsal octavolateral nucleus of fish), a characteristic found in most other vertebrate lineages.

Variation is not limited to the structure of nuclei, but is also expressed in the way in which different brain regions are interconnected. For instance, there appears to be significant variation in the way somatosensory pathways are organized in the brainstem of different species. A three-station projection system from the periphery to the rostral Wulst via the dorsal column nucleus and dorsal thalamus is probably present in all species for the mediation of tactile input from the body. This is accompanied by a separate, disynaptic projection system from the beak and oral cavity to the forebrain nucleus basorostralis pallii (Bas), via the principal sensory trigeminal nucleus (PrV). However, in some species, e.g., budgerigars, there is in addition a complete representation of the head and body in Bas, which is mediated by disynaptic projections via PrV (for the beak) and an adjacent subprincipal nucleus (for the body). In other species, e.g., the barn owl, a complete body representation in Bas is mediated both by a disynaptic projection via PrV (for the beak) and a trisynaptic projection via the dorsal column

nucleus and a large lateral pontine nucleus known as pontis externus (for the body) [5].

These examples show that variation in the brainstem can occur, including changes in relative size, lamination, and cytoarchitecture. This variation may be related to specific sensory specializations associated with loss or gain of function. Finally, although not specifically mentioned in the literature, there may be significant differences in the size of the brainstem in males versus females of some species (Wild, unpublished observations).

### Structural Diversity in the Avian Forebrain

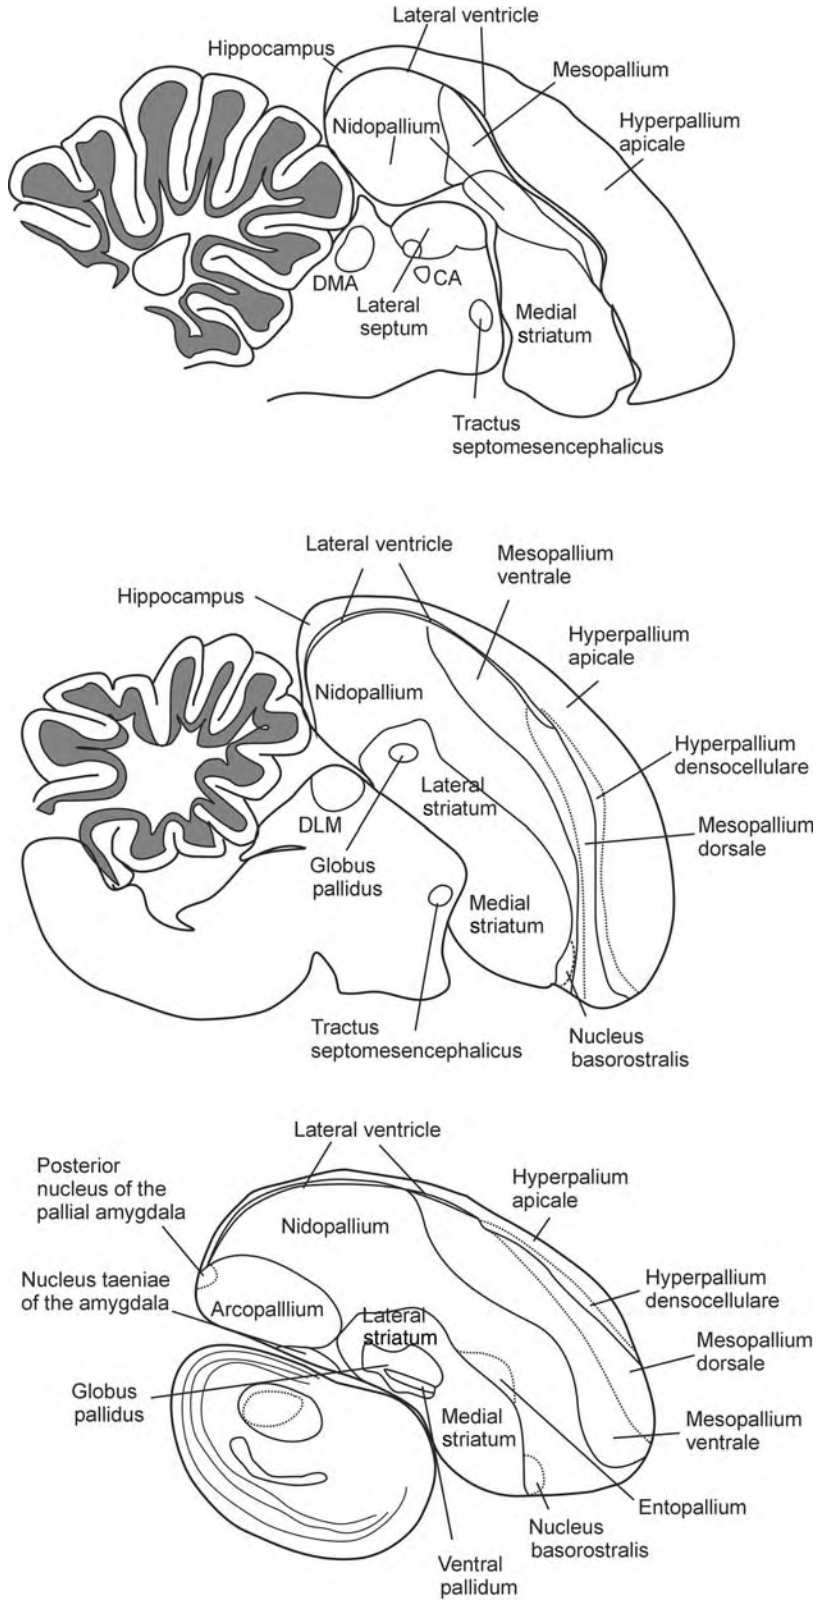
Information from spinal and cranial nerves (with the exception of olfactory inputs) can be processed locally at the level of reflex arcs or can be routed for further processing in the forebrain. As in mammals, a significant number of inputs are routed through different thalamic nuclei dedicated to specific sensory or multimodal processing. However, unlike the case in mammals, the thalamus is not an obligatory relay to the forebrain in birds. Rather, several ascending systems, including an auditory and a somatosensory component, bypass the thalamus to innervate the nucleus basorostralis (Bas), which does not receive thalamic inputs. This suggests that two integration pathways (thalamic and nonthalamic) occur in the avian forebrain and it is not known to what extent (if any) these two pathways converge. It is, therefore, not surprising that it is in the organization of the telencephalon that the most obvious anatomical differences between birds and mammals are observed.

The common reference to "grey matter" highlights one of the most intriguing differences between the brains of birds and mammals, for while bird brains are full of "grey matter" – i.e., nerve cell bodies – these are not organized in the same way as are those that make up the "grey matter" of the mammalian cortex (Fig. 2). A hexalaminated and, roughly according to brain size, convoluted neocortex is the hallmark of the mammalian pallium (i.e., the dorsal part of the telencephalon), although it is sobering to remember that for the most part this cortex is no more than 2-mm thick. Other large, but nonlaminated collections of grey matter in a nuclear arrangement are located in the subpallium, where they are known as basal ganglia. Prior to the 1960s, it was thought that the great majority of the telencephala of birds, including large dorsal and ventroposterior parts then known as neostriatum, ectostriatum, hyperstriatum, and archistriatum, were collectively equivalent to the striatum of mammals, with only relatively thin portions of the medial and dorsal telencephalic walls being similar to the hippocampal and dorsal cortices, respectively, of other amniotes (Fig. 2). This erroneous assumption prevailed long after it was shown neurochemically that only those basal parts of the avian telencephalon lying ventral to the lamina medularis dorsalis (LMD, as it was then known) are similar to mammalian basal ganglia [6]. Modern studies of the regional expression of genes regulating telencephalic development have confirmed the location of the basal ganglia, which develop from a ventral territory known as the subpallium [2]. To correct the terminology for neural territories dorsal to LMD, the Avian Brain Nomenclature Forum held at Duke University (USA) in 2002 replaced the names of structures having the suffix "striatum" with names having the suffix "pallium," thus, nidopallium, entopallium, hyperpallium, and arcopallium [7].

Analogies can be made between avian and mammalian brains, regardless of their homologous relationship. Thus, the Wulst, which is largely a visual structure receiving a major thalamic input from the equivalent of the dorsal lateral geniculate nucleus of mammals, can be said to be analogous to mammalian neocortex and is often said to be homologous to it. That is, it is generally recognized that the same simple cortical structure that was probably present in stem amniotes gave rise to the superior part of the neocortex in mammals and to the Wulst in birds. However, the large part of the pallium that derives from the underlying DVR can also be considered analogous to mammalian neocortex, in that it receives major visual, auditory, and somatosensory inputs from discrete thalamic nuclei. The idea that components of the DVR are homologous to mammalian neocortex continues to be debated in comparative neuroanatomy [6]. The major point of contention focuses on the origin of the mammalian temporal cortex, this being thought to arise either de novo in the mammalian lineage or to be derived from a part of the dorsal cortex of stem amniotes that gives rise to at least rostral parts of the DVR in birds. Karten proposed that the primary sensory areas of the DVR are made up of neurons equivalent to those in layer IV of corresponding regions of mammalian neocortex (although such areas are now known to contain other types of neurons as well, for instance those that project to the striatum [6,8]). Other workers, basing their ideas on embryological and genetic expression analyses, are of the opinion that the sauropsid DVR derives from a subcortical pallial region in stem amniotes that in mammals gives rise to the claustrum, endopiriform region and/or pallial amygdala [2]. The evidence for and against these viewpoints has been thoroughly discussed [2,6].

### Structural Diversity Associated with Behavioral Specializations

Birds also have the ability to invent new nuclei as they see fit; that is, avian brains are labile to innovation. For example, birds that have evolved the ability to learn their vocalizations (e.g., song) have specialized



**Evolution of the Brain in Birds. Figure 2** Organization of the avian telencephalon. Medial to lateral series of schematics of sagittal sections of a brain of a zebra finch, illustrating the major components of the forebrain (Reproduced with permission from C. Siang and E. Jarvis, Duke University).

nuclei in their telencephalon that are not present in nonvocal learning species, even in the suboscine passerines; in vocal learners, these nuclei appear to have evolved independently at least three times during avian evolution, viz, in oscines, parrots, and some hummingbirds [5]. Because vocal learning is dependent on auditory feedback, some of these specialized nuclei in vocal learners are thought to have "grown out of" regions in the brains of ancestral species that gave rise to areas involved in higher level auditory processing in both vocal learners and nonvocal learners. In vocal learners [9], however, the specialized nuclei participate in auditory-vocal processing and integration and eventually give rise to a unique, major descending pathway from the telencephalon that directly innervates vocal motor neurons and respiratory premotor neurons in the medulla for the control of vocal production (song).

In other cases, birds appear to have evolved extreme behavioral specializations that may be mediated by novel brain structures or neural mechanisms remaining to be identified. For instance, the New Caledonian crow (*Corvus moneduloides*) manufactures tools from leaves to extract grubs from trees, a highly sophisticated and culturally transmissible trait that appears to exceed in intelligence the intellectual abilities of many primates (Fig. 3) [10]. The New Zealand kea, a notoriously mischievous parrot, also possesses a high level of intelligence evidenced by high-level problem solving, often involving social cooperation. However, since we do not understand the neural basis of human intellectual variation, it may be just as difficult to understand similar variations amongst birds and other animals, unless the behavior in question happens to be mediated by specialized nuclei as song learning is in songbirds.

**Evolution of the Brain in Birds. Figure 3** New Caledonian crows manufacture and use tools. Photograph of a New Caledonian crow (*Corvus moneduloides*) holding a recently manufactured tool (Reproduced from Gavin Hunt and Russell Gray, University of Auckland).

### Developmental Mechanisms Underlying the Evolution of Avian Brains

In birds, but not in mammals, relative brain size depends upon developmental mode. Precocial birds (those that are relatively mature in their development at birth) are born with larger brains with respect to body weight and grow to have proportionately smaller brains. The opposite is true for altricial birds (those that are relatively immature in their development at birth). Altriciality may be an evolutionary prerequisite for birds to attain larger brains, where altriciality is a necessary (but not sufficient) condition associated with increases in brain size. This is not true for mammals; brain size is not dependent on the species' developmental mode. Thus, the differences in the allometric relationships between different brain regions in birds and the dependency of total brain size on avian developmental mode would imply that the mechanisms that underlie the regulation of brain size in birds may be quite different to those proposed for mammals.

Increases in brain size must ultimately be brought about by increases in neurogenesis. This may be achieved by increasing the rate at which neuronal precursors are produced, increasing the length of time over which they are produced, decreasing the extent of neuronal death or a combination thereof. For example, a late neurogenesis thought to occur in altricial avian species may contribute to the relative enlargement of the brain. Indeed, Finlay and Darlington have proposed that in mammals protracted neurogenesis underlies the increase in the neuronal precursor population and an overall increase in the number of neurons and may be a mechanism by which specific brain regions can be enlarged [2]. Altriciality in birds may be accompanied by changes in neurogenetic times. Thus, studies similar to those of Finlay et al. need to be performed in birds.

Histological and cytoarchitectural changes are also the result of changes in developmental programs. Thus, the variation seen in the organization of avian brains must be brought about by diverging developmental programs that lead to the diversification of brains at different levels of organization. The developmental programs that give rise to the avian brain are not too different from those of other vertebrates. However, despite these common mechanisms, downstream cascades of gene action must certainly be regulated differentially to give rise on the one hand to brains that

look very different from those of other vertebrates and on the other to brains within different bird species that also differ markedly among themselves.

[2]CNRS, Institute of Neurobiology A. Fessard, Gif sur Yvette Cedex, France

## Definition

Study of brain evolution across and within each of the major radiations of fishes reveals a Bauplan or morphotype of the fish brain that exhibits many common ancestral neural traits – e.g. cranial nerves, brain subdivisions and the basic organization of ascending sensory pathways and of neurochemical phenotype distribution – shared by all craniates/vertebrates. At the same time many variations are revealed. The latter include substantial differences in pallial cytoarchitecture, tectal and cerebellar organization and emphasis of primary sensory centers. In sum, these findings are not consistent with the previously held notion of a linear *Scala naturae* in vertebrate brain evolution but rather with an appreciation of independent evolutionary events that have occurred on the foundations of the morphotype across and within different vertebrate radiations.

## Characteristics

### Quantitative Description

The phyletic (cladistic) method of establishing ancestral and derived brain characters using data from modern functional neuroanatomical and chemoarchitectonic studies of fish brains supports the view of a largely conservative neural organization throughout the craniate/vertebrate neuraxis in which many specializations may be detected. For example, ascending sensory pathways into the telencephalic pallium, motor output systems and modulatory systems (dopamine, noradrenaline, serotonin, acetylcholine) of lampreys, cartilaginous fishes and actinopterygian fishes share many commonalities still present in tetrapods. Hagfishes also have many of these vertebrate traits, but they lack external eye muscles and their innervating cranial nerves, as well as a cerebellum. The characteristics that are shared across all extant fishes are those likely to have been present in the common ancestor of all craniates/vertebrates and thus form its Bauplan or morphotype.

### Systematics/Species Diversity

Extant vertebrate (or craniate) fish groups (Fig. 1a; after Forey and Janvier [1]; Lauder and Liem [2]) include the two ►agnathan (jawless) or cyclostome, taxa of myxinoids (hagfishes: 32 species) and petromyzontids (lampreys: 41 species) and many gnathostome (jawed) vertebrate taxa.

The latter comprise three major taxa: (i) ►chondrichthyans (cartilaginous fishes), with roughly 1,000 extant species including holocephalans, sharks and batoids (rays and skates), (ii) actinopterygians (ray-finned fishes), which comprise slightly more than half of all living vertebrate species (i.e. 24,000) and (iii) ►sarcopterygians (lobe-finned fishes). The sarcopterygian radiation (Fig. 1a) includes two clades of fishes– the African, Australian and South American lungfishes (Dipnoi: six species) as well as the Comoran

and Indonesian coelacanths (Actinistia; two species of *Latimeria*) – and also the large clade of the tetrapods (amphibians, mammals, sauropsids).

There are two major hypotheses about the systematic relationship of the two agnathan taxa with the ►gnathostomes (Fig. 1a). Morphological and paleontological data support the theory that the myxinoids (hagfishes) form an outgroup to gnathostomes and petromyzontids (lampreys), the latter two would then represent the vertebrates. Molecular genetic analyses [3,4] provide new evidence for the (classic) hypothesis that hagfishes and lampreys form a ►monophyletic taxon (the cyclostomes); hagfishes would thus be included in the vertebrate taxon. Consequently, their lack of vertebrate characters (for some in the nervous system, see below) would be due to secondary losses within the myxinoid taxon).

Of all extant fish taxa, actinopterygians comprise by far the largest radiation (Fig. 1b). Basal actinopterygian groups (bichirs, sturgeons, gars and bowfin) are small in extant species numbers, in contrast to their fossil representatives, the paleozoic chondrosteans (especially the palaeoniscoids) and mesozoic "holosteans". These fossil radiations independently gave rise to many forms apparently adapted to all sorts of environments, probably from deep sea and free water to coral reefs. The three most basal living teleost groups are osteoglossomorphs (e.g. the African mormyrids and freshwater butterflyfish *Pantodon buchholzi* or the South American arapaima and arawana), elopomorphs (tenpounders, tarpons and eels) and clupeomorphs (herring-like fishes) and they include at present more species than non-teleost actinopterygians. The pinnacle of recent teleost species diversity is reached by more derived euteleosts, the largest groups among them being the ostariophysans (6,000 mostly freshwater species, including the cypriniforms, characiforms and siluroids) and the percomorphs (9,000 mostly marine species, including many coral reef forms). The fossil origin of teleosts lies in the early Mesozoic (late Triassic, free-water fish swarms, pholidophorids, leptolepids). However, teleost speciation, in particular that of acanthomorphs (which include percomorphs), increased tremendously towards and after the Cretaceous-Tertiary boundary. A double duplication of the whole genome of a chordate ancestor (the 2R hypothesis) may have been instrumental in the emergence of vertebrates (or craniates), more than 500 million years ago and an additional round of genome duplication occurred between nonteleost actinopterygians and teleosts around 335–404 million years ago [5]. This genetic complexity of teleosts may have been critical for their tremendous species diversification, leading to the invasion of all aquatic environments, which cover 80% of the earth's surface.

## Brain Weight-Body Weight Data

Vertebrate brain size/weight increases on average at a coefficient of 0.66 of the body weight, i.e. the steepness of the regression line reveals negative allometric growth of brain versus body weight [6,7]. Relative brain size (degree of encephalization) is indicated by real brain weight over expected brain weight (if real brain weight is on the regression line, the ratio has a value of 1). A comparison of the value for humans (6.45) with that of some actinopterygians, e.g. trout (1.2), goldfish (2.2) or the African electric fish *Gnathonemus petersii* (5.5), reveals independent increases in relative brain weight between and also within major vertebrate taxa (see Wullimann and Vernier [8]). Similar brain value diversity is seen in chondrichthyans. In particular, galeomorph sharks and myliobatiforms (stingrays) among batoids show independent brain enlargement [9].

Minimum convex polygons visualize total brain weight/body weight relationships between major taxonomic groups (Fig. 2). Polygons for mammals and birds lie above those of agnathans, amphibians and reptiles, i.e. mammalian and avian brains are consistently much larger for a given body weight (Fig. 2a). However, if cartilaginous and ray-finned fishes (in particular mormyrids) brain weights are added, their polygons overlap considerably with those of birds and mammals (Fig. 2b). This may largely but not exclusively be accounted for by disproportional growth of the cerebellum [9]. Clearly, early diverging (anamniote) vertebrate groups are not intrinsically constrained to have small relative brain weights. Brain weight-body

weight data show that relative brain enlargement in evolution occurred several times each in cartilaginous and ray-finned fishes independently of that in mammals and birds. This homoplastic (convergent) evolution of vertebrate brain enlargement falsifies the common ladder-notion of *Scala naturae* [10].

## Phyletic Analysis

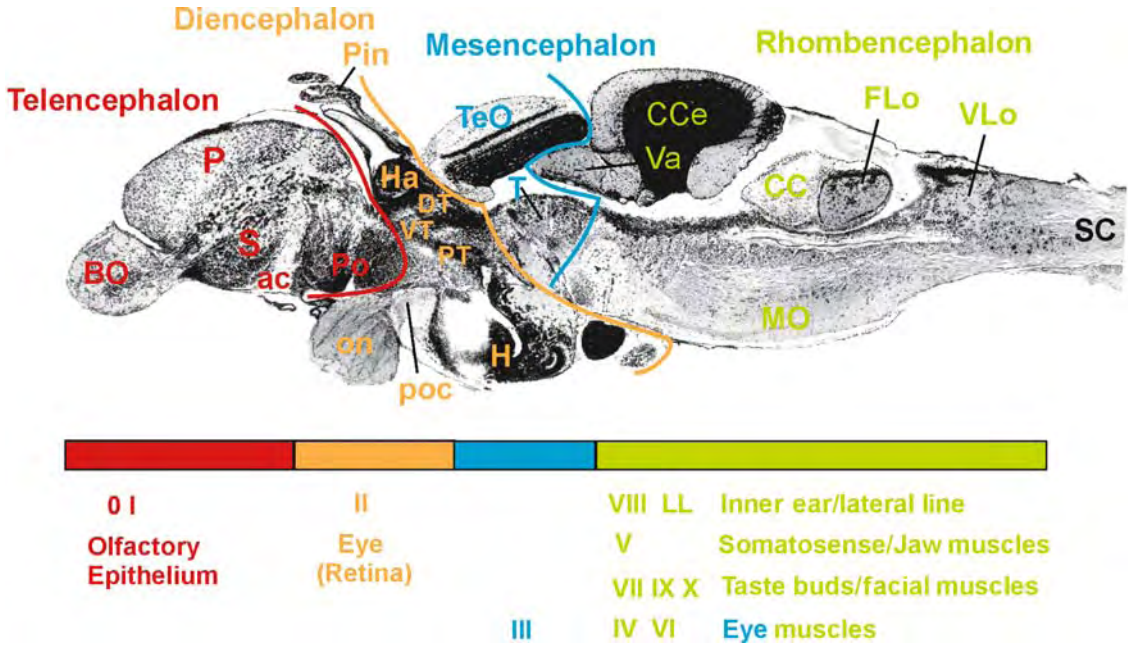
To assess vertebrate brain evolution, the comparative (cladistic) method for establishing the evolutionary polarity of brain traits is used. It analyzes single organismic characters instead of entire organisms or their entire brains, leading to the identification of

ancestral (plesiomorphic) or derived (apomorphic) neural characters through the usage of well-supported ►cladograms (Fig. 1). Cladograms are exclusively based on shared derived characters (synapomorphies). Sister groups, such as sarcopterygians/actinopterygians (Fig. 1a) are characterized by synapomorphies inherited from their last common ancestor, distinguishing them from outgroup taxa (e.g. cartilaginous fishes in Fig. 1a). The outgroup comparison determines the evolutionary polarity of particular neural characters. If two conditions occur in sister groups [such as evagination of telencephalic hemispheres in sarcopterygians and eversion in actinopterygians (discussed below)], the condition in the outgroups is investigated (evagination in cartilaginous fishes), which, for reasons of parsimony (i.e. principle of choosing the simplest explanation), is considered to represent the ancestral condition.

## The Shared Ancestral Craniate/Vertebrate Brain Morphotype (Bauplan)

Instead of stepwise addition of brain parts at the rostral pole of the neuraxis during evolution, a craniate/vertebrate ►Bauplan of basic brain parts appears to have been initially present from which novelties arose [10–13]. All craniate/vertebrate brains (exemplified for the zebrafish in (Fig. 3) exhibit in rostrocaudal order a telencephalon, a diencephalon (these two together comprise the prosencephalon or forebrain), a mesencephalon (midbrain) and a rhombencephalon (or hindbrain).

In gnathostomes, the hindbrain includes the metencephalon, (which contains the cerebellum) and the myelencephalon. The craniate/vertebrate mesencephalon includes a dorsally lying optic tectum (a visual-multisensory structure that corresponds to the mammalian superior colliculus) and torus semicircularis (a lateral line-auditory structure in fishes, amphibians and sauropsids that corresponds to the mammalian inferior colliculus), as well as a ventrally lying tegmentum. Three major divisions of the diencephalon, i.e. pretectum, dorsal thalamus and ventral thalamus (new: prethalamus) – classically considered a dorsoventral series – are now seen as a caudorostral sequence of three transverse forebrain neural tube units (prosomeres) along the longitudinal brain axis (following the ►neuromeric model of Puelles and Rubenstein [14]), with the posterior tuberculum representing basal portions of prosomeres 2 and 3 and the region of the nucleus of the medial longitudinal fasciculus being



**Evolution of the Brain in Fishes. Figure 3** Sagittal section of adult zebrafish brain exemplifies gnathostome brain Bauplan (modified after Wullimann, M.F., B. Rupp and H. Reichert: Neuroanatomy of the zebrafish brain, Birkhäuser, Basel, 1996). the basal portion of prosomere 1. The craniate/vertebrate telencephalon includes a pallium (which includes the isocortex [neocortex] in mammals as well as other components) and a subpallium (which includes the striatum, pallidum and most components of the septum in mammals) representing together with the hypothalamus (as well as the eminentia thalami and preoptic region) the most rostral and prechordal part of the neural tube.

## Cranial Nerves

Two of twelve cranial nerves traditionally recognized in human neuroanatomy, the hypoglossal (XII, motor innervation of tongue) and spinal accessory nerve (XI, motor innervation of some neck muscles) are unique to tetrapods. The remaining ten nerves, as well as an additional one (the terminal nerve), characterize almost all vertebrates. Thus, in lampreys and gnathostome fishes, the olfactory nerve (I) enters the olfactory bulb at the rostral pallial pole of the telencephalon; the terminal nerve (0) is also associated with the telencephalon. The optic nerve (II) enters the vertebrate diencephalon at the ventral boundary region of preoptic region and hypothalamus. The oculomotor nerve (III) exits the mesencephalic tegmentum. The vertebrate rhombencephalon is ancestrally characterized by its association with the majority of cranial nerves and their primary motor and sensory centers, i.e. the trochlear (IV), trigeminal (V), abducens (VI), facial (VII), otic (VIII), glossopharyngeal (IX) and vagal (X) nerves (see ►Evolution of the Hindbrain; ►Evolution of the Oculomotor System). Additionally, fishes and some amphibians have lateral line nerves (including a mechanoreceptive component – and in some taxa an electroreceptive component). Myxinoids generally share this pattern but lack external eye muscles and thus the associated cranial motor nerves (i.e. III, IV and VI), as well as a terminal nerve and the electroreceptive – but not the mechanoreceptive – component of the lateral line nerves [8,10,15,16]. As discussed above, the absence of these and additional neural characters (cerebellum, see above) is either due to secondary reduction within this taxon [3] or alternatively represents the ancestral craniate condition [1]. The sensory organs and motor structures subserved by craniate cranial nerves are listed for the zebra fish in Fig. 3.

## "New Head" Hypothesis

This hypothesis explains in developmental terms the evolution of the considerable increase in complexity of the craniate/vertebrate head compared to protochordates [17]. In addition to neural tube (all central nervous system somatomotor and visceromotor nerve components) and neural crest (peripheral nervous system sensory and visceromotor nerve components) – that are both involved in spinal nerve development as well – another set of neuroectodermal structures, the placodes (epidermal thickenings with neurogenic fate), gives rise to some of the cranial nerve components in the head and to most special sense head organs. Although primordia of neural crest and placodes have been described in cephalochordates and urochordates [18,19], the New Head of craniates relies on the emergence of new organizing centers at the cephalic animal pole, which are maintained and regulated by placodes and migratory neural crest. This New Head hypothesis gives a clear definition of sensory cranial nerves including distinct placodal origin, resulting peripheral ganglion and sensory receptor structures and most importantly separate primary central nervous projection nuclei. It falsifies the so-called octavolateralis hypothesis, which assumed that lateral line mechanoreceptors on the fish body surface were internalized in evolution into the labyrinth to serve tetrapod auditory function, as well as the related concept of a primary sensory octavolateralis region in fishes where lateral line and otic nerve input overlap. The ancestral condition for vertebrate fishes is from dorsal to ventral, three separate sensory medullary columns dedicated to receiving segregated lateral line electrosensory, mechanosensory and otic nerve information [20].

## Ascending Central Nervous Sensory Pathways

The previously held smell-brain theory suggested that the fish telencephalon is dominated or even exclusively reached by secondary olfactory input from the olfactory bulb. Thus, a multisensory telencephalon or pallium was seen as a derived amniote or mammalian feature. However, the synaptic relay from primary sensory centers throughout the ascending neuraxis into subpallium and/or pallium in all fishes reveals general similarity to the situation in amniotes.

## Actinopterygians

In teleosts, almost all sensory pathways have been neuronally traced from primary sensory centers into the telencephalon (review Wullimann, [21]), which definitely receives largely non-overlapping information from all sensory systems (see ►Evolution of the Telencephalon: in Anamniotes). Secondary olfactory input reaches a limited pallial territory (i.e. the homologue of the lateral pallium or olfactory cortex) and most subpallial areas. The teleostean visual system exhibits a direct retino-thalamofugal and an indirect retino-tecto-thalamofugal system with synaptic relays in the dorsal thalamus, both of which may be terminating in the subpallium and not in the pallium. However, in certain teleosts, tectofugal visual information reaches the pallium via the preglomerular region, a complex of migrated nuclei lateral to the

posterior tuberculum (see below). The auditory and lateral line mechanoreceptive systems ascend multisynaptically in the lateral longitudinal fascicle via mesencephalic torus semicircularis and diencephalon to the pallium, i.e. they are very similar to the lateral lemniscal system of tetrapods. The same organizational scheme applies to the electroreceptive system, which is lost in neopterygians (Ginglymodi, Halecomorphi and Teleostei; see Fig. 1b), but re-appears in certain teleost groups, i.e. in osteoglossomorph African mormyrids and in South American knife-fishes and catfishes (the later two both ostariophysans). Gustatory information in teleosts reaches the diencephalon and telencephalon via a medullary secondary gustatory nucleus, comparable to the parabrachial nuclear region of mammals. Finally, teleosts possess a direct spinal ascending somatosensory system similar to the mammalian anterolateral (protopathic) system in addition to indirect spinal ascending projections which are relayed at the obex level, comparable to the mammalian medial lemniscal (epicritic) system.

A general, notable difference between teleost and amniote ascending sensory circuitry is that the predominant diencephalic targets of teleostean ascending sensory projections are not in the dorsal thalamus, but rather in the preglomerular nuclei located in the lateral periphery of the posterior tuberculum (see ►Evolution of the Telencephalon: in Anamniotes). This preglomerular region has striking functional similarity to the amniote dorsal thalamus, as both make up a large proportion of the diencephalon, are subdivided into many nuclei associated with specific sensory systems and have reciprocal connections with the pallium. A hallmark of teleosts is that they evolved into sensory specialists for all modalities, which is prominently displayed in functional neuroanatomy [10,21].

## Chondrichthyans

Except for the little investigated gustatory system, the available information for the remaining sensory systems in cartilaginous fishes reveals that there is an ancestral condition of ascending sensory pathways and centers common to all gnathostomes (see ►Evolution of the Telencephalon: in Anamniotes). These data in cartilaginous fishes suggest that a dual innervation of the diencephalon (dorsal thalamus/posterior tubercular region) by atleast some ascending sensory systems is the ancestral pattern for gnathostomes. Also, the chondrichthyan telencephalon is clearly multisensory in nature. Together, the findings for actinopterygians and chondrichthyans disqualify the smell-brain theory because they demonstrate that ascending pathways of most if not all sensory systems reach the telencephalon and thus that this condition was also most probably present in the ancestral gnathostomes.

## Agnathans

Although the telencephalon, including the pallium, is far more dominated by secondary olfactory input in hagfishes and lampreys (see ►Evolution of the Telencephalon in Anamniotes) than in gnathostome fishes, this condition does not revive the smell-brain theory. Extant agnathans differ much from their ancestors in morphology and life habits that are seemingly very specialized for olfactory orientation, possibly representing adaptive novelties. Moreover, both in lampreys and myxinoids, the telencephalon (and pallium) is of a multisensory nature, not, as the smell-brain theory would predict, of an exclusively olfactory nature.

## Integrative/Motor Centers

The cytoarchitectonic and modular organization of the craniate/vertebrate optic tectum, its segregated multimodal input and the topographical representation of this input and output to the reticular formation very probably provide an ancestral neuronal machinery apparently exquisitely designed for integrative orientation tasks such as object identification and location and coordinated motor control. In contrast, a cerebellum exhibiting the typical three-layered cortex with comparable cell types and internal circuits is only seen in gnathostomes, probably already in the ancestral stock, with functions in motor learning and coordination. Both the optic tectum and the cerebellum act on the motor structures with descending projections to medullary and spinal levels, i.e. reticular formation, caudal (inferior) raphe region, vestibular and sensory trigeminal nuclei and the nucleus of the medial longitudinal fasciculus.

## Neurochemical Organization

Studies on neurotransmitter/neuromodulatory systems largely confirm the existence of a common Bauplan of brain organization in craniates/vertebrates [8]. In particular, the neurochemical anatomy of fish neuromodulatory systems, i.e. dopamine, noradrenaline, serotonin, histamine and acetylcholine, reveals a conserved picture. In addition to their role in motor programming and sensory processing, these neuromodulators participate in the ascending modulatory systems involved with more specific behavioral processes such as reward and motivation, awareness, aggression or escape, sleep, thirst and hunger. Accordingly, many projections course rostrally in a very divergent manner, probably accompanying the evolutionary invention of the telencephalon in craniates. Among those systems that were probably ancestrally present are a noradrenergic locus coeruleus, serotoninergic superior raphe nuclei, dopaminergic basal diencephalic (all craniates/vertebrates) and mesencephalic (all except actinopterygians) and possibly both brainstem and basal forebrain cholinergic populations as seen in amniotes.

## Definition

The evolution of the human brain from hominids existing perhaps 3–5 MYA (million years ago) to the present has been a mosaic process of size increases intercalated with episodes of ►reorganization of the cerebral cortex. The fossil evidence shows that reorganization preceded large-scale brain size increase, whether ►allometric or not, by about 2–3 MYA and again around 1 MYA, involving a reduction of primary visual cortex and cerebral asymmetries, including those within Broca's region. These changes were followed by nearly a tripling of brain size.

## Characteristics

### What is Paleoneurology?

►Paleoneurology is the study of the fossil evidence for brain evolution and is, at present, the only direct line of evidence as to how different animals' brains have evolved through time. Paleoneurology is not a new branch of paleontological study as earlier publications go back to those of Oken, who found petrified mud in a crocodilian skull in 1819, as mentioned by Owen in 1841. Tilly Edinger wrote a valuable monograph on the evolution of the horse brain and her 1929 [1] and 1949 [2] papers on the history of paleoneurology are an important critique of comparative neurology's mistaken notions of human evolution. Kochetkova's [3] treatise

on ►endocasts is another valuable source, both for history and methods, as well as descriptions of some of the fossil hominids.

## What are Endocasts?

The objects studied are called endocasts. These are simply casts that are made from the inside table of bone of crania. It is particularly important to realize that the endocasts are just that; they are *not* casts of brains, because in life, the brain is surrounded by three meningeal layers, the dura mater, arachnoid tissue and cerebrospinal fluid and lastly the pia mater, a thin investing tissue directly overlying the brain. With death, these tissues as well as the brain dissolve, leaving a cranium that will in time fossilize.

## How does Paleoneurology Differ from Comparative Neurology?

Comparative neuroscience studies the brains of living animal species and is a particularly rich source of data from a microscopic level to that of whole brains. These data are essential to the understanding of the relationships between structure, function and behavior. In other words, how the brain varies in terms of its cellular makeup, cytoarchitecture, fiber systems, neural nuclei, axons and dendrites and the supporting matrix of glial cells, neurotransmitters and neuroreceptors can hopefully be related to variability of behavior. Paleoneurology is correspondingly exceedingly poor in data, as only the surface features of the once living and pulsating brain can be observed if – and only if – they are imprinted onto the internal table of bone. The drawback of comparative studies is that each species is currently an end product of its own separate line of evolution and therefore cannot provide any real time depth to past evolutionary events that affected the brain. Nevertheless, without comparative studies, there would be no possibility of correctly identifying and interpreting those surface features of the endocast that may have changed during evolutionary time from species to species.

## How are Endocasts Made?

First, it is necessary to appreciate that the data obtainable from endocasts depend on the completeness and quality of the endocast and this will be affected by how the endocast has been made. Some endocasts are natural, i.e., made by fine sediments collecting (through the foramina of the cranium) in the cranium of the deceased animal and with time being compacted and eventually turned to stone. Some of these endocasts can obtain an almost jewel-like quality. At least three endocasts of our ancestral hominid australopithecine line of 2–4 MYA were made in this way (e.g., Taung, Sts 60, Sk 1585, Type 2; see [4] for descriptions). Endocasts can also be man-made, by directly covering the surface of the internal bony table with a casting medium, such as latex rubber or various forms of silicon rubber (Figs. 1 and 2). Endocasts can also be made from the data collected during CT scans, which can be rendered as a "virtual" endocast on the computer. This data set, in turn, can be sent to a machine that will literally carve out an endocast from a block of plastic, producing what is called a stereolithic endocast. For example, the recent "hobbit" endocast of the putative *Homo floresiensis* hominid was made this way [5], as was the virtual endocast for Saccopastore, a Neandertal from Italy [6]. Increasingly, CT scans are used for endocranial analyses.

## What Data can Endocasts Provide?

### *Overall Brain Volume*

The most useful data gleaned from endocasts is the size of the once living brain, usually determined by either water displacement of the endocast or by a computer algorithm which simply adds sections taken from a CT scan of either the endocast or the cranium. Endocast volumes are somewhat larger, by about 8–12%, than the actual once-living brain, as the endocranial volume (ECV) includes meninges, cerebral fluid (including cisternae) and cranial nerves. Fossil hominids, of which we are the present-day terminal end products, had brain sizes varying from roughly 385 ml to 1700 ml, while the average for our own species is about 1400 ml. If the body weight is known from estimates made from measuring postcranial bones, then it is possible to calculate some derived statistics that may have some epistemological value. For example, "relative brain size" (RBS) would be the weight of the brain divided by body weight. Modern humans have an RBS of roughly 2%, and this value is neither the smallest nor largest in the animal kingdom or even in the primate order. It is also possible, when body and brain sizes are known, to calculate a statistic called the "encephalization quotient" (EQ). An EQ's value depends on the database used to make the calculation. For example, equations derived from two different data sets appear below, with the corresponding modern human value:

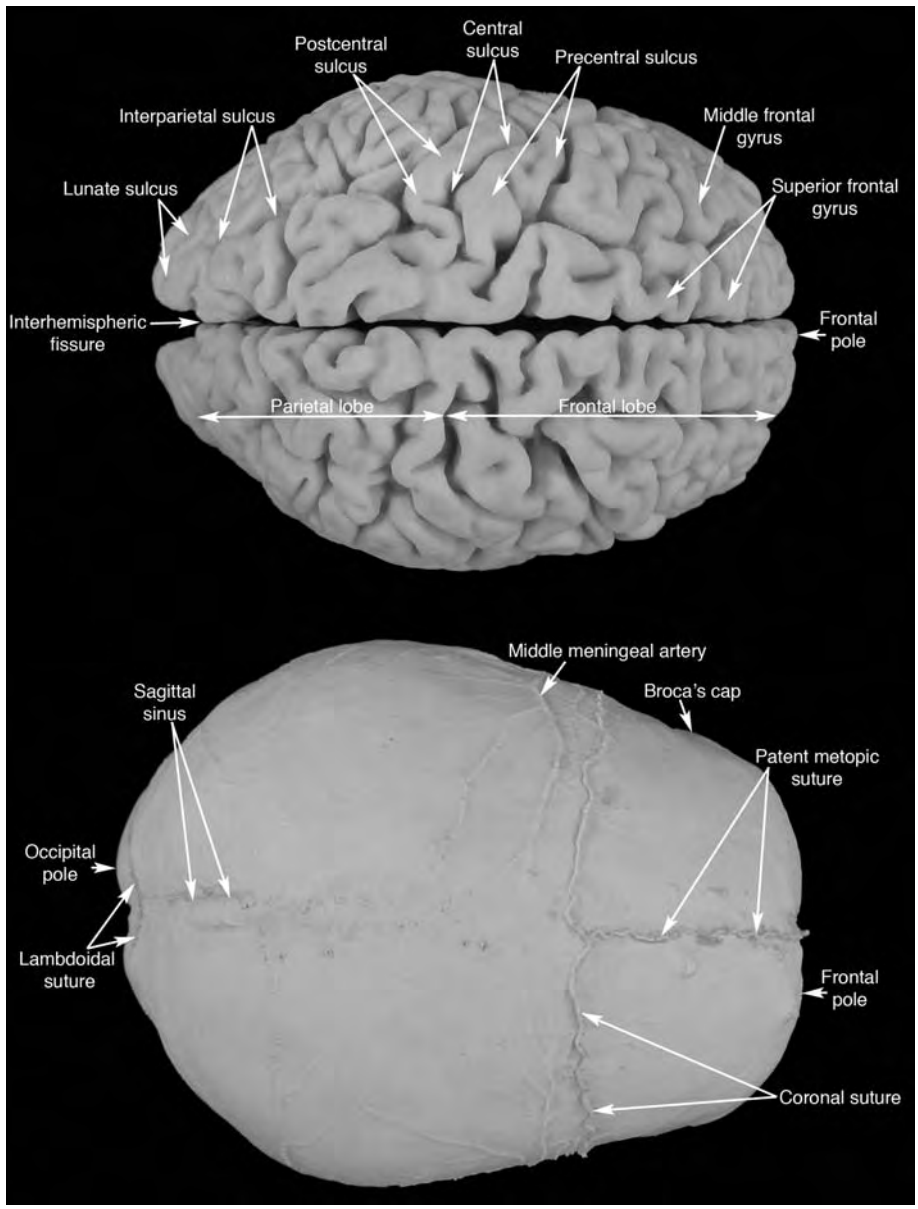
EQ(1) = Brain weight (of any species)/0.12 × Body weight $^{0.66}$ [7]

The human value is 6.91, 4.02 for chimpanzee and 1.8 for gorilla.

EQ(2) = Brain weight/1.0 Body weight $^{0.64}$

This is the "homocentric" equation of Holloway and Post [8], which then expresses each EQ as a direct percentage of the human value, taken as 100%. The chimpanzee EQ is 39.5% and the gorilla 19.1%.

While these values appear very different, the relative position within the primate order is almost static, the rank order correlation being about 0.9 [8].



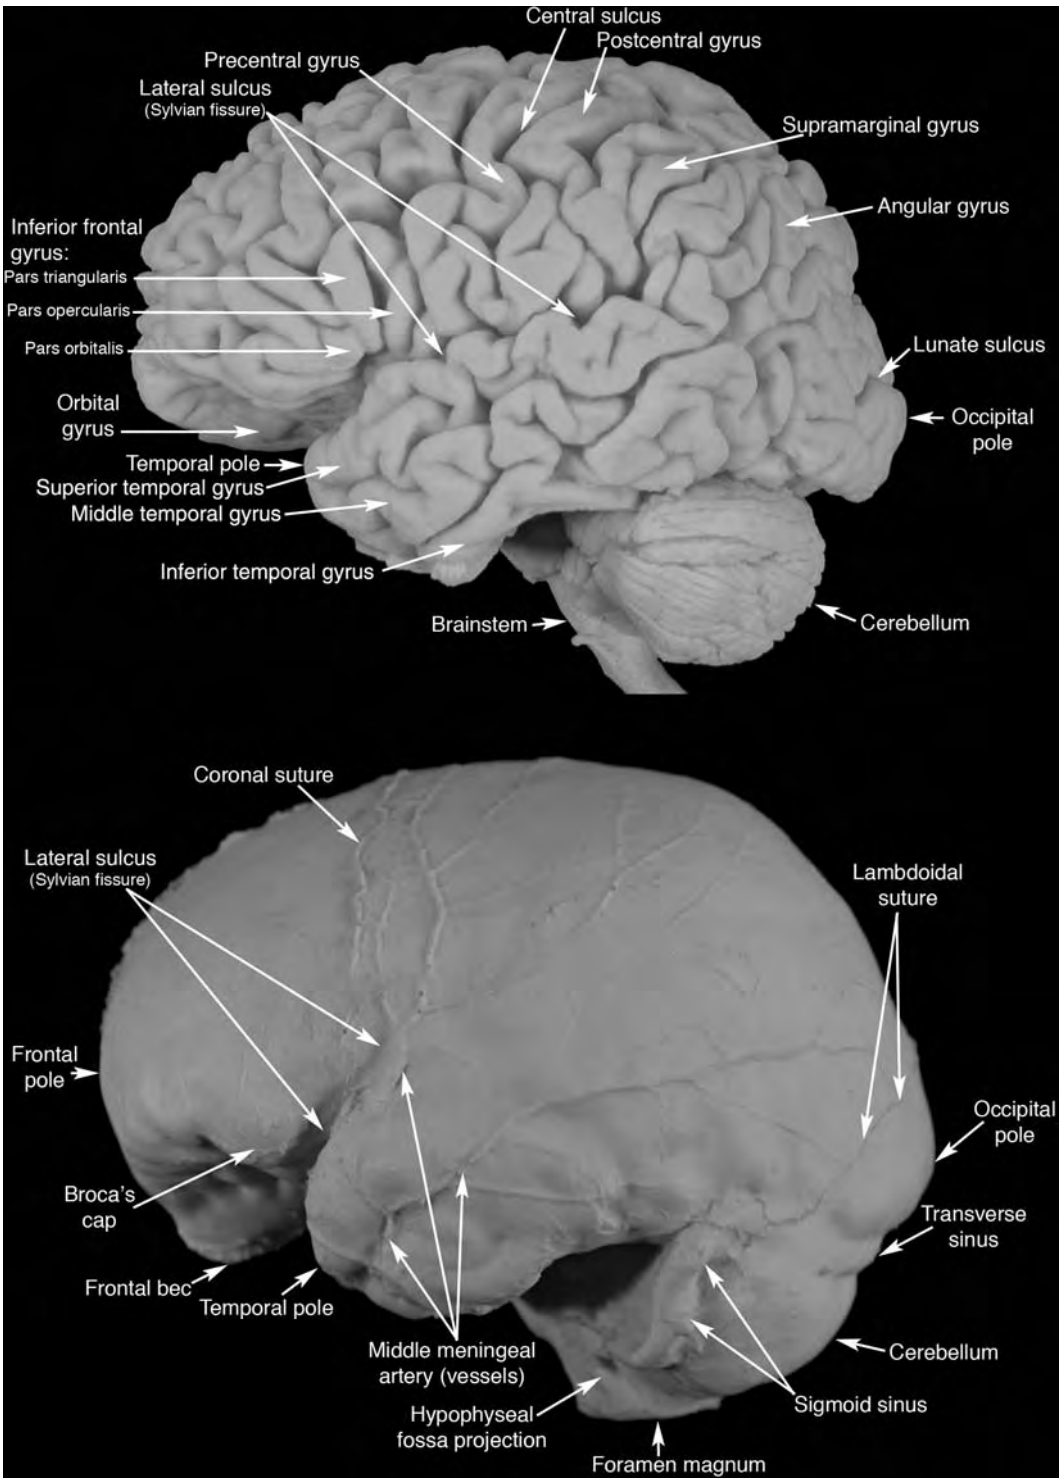
**Evolution of the Brain in Humans – Paleoneurology. Figure 1** A dorsal view of a cast of a modern human brain and its accompanying endocast. Note that the left occipital lobe is wider and projects more posteriorly than the right side and that the right frontal lobe width is slightly larger than the left. This is typical of the torque petalial pattern associated with right-handedness.

### *Relative Sizes of Lobes*

Endocasts provide a very rough idea of the relative sizes of the lobes of the cerebral cortex. It is rough because all the sulci on a primate endocast, particularly a hominid one, cannot be seen. It is thus not possible to find the central sulcus accurately in order to delineate the frontal lobe or to find the precentral sulcus to delineate the prefrontal lobe.

### *Convolution Pattern*

Endocasts do provide glimpses of the underlying ►convolution (gyri and sulci) pattern, depending both upon the state of preservation of the endocast and the faithfulness of convolutional imprinting on the internal table of bone. Alas, this is seldom complete and such incompleteness often leads to controversy, at least within paleoanthropology. For example, the Taung



**Evolution of the Brain in Humans – Paleoneurology. Figure 2** The same brain and endocast in lateral view, showing the difference in details between a cast of the brain and its endocast.

endocast (natural), found with the partial cranium and jaw of *Australopithecus africanus* and described by Raymond Dart in 1925, showed a depression taken by Dart to represent the lunate sulcus or what would have been the approximate anterior limit of primary visual cortex (V1). This appeared to Dart to be in a relatively posterior position, signaling that, even in this early representative of hominids, the brain was organized

differently from that of any ape and was moving toward a more human-like condition (Fig. 3). This depression was in the same region as the lambdoid suture and thus could not be definitively recognized. Putting a lunate in the position expected of an ape such as the chimpanzee or gorilla would violate the existing morphology and the placement of the lunate sulcus even anterior to this would result in a position comparable to an Old World monkey. It was not until 2005 that a description of a posteriorly-placed lunate on the Stw 505 *A. africanus* specimen was made by Holloway et al. [4], effectively settling this controversial issue as to whether the hominid brain had to enlarge before cortical reorganization took place.

### Asymmetry

Endocasts, depending on completeness (both halves necessary) and relative lack of distortion, show varying degrees of asymmetry of the once throbbing cerebral hemispheres and these asymmetries become interesting for their relationship to cerebral specializations, including possible handedness and language. For example, when the endocasts show a bulging left hemispheric projection of the occipital lobe posteriorly (and often laterally), combined with a wider right frontal bulge (these bulges are called petalias), this pattern matches what we know from modern human endocasts and radiography to be the result of a torque-like growth pattern. [see 9–11]. Modern humans also show asymmetries in the Broca's cap regions of the third inferior convolution of the frontal cortex. These asymmetries probably differ by handedness as well as by unknown functional relationships. Such asymmetries are present in Neandertals and even earlier on some *Homo erectus* specimens (indeed they are clear on the 1.8 million year-old *Homo rudolfensis* specimen, KNM-ER 1470). They cannot prove that this or that hominid had language, but if these asymmetries are homologous to those found in modern humans, well, why not? What is curious is that scientists speculating about the origins of language never bother to look at the paleoneurological evidence [e.g., 12].

### Statistical Analyses

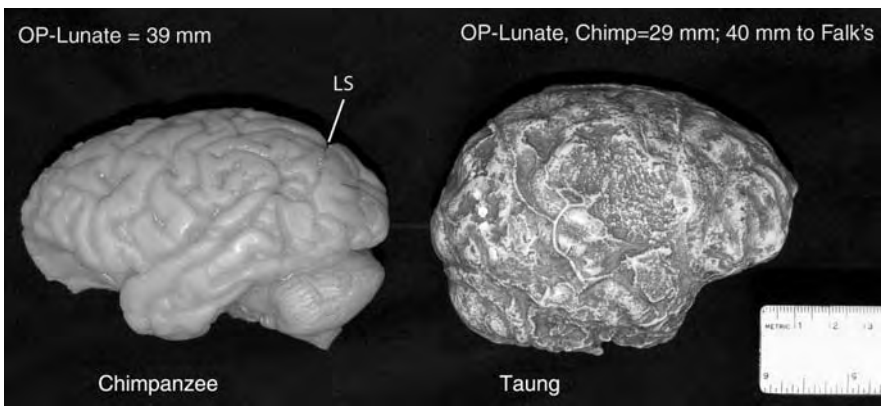
Endocasts have shapes and are thus amenable to measurements that can be taken with calipers or from CT scans. Such data sets can then be statistically analyzed using a variety of multivariate statistical techniques.

### Blood Supply Patterns

The blood supplies to the meninges show different patterns in different hominid taxa and thus might be useful, in some cases, for identifying hominid phyletic lines [13].

### Human Brain Evolution as Seen from Paleoneurology

It is important to keep in mind that roughly 4 MY of evolutionary time has existed for hominid evolution to date and that the number of brain endocasts for hominids that provide reliable data either for size or cerebral organization is very small, numbering no more than about 160, including modern *Homo sapiens* from the end of the Pleistocene (See Holloway et al. [4] Appendix, for a complete listing up to that date). In essence, there is one brain endocast for every 235,000+ years of evolutionary time. Nevertheless, we believe we



**Evolution of the Brain in Humans – Paleoneurology. Figure 3** Lateral views of a chimpanzee brain cast, and the hominid Taung *Australopithecus africanus* endocast. The lunate sulcus (LS) of the chimpanzee lies much farther anteriorly than on the Taung endocast. The dots on the Taung endocast show where a typical chimpanzee LS would lie, if Taung showed a typical ape-like pattern. The distance from the occipital pole (OP) to the LS is roughly 30–40 mm on chimpanzee brains. The measurement from OP to Falk's LS line on the Taung endocast is about 40 mm. Both the typical chimpanzee LS placement and that of Falk violate the sulcus morphology on the Taung endocast.

can perceive a mosaic of brain evolutionary events that involve size increases interspersed with elements of cerebral organization, as shown in Tables 1, 2 and 3. At least two important reorganizational events occurred rather early in hominid evolution, (i) a reduction in the relative volume of primary visual striate cortex (PVC, area 17 of Brodmann), which occurred early in australopithecine taxa, perhaps as early as 3.5 MYA and (ii) a configuration of Broca's region (Brodmann areas 44, 45, and 47) that appears human-like rather than ape-like by about 1.8 MYA. At roughly this same time, cerebral asymmetries, as discussed above, are clearly present in early *Homo* taxa, starting with KNM-ER 1470, *Homo rudolfensis*.

The first change suggests that the relative reduction in PVC was accompanied by a relative increase, most

**Evolution of the Brain in Humans – Paleoneurology. Table 1** A Table showing the reorganizational changes based on the paleoneurological record of hominid endocasts

| Brain changes (Reorganization) | Taxa | Time (MYA) | Endocast evidence |
|---|---|---|---|
| (1) Reduction of primary visual striate cortex, area 17, and relative increase in posterior parietal cortex | *A. afarensis* | 3.5–3.0 | AL 162–28 endocast |
| | *A. africanus* | 3.0–2.0 | Taung child, Stw 505 endocast |
| | *A. robustus* | ca. 2.0 | SK 1585 endocast |
| (2) Reorganization of frontal lobe (Third inferior frontal convolution, Broca's area, widening prefrontal) | *Homo rudolfensis* | 2.0–1.8 | KNM-ER 1470 endocast |
| | *Homo habilis* | | Indonesian endocasts |
| | *Homo erectus* | | |
| (3) Cerebral asymmetries, left occipital, right-frontal petalias | *Homo rudolfensis* | " | KNM-ER 1470 endocast |
| | *H. habilis, H. erectus* | | Indonesian endocasts |
| (4) Refinements in cortical organization to a modern Homo pattern | *? Homo erectusto Present ?* | 1.5–10 | *Homo* endocasts *(erectus, neanderthalensis, sapiens)* |

Changes in the reorganization of the hominid brain based on endocasts (after [14]).

**Evolution of the Brain in Humans – Paleoneurology. Table 2** A Table showing the major allometric and non-allometric increases in brain size based on the hominid endocasts

| Brain changes | Taxa | Time (MYA) | Evidence |
|---|---|---|---|
| (1) Small increase, Allometric* | *A. afarensis to* | 3.0–2.5 | Brain size increases from 400 ml to 450 ml., 500+ ml. |
| | *A. africanus* | | |
| (2) Major increase, rapid, both allometric and non-allometric | *A.africanus to* | 2.5–1.8 | KNM-1470, 752 ml (Ca 300 ml) |
| | *Homo habilis* | | |
| (3) Small allometric increase in brain size to 800 ml-1000 ml (Assumes habilis was KNM 1470-like) | *Homo habilis to* | 1.8–0.5 | *Homo erectus* Brain |
| | *Homo erectus* | | Endocasts and postcranial |
| | | | Bones, e.g., KNM-ER 17000 |
| (4) Gradual and modest size increase to archaic homo sapiens mostly non-allometric | *Homo erectus to* | 0.5–0.10 | Archaic *homo* and |
| | *Homo sapiens* | | Neandertal endocasts |
| | *neanderthalensis* | | 1200–1700 + ml |
| (5) Small reduction in brain size among modern homo sapiens, which was allometric | *Homo s. sapiens* | 0.015 to present | Modern endocranial capacities |

Major size changes in human brain evolution (after [14]).
(* NOTE: Allometric means related to body size increase or decrease, while non-allometric refers to brain size increase without a concomitant body-size increase.)

**Evolution of the Brain in Humans – Paleoneurology. Table 3** A table showing the major cortical areas (Brodmann's) involved in reorganization changes

| Cortical regions | Brodmann's areas | Functions |
|---|---|---|
| Primary visual striate cortex | 17 | Primary visual |
| Posterior parietal and anterior occipital (peri- and parastriate cortex) | 18, 19 | Secondary and tertiary visual integration with area 17 |
| Posterior Parietal, Superior Lobule | 5, 7 | Secondary somatosensory |
| Posterior parietal, inferior lobule (mostly right side. left side processes symbolic-analytical) | 39 | Angular gyrus perception of spatial relations among objects, face recognition |
| Posterior parietal, inferior lobule (mostly right side. See above) | 40 | Supramarginal gyrus spatial ability |
| Posterior superior temporal cortex | 22 | Wernicke's area, posterior superior temporal gyrus. Comprehension of language. |
| Posterior Inferior Temporal | 37 | polymodal integration, visual, auditory. Perception and memory of objects' qualities. |
| Lateral prefrontal cortex (including mirror neurons) | 44, 45, 47 | Broca's area (Broca's Cap) |
| | (also 8, 9, 10, 13, 46) | Motor control of vocalization, language Complex cognitive functioning Memory, inhibiton of impulse, foresight, etc |

Major cortical regions involved in early hominid evolution (With major emphasis on the evolution of social behavior, and adapting to expanding environments) (after [14]).

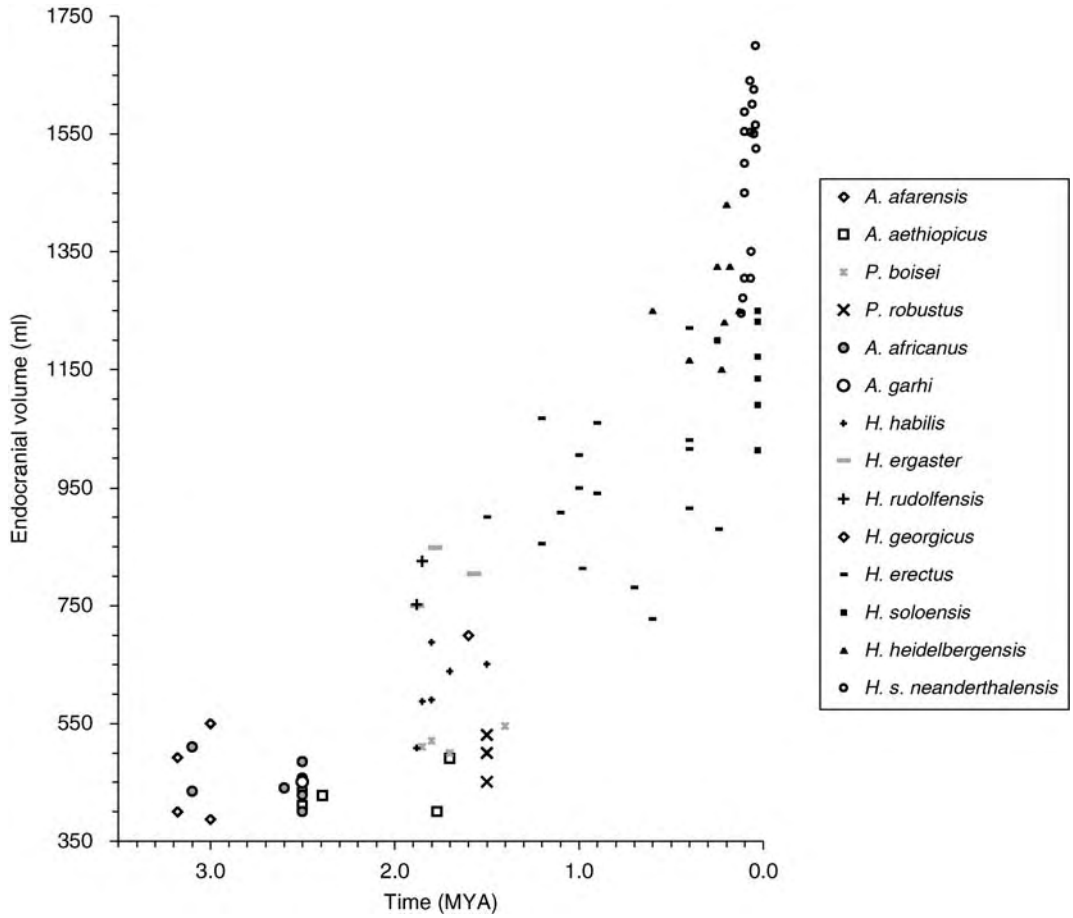
Average Statistics for Different Hominid Taxa (after [14]).

likely in the inferior parietal and posterior temporal lobes. Exactly what selective forces led to this shift can only be guessed, but following the archaeological record of stone tool development at roughly 2.6 MYA, these changes are perhaps best explained as a response to an expanding ecological niche, where scavenging, some small game hunting and a vegetarian food base necessitated a more complex appreciation of

environmental resources, as well as social behavioral stimuli within foraging hominid groups. A positive feedback model for these and other interacting variables was suggested by Holloway [15,16].

Certainly, the second reorganizational pattern, involving Broca's region, cerebral asymmetries of a modern human type and perhaps prefrontal lobe enlargement, strongly suggests selection operating on a more cohesive and cooperative social behavioral repertoire, with primitive language a clear possibility. By *Homo erectus* times, ca. 1.6–1.7 MYA, the body plan is essentially that of modern *Homo sapiens* – perhaps somewhat more lean-muscled bodies but statures and body weights within the modern human range. This finding indicates that relative brain size was not yet at the modern human peak and also indicates that not all of hominid brain evolution was a simple allometric exercise. Again, this pattern reflects the mosaic nature of human brain evolution. Neandertals were present at least 200,000 years ago, and those known from Western Europe, Eastern Europe and the Middle East have brain volumes that on average exceeded those of modern man, yet with bodies that appear more massive (lean body mass). The only difference between Neandertal and modern human endocasts is that the former are larger and more flattened. Most importantly, the Neandertal prefrontal lobe does not appear more primitive. Table 4 provides a brief statistical description of the major hominid taxa and their respective sample sizes, endocranial volumetric means and ranges. The EQ values that accompany this Table were calculated using Holloway and Post's [8] homocentric equation (see Holloway et al. [4] p. 13–14 for a more detailed explanation) as well as Martin's EQ's based on a mammalian sample. Figure 4 presents a plot of endocranial volumes against time.



**Evolution of the Brain in Humans – Paleoneurology. Figure 4** Graph showing increase in brain size during the past 3 million years from the fossil hominid endocasts available. While the graph appears smooth and continuous, it should be remembered that each symbol represents several thousand years, and such a graph cannot accurately portray all of the details of brain size changes with time, particularly given the incompleteness of the fossil record. After Holloway et al. [14].

## Concluding Comments

Comparative neurology provides neuroscientists with the basic understanding of neural structural variation and correlated behavioral patterns [17]. Paleoneurology provides the direct evidence for hominid brain evolution but is extremely constrained in its evidentiary details, largely thanks to the meninges that surround the surface of the cerebral cortex. In time, growing understanding of molecular neural genetics may help to pinpoint more of the evolutionary differences between modern man and other primates and may even reliably date some of the key organizational and size changes that occurred in mosaic fashion in the human line. It seems that the most essential aspects of human behavior – strong cooperative (and competitive) social behavioral adaptation, far in advance of any ape, centered within and controlled by language and cognitive abilities involving multi-way interactions between predictive prefrontal and analytic parietal/temporal lobes – emerged relatively early in hominid evolution, setting the stage for positive feedback relationships between growing cerebral size and behavioral complexity, which involved a complex interaction between regulatory gene events and changes in the genes themselves.

## Definition

The cognitive and linguistic capacities of humans are exceptional in comparison to other animals. To understand the neural bases of uniquely human behavioral traits, it is necessary to compare brain structure in humans to close primate relatives, particularly the great apes.

## Characteristics

### The Comparative Approach

Humans express dramatically divergent behavioral attributes compared to other animals in terms of language, social cognition and the manufacture of technology. To discover the human brain specializations that subserve these behavioral capacities, it is necessary to consider neural structure and function in

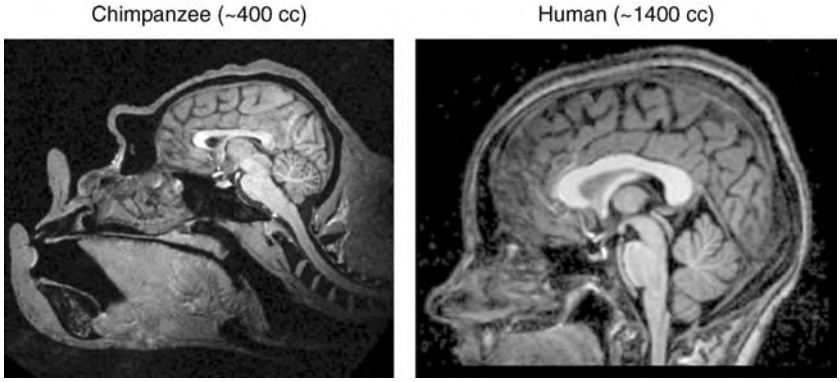
comparison to humanity's closest relatives. Despite pronounced morphological and behavioral differences between humans and other primates, genetic evidence clearly indicates that humans share close phylogenetic affinities with the great apes (orangutans, gorillas, bonobos and chimpanzees). Indeed, humans and chimpanzees are more closely related to each other than either is to gorillas. In light of these phylogenetic relationships, comparisons of human brains to those of chimpanzees and other great apes hold the potential to unveil the neural substrates of human cognitive specializations that have evolved in the 6–8 million years since the last common ancestor (Fig. 1).

## Size and Morphology

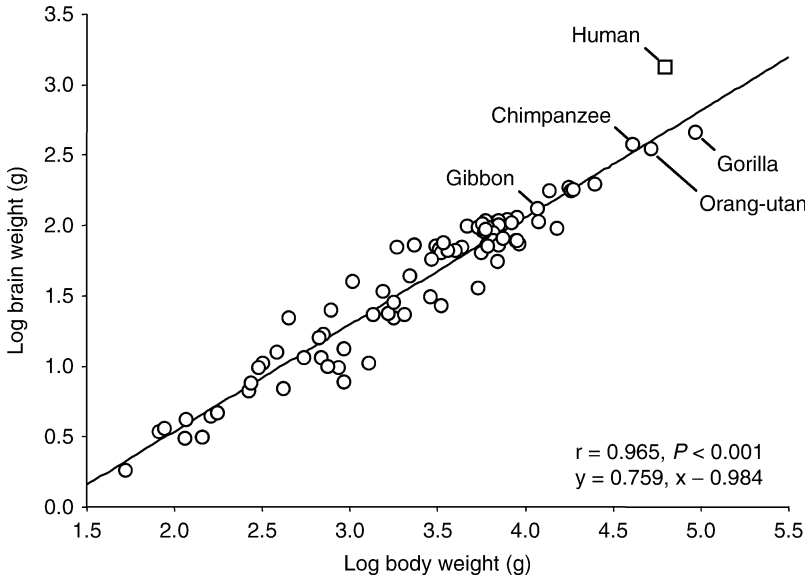
One of the most remarkable features of the human brain is its large size in both absolute and relative terms. Humans have the largest brain of any primate (~1,400 g), being about three times bigger than those of the great apes. Although larger absolute brain sizes can be found among whales and elephants, humans show the greatest deviation among mammals in having exceptionally large brains after controlling for overall body size (Fig. 2) Fossil evidence, furthermore, indicates that the period of most dramatic brain expansion occurred within the human lineage in the last two million years, long after the evolution of other human-specific traits like bipedal walking [1].

It is less obvious, however, whether brain enlargement in humans has been accompanied by disproportionate increases in particular regions. Some alterations of internal organization may be expected because of developmental, functional or architectural constraints that necessitate redesign with changes in total brain size. For example, in comparison to other primates there is more white matter underneath the neocortex in humans. The proportion of neocortical white matter volume in humans, however, conforms to ►allometric scaling expectations based on the demands for interconnections of gray matter at human brain size [2, 3]. Additionally, the human neocortex (gray and white matter combined) occupies a larger fraction of total brain size than it does in great apes. While much of this extra neocortical growth may be explained by evolutionarily conserved schedules of neurogenesis [4], it is significant that the size of the human neocortex actually exceeds what would be predicted for an anthropoid primate of the same brain size [2].

The neocortex is heterogeneous with respect to architecture and function. Therefore, it is also important to consider whether the human neocortex shows regional modifications in organization. The overall degree of cortical folding or gyrification generally increases with larger brain size in primates and the human brain fits this pattern. Nonetheless, the prefrontal part of the neocortex in humans displays a greater amount of ►gyrification than would be expected for an anthropoid primate of the same size [2]. This suggests that relatively more cortical tissue is buried within sulci in the human prefrontal cortex, which may correlate with enhancement of the cognitive functions mediated by this neocortical region. However, studies that have directly examined whether the prefrontal cortex is enlarged in humans have yielded somewhat contradictory results. While it seems that total frontal cortex size in humans is no greater than expected based on apelike scaling trends for brain size [5], further data may be necessary to resolve whether the prefrontal cortex or any of its constituent cytoarchitectural areas show disproportionate enlargement in humans.



**Evolution of the Brain in Humans – Specializations in a Comparative Perspective. Figure 1** Midsagittal magnetic resonance image sections of chimpanzee and human heads. In comparison to the chimpanzee, the human brain is dramatically enlarged relative to other cranial components. From this view, it is also clear that the majority of human brain expansion is due to enlargement of a subset of structures, including the neocortex and cerebellum, whereas others, like the brainstem, are relatively unmodified.



**Evolution of the Brain in Humans – Specializations in a Comparative Perspective. Figure 2** The allometric scaling relationship between mean brain weight and body weight among 85 primate species based on data presented in Holloway [7]. A least-squares regression line is fitted to the nonhuman primate data (y = 0.759, x –0.984, $r$ = 0.965, $P$ < 0.001). Note that the value for human brain size is the greatest departure from the allometric scaling trend seen in all other primates.

Beyond the prefrontal cortex, there is evidence of human-specific reorganization of the size of other cortical areas. The primary visual cortex (Brodmann's area 17 or V1) and the primary motor cortex (area 4) are quite similar in absolute volume in humans and great apes, despite vastly different brain size among these species [6]. In fact, the primary visual cortex in humans is substantially smaller than predicted for total brain size [7], probably because it scales closely to the size of the eye rather than the brain. These data suggest that human neocortical enlargement entailed selective expansion of certain "association" areas of the parietal, temporal and prefrontal cortex, whereas primary sensory and motor areas remained more closely correlated with direct inputs and outputs from the periphery. The hypothesis of regional modification in human neocortical evolution is further supported by the observation that human temporal lobes, especially the underlying white matter, are enlarged beyond allometric predictions based on apes [8]. It is also interesting that a subset of thalamic nuclei in humans show differences from apes. After taking scaling into account, humans have more neurons than other hominoids in the anterior principal (anteroventral) nucleus, mediodorsal nucleus and pulvinar, while neuron numbers in sensory relay nuclei are generally conservative [9]. This suggests that the "association" regions of the neocortex have expanded in humans in parallel with the specific thalamic nuclei that furnish them with reciprocal connections. Taken together, the studies reviewed above indicate that some regions within the human neocortex have become selectively modified in size.

The neocortex is not the only brain structure that is uniquely expanded in humans. After the neocortex, the human cerebellum shows the next greatest degree of enlargement relative to body size. This is not surprising given the extensive connections that link neocortex and cerebellum. In fact, the two structures appear to have evolved in tandem as a coordinated system in primates, although fossil endocast data suggest that recent human evolution was characterized by a burst of cerebellar expansion that was unmatched by a parallel increase in neocortex size. Beyond relative cerebellar size, humans also differ from other primates in the size and shape of the cerebellar dentate nucleus. In particular, the ventral portion, believed to send outputs to non-motor regions of the frontal lobe by way of the ventrolateral thalamus, is better developed in humans than in great apes. These connections may be the anatomical substrate supporting the postulated cerebellar involvement in cognition, beyond its traditionally recognized role in motor coordination [8].

## Asymmetry

Human brains exhibit structural and functional lateralization in a number of different respects. Humans have a unique capacity for the generation and communication of symbolic thinking in the form of language. Concomitantly, a majority of humans show left hemisphere

dominance for language functions and display associated anatomical asymmetries of the brain. Human brains are especially asymmetric in the region of cortex along the sylvian fissure [10]. In most human brains, the left sylvian fissure is longer and more superiorly oriented than the right. In addition, the ▶planum temporale, located on the superior temporal plane between Heschl's gyrus and the termination of the sylvian fissure, is larger on the left in most human brains. These asymmetries may be significant for language lateralization because this region of posterior temporal cortex corresponds to cytoarchitectural area Tpt, a site that has been identified as a major component of Wernicke's area. Whether or not these asymmetries can be considered human evolutionary specializations can only be determined in reference to great apes. Notably, the sylvian fissure and planum temporale have been demonstrated to display humanlike left dominant asymmetry in chimpanzees, gorillas and orangutans [11]. The full extent to which these gross anatomical asymmetries in great apes reflect underlying microstructural differences in circuitry between the left and the right is not yet clear. However a comparative study of area Tpt cytoarchitecture demonstrated that humans have left dominance in terms of greater spacing between minicolumns and more overall neuropil volume, allowing for interconnectivity among cells [12]. It is interesting that these histological asymmetries are absent in macaque monkeys and chimpanzees.

The gyri of the inferior frontal cortex in the location of Broca's area exhibit morphological asymmetries in humans. Although it has been claimed that similar anatomical asymmetries of the inferior frontal gyrus exist in African great apes (gorillas, bonobos and chimpanzees), the poor correspondence between cytoarchitectural boundaries and the location of sulci makes it difficult to asses the significance of external landmarks for revealing asymmetries of Brodmann's areas 44 and 45 [13]. At the histological level, Broca's area in humans displays lateralization of pyramidal neuron dendritic arborization and overall neuron packing densities. However, it is not yet known whether comparable microstructural lateralization exists in the homologous areas of great apes.

A further aspect of human cerebral asymmetry can be observed as greater width and protrusion of the left occipital pole and right frontal pole, called ▶petalias [7]. In humans, this typical petalia torque pattern is most strongly observed in right-handed individuals. The characteristic humanlike pattern of left occipital-right frontal petalias is not expressed in great apes to the same degree.

## Histology and Connectivity of the Neocortex

More subtle alterations of histological architecture in the absence of large-scale volumetric reorganization also have occurred in the course of human brain evolution. For example, the human primary visual cortex shows modifications of dendritic compartments and interneurons in layer IVA relative to great apes, which might relate to changes in the way that humans process motion information [6]. The anterior cingulate and paracingulate cortex have also undergone modifications in histological organization at various times along the evolutionary lineage leading to humans. Very large ▶spindle-shaped neurons, also known as Von Economo neurons, located in layer Vb are present in the anterior cingulate cortex of humans and great apes, but not that of any other primates [14]. In comparison to other species, in humans these unusual neurons are especially large in size, more numerous and aggregated in clusters. Because their distinctive morphology derives from the presence of thick singular apical and basal dendrites, these neurons might be specialized to transmit rapid outputs to subcortical targets. In addition to the spindle-shaped neurons, great apes and humans are also unique among primates in displaying calretinin-containing pyramidal cells in layer V of anterior cingulate cortex [15]. The location of these two classes of specialized neurons in the anterior cingulate cortex suggests that great ape and human brains are adapted for the integration of emotion and cognition. In particular, it is possible that these connections are involved in the rapid processing of judgments in circumstances of social uncertainty. Furthermore, it is interesting that calretinin-containing pyramidal neurons are also found in the anterior paracingulate cortex (area 32) only in humans, but not great apes. This area is implicated in "theory of mind," a cognitive capacity that is exceptionally well developed in humans.

Finally, although there are extremely few comparative data on connectivity patterns in humans and great apes, a set of intriguing results from axon degeneration studies suggest that the human brain is distinguished among primates in having direct projections from neurons in the primary motor cortex to the motoneurons of the larynx in the nucleus ambiguus [16]. These direct cortico-motoneuron connections would be situated to provide enhanced voluntary motor control for speech production. Additionally, a recent comparative study used diffusion tensor imaging to show that the arcuate fasciculus language tract has a much larger projection to the middle and inferior temporal cortex in humans compared with chimpanzees or macaques.

## Evidence from Gene Expression and Gene Sequence Evolution

Distinctive aspects of the human brain phenotype arise from alterations to the genes that direct processes involved in neural development, physiology and

structure. Several genes that participate in orchestrating brain development show evidence of natural selection in the lineage leading to humans [17]. For example, the genes *ASPM* and *MCPH1* have undergone high rates of nonsynonymous amino acid substitution at different branch points in the evolutionary history of apes, including a marked upsurge in humans since the last common ancestor with chimpanzees. Because the proteins encoded by these genes are involved in neuroblast proliferation during embryonic development and mutations within these genes can cause pathological reduction in brain volume (microcephaly), these data suggest that some part of human brain enlargement may be related to their evolution. The transcription factor *FOXP2* also displays evidence of sequence changes in human evolution [18]. Specific linguistic impairment, intellectual deficits, orofacial dyspraxia and structural abnormalities of language-related brain areas have been shown to occur in members of a single human family that share a point mutation in the *FOXP2* gene. The FOXP2 transcription factor is highly conserved across mammals, with identical amino acid sequences in rhesus macaques, gorillas and chimpanzees. Humans however, have mutations that yield two amino acid substitutions in comparison to other primates, suggesting that this gene may be involved in the evolution of language and speech.

Several studies of gene expression in the brain using microarray techniques broadly agree in showing that the human cortex is distinguished from that of chimpanzees and other primates in displaying up-regulation of the expression of many genes related to neuronal signaling, plasticity, and activity [19]. These observations are further supported by findings that genes that encode various subunits of the mitochondrial electron transport chain show evidence of natural selection in the human lineage [20]. These changes would presumably enhance the aerobic energy producing capabilities of cells that have high metabolic rates, such as neurons.

## Conclusions

Research efforts directed at understanding the human brain in comparative perspective are still in their infancy. As more data accumulate to articulate the phenotypic differences between human brains and those of humanity's close relatives, greater insights will be gained into how neuroanatomical and genetic changes translate to human behavioral specializations.

# Evolution of the Brain in Urbilateria

Simon G. Sprecher
Department of Biology, Center for Developmental Genetics, New York University, New York, NY, USA

## Synonyms

Brain evolution; Urbilateria

## Definition

Morphological and neuroanatomical properties of the brains of phylogenetically distantly related animal phyla differ in many aspects. However, using molecular genetic techniques to study the process of brain development, it has become evident that the fundamental genetic program underlying brain development has been largely conserved throughout evolution. It has therefore been proposed that the last common ancestor of all bilaterian animals, the ►Urbilateria, possessed a brain-like structure defined by an ancestral developmental genetic program.

## Characteristics

### Phylogenetic Implications

In classical phylogenetics, major criteria for classification involved morphological and anatomical characteristics. For example, the presence of a secondary body cavity called the coelom had importance in determining where to place a given animal phylum within the phylogeny. Similarly, animal phyla sharing major morphological characteristics in their body plan, such as the obvious segmental organization of annelids and arthropods, were often grouped in closely related clades. However, advances in molecular genetic analysis during the last decade have led to the proposal of a novel molecular based phylogeny [1,2]. This phylogenetic tree is largely based on ribosomal and Hox gene sequence analysis. One of the most striking implications of this revised phylogeny is that none of the bilaterian phyla present today represents a truly ancestral, basal state (Fig. 1).

Therefore, the characteristics of the ►urbilaterian ancestor, at the base of all bilaterally symmetrical metazoan animal phyla, cannot be directly derived from currently existing animal phyla. Previously basally located and/or out-grouped phyla such as the Platyhelminthes ("flatworms") are now placed among highly evolved phyla such as arthropods and annelids. Molecular genetic features, which act in a comparable manner in ►protostome phyla and ►deuterostome phyla, presumably existed in the urbilaterian ancestor. Studies of the molecular basis of brain development in animal model systems as different as the mouse and the fruit fly (*Drosophila melanogaster*) provide insights into the way in which the urbilaterian brain may have evolved [3,4].

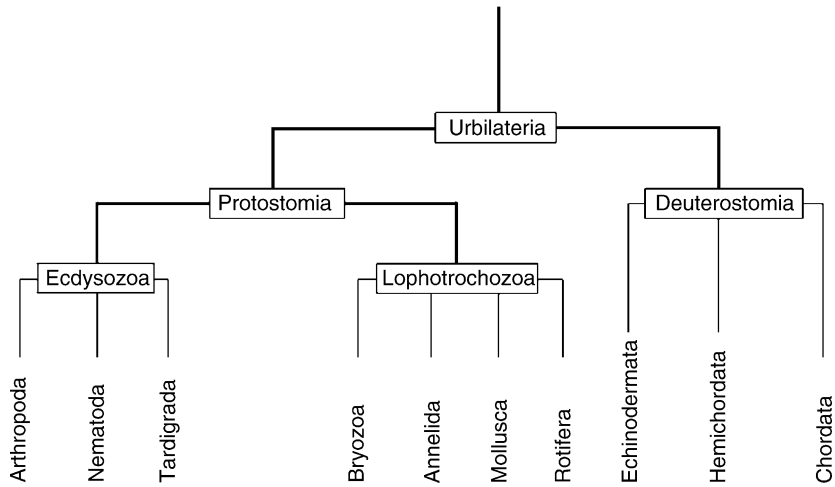
### Dorsoventral Patterning System

A major difference between the central nervous systems (CNS) of invertebrates and vertebrates is that their relative locations along the body axis are dorsoventrally inverted; the CNS of invertebrates is located ventrally, whereas the CNS of vertebrates is dorsal. Possible scenarios leading to the opposite location of the CNS in these animal groups have been the center of a debate for almost two centuries. Accordingly, animal phyla were grouped together into Gastroneuralia (e.g., insects, containing a ventrally lying CNS) and Notoneuralia (e.g., chordates, containing a dorsally lying CNS). Nevertheless, the major patterning systems that are responsible for specifying the neurogenic region and subdividing the CNS into longitudinal columns are surprisingly similar in insects and vertebrates. In vertebrates the opposing action of the two signaling molecules Chordin (dorsal) and BMP4 (ventral) is required for the specification of the neurectoderm, where Chordin promotes and BMP4 inhibits neurogenic cell fate. In contrast, during early embryogenesis in *Drosophila,* the Chordin homolog Short gastrulation (Sog) is expressed ventrally and the BMP4 homolog Decapentaplegic (Dpp) is expressed dorsally. Nevertheless, Dpp also act to inhibit neurogenic cell fate, whereas Sog promotes neurectoderm formation [3,4]. A set of three homeobox genes, the columnar patterning genes *ventral nervous system defective* (*vnd*, ventral column), *intermediate nervous system defective* (*ind*, intermediate column) and *muscle specific homeobox* (*msh*, lateral column), subdivide the insect neurectoderm into three longitudinal stripes. These columnar patterning genes are essential for the formation of neuronal stem cells as well as for the specification of their identity. In vertebrates the genes *Nkx2*, *Gsh* and *Msx* (homologs of the Drosophila genes *vnd*, *ind* and *msh* respectively) act in a similar way in the developing spinal cord [5]. However, their relative expression along the body axis is dorsoventrally inverted (Fig. 2).

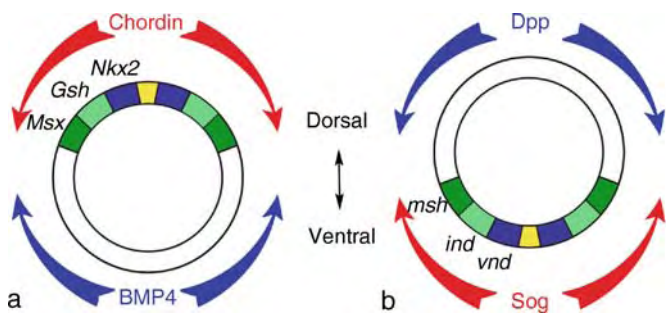
In addition to the comparable columnar subdivision of the CNS in insects and vertebrates, the developmental fate of precursors and the neurons produced within a specific columnar domain are sometimes similar. For example, in both animal phyla, precursors of the medial column give rise to interneurons that pioneer the medial longitudinal fascicles and to motorneurons that exit via the lateral nerve root.

The Dpp/Sog and BMP4/Chordin interactions and the expression of columnar patterning genes are both inverted in a dorsoventral manner between insects and vertebrates. It has therefore been proposed that the ventral neurectoderm of insects may correspond to the dorsal neurectoderm of vertebrates. The evolutionarily

E



**Evolution of the Brain in Urbilateria. Figure 1** Phylogeny of the bilaterians mainly based on molecular data. Note that phyla which have previously been considered as "primitive" such as the Platyhelminthes are now placed among the Lophotrochozoa and no longer represented as an out-group. Therefore characteristics present in distantly related groups with molecular resemblance argue for monophyletic origin of these features. For simplification, not all phyla are included.



**Evolution of the Brain in Urbilateria. Figure 2** Induction and subdivision of the neurogenic region in vertebrates (a) and insects (b). Schematic diagram shows the opposing action of the signaling molecules Dpp/BMP4 (*blue*) and Sog/Chordin (*red*), which define the neurogenic region. Columnar subdivision of the neurectoderm requires the homeobox genes *msh*/*Msx* (ventrolateral/dorsolateral), *ind*/*Gsh* (intermediate) and *vnd*/*Nkx2* (ventromedial/dorsomedial). The action of the signaling molecules as well as the columnar sub-organization of the neurepithelium is dorsoventrally inverted in insects and vertebrates.

conserved action of signaling molecules that specify the neurogenic region and the homologous set of homeobox genes that subdivide the neurectoderm into longitudinal columns imply that these molecular mechanisms are ancestral features and might have been already present in urbilaterians [3,4].

## Anteroposterior Patterning System

Studying the basic body plan of insects has lead to the identification of important molecular patterning systems, including many transcription factor cascades and major signaling pathways. Among these transcription factors, the homeotic or ►Hox genes are of great interest, since they specify segmental identity along the anteroposterior body axis. Interestingly, the expression of ►homeotic genes in the brain along the anteroposterior axis is virtually identical between vertebrates and insects. In the developing brain of *Drosophila* the homeotic gene *labial* (*lab*) is expressed in the tritocerebral ►neuromere. In *lab* mutant *Drosophila* embryos, neuronal stem cells are generated and proliferate correctly; however their progeny fails to express neuron specific markers. Thus, *lab* is required for the specification of neuronal identity. The mouse

homologs of *lab*, *Hoxa-1* and *Hoxb-1*, play a comparable role in the development of the vertebrate hindbrain. In Hox1 mutant mouse embryos formation of rhombomere 4 (r4) is defective. Double knockout of *Hoxa-1* and *Hoxb-1* causes a reduced size of r4 and additionally a loss of expression of r4 specific markers, resulting in a domain of unknown identity between r3 and r5. In both invertebrates and vertebrates, Hox gene action is necessary for the development of the posterior part of the brain [3,4]. In more anterior regions another set of transcription factors are involved in brain development. Insect "cephalic gap genes," such as *orthodenticle* (*otd*) and *empty spiracles* (*ems*), are essential for brain development and are involved in the formation of neuronal stem cells. In *otd* mutant embryos large parts of the neuronal stem cells of the anterior brain primordium do not develop, resulting in a large deletion of the anterior embryonic brain. A similar defect is seen in *ems* mutant embryos where large parts of anterior brain neuromeres are deleted. Defects observed in *ems* mutants locate slightly posterior to the defects seen in *otd* mutants. The mouse homologous genes of *otd* and *ems*, *Otx2* and *Emx2*, have similar functions in the development of the anterior vertebrate brain. The *Otx2* gene is expressed during early stages in the anterior visceral endoderm, where it is involved in the fundamental processes of anterior neurepithelium patterning. In *Otx2* mutant mouse embryos the rostral neurectoderm, which gives rise to the forebrain, midbrain and rostral hindbrain, does not get specified. *Emx2* is expressed in the ventricular zone of the developing cerebral cortex. In *Emx2* mutant mouse embryos the cerebral hemispheres and hippocampus are severely reduced in size and lack the dentate gyrus. Thus, in both mouse and *Drosophila*, *otd*/*Otx* and *ems*/*Emx* gene families are essential in the processes of patterning the anterior brain region.

Cross phylum rescues carried out in both *Drosophila* and mouse showed that *otd* and *Otx* genes were able to functionally replace each other during embryonic brain development. Neuronal specification defects in the brain of *otd* mutant *Drosophila* embryos ubiquitously expressing the mouse *Otx2* gene were largely restored. Similarly, the ubiquitous expression of *Emx2* in *ems* mutant *Drosophila* embryos rescued during early brain development results in a largely normal anterior brain region. In mouse the expression of the *Drosophila otd* gene was able to rescue the forebrain and midbrain patterning defects caused by the *Otx2* mutation. These observations support the notion that the function of *otd*/*Otx* and *ems*/*Emx* genes in brain development is evolutionarily conserved between protostomes and deuterostomes. Both gene families might therefore have been involved in patterning the anterior brain region of the urbilaterian ancestor.

## Tripartite Organization of the Brain

Genetic analysis of major developmental patterning genes suggests that the embryonic vertebrate brain consists of a tripartite basic organization. This ground plan consists of an anterior forebrain/ midbrain region, an intermediate midbrain/hindbrain boundary region (MHB) and a posterior hindbrain region. These developing brain regions are characterized by the specific expression domains of *Otx*, *Pax2/5/8* and Hox genes respectively. In both insects and vertebrates, it has been shown that the anterior brain regions depend on *otd*/*Otx* gene action and the posterior regions upon Hox gene activity (see above). In vertebrates the MHB is specified at the interface of an anterior *Otx2* expression domain and a posterior *Gbx2* expression domain, where the *Pax2/5/8* genes are expressed. Similarly, in *Drosophila* the expression domain of the *Gbx2* homolog *unplugged* (*unpg*) abuts an anterior *otd* expression domain. As in vertebrates, the expression of the two *Pax2/5/8* orthologs *Pax2* and *Pox neuro* (*Poxn*) coincides with the *unpg*-*otd* interface. Thus, as in vertebrates, the expression of *otd* adjacent to *unpg*, in combination with *Pax2*/*Poxn* genes expression, subdivides the embryonic *Drosophila* brain into three parts [6]. A specific feature of the vertebrate MHB is that at the interface, the expression of *Otx2* and *Gbx2* are antagonistic and orchestrate the expression of downstream factors [7]. When *Otx2* is mutated, *Gbx2* expression shifts into more anterior regions, whereas if *Gbx2* is mutated, *Otx2* expression extends posteriorly. Similarly, in *Drosophila* the expression of *otd* extends into more posterior regions in *unpg* mutants, whereas *unpg* extends anteriorly in *otd* mutant embryos [8]. This cross-repressive interaction of *otd*/*Otx2* and *unpg*/*Gbx2* seems to be evolutionarily conserved and is probably an ancestral feature of this brain region (Fig. 3).

Therefore, not only is the tripartite organization of the embryonic brain conserved between insects and vertebrates, but the genetic interaction of the major patterning genes and their developmental roles is also at least partially conserved.

Thus, mammalian and insect dorsoventral and anteroposterior patterning systems and the tripartite organization of the brain show close similarities in distantly related animal phyla. Even though vertebrate and insect brains differ significantly in their neuroarchitecture, it seems likely they have a common evolutionary origin in a brain-like structure that may have existed before the split of deuterostomes and protostomes. Moreover, key elements of the ancestral molecular genetic program that controlled the development of the brain in urbilaterians are likely to be evolutionarily conserved and therefore common to the development of the brain of all bilaterian animals including our own.

# Evolution of the Diencephalon

Ann B. Butler
Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

The diencephalon is the more caudal of the two divisions of the forebrain. It lies between the more rostral division of the forebrain, the telencephalon, and the rostral end of the midbrain. The diencephalon comprises four divisions in its major, rostral part – the epithalamus, dorsal thalamus, ventral thalamus (or subthalamus), and hypothalamus – as well as the more caudally lying pretectum and, in some vertebrates, the posterior tuberculum.

## Characteristics

The diencephalon varies substantially in the degree of elaboration of its various components – epithalamus, dorsal thalamus, ventral thalamus, hypothalamus, pretectum, and the migrated nuclei of the posterior tuberculum – across vertebrates. The hypothalamus, pretectum, and posterior tubercular nuclei are arguably most complex in most taxa of ray-finned fishes, while the dorsal thalamus and ventral thalamus are most elaborated in amniotes. The more dorsal part of the epithalamus is also quite variable, while its habenular portion is relatively conservative, at least in some of its features.

### Epithalamus

The epithalamus comprises two main divisions – that of the habenular complex and related nuclei and that of its roof, the epiphysis, which is the more variable in terms of evolutionary specializations across the various vertebrate taxa.

#### *Epiphysis: Pineal/parietal and other Specializations of the Epithalamic Roof Plate*

The epiphysis has been identified in lampreys and jawed vertebrates and is generally involved in the

regulation of diurnal rhythms [1,2]. While absent in extant hagfishes, the fossil evidence indicates that the epiphysis was present in ancestral vertebrates. A pineal component, which in most cases is directly photoreceptive, is the most commonly occurring epiphyseal structure, present in lampreys and all jawed vertebrate taxa except crocodiles. Pineal projections vary to some degree across vertebrates, but its most common central target (particularly in ray-finned fishes and tetrapods) is the habenula. A more rostral epiphyseal structure, the parapineal organ, is present only very sporadically across vertebrate taxa – having been identified only in lampreys, trout, and the crossopterygian fish *Latimeria*. Like the pineal, it is also photoreceptive, and the parietal eye of lizards and the tuatara *Sphenodon*, which has a pigmented, retinal structure, may likewise be a parapineal outgrowth. Frogs also have a rostral epiphyseal outgrowth called the frontal organ. In birds, the pineal may be light-receptive, since its cells have opsin-containing membraneous segments, whereas in mammals, the pineal is blocked from direct light reception by the overlying cortex and skull. In both birds and mammals, the pineal is known to receive sympathetic innervation.

### Habenula

The habenular nuclei are a strikingly constant feature of vertebrate brains [1,2]. In all vertebrates studied to date (including a good sampling across fishes and tetrapods), the major afferent and efferent connections are similar. The two major afferent inputs arise from the basal ganglia, motor-control parts of the subpallium, the more ventral part of the telencephalon (particularly from the internal segment of the globus pallidus and its homologues), and from limbic (predominantly septal and hypothalamic) sources related to visceral and related functions, the latter coming into the habenular nuclei via the stria medullaris. The major output is via the fasciculus retroflexus to the interpeduncular nuclei.

The habenular nuclear complex is prominent in most fishes (lampreys, hagfishes, and cartilaginous and ray-finned fishes) and across tetrapods. In mammals, two additional nuclei have been classified as part of the epithalamus, the anterior and posterior paraventricular nuclei [3], but whether these nuclei also have homologues in other vertebrates is unknown. In most vertebrates, the habenular nuclei are markedly asymmetric in size, but the significance of this feature, if any, is unknown.

## Dorsal Thalamus

In mammals, the dorsal thalamus comprises a diverse set of nuclei, most of which are organized into groups and including multiple specific sensory relay nuclei, nuclei that are predominantly interconnected with limbic system structures, motor-system related relay nuclei, and intralaminar nuclei with widespread cortical projections. In nonmammalian amniotes, homologues of many of these nuclei have been identified. In contrast, in anamniotes, the dorsal thalamus is a relatively smaller part of the diencephalon with rostral and caudal portions distinguishable on the basis of their location and amount of afferent input from the midbrain roof. Despite marked differences in the degree of elaboration and many hodological differences, the basic organization of two rostrocaudally aligned divisions also applies to the amniote dorsal thalamus and allows its evolutionary history to be illuminated.

### Overview of Dorsal Thalamic Divisions and Evolution

The organization and evolution of the dorsal thalamus, particularly in mammals, which have a large number of different nuclear groups, was long regarded as difficult to fathom, since comparisons between mammals and other amniotes and between amniotes and anamniotes were difficult to make. The pioneering work of Karten and his colleagues in the 1960s and 1970s, establishing that ascending auditory and visual pathways [4] are present in birds that are similar to those in mammals represented a major breakthrough in understanding dorsal thalamic organization. The large number of nuclear groups present in mammals still did not allow for comparisons of most of their nuclei across amniotes. Nonetheless, the visual system pathways, one through the dorsal lateral geniculate nucleus (nucleus opticus principalis thalami, or OPT) and the other through nucleus rotundus, demonstrated a basic dichotomy between parts of the thalamus that Butler [5] subsequently generalized across other sensory systems and that revealed a basic thalamic organization of two divisions.

The two divisions of the dorsal thalamus, present in all vertebrates, are (i) a developmentally more rostral part that receives its predominant inputs directly, or lemniscally (in reference to a direct, ribbon-like pathway), called the lemnothalamus, and (ii) a more caudal part that receives its predominant inputs via a less direct route through the midbrain roof (the colliculi in mammals), called the collothalamus [5]. These divisions are consistent with the embryological development of the dorsal thalamus in mammals [6]. Across amnitoes, the two divisions underwent different evolutionary histories: in early mammals, the lemnothalamus became elaborated first, particularly in regard to the elaboration of the limbic, visual, and somatosensory systems, followed by elaboration of the collothalamus in several orders, while the reverse sequence occurred in the sauropsid line that led to modern birds [5]. These elaborations of the thalamic divisions occurred in conjunction with corresponding elaboration of their respective targets in the pallium (the more dorsal,

E

sensory-receptive and integrative part of the telencephalon), the lemnopallium and collopallium [1].

### Dorsal Thalamic Organization Across Vertebrates

Rostral, lemnothalamic and caudal, collothalamic divisions are generally present in fishes. In hagfishes, the dorsal thalamus and pallium have become elaborated in an apparently unique way, and the identity of the various thalamic nuclei and pallial areas remains obscure. In most other fishes, however, the lemnothalamic nucleus anterior predominantly receives a direct retinal input, while the more caudal part of the dorsal thalamus predominantly receives tectal (midbrain roof) inputs [1,2].

In contrast to other vertebrates, thalamic and pallial organization differs in amphibians in some particulars. The lemnothalamus does not receive direct retinal [7] or somatosensory [8] projections but rather indirect ones via the ventral thalamus; it is heavily interconnected with the limbic, medial pallium [9]. The collothalamus, while in receipt of tectal projections, projects predominantly to the striatum (a component of the basal ganglia) within the subpallium, rather than to the pallium [9]. Thus, the lemnothalamus of amphibians appears to correspond to the limbic-related parts of the lemnothalamus of amniotes rather than to its visual and/or somatosensory system components, and while collothalamic projections to the striatum correspond to those in amniotes, the major collothalamic-pallial projections present in amniotes are lacking. Whether these differences reflect secondary evolutionary events within the amphibian lineage or characterized the common tetrapod ancestral condition is unknown.

Within amniotes, the lemnothalamus comprises the nuclei that receive direct visual and somatosensory inputs as well as motor feedback pathways and also limbic system-related nuclei and the diffusely projecting, rostral set of intralaminar nuclei. In mammals, these include the anterior, medial, rostral intralaminar, and ventral nuclear groups as well as the dorsal lateral geniculate nucleus, and similar nuclei have been identified in sauropsids [5,10–13]. In mammals, the collothalamus comprises the lateral, posterior, and posterior intralaminar nuclear groups, as well as the medial geniculate nucleus [5], and similar nuclei have been identified in sauropsids, although debate continues as to the more individual nuclear comparisons with mammals. For more information on dorsal thalamic evolution, see: Butler, Evolution, of Dorsal Thalamus, this volume.

## Ventral Thalamus

In amniotes, the ventral thalamus, often called the subthalamus in mammals, mainly consists of a visual system component and motor system-related nuclei that are involved in circuitry with the basal ganglia. An additional ventral thalamic component is the thalamic reticular nucleus, a GABAergic cell group of importance in palliothalamic loops. In anamniotes, several ventral thalamic nuclei are present – called nuclei ventrolateralis, ventromedialis, and intermedius in ray-finned fishes [1], for example – that are known to be retinorecipient, but their efferent projections have not yet been described. In frogs, two prominent structures called the nucleus and neuropil of Bellonci are, likewise, retinorecipient ventral thalamic components [7].

### Ventral Thalamic Visual Nuclei

In sauropsids (reptiles and birds), the ventral lateral geniculate nucleus is a retinorecipient nucleus of marked prominence that lies ventral to the dorsal lateral geniculate nucleus along the medial margin of the optic tract [1]. It is connected with other brainstem nuclei that participate in the production and regulation of eye movements. In mammals, the position and relative size of this nucleus varies considerably; it is called the pregeniculate nucleus in primates. An additional, visual, ventral thalamic component present across amniotes is the intergeniculate leaflet [10], which is also connected with other brainstem visual structures.

### Motor Ventral Thalamus

Nuclei of the ventral thalamus that participate in basal ganglia-related circuitry have not yet been identified in any anamniotes and may be uniquely involved in amniotes in relation to motor system functions for their terrestrial, tetrapodal niche. In mammals, the most salient of the ventral thalamic nuclei is the subthalamic nucleus, which receives inhibitory (GABAergic) input from the external segment of the globus pallidus (GPe) and provides excitatory (glutamatergic) input to the internal segment of the globus pallidus (GPi). The latter is inhibitory to the ventral anterior and ventral lateral nuclei of the dorsal thalamus, so activity in the subthalamic nucleus promotes inhibition of these dorsal thalamic nuclei via GPi. Similar circuitry is present in reptiles and birds [14]. In birds, the subthalamic nucleus (previously called the anterior nucleus of the ansa lenticularis) receives homologous pallidal input and projects to homologous dorsal thalamic nuclei [15].

### Thalamic Reticular Nucleus

The thalamic reticular nucleus (TRN) appears to be most robustly developed in mammals, where it is involved in thalamocortical loop circuitry and may be a crucial part of the neural basis for the generation of consciousness [3,16,17]. The mammalian TRN comprises populations of GABAergic neurons that are reciprocally connected in topographical manner with thalamic nuclei and likewise receive ordered inputs from neocortical areas that are interconnected with the same thalamic nuclei. A homologous TRN is present in birds (previously called the pars dorsalis of the superior

reticular nucleus), comprising a ventral thalamic, GABAergic population of neurons that has circuitry similar to that of the TRN of mammals [18]. Among reptiles, a homologous nucleus with like features has been found in turtles [19]. In contrast, in crocodiles, a TRN may be present, but it contains few GABAergic neurons [20].

## Hypothalamus

The hypothalamus is a highly complex part of the diencephalon, primarily involved in the regulation of a host of visceral and limbic-related functions [1,2]. In many fishes, the hypothalamus includes a large, ventral lobe that is interconnected with various sensory systems, particularly the visual system via projections from pretectal nuclei, and that may be involved in the motor control of feeding behavior. In all vertebrates, the hypothalamus is interconnected with the pituitary gland and is involved with regulation of many functions via the autonomic nervous system.

In mammals, the hypothalamus is organized into sets of nuclei in three medial to lateral zones – periventricular, medial, and lateral – with preoptic, supraoptic, tuberal, and mammillary regions in rostral to caudal order through those zones, and this basic organizational scheme is discernable in other vertebrates as well. Across all vertebrates, the hypothalamus is highly interconnected with both limbic and visceral regulatory systems. For more information on the evolution of the hypothalamus, see: Bruce, Evolution, of the Hypothalamus: in Amniotes; and Hodos, Evolution of the Hypothalamus: in Anamniotes, this volume.

## Pretectum

The pretectum forms a transitional region between the dorsal thalamus and the roof of the midbrain. The pretectal nuclei are variously elaborated in different vertebrate taxa but share a predominant relationship to the visual system. Some of the pretectal nuclei are highly interconnected with the vestibular system and with tegmental nuclei that form the accessory optic system; these pathways are involved in the regulation and control of eye movements.

In all vertebrates, the pretectal nuclei can be grouped into superficial, central, and periventricular sets, although this organization is most salient in fishes. Among the latter, the pretectum is particularly well developed in teleosts [1,2]. In teleosts, various pretectal nuclei receive retinal and tectal inputs and are connected with other pretectal nuclei that in turn project to parts of the hypothalamus; these circuits may be involved in feeding behavior. Among amniotes, the pretectum is elaborated to a greater degree in sauropsids (reptiles and birds) than in mammals. Some probable homologies can be recognized across amniotes, such as the area pretectalis of birds and the olivary pretectal nucleus of mammals, which regulate pupillary constriction via projections to the Edinger-Westphal nucleus of the oculomotor nuclear complex. Various other nuclei share some characteristics but not others, indicating that some independent evolution of pretectal nuclei may have occurred within the sauropsid and mammalian lineages.

## Migrated Posterior Tuberculum

The posterior tuberculum is a caudal diencephalic region that is most clearly recognizable in anamniotes (see Vernier and Wullimann, Evolution, of the Posterior Tuberculum and the Preglomerular Nuclear Complex, this volume). Its unmigrated portion is in the tegmental region and contains some dopaminergic neurons. Its migrated portion is classified as a caudal diencephalic component, mainly because its several nuclei are involved in the relay of various sensory system inputs from the sensory nuclei to the telencephalon [1]. Thus, the migrated nuclei of the posterior tuberculum mimic some of the dorsal thalamic nuclei of amniotes. The migrated nuclei of the posterior tuberculum have been most studied in ray-finned fishes, particularly teleosts, in which they form a complex known as the preglomerular nuclear complex. These nuclei relay ascending sensory information – particularly lateral line (electrosensory and mechanosensory) and gustatory – to various parts of the telencephalon. For more information on the evolution of the lateral line systems, see: Braun, Evolution, of the Mechanosensory and Electrosensory Lateral Line Systems.

# Evolution of the Dorsal Thalamus

Ann B. Butler
Department of Molecular Neuroscience, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

## Definition

The dorsal thalamus is a part of the diencephalon, the more caudal of the two components of the forebrain. It comprises a number of nuclei that relay sensory inputs and other information to the telencephalon, the more rostral forebrain component. It has two divisions, based on their predominant sources of afferent input, that can be identified across all jawed vertebrate groups – the lemnothalamus, which receives predominantly direct (lemniscal) inputs, and the collothalamus, which receives its predominant inputs via a relay through the midbrain roof (called the colliculi in mammals).

## Characteristics

The dorsal thalamus contains only three nuclei in most fishes and amphibians, a rostrally lying nucleus called nucleus anterior and two (or sometimes several) nuclei that lie more caudally. The latter nuclei receive their predominant input from the midbrain roof, while in fishes, nucleus anterior is the direct target of retinal projections. The dorsal thalamus of reptiles and birds contains numerous nuclei, and in most mammals these nuclei are even more numerous and comprise a number of nuclear groups.

Despite the relative complexity of the dorsal thalamus in amniotes, Butler [1,2] realized that a rostral, lemnothalamic division and a caudal, collothalamic division can be recognized across at least all jawed vertebrates, based on commonalities of input patterns, projection patterns, and embryological development. The prefix "lemno-" in the term for the rostral division refers to a ribbon, indicating a ribbon-like, i.e., direct, input of afferent sensory projections. (In mammals, a number of such direct pathways have this flat, ribbon-like shape, e.g., the medial lemniscus and the trigeminal lemniscus). The prefix "collo-" in the term for the caudal division refers to the midbrain colliculi of mammals, which form the roof of the midbrain. The organization of the dorsal thalamus will be discussed in these terms in the present essay; for an alternative view see Bruce, Evolution, of the Brain: in Reptiles, this volume.

In mammals, dorsal thalamic sensory relay nuclei are the exclusive relay system for this information to the telencephalon, a situation that, as far as is currently known, is also the case in reptiles and amphibians. A markedly different arrangement occurs in ray-finned and cartilaginous fishes, in which some laterally migrated nuclei of a more caudal diencephalic division, the posterior tuberculum, as well as, in some instances, parts of the hypothalamus and ventral thalamus, participate in sensory relay pathways to the telencephalon that are in addition to the sensory relays through the dorsal thalamic nuclei. In birds, while most sensory relay to the telencephalon occurs through dorsal thalamic nuclei, an exception occurs within their trigeminal system: the principal trigeminal nucleus projects directly to a part of the telencephalic pallium (the more dorsal part of the telencephalon), bypassing the dorsal thalamus.

Variation also occurs in the telencephalic targets of collothalamic (and/or posterior tubercular nuclei)

across different vertebrate groups. In fishes, the location and input patterns of the migrated nuclei of the posterior tuberculum, most frequently referred to as the preglomerular nuclear complex (see Vernier and Wullimann, Evolution, of the Posterior Tuberculum and Preglomerular Nuclear Complex, this volume), are similar to that of the collothalamus. The collothalamus generally projects to the lateral aspects of the pallium (ventral and lateral pallia and/or the lateral part of the dorsal pallium) and also to the striatum (a motor-control region) within the subpallium (the more ventral part of the telencephalon). Likewise, their projections of the preglomerular nuclear complex are generally to the to the more lateral aspects of the pallium ("lateral" being in used here in reference to original position embryologically, regardless of position in the adult case, as discussed below). While in amniotes, the collothalamic nuclei generally project also to the lateral aspects of the pallium as well as to the striatum, in amphibians, the collothalamus projects almost exclusively to the striatum, with only a very minor projection to the lateral-most edge of the pallium. Whether the latter condition is a specialization within the amphibian lineage or representative of the primitive tetrapod condition is currently unresolved.

Similar variation occurs in the telencephalic targets of lemnothalamic nuclei across different vertebrate groups. In fishes, while the picture is somewhat cloudy, the general case appears to be that the lemnothalamus projects to the more medial aspects of the pallium ("medial" also used here in reference to the original position during embryological development). In amphibians, the projections of the lemnothalamus are robust and strongly to the medial pallium, which is somewhat elaborated in contrast to the very poorly developed other pallial regions. In amniotes, the lemnothalamic nuclei project only sparsely to the medial pallium (hippocampus) but robustly to various parts of the medial part of the dorsal pallium. In mammals and birds, projections to the striatum from the rostral intralaminar nuclei have also been gained. Further, variation in inputs to the lemnothalamus varies significantly between amphibians and amniotes. Thus, relative to amphibians, shifts in the afferentation of the lemnothalamus and in both the lemnothalamic and collothalamic projection patterns occur, in conjunction with dramatic differences in the elaboration of the various pallial areas that receive them.

## Collothalamus

In fishes and amphibians, the caudal portion of the dorsal thalamus, composed of two or several nuclei, receives its predominant input from the midbrain roof. This portion of the dorsal thalamus also generally projects to the more lateral aspects of the pallium and/or to the striatum. Likewise, several nuclei are present in the more caudal part of the dorsal thalamus of reptiles, birds, and mammals that receive similar predominant inputs from the midbrain roof and project to the more lateral aspects of the pallium and to the striatum. Further the projections from these nuclei to the telencephalon are exclusively ipsilateral across all taxa.

The evolutionary relationship of this set of predominantly midbrain roof-recipient nuclei was not difficult to interpret, based on this major shared feature of afferent input. Beginning in the 1960s, Harvey Karten and his colleagues [3] identified major ascending sensory pathways in a bird (the pigeon *Columba livia*) for both the auditory and visual systems that were relayed through the midbrain roof to the dorsal thalamus and thence to the telencephalic pallium. During the same period of time, Irving Diamond and his colleagues [4] identified multiple visual pathways in mammals that likewise are relayed through the superior colliculus to subdivisions of the lateral posterior/pulvinar complex (LP/pul) within the dorsal thalamus and thence to extrastriate visual cortices. The auditory system pathway through the inferior colliculus to subdivisions of the medial geniculate body and thence to auditory cortices was already well known at that time [5]. (Note that, in regard to terminology as used here, the lateral lemniscus is part of the collothalamic auditory system in spite of its "lemniscal" name, because it is a direct path to the midbrain roof, not to the thalamus). In birds, the comparable auditory pathway is relayed through a dorsal thalamic nucleus called nucleus ovoidalis to a part of the nidopallium (then called neostriatum) called Field L, and the comparable visual pathway is through nucleus rotundus to the entopallium (then called ectostriatum). During the next decade or so, similar pathways were found in a variety of reptiles, including turtles, lizards, and crocodiles.

Thus, while some controversy continues regarding specific, one-to-one homologies, it is widely accepted that the various, predominantly midbrain roof-recipient nuclei in reptiles, birds, and mammals are homologous to each other as a group and are evolutionarily derived from a shared set of nuclei in the common amniote ancestor and likewise homologous to the several predominantly midbrain roof-recipient nuclei in anamniotes. That these nuclei comprise one of two fundamental divisions of the dorsal thalamus could be appreciated only with understanding that there are just the two divisions, i.e., recognizing the fundamental unity and evolutionary continuity of the constituents of the lemnothalamus and that the collothalamic and lemnothalamic divisions comprise all of the dorsal thalamic nuclei/nuclear groups in anamniotes and amniotes alike [1,2].

## Lemnothalamus

Before the lemnothalamus, i.e. the developmentally rostral part of the dorsal thalamus that does not receive its predominant inputs by way of relay from the midbrain roof, was identified as a unitary division of the dorsal thalamus, the evolutionary source of many

of the dorsal thalamic nuclei/nuclear groups in amniotes was not understood. The nucleus anterior of fishes receives a substantial and direct projection from the retina, indicating that it might be homologous to the dorsal lateral geniculate nucleus (DLGN) of mammals and the equivalent cell group in reptiles [6] and birds, referred to by a variety of terms, including the nucleus opticus principalis thalami (OPT) in birds [3], but which will be referred to here in all amniotes as the dorsal lateral geniculate nucleus.

In contrast to the single nucleus anterior present in the rostral part of the dorsal thalamus in both fishes and amphibians, reptiles have several nuclei in that region [6], including nucleus dorsolateralis anterior (DLA), nucleus dorsomedialis, and perirotundal nuclei, in addition to the more laterally situated, retinorecipient DLGN [7]. Birds have even more individual nuclei within this part of the dorsal thalamus [8–10]. For most mammals, the situation is even more complex, with placental mammals (and marsupials and monotremes to a lesser but nonetheless substantial extent) having multiple nuclear groups in addition to the DLGN, including the medial, anterior, rostral intralaminar, and ventral nuclear groups. The question of how these various nuclei in sauropsids and nuclear groups in mammals were related evolutionarily to each other, to the DLGN, and to the more caudal, predominantly midbrain roof-recipient nuclei was resolved by recognizing commonalities of development and partially overlapping patterns of connectivity across them. In brief, the direct retinal projections overlap to varying degrees with somatosensory (spinal and/or dorsal column), raphe, hypothalamic, and minor (as opposed to predominant) tectal inputs across these nuclei in amniotes [1], while in fishes, nucleus anterior receives direct retinal input, as noted above, and also the minor tectal and raphe inputs. At the time that the lemnothalamic division of the dorsal thalamus was recognized [1], it was thought that the nucleus anterior of amphibians also received direct retinal and somatosensory inputs, which thus also fit the pattern in both fishes and amniotes. Recent work of Gerhard Roth and his colleagues [11,12] has shown that, instead, these inputs end on ventral thalamic nuclei that in turn project to nucleus anterior, and, also in contrast to the situation in other vertebrates, these inputs appear to be inhibitory, rather than the excitatory inputs of the directly projecting sensory systems. Nonetheless, nucleus anterior of amphibians clearly comprises the lemnothalamus and is homologous to its namesake in fishes. The pattern of projections to it in amphibians may be a specialization within that lineage rather than characteristic of the ancestral tetrapod lineage. Studies of these projections in lungfish may help to resolve this question.

Additional data that support viewing the above noted nuclei in amniotes as lemnothalamic and homologous as an entire group to nucleus anterior of anamniotes are their shared pattern of projections to the telencephalon. Projections from some of the lemnothalamic nuclei are bilateral, in all vertebrate groups examined including mammals [13,14], rather than being solely ipsilateral[1] like the collothalamic nuclei. Also, they tend to be to the medial pallium and/or medial part of the dorsal pallium rather than to the lateral aspects of the hemisphere. Additionally, they do not project to or give off any collateral branches to the striatum.

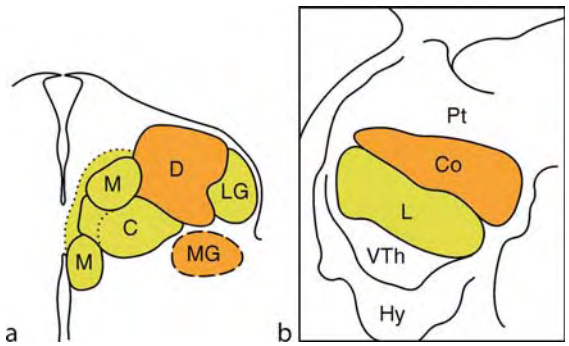
## Developmental Perspectives on the Lemnothalamus and Collothalamus

The above analysis of shared patterns of connections, both afferent and efferent, was enlightened by a much earlier study of the embryological development of the dorsal thalamus in a rabbit, carried out by Rose [15] (Fig. 1a). Rose identified five neuronal masses in the developing dorsal thalamus of 50-mm rabbit embryos. A medial geniculate pronucleus gives rise to the medial geniculate body, and a single dorsal pronucleus gives rise to both the posterior nuclear group and the lateral posterior/pulvinar complex. The latter two pronuclei thus constitute the embryonic collothalamus. The three other pronuclei comprise the medial pronucleus, which gives rise to the medial nuclear group, the central pronucleus, which gives rise to the anterior, (rostral) intralaminar, and ventral nuclear groups, and a dorsal lateral geniculate pronucleus, which gives rise to the DLGN.

The developmental affinity of the anterior, (rostral) intralaminar, and ventral nuclear groups was an additional clue in the identification of the lemnothalamus as a unitary, rostral thalamic division. Further, the caudal and lateral position of the DLGN in most adult mammals is explicable as the result of the expansion of the derivatives of the medial and central pronuclei [15].

Recent developmental findings have supported the idea of a bipartite dorsal thalamus. In developing mice embryos, calretinin is expressed in the collothalamus but not in the lemnothalamus, and the gene Math4a has

[1] Butler 1> originally included all intralaminar nuclei as part of the lemnothalamus. Based on a detailed analysis of dorsal thalamic connectivity in birds, Veenman et al. 10> cogently argued that while the set of rostral intralaminar nuclei across amniotes are indeed a lemnothalamic component, the posterior and more laterally lying intralaminar nuclei, including the parafascicular, paracentral, and central lateral nuclei of mammals, should be considered collothalamic, based on multiple factors, including their substantial tectal input and striatal projections. Bilateral projections to the pallium have been found in mammals that originate from the parafascicular and paracentral nuclei 13,14>, but in these studies, the retrogradely labeled neurons on the contralateral side are quite few and are restricted to the medialost portions of these nuclei. Thus, it is highly likely that this entire medial thalamic region of mammals, including the medialost portions of the parafascicular and paracentral nuclei, is part of the collothalamus.



**Evolution of the Dorsal Thalamus. Figure 1** a. Developing pronuclei in the dorsal thalamus of a rabbit, based on data from [15], shown in a semi-schematic drawing of a rostrocaudally compressed, transverse hemisection through the diencephalon on the right side. Collothalamic nuclei are shown in tan and lemnothalamic nuclei in green. The border of the medial geniculate pronucleus is shown in dashed lines, since it actually lies caudal to this level. The more rostrally present continuity between the two poles of the medial pronucleus is indicated by the dotted lines connecting them and the unlabeled green area that bridges them. b. Distribution of calretinin in the collothalamus, shown in tan, and *Math4a* in the lemnothalamus, shown in green, in a semi-schematic drawing of a parasagittal section through the diencephalon of the developing mouse, with rostral toward the left. Data from [16]. Abbreviations: *C*, central pronucleus; *Co*, collothalamus; *D*, dorsal pronucleus; *Hy*, hypothalamus; *L*, lemnothalamus; *LG*, dorsal lateral geniculate pronucleus; *M*, medial pronucleus; *MG*, medial geniculate pronucleus; *Pt*, pretectum; *VTh*, ventral thalamus.

the opposite pattern, being expressed in the lemnothalamus but not in the collothalamus [16] (Fig. 1b).

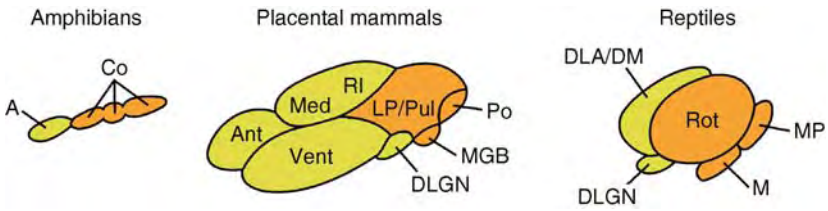
## Differential Evolution of the Lemnothalamus and Collothalamus Across Amniotes

The basic features of the lemnothalamus that are shared across most major vertebrate taxa are thus (i) a developmentally rostral position, (ii) a mixture of sensory and other inputs, most of which come directly to the lemnothalamic nuclei rather than being relayed through the midbrain roof, (iii) projections to the more medial aspects of the telencephalon that are (iv) either ipsilateral or bilateral, and (v) a lack of any projections to the striatum. The basic features of the collothalamus that are likewise shared across most major vertebrate taxa are that it is (i) developmentally caudal in position, (ii) receives its predominant inputs via relay through the midbrain roof, (iii) projects to the more lateral aspects of the telencephalon but (iv) exclusively ipsilaterally, and (v) also projects to the striatum.

Against the backdrop of this basic set of features, substantial variation occurs in these two thalamic divisions across vertebrate taxa and most dramatically within amniotes. As noted above, the set of features seen in modern amphibians for each of these divisions may or may not be similar to the ancestral tetrapod pattern for the afferent pattern to the lemnothalamus and for the efferent projections of both divisions to the telencephalon. Nonetheless, both divisions themselves were clearly present in the common tetrapod and common amniote ancestors, and differential elaboration of each division occurred in the ancestral mammalian line on the one hand and in the ancestral reptilian line on the other.

In ancestral reptiles, which subsequently gave rise to modern reptiles, including birds, the collothalamus was most likely elaborated to a much greater extent than the lemnothalamus (Fig. 2). As is the case in modern reptiles, nucleus rotundus is the largest dorsal thalamic nucleus, and it and the other collothalamic nuclei occupy a larger volume of the thalamus than do the lemnothalamic nuclei. This is reflected in the volume of the pallium occupied by the respective targets of these nuclei. While in some reptiles, such as turtles and snakes, neither the dorsal ventricular ridge (collothalamic target) or the dorsal cortex (or general cortex/pallial thickening) are greatly expanded, in others, such as crocodiles and some lizards, the dorsal ventricular ridge is relatively very large and is populated with multiple, migrated cell groups. In birds, the dorsal ventricular ridge (its main components now called mesopallium, nidopallium, and arcopallium) reaches its greatest development in both size and complexity. Within the sauropsid line, comparative analysis indicates that elaboration of the lemnothalamus then secondarily occurred in birds. Birds thus have some lemnothalamic nuclei that appear to be homologous in a one-to-one fashion with corresponding nuclei in mammals, such as the dorsal column-recipient nucleus dorsalis intermedius ventralis anterior (DIVA) in birds and the ventroposterior lateral nucleus of mammals [17]. However, such comparisons must be restricted to the level of a field homology, since in reptiles, and thus probably in the common sauropsid ancestor, this cell group is contained within the DLA-DM-perirotundal complex of nuclei rather than as a discrete nucleus [6].

In ancestral mammals, the opposite scenario appears to have occurred, such that the lemnothalamus was elaborated to a much greater extent than the collothalamus. As is the case in modern monotremes and to a lesser degree in marsupials, and thus probably the case in the stem, ancestral mammals, the lemnothalamic nuclei were expanded and elaborated to a greater degree than the collothalamic nuclei, likely in conjunction with selective pressures for increased spatial mapping abilities (anterior nuclear group), elaboration of the somatosensory system with the loss of scales and gain



**Evolution of the Dorsal Thalamus. Figure 2** Schematic comparison of lemnothalamic (green) and collothalamic (tan) regions in the brains of an amphibian, a placental mammal, and a reptile. Rostral is towards the left for comparison with Fig. 1b. In amphibians and probably in the most basal, ancestral amniote condition, the caudally lying collothalamus and the rostrally lying lemnothalamus are both rather small and lie in a periventricular (nonmigrated) position. In amniotes, these two thalamic divisions both contain multiple nuclei. In early mammals (not shown here), the lemnothalamus was elaborated to a greater extent than the collothalamus, with some elaboration of the collothalamus occurring secondarily, and to a large extent independently, in a number of orders of placental mammals. The large expansion of the rostral part of the lemnothalamus accounts for the relatively caudal position of the dorsal lateral geniculate nucleus in adult placental mammals. In ancestral and modern reptiles, the collothalamus was elaborated initially to a greater extent than the lemnothalamus. Secondary elaboration of a number of lemnothalamic components has occurred in birds (not shown here). Abbreviations: *A*, nucleus anterior; *Ant*, anterior nuclear group; *Co*, collothalamic nuclei; *DLA/DM*, dorsolateral anterior and dorsomedial nuclei (and perirotundal nuclei); *DLGN*, dorsal lateral geniculate nucleus; *M*, nucleus medialis; *MP*, nucleus medialis posterior; *Med*, medial nuclear group; *MGB*, medial geniculate body; *LP/Pul*, lateral posterior/pulvinar complex; *Po*, posterior nuclear group and posterior intralaminar nuclei; *RI*, rostral intralaminar nuclei; *Rot*, nucleus rotundus. Note that in actuality not all of the nuclear groups represented for mammals or reptiles would be visible on the lateral surface of the thalamus, as represented here.

of body hair (ventral nuclear group), importance of the visual system (dorsal lateral geniculate nucleus), elaboration of the prefrontal cortex (medial nuclear group), and continuation of the importance of the reticular activating system (intralaminar nuclear group). Correspondingly, the pallial areas in receipt of lemnothalamic projections are relatively extensive in modern monotremes, while those receiving collothalamic projections are quite small [18].

Within a number of orders of placental mammals, it is thus most likely that elaboration of collothalamic components occurred secondarily, with corresponding elaboration of their telencephalic targets, both pallial and subpallial. In general, collothalamic nuclei in mammals project to two major pallial targets – both the lateral nucleus of the pallial amygdala and one or more areas of neocortex – as well as to the striatum. While the medial geniculate body, with its several subdivisions, and its telencephalic targets is relatively constant across different orders of mammals, the projections of the posterior nuclear group are arguably more variable, and the projections of the lateral posterior/pulvinar complex are markedly so. The latter set of neuronal cell groups and their pallial targets have dramatically increased in complexity and number within several mammalian orders, particularly carnivores and primates [18,19].

Thus, while both lemnothalamic and collothalamic components are expanded and elaborated in both birds and various orders of mammals, the ancestral divergence of the reptilian and mammalian lines was apparently characterized by different evolutionary strategies. Within the ancestral reptilian line, elaboration of the collothalamus and its telencephalic targets was strongly selected for, while in the ancestral mammalian line, elaboration of the lemnothalamus was strongly selected for. Subsequently, in some but not all descendants of each of these lineages, the other division of the dorsal thalamus was likewise elaborated.

## Synonyms

Rhombencephalon; pons + medulla oblongata; brainstem (with midbrain); Hindbrain

## Definition

The hindbrain is wedged between the midbrain and the spinal cord. It consists of the pons (rostrally) and the medulla oblongata (caudally). Because of the unique shape of the ventricle within the developing hindbrain, it is referred to as the "rhombencephalon." The border with the midbrain is defined dorsally by the crossing of the trochlear nerve and ventrally by the superior pontine sulcus (in mammals). In developmental/comparative terms, this boundary is marked by the midbrain-hindbrain-boundary of gene expression. The transition to the spinal cord is marked dorsally by the closure of the IVth ventricle and ventrally by the decussating cortico-spinal tract (in mammals). In lampreys it is characterized by the sharp transition from hindbrain branchial motoneurons to spinal somatic motoneurons. The brainstem receives all mixed cranial nerve sensory information and provides information processing for fast reactions as well as change of attention and vegetative functions through the reticular formation. The area around the midbrain-hindbrain boundary develops into the cerebellum, an evolutionarily diverse part of the hindbrain (see Evolution, of the Cerebellum).

## Characteristics

As with the spinal cord, the hindbrain is composed of an alar plate, receiving and processing sensory information and a basal plate, harboring cholinergic motoneurons and the transmitter rich, reticular formation (see Evolution, of the Reticular Formation). The roof plate is extended and attenuated to form the choroid plexus of the fourth (IVth) ventricle. Formation of the IVth ventricle commences through a complex morphogenetic movement of the alar plates into lateral positions. In some vertebrates (= craniates as used here) with little developed cerebellum and forebrain, the hindbrain makes up nearly 40% of the total brain (e.g., lamprey). However, while its absolute size increases in more complex brains, its relative size is reduced compared to forebrain and cerebellum. Although notably conserved in its overall form and basic content, there are noteworthy gains and losses in the motor and sensory components of the hindbrain of vertebrates, the molecular basis for which is now beginning to be understood.

Within the central nervous system, the hindbrain contains all of the mixed cranial nerves (the trigeminal, facial, glossopharyngeus, and vagus nerves), the one cranial nerve with only branchial motoneurons (BM; the accessory nerve), and three of the four cranial nerves with only somatic motoneurons (SM; the hypoglossus, abducens and trochlearis nerves). The cranial nerve nuclei of the hindbrain receive general somatosensory information from the face (via the trigeminal, facial, and vagal nerves), special visceral afferents (taste information via the facial, glossopharyngeus, and vagus nerves) and some special somatic afferents (vestibular and

auditory information via the vestibulocochlear nerve and, if present, lateral line mechanosensory and electroreceptive information via the lateral line nerves). The hindbrain provides almost all input to the cerebellum via inferior olive, pontine nuclei (if present), vestibular primary and secondary fibers and part of the dorsal spinocerebellar tract (from the external cuneate nucleus). Almost all sensory information crosses in the hindbrain to the contralateral side, providing an intricate topography that leads to unique phenotypes of defects with regional lesions (see pathology).

## Branchiomotor Motoneurons (BMs): Features, Development and Evolution

BMs (formerly misnamed as special visceral motoneurons) are a defining component of the vertebrate hindbrain, because they are present throughout and only in the hindbrain [1]. BMs innervate muscle associated with the branchial arches. BMs are different from somatic motoneurons (SMs) in that they project through dorsal roots rather than forming distinct ventral roots. In contrast to spinal nerves, where dorsal and ventral roots converge to form a mixed spinal nerve, in the hindbrain BMs form together with the sensory neurons a mixed dorsal root. The trigeminal BMs apparently require the sensory fiber root to exit the brain, whereas the facial BMs of mammals are unique in that they form an apparently segregated root. Such intermediate and segregated roots are also known for the accessory nerve that originates in the cervical spinal cord. This feature indicates that the apparently primitive motor fiber association with the sensory fibers can be secondarily segregated in evolution.

In contrast to the spinal cord, where overlapping distributed somatic motoneurons project through distinct rootlets to form a single ventral root, BMs form discrete aggregates in a regular pattern that relates to the embryonic development of hindbrain compartments, the rhombomeres [2]. For example, trigeminal BMs of mammals form in rhombomere 2 (r2) and r3, facial BMs in r4, glossopharyngeal BMs in r6, and vagal BMs in r7. While the rhombomeric patterning appears to be conserved across vertebrates, no other chordate has such units and the content of these rhombomeres appears to change somewhat across different vertebrate groups. For example, in the lamprey the trigeminal BMs extend from r2 into the first half of r4, facial BMs are found in the second half of r4 and all of r5 [3].

BMs become postmitotic near the floor plate and generally migrate more laterally to form a column of motoneurons that in its topology resembles the intermediate column of visceral motoneurons (VMs) in the intermediate column of the thoracic spinal cord. This topology has been long known, and it has been conjectured that BMs develop out of generalized VMs. It was also assumed that these neurons innervate muscles derived from the lateral plate mesoderm (hypomere), which was later shown to be wrong. Combined with a relatively late evolution of VMs in the hindbrain, as compared to the appearance of hindbrain visceral motoneurons only after parasympathetic ganglia evolved in ancestral jawed vertebrates, this evolutionary scenario suggests that BMs are a distinct and unique class of motoneurons only present in the hindbrain.

One unique feature of BMs is their rather variable topology and adult distribution. This feature results from longitudinal as well as radial migrations that are not observed for any other class of motoneurons [1]. Facial BMs migrate, for example, only laterally in lampreys, some ray-finned fish, frogs and birds. However, they show extensive longitudinal migrations to settle in a more caudal rhombomere in cartilaginous fish, some ray-finned fish, salamanders and mammals. While we begin to understand the molecular basis for this migration [4], the functional significance of this process remains enigmatic.

One unique population of neurons, apparently derived from facial BMs, are the so-called inner ear efferents [5]. Unlike any other motoneuron, these neurons innervate placodaly derived hair cells and sensory neurons of the ear rather then facial muscle fibers or neural crest derived autonomic neurons. Like facial BMs, inner ear efferents derive from r4 but segregate from BMs as a result of differential migration in many, but not all, vertebrates. In mammals, these neurons appear to activate a unique contractile system that allows length changes of outer hair cells to adjust to sound intensity.

## Visceromotor Motoneurons (VMs): Features, Development and Evolution

Hindbrain VMs form three discrete aggregates of preganglionic parasympathetic neurons that are associated with the facial (superior salivatory nucleus), the glossopharyngeal (inferior salivatory nucleus) and the vagus (dorsal motor nucleus of the vagus) nerves. The only other places in the central nervous system that contains preganglionic parasympathetic VMs are the midbrain (Eddinger–Westphal component of the oculomotor nucleus) and the sacral spinal cord. VMs of the hindbrain project to cranial visceral ganglia, which, in turn, innervate glands (facial nerve to the sphenopalatine ganglion to the lacrimal gland; facial nerve to the submandibular ganglion to the submandibular and sublingual glands, and the glossopharyngeus nerve to the otic ganglion to the parotid gland) or abdominal viscera (vagus nerve to the parasympathetic postganglionic neurons to the viscera). Cranial parasympathetic ganglia and VMs are absent in cyclostomes (lampreys and hagfishes) and may have evolved with terrestrial vertebrates [1], possibly with the evolution of

parasympathetic ganglia from the neural crest. VMs derive from rhombomeres 5–7 and thus form a column that parallels the special visceral sensory (taste) nucleus of the solitary tract. VMs typically show only lateral migration with a limited additional migration away from the IVth ventricle. Neither the origin of the parasympathetic ganglia nor of VMs innervating them is understood at the molecular level.

### Somatomotor Motoneurons (SMs): Features, Development and Evolution

Mammalian descriptive neuroanatomy recognizes three SM nuclei in the hindbrain — the hypoglossus, which innervates intrinsic muscles of the tongue, the abducens, which innervates the lateral rectus muscle of the eyes and the trochlearis, which innervates the superior oblique muscle of the eye. All these motoneurons are classically considered to be rostral continuations of spinal SMs. Indeed, they share with the SMs an overall topology near the floor plate and the discrete exit independent of sensory roots. However, SMs of hindbrain do not form mixed nerves with sensory fibers.

Although this terminology is accepted in the mammalian literature, comparative neuroanatomy questions that any of the hindbrain SMs can be compared to spinal SMs. After all, in contrast to the spinal cord, SMs coexist with BMs in the hindbrain. In addition, lampreys and hagfish, being jawless, have no tongue and the most rostral spinal motoneurons that might have evolved into the hypoglossal SMs are immediately caudal to the last BMs of the vagus. Therefore, the caudal rhombomeres of lampreys and hagfish do not develop SMs, suggesting that the evolution of the hypoglossus as a part of the hindbrain is tied into the evolution of jaws and tongues. As with the hypoglossus, the abducens of jawed vertebrates is clearly identified as an SM, but this nucleus does not exist in hagfish. In lampreys, it is organized like a BM population that projects rostrally to exit through the trigeminal nerve. Whether these unique features of the lamprey abducens reflect a primitive condition, lost in hagfish, or signify a parallel evolution to the similarly named nucleus of jawed vertebrates, remains unresolved. The last SM of the hindbrain, the trochlearis, is unique in several aspects. For one thing, its axons extend dorsally to exit to the contralateral orbit, the only motoneuron to do this. Secondly, the neurons may migrate dorsally to remain near their root in lampreys, a feature unknown in any other vertebrate. Lastly, the trochlearis SMs are the only motoneurons that form in r1 and depend critically on the development of the midbrain-hindbrain boundary for their development [6]. Combined, these data suggest that the ancestral vertebrate brainstem may not have had any SMs but evolved them by recruiting SMs of the rostral spinal cord (hypoglossus), diverting a BM population to assume a SM phenotype (abducens) and/or evolving a unique motoneuron population with the evolution of the midbrain-hindbrain boundary (trochlearis).

### Somatosensory Nuclei: Features, Development and Evolution

The somatosensory nuclei of the brainstem and the central projections of the predominantly neural crest-derived cranial and spinal ganglia are rostral extensions of the substantia gelatinosa (lamina II) of the spinal cord and Lissauer's tract from the dorsal root ganglia, respectively. This continuity is most obvious in the continuation of spinal Lissauer's tract. The topography of central projections from the three subdivisions of the trigeminal ganglion are conserved across vertebrates, except for hagfish where the central projection is expanded and dorso-ventrally reversed. As with spinal somatosensory information, second order somatosensory neurons project mostly to the contralateral side, reaching mostly the thalamus in parallel with the spinal second order projection (see Evolution of the Trigeminal Sensory System).

Primary afferents reach the hindbrain from neural crest-derived cranial ganglia, which require the bHLH gene ►*Neurogenin1* for development, whereas both ►*Neurogenin 1* and ►*Neurogenin 2* are required for spinal ganglia [7]. In lampreys, cranial ganglia appear to derive solely from placodes, whereas in jawed vertebrates, placodes other than epibranchial placodes (see below) contribute a subpopulation of cells only to the trigeminal ganglion [8]. It remains unclear whether this evolutionary change in developmental origin of seemingly identical sensory neurons is related to the multiplication of neurogenins in jawed vertebrates [9] or indicates that the neural crest contribution to cranial ganglia evolved after placodes formed cranial ganglia. The topography of the central projections is defined by rhombomere-specific expression of hox genes [10] and depends on retinoic acid expression.

Unique features of the spinal trigeminal nuclei of cyclostomes are the dorsal cells. These cells appear to be functionally equivalent to the mesencephalic nucleus of jawed vertebrates [1]. However, since jawless vertebrates have no specialized muscle spindles, it remains unclear whether these cells contact proprioceptors.

### Sensory Nuclei for Taste and Viscerosensory Perception: Features, Development and Evolution

Taste, in most vertebrates, is localized to specialized organs in the oral cavity that are innervated by three cranial nerves — the facial, glossopharyngeus and vagus nerves. However, in hagfish, taste bud like organs are distributed over the body and are innervated by both cranial and spinal nerves. In addition, many bony fish and other aquatic vertebrates have single chemosensory cells that respond to various stimuli in the aquatic

E

environment and have taste buds distributed over the body [11]. Cranial nerves innervating the taste buds show an unusual central projection that suggests that this system is uniquely derived in hagfish and differs in many respects from all other vertebrates. In lampreys and jawed vertebrates, the central taste projection is a medial addition to the trigeminal projection targeted to a unique nucleus, the rostral portion of the nucleus of the solitary tract, also known as the gustatory nucleus. Taste bud-innervating neurons derive from unique embryonic anlage, the epibranchial placodes. In mammals, these placodes are dependent on the bHLH gene ►*Neurogenin 2*. Developmental of the central solitary nucleus critically depends on specific genes [12]. Taste is part of the viscerosensory component of cranial nerves and may be the evolutionarily oldest part of it [1]. It clearly existed prior to the formation of the autonomic motor system. How other viscerosensory components of cranial nerves evolved to innervate the viscera and the heart is unclear.

Peripheral taste organization varies most in bony fish and may show expansion of the facial nerve to innervate taste buds outside the oral cavity. In some species, taste receptors project centrally into a greatly enlarged component of the solitary tract nucleus. In others, their central projections may have enlarged the taste system related to the glossopharyngeus and have evolved a lobed, multilayered nucleus in hindbrain that rivals the cellular complexity of the electrosensory and auditory nuclei of other vertebrates [11].

### Octavolateral Sensory Nuclei: Features, Development and Evolution

A unique feature of the hindbrain, without an apparent equivalent in the spinal cord, is the set of octavolateral nuclei that receive the primary afferents of the vestibular part of the ear, and, if present, of the auditory part of the ear and the mechanosensory lateral line and electrosensory organs. Of all the nuclei in the hindbrain, the electrosensory nuclei of bony fish and the auditory nuclei of terrestrial vertebrates (see Evolution, of Mechanosensory and Electrosensory Lateral Line Systems, Evolution, of the Auditory System: Reptiles and Birds, Evolution, of Auditory System: Anamniotes, Evolution, of Auditory System: Mammals) show the most expansion, indicating a unique level of plasticity not found in other, evolutionarily conserved, parts of the hindbrain (except for the cerebellum). These diversifications seem to correlate with the appearance and functional expansion of multiple electrosensory organs in bony fish and diversification of sound pressure receptors in terrestrial vertebrates. Interestingly, the basic organization of the central projections of electrosensory and mechanosensory lateral line and vestibular neurons to second order nuclei follows a stereotypic order along the dorsoventral axis of the hindbrain alar plate in jawless vertebrates [1]. In dorsal-to-ventral order, it consists of electrosensory lateral line, mechanosensory lateral line and vestibular nuclei and their projections to their respective second order nuclei. This arrangement suggests that central nuclei evolve in relationship to numerical and structural diversification of the periphery. During development, the specific projections seem to develop on a staggered time table with the more ventral projections developing before the more dorsal projections. In the auditory system, specialized receptors evolve in the auditory periphery prior to the formation of discrete second order nuclei. However, the evolution of central nuclei is required for the development of distinct central projections [13]. Recent work suggests that formation of mammalian auditory nuclei depends on the bHLH gene Atonal homolog 1 (►*Atoh1*) [14]. In the spinal cord, ►*Atoh1*-expressing precursors form only a small contingent of second order proprioreceptor neurons, whereas in the hindbrain its transcription is essential for the formation of the two largest and evolutionarily most diverse areas, the cerebellum and the auditory nuclei [15]. Combined, these data suggest that evolution of these areas may result from expansion of a small population of cells, a mechanism that may be applicable for most allometric growth of nuclei in brain evolution. It remains to be shown whether the expansion of electrosensory nuclei in teleost fish is also related to the expansion of ►*Atoh1*-expressing cell populations. An interesting aspect of the evolution of the octavolateral area is the frequent loss of some systems (mechanosensory lateral line and electrosensory system) and gain of others (sound pressure reception system). This situation has led to the suggestion that loss of one set of systems permitted the expansion of the other in terrestrial vertebrates. While this idea has been ruled out for the mechanosensory lateral line that co-exists in some anurans with a sound pressure receiving system, there is a possibility that the loss of electroreception could, in terrestrial vertebrates, have led to or allowed the rapid expansion of the central auditory nuclei sources. More molecular data on development of salamander and frog hindbrains are needed to provide a mechanistic basis for this speculation.

### Molecular and Evolutionary Developmental Conservation and Changes in the Hindbrain

Overall, the basic dorso-ventral patterning of the hindbrain resembles that of the spinal cord and depends on long range diffusible factors such as sonic hedgehog (►*Shh*) formed in the floor plate and its interactions with more dorsally expressed gene products such as ►*Bmp4, Gli3* and ►*Wnt1*. Within these expression gradients, discrete regions of the neural tube are specified to express discrete sets of genes such as bHLH genes. These bHLH genes work, either alone or

in combination with other genes, to specify cell fate in a region specific fashion [16].

In contrast to the spinal cord, the hindbrain shows not only a clear dorso-ventral specification gradient but also a rostro-caudal gradient that specifies discrete dorso-ventral cellular populations to adopt unique rostro-caudal fates [17]. In the central sensory nuclei this situation is most obvious in the ►*Atoh1* expressing area. ►*Atoh1* is required for formation of the external cuneate nucleus that relates spinal cord proprioception to the cerebellum [15]. More rostrally, the equivalent area has been found to give rise to neurons that migrate to form the pontine nuclei. Even more rostrally, the same ►*Atoh1* expressing population forms the auditory nuclei, and, more rostral still, the cerebellum forms [18]. This sequence suggests both the DV and AP patterning processes are interlaced in the hindbrain. Thus, a single dorso-ventral population, specified by ►*Atoh1*, is diversified by its relationship to a rostro-caudal gradient likely reflected in the Hox code.

## Function

Except for the variable presence of electrosensory/mechanosensory lateral line, auditory systems and the expansion of taste-specific area and the cerebellum, the hindbrain is fairly stable across evolution. Most important exceptions to this stability are related to the expansion of ►*Atoh1*-dependent precursor populations. Likewise, the expansion of taste nuclei may relate to another bHLH gene, ►*Mash1* [19]. How an expanded sensory periphery relates to expanded central nuclei and these in turn to an expanded reliance on such a modality for communication with conspecifics or the environment remains unclear. Likewise, in the motor system, there is variation in migration of BMs that, in extreme cases, can move motoneurons from their origin in rhombomere 4 into the rostral spinal cord. Although speculations about the functional significance of such migrations abound, proper testing of them will require functional interference with such migrations [4] and establishing specific losses in function.

## Pathology

Evolution must ultimately occur as a result of selected alterations to the genetic mechanisms responsible for morphogenesis. These same mechanisms malfunction in hindbrain related pathologies. Mutations to the Zic family of zinc finger transcription factors have been implicated in instances of the human Dandy–Walker malformation (DWM) and its phenocopy in mice [20]. Although DWM is characterized by its cerebellar phenotype, the Zic genes are expressed throughout the dorsal hindbrain. Alterations to the precerebellar nuclei of the hindbrain are thus to be suspected as well. Similarly, while no specific human pathology has yet be identified, mutation to the ►*Atoh1* (►*Math1*) gene results in the neonatal death of mouse pups from what appears to be respiratory arrest resulting from the absence of relevant hindbrain neuronal populations.

## Synonyms

Medial pallium; Ammon's horn; Hippocampus

## Definition

The hippocampus or ►medial pallium is a part of the cerebral cortex that develops from the medial edge of telencephalic ►pallium (from the distal, anterior portion of the embryonic telencephalic ►alar plate). The medial pallium, which is present in all vertebrates, has a long evolutionary history (Fig. 1) characterized by features some of which are conserved, such as many of its connections to other brain regions, and others which are divergent, such as the striking variation in cytoarchitectural organization across vertebrate groups. The hippocampus is important for memory representations of space that can guide navigation and, in some animal groups, the encoding of episodic memory.

## Characteristics

### Mammals

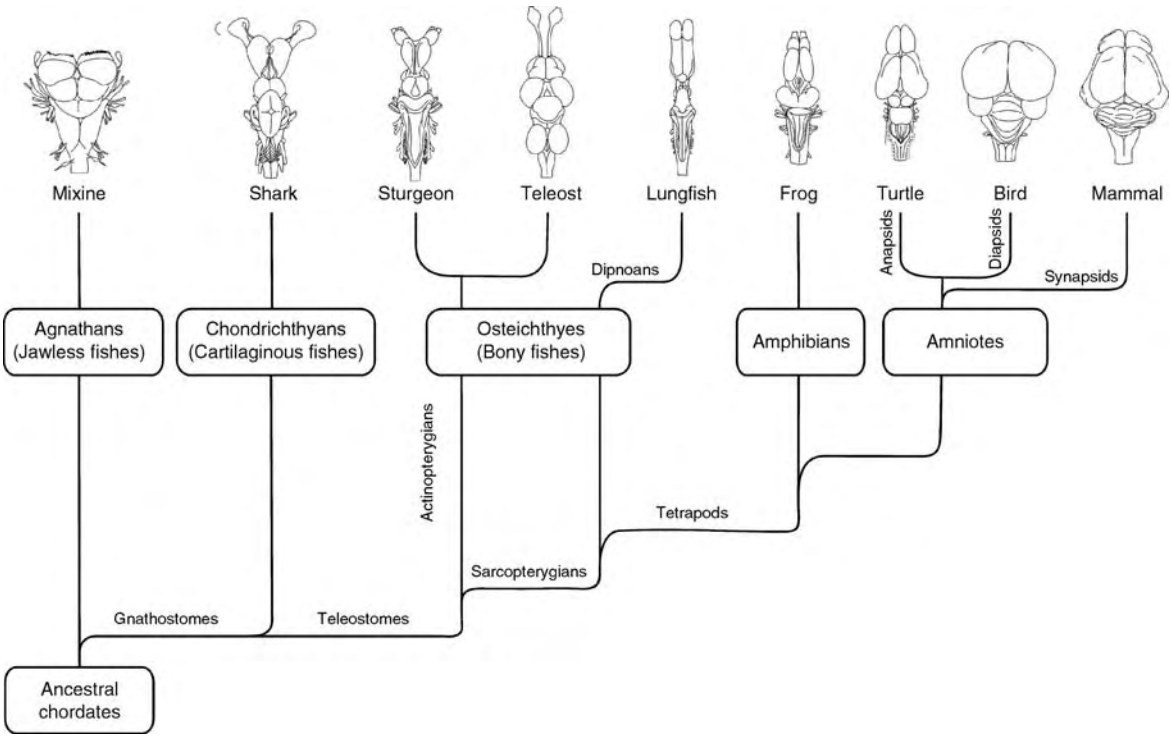
The well-described mammalian hippocampus (Fig. 2) is generally viewed as a three layered structure consisting of three major subdivisions: the dentate gyrus, the Ammon's horn (fields CA1, CA2 and CA3) and the subiculum [1,2,3,4]. There are two major pathways that connect the hippocampus with the rest of the brain. One, via the neighboring parahippocampal regions (e.g. entorhinal cortex), connects it to higher order, sensory associational regions of the neo(iso)cortex. The other mainly connects the hippocampus with subcortical structures via the fornix. The distinctive principal granule cell and pyramidal cell layers of the dentate gyrus and Ammon's horn respectively, participate in a prevailingly feed-forward series of connections that enable the hippocampus to participate critically in a neural system that supports navigation and memory processes that include space as a defining feature, e.g. episodic memory.

### Birds

The medial pallium and ►dorsomedial pallium (collectively referred to as HF below) of birds (Fig. 2) was considered the homologue of the mammalian hippocampus by early twentieth century comparative neuroanatomists [2,3,4]. Both develop from the same portion of the enlarging prosencephalon and both display a similar pattern of developmental gene expression. Although the distinctive cytoarchitectural organization of a mammalian dentate gyrus and Ammon's horn is not readily detectable, the avian HF has a suggestive layered organization, most evident near the "V" shaped cell layers in medial HF. Bitufted spinous neurons, which resemble mammalian hippocampus pyramidal cells, populate the "V" layer. Multipolar spinous neurons populate more dorsomedial regions.

Despite the apparent differences in cytoarchitectural organization between the mammalian hippocampus and HF, across other neurobiological dimensions noteworthy similarity can be found [5]. Shared extra-HF/hippocampal connectivity includes similarly organized connections with the septum, lateral hypothalamus, amygdala (archipallium in birds), brainstem monaminergic nuclei and telencephalic sensory processing regions. A discernable intra-HF/hippocampal feed-forward processing circuit, which resembles the trisynaptic circuit in the mammalian hippocampus, has been described in HF, including a robust commissural projection to the contralateral HF. However, interpretation of internal connectivity in terms of explicit comparisons between avian and mammalian hippocampal subdivisions is not yet fully resolved [6,7]. The avian HF and mammalian hippocampus also share a generally similar neurochemical profile.

At the electrophysiological level, both the mammalian hippocampus and avian HF display NMDA-dependent and NMDA-independent changes in synaptic efficacy referred to as ►long-term potentiation. However, it has been suggested by some researchers that one type of NMDA-independent long-term potentiation



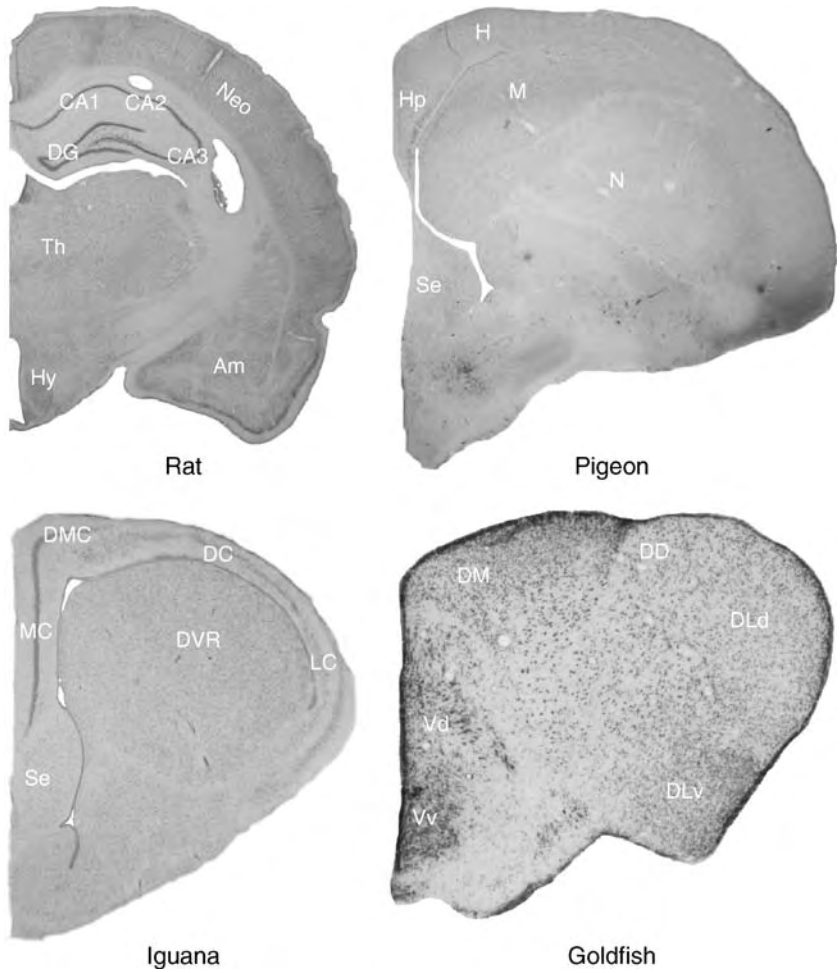
**Evolution of the Hippocampus. Figure 1** Cladogram illustrating the phylogenetic relationship among the main groups of extant vertebrates.

observed in the avian HF is not found in mammals. Field potential recordings of the mammalian hippocampus and avian HF have revealed similar slow-wave oscillations in the theta range, the so-called ►theta rhythm. Contrasting the spatial response properties of hippocampal/HF neurons recorded from freely moving rats and homing pigeons is particularly interesting [8]. The spatial response properties of pigeon and rat HF neurons reveal surprising similarity in the contribution of position, direction and trajectory toward explaining spatial variation in firing rate. By contrast, the asymmetrical distribution of spatial response properties of neurons in the left and right HF of homing pigeons, but not the hippocampus of rats, indicates a difference in network organization. This pattern of differences and similarities suggests that the evolution of hippocampal/HF organization may be characterized by inertia with respect to the combination of spatial dimensions that can determine variation in a neuron's action potential firing rate, but considerable plasticity in how neurons with different spatial response properties are organized into functional networks.

The hippocampus of modern mammals and the HF of modern birds are separated by about 300 million years of independent evolution. It is therefore remarkable that despite this "evolutionary distance", the hippocampus/HF of modern mammals and birds plays a remarkably similar role in the map-like or relational representation of space [5]. This is best illustrated by studies in which control and hippocampus/HF lesioned rats and homing pigeons were trained on tasks in which alternative spatial representational strategies could be used to navigate to a goal location. One strategy was a route-like strategy based on the association of the goal direction with fixed orientation response to a landmark (s). The other was a map-like strategy based on learning the spatial relationship among landmarks distributed in space and using that relational representation to navigate to the goal. It was shown that in both rats and pigeons the map-like strategy was abolished by HF lesion while the route-like strategy was unaffected.

## Reptiles

The medial pallium of reptiles (Fig. 2) is considered homologous to the avian and mammalian hippocampal formation [2,3,4,9]. In reptiles, the ►medial (limbic) ►pallium is a three-layered cortex, which is comprised of medial (MC) and dorsomedial (DMC) subdivisions. The reptilian MC and DMC are thought to be homologous to the dentate gyrus and Ammon's horn of the mammalian HF, respectively. In addition, the adjacent medial portion of dorsal cortex (DC) has been compared



**Evolution of the Hippocampus. Figure 2** Photomicrographs of mid-telencephalic, transverse brain sections in representative species of four different vertebrate groups showing the position of the medial pallium (hippocampus). Abbreviations (see text). *Rat*: *Am*, amygdala; *CA1, CA2* and *CA3*, fields 1, 2 and 3 of Ammon's horn; *DG*, dentate gyrus; *Hy*, hypothalamus; *Neo*, neocortex; *Th*, thalamus. *Pigeon*; *Hp*, hippocampus; *H*, hyperpallium; *M*, mesopallium, *N*, nidopallium; *Se*, septum. *Iguana*: *DC*, dorsal cortex; *DMC*, dorsomedial cortex; *DVR*, dorsal ventricular ridge; *LC*, lateral cortex; *MC*, medial cortex; *Se*, septum. *Goldfish*: *DD*, dorsal division of area dorsalis (the area dorsalis is the pallium.); *DLd*, dorsal subdivision of the lateral division of the area dorsalis; *DLv*, ventral subdivision of the lateral division of the area dorsalis; *DM*, medial subdivision of the area dorsalis; *Vd*, dorsal nucleus of the area ventralis (the area ventralis is the subpallium.); *Vv*, ventral nucleus of area ventralis.

with the transitional entorhinal cortex that borders the mammalian hippocampus.

MC contains small neurons, whereas DMC contains large neurons. As in mammals and birds, pyramidal-like, bitufted spinous neurons are present in the reptilian medial pallium and this characteristic seems to be an apomorphic (derived) feature of amniotes, because this cell type has not been found in anamniotes [10]. The pattern of connectivity of the medial cortex of reptiles resembles the hippocampus of mammals and HF of birds. The MC receives afferent projections from the DMC, DC and lateral (olfactory) cortex and projects back reciprocally to the DMC and DC. Thus, whereas the MC of reptiles receives afferent projections from several telencephalic cortical regions, the DMC is primarily connected with just the MC. In addition to reciprocal connections with MC, there is a substantial commissural connection between the DMCs of the two hemispheres. Both MC and DMC are reciprocally connected with the septum and receive ascending projections from the anterior dorsomedial nucleus of the dorsal thalamus, the mammillary and periventricular regions of the hypothalamus, the raphe nuclei, the locus coeruleus and the reticular formation.

At a functional level, recent evidence indicates that the medial pallium, like the hippocampus of mammals and HF of birds, is important for some types of spatial learning and memory [9]. The MC of turtles is specifically involved in what has been called map-like, allocentric or relational spatial representations of the environment. Lesions to MC in turtles produce deficits in a variety of map-like, relational spatial tasks but not in cue learning and other egocentrically referenced learning tasks. In addition, although the available data are still scarce, medial pallial dependent learning and memory may be based on some conserved cellular/molecular mechanisms. For example, as observed in mammals and birds, both NMDA-dependent and NMDA-independent long-term potentiation has been reported in the MC of turtles.

In summary, the medial pallium or hippocampus of amniotes is partially characterized by divergence in cytoarchitectural organization (the distinctive dentate gyrus and hippocampus of mammals, a V-shaped large-cell layer in the HF of birds, a cell layer in the MC of lizards and a scarcity of lamination in turtles). These variations suggest some independent evolutionary elaboration in each separate radiation. However, there are perhaps even more evident similarities. Conserved histochemical, physiological and functional characteristics, as well as some aspects of anatomical connectivity, indicate that these traits were present in the ancestral group of amniotes that gave rise to extant mammals, birds and reptiles. As the amniotes appear to be a monophyletic group that diverged from primitive tetrapods during the early Carboniferous, it is reasonable to assume that medial pallial (hippocampal) dependent spatial cognition is an ancient brain-behavior property present in the stem reptilian ancestor of modern amniotes that was retained during the independent evolution of each extant lineage.

## Anamniotes

A hippocampal-like medial pallium is also present in amphibians, lungfishes, ray-finned fishes, cartilaginous fishes and agnathans [3,11,9,10,12]. In amphibians, the medial pallium is hypertrophied relative to other pallial regions and the medial pallium of lungfishes. The medial pallium of amphibians and lungfishes can be divided into three subdivisions based on cytoarchitectural and histochemical criteria, but the subdivisions are not necessarily comparable between the two groups or with specific subdivisions of the amniote medial pallium. In frogs, intra-telencephalic connections of the medial pallium include reciprocal, extensive connections with the dorsal and lateral pallia, the septal nuclei, the nucleus of the diagonal band, the amygdala and the nucleus accumbens, as well as commissural connections with the contralateral medial pallium. Extra-telencephalic connections include a fornix-like projection to the ventral thalamus, preoptic area and hypothalamus, as well as inputs from the anterior nucleus of the dorsal thalamus and a serotonergic projection from the raphe area. Thus, the extrinsic connectivity of the medial pallium of amphibians [10] is strikingly similar to that of amniotes, with the notable exception of a robust dorsal thalamic non-olfactory-sensory projection into the amphibian medial pallium. Furthermore, the pattern of expression of LIM-homeodomain genes in the pallium of amphibians strongly supports homology with the medial pallium of amniotes.

The degree of cytoarchitectural complexity varies from relatively simple to highly elaborate in the ►telencephalon of squalomorph and galeomorph sharks, skates and rays. The medial pallium (the topological equivalent of the hippocampus) of cartilaginous fishes receives inputs from the ►dorsal pallium and the septal nucleus, and sensory information is relayed from the thalamus and other diencephalic areas.

In agnathans, the elaboration and complexity of cell masses in the telencephalon varies from relatively simple in lampreys to complex in hagfishes. In lampreys, the medial pallium receives inputs from other pallial areas, the septum and various areas of the diencephalon; it projects to a variety of telencephalic, diencephalic and brainstem areas. The presence of a medial pallium and associated pallial and subpallial structures in agnathans indicates that a hippocampal-like structure is a primitive feature of the vertebrate telencephalon, dating back close to the origin of vertebrates.

The telencephalon of ray-finned fishes (actinopterygian fishes) constitutes a special case among vertebrates (Fig. 2). The telencephalon of ray-finned fishes develops by a process of eversion (bending outward of the embryonic prosencephalic alar plate) instead of evagination as occurs in every other vertebrate group. As a consequence of this particular developmental process, the medial-to-lateral topography of the pallial areas observed in other vertebrate groups is reversed in ray-finned fishes. Accordingly, the pallial area most probably homologous to the hippocampus is located laterally in the telencephalon [9].

Among the ray-finned fishes, the teleosts have been most intensively studied. The topography, connections and histochemistry of the ►lateral pallium of teleost fish are remarkably similar to the medial pallium of vertebrates with a developmentally evaginated telencephalon. The lateral area of the teleost pallium (Dl) is characterized by extensive intra-telencephalic connections. Dl has widespread reciprocal connections with other pallial areas, as well as with the contralateral Dl by means of commissural projections. Dl is also reciprocally connected with the ventral nucleus of the area ventralis (Vv), considered to be homologous with the septal nuclei of amniotes. Like the septal formation of amniotes, the Vv of teleost fish sends a large

projection to the midline hypothalamus and cholinergic input to Dl. Dl has reciprocal connections with the preglomerular complex of the posterior tuberculum in the diencephalon, from which it receives a number of multi-sensory inputs (rather than from the dorsal thalamus). Dl also projects to the preoptic area and other diencephalic regions and receives inputs from the preoptic area, the locus coeruleus and the superior raphe. Within Dl, the ventral subdivision (Dlv) is a candidate for a specific homologue of the tetrapod medial pallium. It occupies a distal topological position in the pallium and has extensive interconnections with the suspected homologues of the septal nuclei and preoptic area. The homology of Dlv with the medial pallium is supported also by the distribution pattern of several histochemical and molecular markers. For example, the dopamine receptor subtype D1B, which is characteristic of the mammalian hippocampus, is selectively expressed in the Dlv subdivision of the teleost pallium. The pattern of connectivity and multisensory functional organization of the dorsal subdivision of Dl (Dld) also resembles amniote medial pallium. The primary target of descending projections from Dld is the caudal hypothalamus, a projection that resembles the post-commissural fornix in tetrapods.

A considerable amount of functional evidence indicates that, like the amniote medial pallium, the lateral pallium of teleost fish selectively supports spatial cognition [9]. For example, training goldfish in a spatial task produces a significant and restricted increase in neuronal protein synthesis activity in the lateral pallium compared to fish trained in cue learning or control procedures. In addition, lateral pallial lesions in goldfish produce a dramatic impairment in a variety of spatial learning tasks. By contrast, medial or dorsal pallial lesions do not produce any observable deficit in the same spatial tasks. Moreover, like the medial pallium of amniotes, the lateral pallium of teleost fish seems to be selectively involved in map-like or relational representations of space, as lateral pallial lesions do not affect cue-learning or non-relational, egocentric spatial behavior. Thus, the effects of lateral pallial damage in teleost fish are similar to those observed in amniotes following medial pallial lesions. Like amniotes, LTP mechanisms are present in the pallium of teleost fish and spatial memory formation involves NMDA receptors.

## Hippocampus Evolution: Synthesis

From agnathans to mammals, the medial (lateral in actinopterygians) pallium (hippocampus) of all extant vertebrates shares a suite of developmental and connectivity characteristics, as well as some less studied neurochemical and electrophysiological properties. The similarities indicate a common evolutionary ancestry. Thus, it is reasonable to assume that some basic organizational properties of the medial pallium-hippocampus evolved early in vertebrate phylogenesis – properties that were generally conserved during the independent evolution of the different vertebrate radiations. The conserved properties probably explain the universal role of the medial pallium-hippocampus in spatial cognition. Nonetheless, across vertebrate groups the medial pallium-hippocampus, together with neighboring brain regions, is characterized by considerable variation in morphological and cytoarchitectonic organization, as well as some aspects of intrinsic connectivity. Therefore, the medial pallium-hippocampus in any extant group of vertebrates should be viewed as a composite of both conserved and derived characteristics collectively adapted in part to the spatial ecology of that group and the evolved properties of connected brain regions.

# Evolution of the Hypothalamus in Anamniotes

William Hodos
Department of Psychology, University of Maryland, College Park, MD, USA

## Definition

The hypothalamus is a specialized region of the ventral diencephalon that is involved in regulation of the endocrine system, the autonomic nervous system, and related brain systems. It is concerned with various visceral functions and behavioral processes such as reproductive and parental behavior, temperature regulation, territory management, and biological rhythms. The anamniote hypothalamus has many similarities to that of amniotes, but it also has some important differences.

## Characteristics

The hypothalamus occupies most of the ventral region of the diencephalon. It is a relatively large and well developed region in many anamniote vertebrates, such as jawless fishes, cartilaginous fishes (chiaemaras, sharks, skates, and rays), ray-finned fishes, and amphibians. It consists of a preoptic area at its rostral end and a hypothalamus proper. In cartilaginous and ray-finned fishes, the latter contains a ventral region known as the inferior lobe. The hypothalamus proper consists of specialized cell groups known as nuclei or areas that have many connections within the diencephalon, the telencephalon, and the hindbrain. It also receives a modest axonal pathway from the retina that plays a role in daily and seasonal photoperiodic biological rhythms and behaviors that are linked to these rhythms, such as seasonal breeding and migration. Other sensory systems, such as the gustatory and auditory systems, have input into the hypothalamus as well. The hypothalamus is also involved in a variety of other survival behaviors such as feeding, defense, and escape [1].

### Circumventricular Organs

In anamniotes, the third ventricle of the brain extends into the hypothalamus to form a hypothalamic ventricle. In some localized areas, the ependymal lining of the ventricles is thickened into specialized structures called circumventricular organs, some of which secrete hormones and other neuroactive substances into the cerebrospinal fluid that fills the ventricles and some of which detect the presence of neuroactive substances in the cerebrospinal fluid, which acts as a chemical transport system similar to the cardiovascular system. In anamniotes, the circumventricular organs include the area postrema, the subcommissural organ, the pineal, the median eminence and posterior pituitary, and the paraventricular organ [1].

### Saccus Vasculosus

In many anamniote species, including teleost fishes and sharks, the hypothalamic ventricle protrudes ventrally to form the saccus vasculosus. Among the hypotheses for the functions of this organ are sensory (depth detection and chemical detection), osmoregulation, ionic transport, skeletal growth, tooth regeneration, and a variety of visceral functions [2]. The saccus is innervated by the tractus sacci vasculosi, which terminates in the nucleus sacci vasculosi in the posterior tuberculum [1].

### The Hypophysis

One of the major functions of the hypothalamus is control of the endocrine system via the hypophysis (pituitary), which is attached to the floor of the hypothalamus by the median eminence. The hypophysis consists of a neural zone (the neurohypophysis) and a glandular zone (the adenohypohysis), the latter of which is further subdivided into a distal part and an intermediate part.

The neurohypophysis is innervated by axonal pathways from the hypothalamus that transport to it the hormones oxytocin, isotocin, and argentine vasotocin, which are produced in the hypothalamus [3,4]. These are secreted into the general circulation from the neurohypophysis. These hormones affect such functions as blood pressure, kidney filtration, and contractions of the oviduct that affect movement of the ova.

The adenohypophysis is controlled by a local circulatory system, the hypophyseal portal system, which carries releasing and inhibiting hormones to it from the hypothalamus. These releasing and inhibiting hormones in turn regulate the release (or inhibition) of trophic hormones from the adenohypophysis into the general circulation where they affect the production of hormones from the various endocrine glands, such as the gonads and [1,5]. Unlike the adenohypophysis of amniotes, the adenohypophysis in sharks and teleosts contain finger-like projections of the hypothalamus through which hypothalamic neuronal processes enter [1].

Another role of the neuroendocrine system is the control of skin coloration by melanocyte stimulating hormone (MSH), which affects the dispersion of melanin granules in the melancyte organs of the skin. Neurons from the preoptic area and hypothalamus regulate the release of MSH from the intermediate division of the adenohypohysis which results in skin darkening, which can serve as camouflage or as a social display [1].

### The Preoptic Area

The preoptic area is a transition zone between the diencephalon and the telencephalon. In ray-finned fishes, it is important, along with the posterior region of the

hypothalamus, for the maintenance of body temperature, whether by internal physiological mechanisms or by behavioral means; i.e., moving from a region that is too warm or cold to a location that is within a satisfactory thermal range for the animal. Regulation of body temperature is especially important for aquatic animals because of the effects of temperature on various respiratory gasses, and also because temperatures outside of the animal's optimal range can affect the rate at which important metabolic chemical reactions occur [1].

The preoptic area is present in all fishes. Among jawless fishes, it is less developed in lampreys than in hagfishes, in which it is particularly well developed and consists of four nuclei: dorsal, external, periventricular, and intermediate. This area is also well developed in ray-finned fishes and comprises anterior and posterior parvocellular nuclei and a magnocellular nucleus that contains both large-celled and small-celled subdivisions. The preoptic area is not particular well developed in lungfishes and salamanders, but in frogs it contains an anterior preoptic area and a magnocellular nucleus. [1,3].

Among anamniotes, the functions of the preoptic area have probably been best studied in ray-finned fishes, where it has been reported to be involved in reproductive and parental behaviors such as courtship, nest building, and sperm and egg release and related social behaviors such as aggressive displays. Other functions of the preoptic area in fishes include a role in heart rate and respiration [1].

## Connections of the Preoptic Area

The preoptic area receives epithalamic projections from the epiphysis (pineal) and habenula [1,7]. Other inputs are from the lateral pallium [6]. The preoptic area sends efferent axons to most of the telencephalon, including the olfactory bulb, and also to the habenula and the periglomerular complex [3,7,8], which is an aggregation of nuclei in the posterior tuberculum (a posterior part of the diencephalon unique to fishes) that receive gustatory, visual, and auditory inputs and relay them to the midbrain tectum and the telencephalon. In amphibians, the preoptic area receives input from limbic system structures such as the septum and amygdala, as well as from the hypothalamus, retina, and pineal. Its efferents are to the striatum of the telencephalon, hypothalamus, and spinal cord [1].

## Hypothalamus

In lampreys, the hypothalamus consists of a thin shell around the third ventricle and is comprised of dorsal and ventral divisions. The hypothalamus of hagfishes also is poorly developed. In contrast, the hypothalamus of sharks is well developed into distinct nuclei. In addition to the suprachiasmatic nucleus, it contains a nucleus medius, as well as a periventricular nucleus, and a nucleus lateralis tuberis, which seems to be related to the hypophysis. Also present is a nucleus lobi lateralis which is present in the lateral lobe, a lateral expansion of the ventral hypothalamic region. This nucleus is connected to various subpallial structures of the telencephalon by the basal forebrain bundle and to the pallium by the tractus pallii [1].

In ray-finned fishes, the hypothalamus consists of a dorsal and a ventral division as well as distinct nuclei such as ventral, lateral, and anterior tuberal nuclei in the region of attachment of the hypophysis. The inferior lobe contains a diffuse nucleus and a compact nucleus known as the central nucleus of the inferior lobe. Also contained within the inferior lobe of cyprinid fishes (goldfish and other carps as well as catfishes), which are fishes that are highly specialized for gustation, is a structure called the mammillary body, so named for it superficial resemblance to the mammillary body of the amniote hypothalamus. In these fishes, however, this cell group appears to be specialized for gustatory input to the hypothalamaus; it receives axons from the secondary gustatory nucleus and sends its output to other regions of the inferior lobe [8,9].

In lungfishes and salamanders, the hypothalamus is relatively undifferentiated into distinct nuclei. The hypothalamus in frogs, however, is differentiated into dorsal and ventral regions and a lateral hypothalamic nucleus that may be comparable to the inferior lobes of sharks and ray-finned fishes [1].

Nearby to the preoptic area in many anamniotes is the suprachiasmatic nucleus, a cell group that is a hypothalamic target of axons from the retina and that sends its output to other regions of the hypothalamus and to the periglomerular nuclear complex [1,10,11]. The suprachiasmatic nucleus has been reported to play an important role in biological rhythms that depend on the daily light cycle and its seasonal changes in anamniotes as well as amniotes.

## Connections of the Hypothalamus

The connections of the hypothalamus in anamniotes have not been as well studied as those of mammals. The inferior lobe of fishes receives inputs from a wide variety of sources including the gustatory nuclei [10], preoptic area, dorsal thalamic area, the posterior thalamic nucleus, and parts of the preglomerular nuclear complex [6,9,10,11]. Additionally, it receives visual inputs relayed through pretectal nuclei (the posterior pretectal nucleus in nonteleost ray-finned fishes and two comparable nuclei, nucleus pretectalis superficialis pars intermedius and nucleus glomerulosus, in teleosts) that may be involved in feeding behavior [1]. Its efferents are to the central zone of the pallium, dorsal hypothalamus, mammillary body, and posterior thalamic nucleus [10,12–15].

As in amniotes, an important function of the hypothalamus in anamniotes is the autonomic control of the viscera by way of the hindbrain. A main pathway

for this control is the tractus lobo-bulbaris from the inferior lobe to the reticular formation and motor nuclei of the hindbrain. The inferior lobe also interacts with the cerebellum via the tractus lobocerebellaris. Other connections of the inferior lobe are with the midbrain tegmentum [1].

In amphibians, the hypothalamus receives inputs from the preoptic area, components of the limbic system such as the amygdala and septum, and various thalamic nuclei such as the anterior and central nuclei. Other afferents are from the midbrain including the tegmentum, optic tectum, and torus semicircularis. It efferent targets include the amygdala, preoptic area, and the anterior and posterior nuclei of the dorsal thalamus [1].

In summary, taken together, the preoptic area and the hypothalamus form a complex interface between sensory systems, visceromotor systems, and the endocrine system [1,11,12,15]. The details of their connections vary substantially across the major vertebrate taxa, both anamniote and amniote, according to the variable elaboration of different parts of the neuraxis and the different niches they occupy.

# Evolution of the Hypothalamus in Amniotes

Laura L Bruce
Department of Biomedical Sciences, School of Medicine, Creighton University, Omaha, NE, USA

## Definition

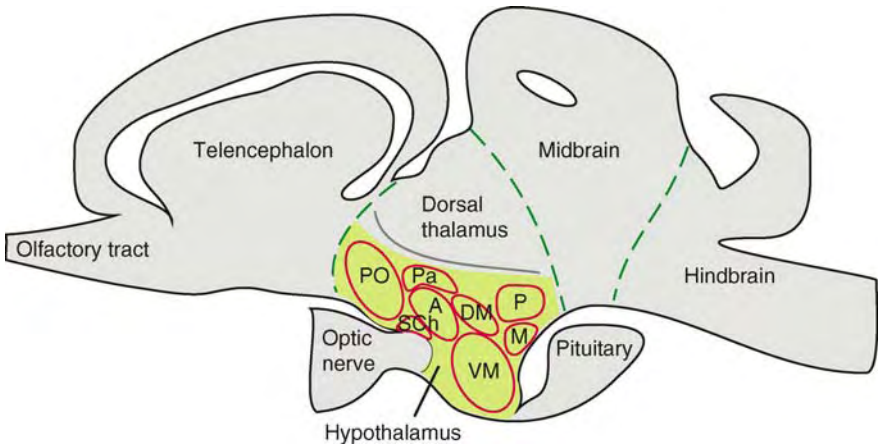
The amniote hypothalamus is located in the ventral part of the diencephalon. It consists of multiple cell groups that regulate diverse functions, including feeding, temperature regulation, diurnal rhythms, autonomic responses and procreation.

## Characteristics

The hypothalamus consists of multiple cell groups with diverse functions, most of which help to regulate survival of the individual (e.g. feeding, temperature regulation, diurnal rhythms, autonomic responses) or survival of the species (e.g. procreation). Many of the nuclei and their neurochemical characteristics are present in all amniotes, suggesting that they were present in the common amniote ancestor.

## Introduction

The amniote hypothalamus is located in the ventral part of the diencephalon or thalamus, forming the walls and floor of the third ventricle (Fig. 1).



**Evolution of the Hypothalamus in Amniotes. Figure 1** The location of the hypothalamus (light green) and some of the major hypothalamic nuclei (red outline) relative to other major brain regions is illustrated in a sagittal section through a reptilian brain. Rostral is to the right and dorsal is up. Abbreviations: *A*, anterior hypothalamic nucleus; *DM*, dorsomedial hypothalamic nucleus; *M*, mammillary body; *Pa*, paraventricular nucleus; *PO*, preoptic area; *SCh*, suprachiasmatic nucleus; *VM*, ventromedial hypothalamic nucleus; *P*, posterior hypothalamic area.

The rostral midline of the hypothalamus is formed by the lamina terminalis, which also forms the rostral wall of the third ventricle and is associated with a vascular organ. The functions of the hypothalamic nuclei are usually essential for survival and thus it is perhaps to be expected that, once evolved, these nuclei would be retained during the further evolution of species.

## General Organization of the Hypothalamus

In all amniotes the hypothalamus is divided into three longitudinal zones: periventricular, medial, and lateral (Fig. 2).

Many of the cell groups in the periventricular zone project to the pituitary and thus regulate the secretion of pituitary hormones. The groups of the medial zone receive sensory information through major connections from the limbic regions in the telencephalon, such as the septum and amygdala. The output of the medial zone regulates the expression of survival and reproductive behaviors. The lateral zone is traversed by the medial forebrain bundle, which interconnects this zone with the brainstem, cortex and amygdala. The medial zone is organized rostrocaudally into four regions, the preoptic, anterior, medial (or tuberal) and posterior (or mammillary) regions. These divisions can be extended into the periventricular and lateral zones, thus dividing the hypothalamus into 12 compartments. The major nuclei of these compartments can be recognized in all reptiles, birds, and mammals (Fig. 2). The following descriptions emphasize nuclei that have been identified in all amniote classes. Comparable connectional, histochemical or functional studies have not been performed yet in some classes and so the lack of data should not be interpreted as absence of homology.

## Functions Associated with Hypothalamic Nuclei

The functions associated with the major hypothalamic nuclei will be addressed in a rostral to caudal and medial to lateral sequence.

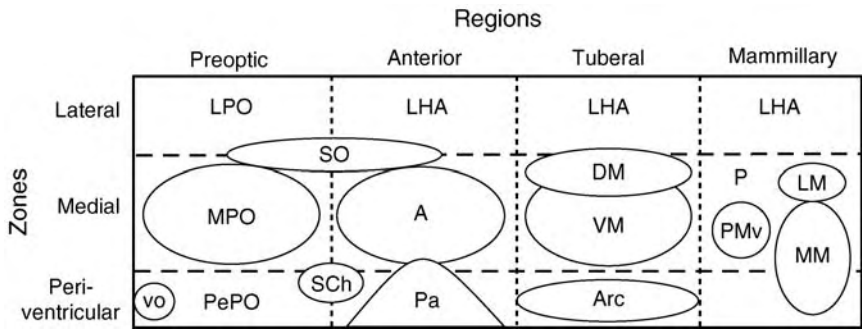
### *Body Fluid Homeostasis*

The hypothalamic vascular organ, together with the nucleus paraventricularis, is involved in osmoregulation. Both angiotensin II and the antidiuretic vasotocin are located in these nuclei and are involved in osmoregulation. Angiotensin II has been shown to elevate blood pressure in birds.

A hypothalamic periventricular organ is present in all vertebrates except mammals. It is located dorsal to the dorsomedial hypothalamus. The cells of this organ are in direct contact with the fluid of the third ventricle and appear to accumulate dopamine and noradrenalin from the cerebral spinal fluid of the third ventricle. The function of this organ is not clear, but it is probably affected by the cerebral spinal fluid and thus may regulate body fluid homeostasis. It is considered to be a primitive trait that was lost in mammals.

### *Temperature Regulation*

In all amniotes the hypothalamus has a critical role in regulating behaviors and physiology relevant to thermoregulation. The medial preoptic area and anterior hypothalamic region activate mechanisms that enhance heat loss (shallow breathing, sweating, vasodilation). Temperature-sensitive neurons are scattered in the medial preoptic and the anterior hypothalamic nuclei. These neurons respond to cooling or warming of either the skin or the surrounding brain tissue. They appear to regulate body temperature through behavioral and



**Evolution of the Hypothalamus in Amniotes. Figure 2** Relative positions of major hypothalamic nuclei. A simplified two-dimensional representation of the right side of the hypothalamus showing the relative positions of major nuclei within the zones and regions that have been identified in all amniotes. Rostral is to the left, lateral is to the top, and the third ventricle (midline) is at the bottom. Abbreviations: *A*, anterior hypothalamic nucleus; *Arc*, arcuate nucleus; *DM*, dorsomedial hypothalamic nucleus; *LHA*, lateral hypothalamic area; *LM*, lateral mammillary nucleus; *LPO*, lateral preoptic area; *MM*, medial mammillary nucleus; *MPO*, medial preoptic area; *P*, posterior hypothalamic area; *Pa*, paraventricular nucleus; *PePO*, preoptic periventricular nucleus; *PMv*, ventral premammillary nucleus; *SCh*, suprachiasmatic nucleus; *SO*, supraoptic nucleus; *VM*, ventromedial hypothalamic nucleus; v*o*, vascular organ of the lamina terminalis. Modified from Simerly [1].

involuntary means, including panting and changes in peripheral blood flow. The mechanisms for hypothalamic temperature control are present in both ectotherms (reptiles) and endotherms (mammals and birds). In addition, endotherms rely on insulation by fat bodies and a high, variable metabolic rate, which probably function independently from hypothalamic regulation. Neurons in the anterior and medial preoptic nuclei also respond to hormones, suggesting that reproduction and body temperature may be closely linked physiologically, although it is unclear where they are integrated. Vasotocin (or arginine-vasotocin) acts in the hypothalamus to reduce shivering and body temperature.

### Reproductive Behaviors

Reptiles have proven to be excellent models for studying the role of the hypothalamus in the regulation of sexually dimorphic behaviors. Many reptilian species exhibit temperature-dependent sex determination (i.e. the incubation temperature of the egg determines the gonadal sex of the individual), whereas other species are parthenogenetic (female-only species in which individuals display both male-like pseudocopulation and female-like receptivity) and in others sex is determined genetically.

Sexually dimorphic behaviors appear to involve neural pathways that express the androgen, estrogen and/or progestin receptors. These pathways appear to regulate hormone-dependent, sex-typical reproductive and agonistic behaviors and have been highly conserved throughout vertebrate evolution, although further studies are needed in birds. In amniotes, these behaviors are regulated by the medial preoptic area, anterior hypothalamic nucleus and ventromedial hypothalamic nucleus.

The medial preoptic area and the anterior hypothalamic nucleus are involved in expression of masculine sexual behaviors in all amniotes, particularly the regulation of male-typical mounting and intromission behaviors. In some mammals the central portion of the medial preoptic nucleus is larger and contains a greater number of neurons in males compared to females. Androgen-receptor expressing cells are more abundant in the preoptic area of males than females. Progestin and estrogen receptors are also present in the preoptic and anterior hypothalamic regions. Thesehypothalamic areas are strongly influenced by olfactory and vomeronasal amygdalar connections, as well as those from parts of the subiculum and septal nuclei, which provide a route for sensory cortical information to influence the masculine sexual behaviors. The preoptic region also regulates parental behaviors in birds and mammals and involves the activation of progestin receptors there.

The ventromedial hypothalamic nucleus regulates estrogen-dependent receptive behaviors, in particular female-typical receptivity. Its lateral part contains abundant receptors for estrogen, progestin and androgen. In lizards the volume of the ventromedial hypothalamic nucleus is larger in females than in males. It receives massive inputs from the amygdala (particularly the lateral amygdalar nucleus, which is homologous with the mammalian accessory basal amygdala) and ventral subiculum, which provide information about all sensory modalities. The reptilian nucleus premammillaris and the mammalian ventral premammillary nucleus both label densely with androgen probes and slightly with estrogen probes, indicating a possible homology. The connections of these nuclei in both reptiles and mammals are similar

to those of the ventromedial hypothalamus, suggesting that they may contribute to the regulation of similar behaviors.

### Circadian Rhythms

The suprachiasmatic nucleus lies above the optic chiasm close to the midline in reptiles and mammals. In birds it includes a medial and lateral subdivision that extends laterally along the optic tract. In all amniotes, the suprachiasmatic nucleus receives visual input directly from the ganglion cells in the retina. In mammals, it appears to be responsible for the maintenance of circadian rhythms of sleep, locomotion, feeding and drinking, adrenal corticosterone secretion and pineal activity and cyclicity of ovarian activity. It is likely that it serves similar functions in other amniotes.

### Neuroendocrine Control

The periventricular hypothalamus is largely involved in controlling the lobes of the pituitary gland and in this sense contains the motoneurons of the neuroendocrine system. Magnocellular nuclei control the posterior pituitary, whereas parvocellular nuclei control the anterior pituitary.

### Magnocellular Neurosecretory System

Large neurons in the supraoptic and paraventricular nuclei comprise the magnocellular neurosecretory system, which is present in all amniotes. These large neurons synthesize the hormones vasopressin and oxytocin in mammals and produce very similar hormones in birds and reptiles. In mammals these neurons send axons to the posterior pituitary, where the hormones are released into the bloodstream. In mammals oxytocin is responsible for lactation, labor, nausea and gastric distention and both arginine-vasopressin (AVP) and oxytocin regulate water balance and blood pressure.

### Parvocellular Neurosecretory System

Small neurons located in a variety of hypothalamic nuclei form the parvocellular neurosecretory system, which regulates the function of the anterior pituitary gland. The neurons are located mainly in the periventricular zone and are particularly numerous in the paraventricular and arcuate nuclei. These neurons contain a variety of stimulatory and inhibitory factors that travel via axons to the median eminence (at the top of the pituitary stalk). There the factors are released into portal veins, which form a venous capillary system between the median eminence and the anterior pituitary lobe. These factors thus reach the anterior lobe, where they stimulate or inhibit cells to release their hormones. In mammals, the hormones include growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), prolactin, luteinizing hormone (LH) and follicle stimulating hormone (FSH). Homologues of many of the mammalian hypothalamic factors and pituitary hormones have been identified in reptiles and birds. Thus, it appears that the parvocellular neurosecretory system was well established in the common amniote ancestor.

Corticotropin releasing hormone (CRH) and its non-mammalian homologue are involved in the stress response. CRH is located in small neurons of the paraventricular nucleus, where it is part of the parvocellular neurosecretory system. CRH is the major physiological stimulus for secretion of adrenocorticotropic hormone (ACTH), or a homologue. ACTH is important in controlling blood pressure and a variety of other functions that will also affect body fluid homeostasis.

### Feeding

The dorsomedial hypothalamus and adjacent regions are involved in regulation of ingestive behaviors. Its connections have been identified in mammals and reptiles and are consistent with this function. It receives connections from many brainstem nuclei, including the parabrachial nuclei and the nucleus of the solitary tract, which are involved in gustatory functions. Vomeronasal and olfactory information strongly influence feeding behaviors, and consistent with this, this hypothalamic feeding region receives such input from the bed nucleus of the stria terminalis. It also receives many intrahypothalamic projections, notably including the ventromedial hypothalamus. The ventromedial hypothalamus and adjacent lateral regions influence metabolism and ingestive behaviors and thus weight regulation. In mammals the lateral hypothalamus is important in appetite and probably serves a similar function in birds and reptiles, although further studies are needed.

### Autonomic Regulation

Neurons in the paraventricular, dorsomedial, lateral and posterior hypothalamic nuclei influence both the sympathetic and parasympathetic divisions of the autonomic nervous system. In mammals neurons in these nuclei project to preganglionic parasympathetic nuclei in the brainstem and spinal cord. Similar hypothalamo-spinal projections have been reported in reptiles suggesting that this pathway is present in all amniotes.

### Spatial Learning

The mammillary body includes the medial and lateral mammillary nuclei. In mammals the mammillary body is commonly believed to be important in spatial learning tasks and in the interaction between emotion and memory. It is strongly influenced by visual and auditory information. A major input to the mammillary body arises from the subicular region of the hippocampal formation via the fornix. It then projects to tegmental nuclei in the brainstem and to the anterior thalamic complex. The latter in turn projects to the limbic cortex

and then to the hippocampus. Although functional studies of the mammillary body have not been performed in reptiles and birds, connectional studies suggest that a similar structure exists. In particular the connections between the mammillary body and the hippocampal formation have been documented.

## Synonyms

Octavolateralis system; Acousticolateralis system; Lateral line; Electrosense; Mechanosense

## Definition

The ►mechanoreceptive and ►electroreceptive lateral line systems are components of the vertebrate ►octavolateralis system, a collection of sensory systems derived from embryonic thickenings called ►dorsolateral placodes. Octavolateralis derivatives include all sensory organs of the ►inner ear, both ►acoustic and ►vestibular, and the hydrodynamic and electric sensors on the body surface termed ►neuromasts and ►electroreceptors, respectively. The term octavolateralis is derived from the combination of *octaval* (eighth) and *lateralis* (lateral) because the inner ear and eighth cranial nerves are the earliest components of the dorsolateral placodes to develop embryonically and are the most prominent aspect of the system in many adult forms. They are the only derivatives found in amniotes. The earliest craniates possessed a mechanosensory octavolateralis system comprised of both an inner ear and spatially distributed ►mechanoreceptors in the integument of the head and trunk. These components are present in all living anamniotic vertebrates, including the aquatic life-stages of most amphibians. The ►electrosensory systems are more diverse and have slightly more recent origins. Lampreys, cartilaginous fishes, non-neopterygian bony fishes, and some urodele (salamanders) and apodan (caecilians) amphibians retain the primitive electrosense. Electrosensory octavolateralis systems were lost during the history of bony fishes, but electroreception appears to have independently re-evolved from octavolateralis precursors multiple times in unrelated groups of teleost fishes.

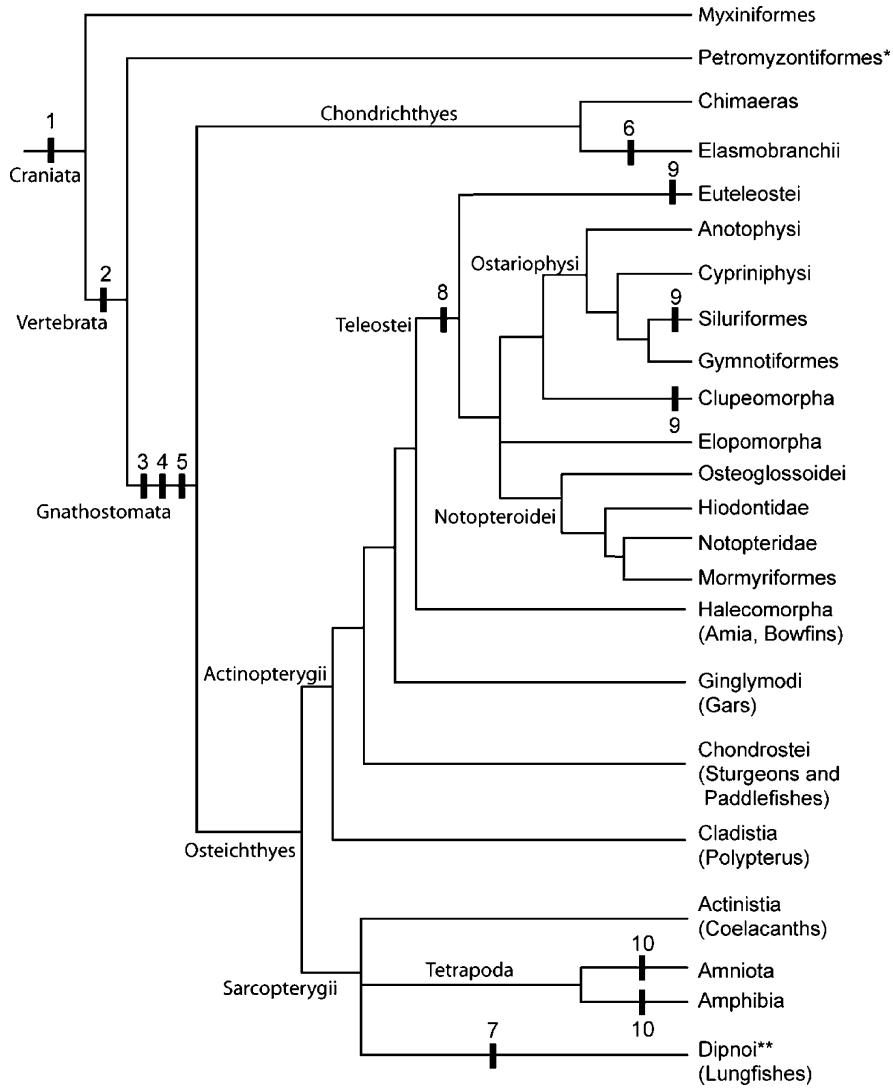
## Characteristics

### Overview

The mechanosensory and electrosensory lateral line systems are components of a larger suite of craniate sensors that also include the inner ear and vestibular systems (Figs. 1 and 2).

The mechanoreceptive lateral line and the inner ear appear to have arisen simultaneously in the ancestral craniate [1]. Electroreceptive systems arose later, with the origin of the vertebrates and have been lost and re-evolved several times independently [2]. The mechanosensory lateral line is composed of neuromasts (see Fig. 3), sensors that detect hydrodynamic disturbances and spatio-temporal patterns of nearby water movements.

The inner ear originally detected hydrodynamic rather than acoustic sources as well, detecting low frequency water disturbances, including the hydrodynamic ►nearfield surrounding sound sources [3]. True acoustic sensitivity (detection of pressure disturbances) has arisen multiple times later in vertebrate history [4]. The earliest electrosensory systems were composed of epidermal ►ampullary organs (see Fig. 3) that



**Evolution of the Mechanosensory and Electrosensory Lateral Line Systems. Figure 1** Branching diagram displaying the phylogenetic relationships of the major craniate groups. Evolutionary events in the history of mechanoreceptive octavolateralis systems are shown as numbered bars. 1) Mechanoreceptive octavolateralis system consists of inner ear and lateral line system in the integument. 2) Multiple lines of neuromast organs on the head and trunk. 3) Multiple classes of neuromasts, canal and pit types. 4) Presence of Cupulae. 5) Some neuromasts receive efferent innervation. 6) Elongated neuromasts fuse creating continuous sensory strip in canals. 7) Multiple neuromasts found between canal pores 8) Large numbers of supernumary neuromasts. 9) Lateral line canal system functionally linked to gas bladder. 10) Loss of lateral line system in some or all taxa. Recent molecular studies [Mallat J and J Sullivan (1998) Mol Biol Evol 15: 1706–1718; Furlong, RF and PWH Holland (2002) Zool Sci 19: 593–598] have argued for a sister group relationship between lampreys and hagfishes (Petromyzontiformes + Myxiniformes), which would necessitate re-optimization of characters 1–5. Existing molecular phylogenetic studies of craniate relationship have been based on small subsets of craniate taxa and the bulk of morphological evidence still suggests that lampreys are more closely related to gnathostomes than either is to hagfishes however, so this hypothesis is shown retained herein. *Petromyzontiformes (lampreys) may be secondarily simplified, as some fossil taxa suggest that character 3 may have arisen earlier than the origin of the gnathostomes. **Multiple neuromasts between canal pores occur in some lungfish taxa only. Linkage between lateral line and gas bladder occurs in clupeomorph fishes [Best ACG and JAB Gray (1980) J Mar Biol Assoc U.K.,60: p. 703–715.], chaetodontid butterfly fishes [Webb JF and WL Smith (2000). Phil Trans Roy Soc Lond B, 355: p. 1125–1129.] and loricaroid catfishes [Aquino AE and SA Schaefer (2002), Zoologischer Anzeiger, 241: p. 223–244.].

Hair cell receptors (in yellow) are found nestled within support cells and project apical cillia into a gelatinous cupula. (b) Ampullary organ. Ciliated receptors (yellow) project their apical surface into a jelly filled ampula that is electrically continuous with the outside environment (shaded). (c) Tuberous organs. Ciliated receptors (yellow) are found in a crypt within the epidermis. The crypt communicates electrically with the external environment via a column of loosely packed epidermal cells (shaded).

were sensitive to DC and very low frequency electric fields. This system of electroreceptors was lost with the origin of neopterygiian fishes (teleosts, gar and bowfins). Several groups of teleost fishes subsequently re-evolved electroreceptive systems, with multiple classes of receptors sensitive to a wider and higher range of frequencies [5]. Some of these electrosensitive fishes also evolved an ►electromotor system capable of generating weak electric fields. These self-generated fields are used in communication and as a sensory carrier for sensing electrically conductive or resistive objects. Electrogenic fishes also possess a second class of electroreceptive organs, ►tuberous receptors, which are specialized for detection of their own electric organ discharge, as well as those of conspecifics. In living fishes, the electroreceptive and mechanosensory lateral line systems are used in all behavioral contexts, general orientation and navigation, intraspecific communication and mate choice, predation, and predator-avoidance [6,7].

## Receptor Complement

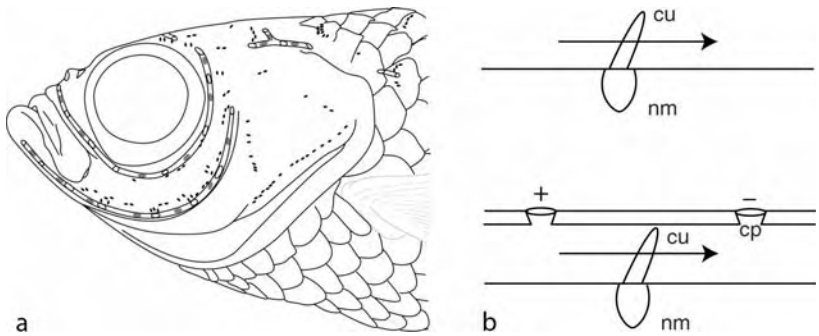
The principal receptor organ of the ►mechanosensory lateral line is the ►neuromast (Fig. 3a). The basic organization of neuromasts, onion-shaped aggregations of ciliated receptor cells, support cells and mantle cells, is remarkably consistent across vertebrates. The surfaces of the receptor cells bear a single true cilium (the kinocilium) flanked by an array of microvilli typically arranged in stair-step descending heights (the stereocillia). In most instances, these hair cells occur in pairs, with each member of the pair bearing oppositely aligned apical bundles. Within a neuromast, all pairs of hair cells are aligned such that each member of the pair faces the opposite pole of a single axis of best sensitivity for the neuromast as a whole. Hair cell responses are highly directionally specific, such that deflection of the apical bundle towards the kinocilium depolarizes the cell's membrane potential and movement away from the kinocilium causes hyperpolarization. The transduction mechanism is primarily mechanical: cytoplasmic bridges, called tip-links, connect the kinocilium and microvilli and are stretched and relaxed by motion of the hair-cell bundle. This change in tension within the apical bundle begins a mechano-electric transduction cascade that alters the membrane potential of the hair cell [8].

The apical bundles are enmeshed in a gelatinous cupula which projects outward from the skin surface. Cupular morphology is poorly documented, and appears to be variable. The most common arrangement is a keel-shaped cupula with a long axis parallel to the axis of the underlying hair cell bundles. The cupula is friction-coupled to the surrounding water, pulled along the surface of the neuromast with local fluid flow, rather than bending or being deflected by water striking its longest face. The combination of friction-coupling provided by cupular morphology and the apical polarity of the receptor cells makes neuromasts highly directionally specific. Lateral line ganglion neurons respond proportionally to the cosine of the angle of incident flow. Ganglionic responses are either inhibitory or excitatory (ganglion cells always display spontaneous activity), depending on which half of the paired population of hair cells are innervated by any particular ganglion cell.

There are three basic types of neuromast organ found in vertebrates. ►Canal neuromasts are those which were primitively found within dermal canals on the head and trunk. In some living vertebrates, homologous neuromasts are found in similar locations superficially, in the absence of canals, in which case they are called ►replacement neuromasts [9]. Such replacement neuromasts may be found in place of all neuromasts (as in salamanders), or they may replace individual neuromast lines or segments (as in many teleosts). The second type of neuromast is the ►pit organ, which are smaller than canal or replacement neuromasts and may have distinctive response properties [10]. Pit organs are found in small lines of neuromasts on the head and trunk of most fishes and were a component of the earliest vertebrate octavolateralis systems [11]. The individual pit organs may be housed in pits, grooves, or short canal segments, depending on the species. Pit organs may be difficult to identify in many teleost fishes, because these fishes also possess large numbers of small superficial neuromasts distributed in clusters or uniform densities across the head and body surface (Fig. 4). These latter neuromasts have been called ►accessory neuromasts [9], and they likely have distinct functions and patterns of innervation [12]. Accessory organs are only found in teleost fishes.

The receptor organs of the electrosensory lateral line are more diverse [5]. Primitively, jawed vertebrates (Gnathostomata) possessed small epidermal organs called ampullary organs (or Ampullae of Lorenzinini in cartilaginous fishes). These consist of an epidermal canal stretching from the skin surface into deeper layers of the integument (Fig. 3b). A small crypt containing as many as several hundred ciliated receptor cells is present at the base of this ampulla, and the apical portions of the receptor cells protrude into the crypt and canal. The crypt and canals are filled with a gelatinous substance that is matched to the resistance of the ambient medium. The receptor cells respond with exquisite sensitivity to changes in voltage across the epidermal surface, i.e., voltage gradients on the order of 1 microvolt/cm or less. Primitive ampullary receptor cells are depolarized by negative external voltages (relative to the interior of the animal) and hyperpolarized by positive external voltages. The electroreceptive octavolateralis system was lost sometime in the lineage leading to neopterygian fishes (Fig. 2). Most neopterygian fishes do not possess electroreceptors of any kind. Two groups of teleost fishes subsequently re-evolved electroreceptive systems, still drawing developmentally from dorsolateral placodes. Electroreceptive teleosts possess ampullary organs much like those of primitive vertebrates, however the polarity of excitation is exactly opposite: teleost receptor cells are excited by positive voltages and inhibited by negative voltages. Both teleost and primitive ampullary organs are most sensitive to DC and low-frequency electrostatic fields, generally less than 50 Hz [2].

A second broad category of electroreceptive organs is the ►tuberous organs found in weakly-electric fishes of South America (Gymnotiformes) and Africa (Mormyriformes). It appears that although these organs share many attributes, they have evolved convergently [2]. These organs are also comprised of an epidermal crypt containing receptor cells (Fig. 3c). Unlike ampullary organs, however, the apical canal is typically loosely packed with epidermal cells. This region of flattened cells with large extracellular spaces acts functionally like the canal of ampullary organs, conducting current through the epidermis to the lumen of the tuberous organ crypt. Several distinct types of tuberous organs are found in each group of electroreceptive teleosts



**Evolution of the Mechanosensory and Electrosensory Lateral Line Systems. Figure 4** Generalized pattern of neuromast distribution in a teleost fish. Large numbers of supernumary accessory neuromasts are depicted as small black ovals. The larger canal neuromasts are shown as grey ovals within dermal canals that open to the surface through pores (open circles). B. Neuromast (nm) responses depend on accessory structures. Superficial neuromasts (above) respond in proportion to the velocity of fluid past the cupula (cu). Canal neuromasts (below) respond similarly, but the velocity of fluid within the canal is proportional to the pressure difference (+/–) at adjacent canal pores (cp).

and reflect the complex information processing demands of a system used for both communication and active sensing [5]. The multiple classes have been best described physiologically, but there are also gross morphological differences between organ types. Nonetheless, all tuberous organs appear to be tuned to higher frequency ranges than ampullary organs (up to several thousand Hz, depending on the species and are only found in species that produce electric fields. Unsurprisingly, tuberous organs function in the detection of self-generated electric signals and those generated by conspecifics. In any given electric fish species, two tuberous organ types detect different aspects of electric signals, usually functionally distinguished by responsiveness to either temporal or amplitude cues. In Gymnotiformes, both functional classes of tuberous organs are involved in both communication and ►electrolocation based on self-generated electric fields. In Mormyriformes, however, the time coding tuberous organs, ►Knollenorgans, are used to detect the electric fields produced by other fishes, but their input to the brain is cancelled during production of the animal's own electric field. Distortions in the animal's self-generated field are used in electrolocation, and these distortions are sensed by the other class of tuberous organ, the ►mormyromasts. Although mormyromasts are less sensitive than Knollenorgans, and Knollenorgans are clearly specialized for communication, the distinction is not completely clear-cut, as mormyromasts may also be used to detect conspecifics during agonistic and other close-range encounters [7].

Curiously, the living coelocanth (Latimeria) does not possess any of these types of electroreceptors, including ampullary organs. Instead, a series of subdermal chambers, called the ►rostral organ, is found in the snout, with three pairs of external pores on the rostrum. The epithelial lining of these pouches contains putative electroreceptor cells and receives innervation from octavolateralis cranial nerves. The physiological properties and relevant stimuli of these receptors are unknown. It is not known if any extinct coelocanths also lacked ampullary organs, but evidence of a rostral organ has been found in fossil taxa [13].

## Agnathan Octavolateralis Receptor Complement

The sensory organs described above are widespread in gnathostome vertebrates, but the antecedent systems were more diverse and are less well-understood in agnathan vertebrates (currently represented by extant lampreys and hagfishes). Lampreys, a putative sister group to the living jawed vertebrates, possess slightly unusual neuromasts, most distinguished by the lack of a cupula and an absence of efferent innervation. In hagfishes, the putative sister taxon to the remaining vertebrates, one family lacks any trace of a mechanosensory lateral line system, and the other appears to have a degenerate system composed of disorganized trenches filled with isolated ciliated receptor cells [14].

There is no trace of any electroreceptive system in hagfishes, and a most unusual system is found in lampreys. Adult lampreys are electroreceptive but do not possess ampullary organs. Instead, small clusters of sensory cells are grouped into organs with an apical microvillar surface rather than a tubular ampulla within the epidermis. These organs, called ►endbuds in the older literature, are innervated by lateral line cranial nerves and are similar in their responses to ampullary organs. That is, they respond to very minute electric fields, on the order of microvolts per centimeter, and are excited by cathodal stimulation, as are primitive ampullary organs. Although it is likely that electroreceptors of some kind were found in the ancestor of lampreys and gnathostomes (Fig. 2), it is not known if they were of the lamprey endbud type, or were more like ampullary organs of gnathostomes. There is evidence of electroreceptive pores (i.e., remnants of ampullae) in the bony armor of some groups of extinct jawless fishes, so it is possible that ampullary organs are the primitive form of electroreceptor [1].

Complicating matters, larval lampreys (ammocoetes) possess a gnathostome-like brainstem circuitry and cranial nerves for electroreception and electroreceptive units in these structures have been demonstrated physiologically. Strikingly, however, they do not possess end-buds. The peripheral electroceptive elements are unknown in ammocoetes. Individual sensory cells are present in the epidermis of larval lampreys, in isolated clusters of two to four cells, without supporting cell types. These are termed ►multivillous cells and they are similar to the receptor cell type found in adult endbuds. These clusters of cells have been suggested to mediate a well-documented extra-ocular photosensory response in ammoceotes. This response is mediated by unknown cutaneous sensors innervated by ganglion cells in the posterior lateral line nerve. Photoreceptive units have also been demonstrated in the medial octavolateralis nucleus (the primary site of *mechanoreceptive* afferents). Multivillous cells contain unique cytoplasmic structures that could conceivably support photopigment deposition, but there is no evidence that these cells mediate the cutaneous photoresponse. The photoresponse and electrosense are clearly mediated by different systems and terminate in medial and ►dorsal octavolateralis nuclei respectively. Thus one receptor type is the only known possible sensor for two distinct modalities [1]. Future research should examine the source of innervation of multivillous cells and their central representation to resolve this question.

## Accessory Structures and the Functions of Neuromasts

Mechanoreceptive neuromasts are found with a variety of supporting structures with biophysical filter

properties that dramatically affect stimulus transduction [12]. Superficial neuromasts on the surface of the integument have cupulae that are directly impacted by fluid velocity at the body surface (Fig. 4).

In many cases, small ridges are found near superficial neuromasts and these could act as directional or spatial filters for fluid flow past the cupulae. Superficial neuromasts may also be found within grooves, trenches or pits, all of which alter the relationship between the cupula and the boundary layer of fluid at the body surface. Superficial neuromasts are generally physiologically responsive to the velocity magnitude past the cupula, but grooves and trenches may alter this relationship, particularly at low frequencies [6,9,12].

In many species, neuromasts are also found deep within the dermis, in epithelial canals that open to the body surface through pores (Fig. 4). These canals develop embryonically from lines of superficial neuromasts as the grooves surrounding them deepen and invaginate into the integument. The morphology of these canals varies greatly across vertebrates, from simple trenches to tubes to highly branched canals with elaborate lattices of pores at the surface. The canal walls vary greatly in diameter, stiffness and in the presence of surface constrictions. The pores themselves may be simple, varying primarily in size and shape, or the pore may also be covered with a membrane or tympanum. All of these variations have significant filter properties that alter the relevant stimulus to the neuromast, that is, fluid-flow within the canal. In all cases, it is believed that the canal itself acts as an acceleration-to-velocity transducer. That is, the velocity of fluid motion within the canal (the proximate stimulus to the neuromast) is proportional to the acceleration (or pressure gradient) across the adjacent canal pores. This transduction process renders the canal neuromast system acceleration-sensitive [3]. Generally, the canal also acts as a high pass filter, reducing the amplitude of fluid motion at low frequencies. The high-pass cutoff point is an inverse function of canal diameter: small diameter canals attenuate low frequency accelerations more intensely than wide canals. It may be difficult to apply this generalization however as limited regions of constriction can impart high-pass properties to otherwise wide-diameter canals [12]. The pores act as sampling points, so pore number and placements affect the spatial receptive properties of each neuromast. A neuromast within a branched canal, where each neuromast is flanked by multiple pores will sample water motions over a wider spatial zone than a neuromast in an unbranched canal with a single pore. Although there are few empirical data on neuromast responsiveness in complex canals systems, it is likely that such spatial averaging result in an increased signal-to-noise operating ratio at a cost of reduced spatial acuity [12].

## Phylogenetic Overview of Receptor Distribution

The distribution of electroreceptors is relatively conservative. Most electroreceptive animals have a high concentration of ampullary receptors on head, which was probably the primitive condition for bony fishes [13]. Ampullary organs are also present on the trunk (primarily dorsally) in lungfishes and in electroreceptive teleosts. The total number of receptors generally ranges from several hundred to several thousand. These receptors are mapped somatotopically in the ►electrosensory lateral line lobe or dorsal octaval nucleus. Tuberous receptors are only found in electrogenic teleost species, but have a similar distribution on the body surface, with highest densities on the snout and dorsal body surface. There are generally fewer tuberous receptors (several hundred) than ampullary organs (several thousand or more) in any given species. Some species have specialized "electrosensory appendages," such as the proboscis of so-called elephant-nose mormyrids (actually an extension of the jaws) or the dorsal filament of some apteronotid gymnotiforms, and these probe-like structures have a high density of electroreceptors [7].

The primitive distribution of mechansensory octavolateralis sensors appears to be multiple arrays of canal neuromasts on the head and trunk [11,15]. A second class of smaller neuromasts grouped into three to six lines on the head and dorsal trunk were also present in the earliest vertebrates, although these may be found in pits or grooves in many taxa. These are the ►pit lines, which in most living vertebrates are found in superficial pits [15]. All gnathostome groups with the mechanosensory octavolateralis system possess both a main system of (usually canal-based) lines and a pit line system [11]. The main canal system is typically comprised of canals above and below the eye (supra- and infraorbital canals), and a mandibular-preopercular canal (see Fig. 4). These canals connect through a temporal canal caudal to the eye and this temporal canal may continue caudally as a trunk canal. Several short canal segments (either contiguous with this main array or not) are also usually present on the rostral snout and dorsal head, including two or more commissural canals. This pattern is so consistent across taxa that a similar distribution must have characterized the earliest vertebrates. The number of canals on the trunk is more uncertain. All living vertebrates have a line of neuromasts running down the trunk and they are most often contained within a canal. In most vertebrate groups, a ventral canal is also usually present, running along the ventral body surface. A third canal is also present dorsally, although this group of neuromasts typically does not extend the entire body length. In many taxa, these canals are reduced or eliminated and phylogenetically homologous lines of superficial neuromasts are present on the head and trunk. Canal

E

reduction can occur globally, as in amphibians, which lack any canals at all; or locally, as is the case in many teleosts, where individual segments of canals have been replaced by superficial lines of neuromasts. These are called ►replacement neuromasts, to distinguish them from other superficial organs and recognize their phylogenetic lineage as canal organs [9].

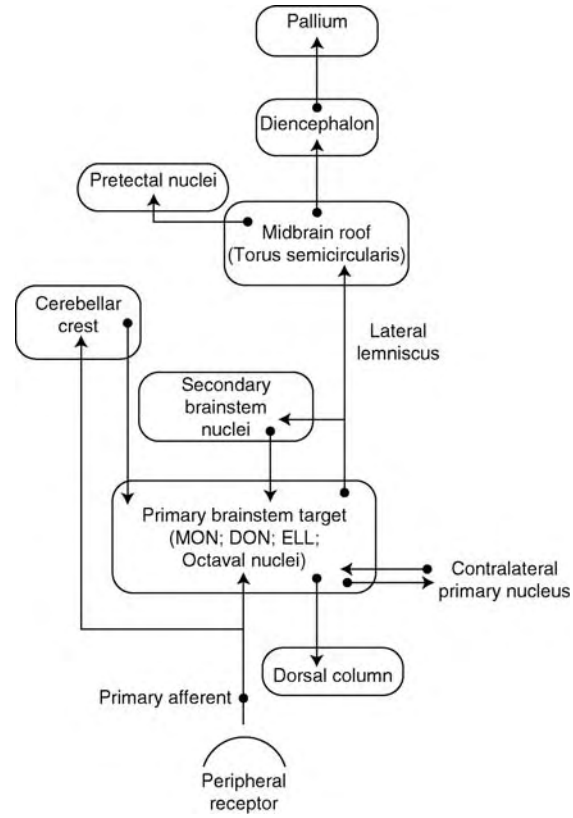
In many taxa (e.g., teleosts), individual neuromasts are found between each pair of canal pores. In other taxa, (Chondricthyes and lepidosiren and protopterid lungfish), the neuromasts proliferate or grow within the canals and multiple neuromasts are present between each pair of pores [15]. In some sharks, these neuromasts may even fuse, forming a continuous sensory epithelium lining the canal. This pattern of neuromasts distribution likely affects spatial processing, but nearly all behavioral and physiological studies of canal neuromast function have been performed using animals with a single neuromast between canal pores, so one can only speculate as to how this impacts mechanosensory function. Although the vast majority of living taxa have a single neuromast between canal pores, the phylogenetic distribution of multiple neuromasts suggests that multiple neuromasts may have actually been the primitive state [15].

Teleost fishes are unique in possessing large numbers of superficial neuromasts, called ►accessory neuromasts. These neuromasts are typically found in clusters rather than lines, and are often associated with or surrounding the canal pores on the head and trunk. There may also be thousands of them widely distributed across the body surface. These neuromasts are typically smaller than canal or replacement neuromasts, and are innervated by diverging sensory neurons. A single sensory afferent may contact a cluster of neuromasts (all with a similar apical orientation), whereas canal neuromasts have an exclusive innervation (a sensory afferent only innervates a single canal neuromast). It has been shown that teleosts use superficial neuromasts to orient to the direction of current flow (rheotaxis), and it is likely that this behavior is mediated by accessory rather than replacement or pit neuromasts [12].

## Central Pathways

The inner ear endorgans, mechanosensory lateral line, and electrosensory systems are each innervated by exclusive populations of cranial ganglion cells. Despite many differences in the physical nature of relevant stimuli and the somewhat independent processing pathways, the central anatomy of octavolateralis systems share many similar features, as depicted in Fig. 5 [14,16].

This likely reflects their shared developmental and evolutionary origins, but also reflects commonalities in information-processing requirements [16]. All octavolateralis systems analyze spatial, temporal, or spectral



**Evolution of the Mechanosensory and Electrosensory Lateral Line Systems.**
**Figure 5** Generalized pattern of octavolateralis central pathways, modified after [1 and 12]. DON: dorsal octavolateralis nucleus; ELL: electrosensory lateral line lobe; MON: medial octavolaterlis nucleus. Not all connections are shown, but note that the cerebellar crest (or eminentia granularis) also receives inputs from somatosensory afferents and descending inputs from multiple higher brain regions.

discontinuities in a stimulus field (sonic, hydrodynamic, or electrostatic), and this has resulted in similar neural structures and pathways. Each octaval modality has a distinct primary hindbrain target and most primary afferents also send collaterals to a rhombic lip region called the eminentia granularis or the cerebellar crest (see Fig. 5). These regions issue parallel fibers that overlie the primary brainstem nucleus and form a cerebellum-like circuit that adaptively filters and processes primary inputs [14,16]. Each primary nucleus is organized topographically, although inner ear and/or lateral line projections are coarsely organized in some or all species. Electroreceptive afferents terminate somatotopically, and when multiple classes of electroreceptors are present, each class of afferent forms a parallel somatotopic map in a specific hindbrain region. Afferents from the inner ear maculae and semicircular

canal cristae terminate in a complex of nuclei called the ►octaval nuclei (anterior, descending, magnocellular, and posterior), each of which receives inputs from all the inner ear end organs. The dorsomedial region of the descending nucleus receives the heaviest projections from putatively ►acoustic end organs and its efferents form an ascending lemniscal pathway to the midbrain. Mechanosensory lateral line afferents project primarily to a dorsal medullary nucleus called the ►medial octavolateralis nucleus (MON). Primitive ampullary organs are represented in a region just dorsal to the MON, called the dorsal octavolateralis nucleus ►(DON). In teleosts, which lack the primitive electrosense, but have re-evolved ampullary organs, these sensors are represented in a non-homologous brainstem region called the electrosensory lateral line lobe (ELL). Where multiple classes of electroreceptors are present (i.e., gymnotiforms and mormyrids), each class is represented in a separate segment of the ELL.

The brainstem primary nuclei project to other brainstem nuclei (e.g., olivary nuclei) and to midbrain nuclei through the ►lateral lemniscus. Each modality is represented in distinct regions of the ►torus semicircularis, and each of these toral regions have unique efferent targets. Although there is an opportunity for the convergence of modalities in the hindbrain (through the parallel fiber pathways and a small degree of overlap of primary afferents), the integration of modalities appears to first occur in the midbrain tectum. Diencephalic targets may be uni-modal, particularly in the electrosensory pathway, but at least some thalamic nuclei and most pallial areas appear to receive inputs from multiple octavolateralis pathways [14,16].

# Evolution of the Optic Tectum in Amniotes

Salvador Guirado, José Carlos Dávila
Departamento de Biología Celular, Genética y Fisiología, Facultad de Ciencias, Universidad de Málaga, Málaga, Spain

## Definition

The optic tectum in amniotes is a laminated structure located in the roof of the mesencephalon. It consists of various layers of cells and fibers, the number and thickness of which varies among reptiles, birds and mammals. Generally speaking, numerous cells localized to distinct depths of the optic tectum are

characterized by radially oriented dendritic trees that are in regions with a variety of sensory afferent fibers coursing parallel to the mesencephalic surface, whereas other cells with horizontal morphologies are exposed to a lesser variety of sensory afferent inputs. As a result, the mesencephalon is provided with a 3D sensory map of the external world and, through its efferent connections to motor centers, elicits a number of motor responses such as escape, freezing, or orientation. These motor responses may be selected or inhibited by a further evaluation of the sensory input through neural circuits involving the ascending connections of the optic tectum to the thalamus and telencephalon.

## Characteristics

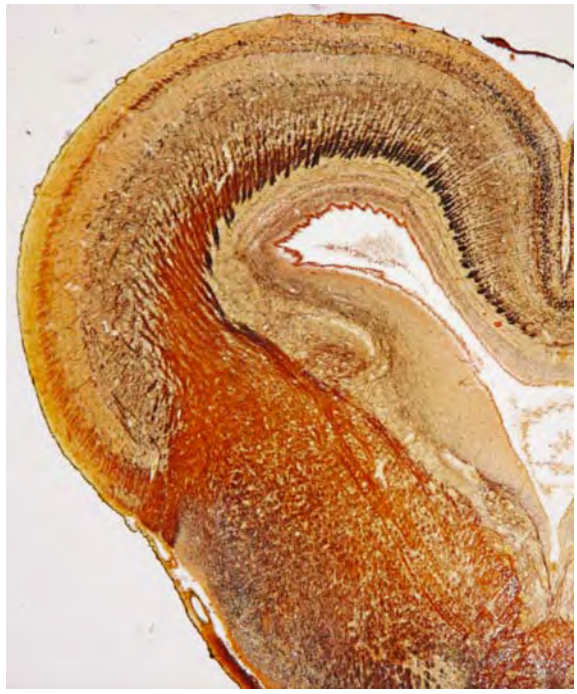
### Structure of the Optic Tectum in Reptiles

From the pioneering studies of Pedro Ramón y Cajal (Santiago Ramón y Cajal's brother, usually known as P. Ramón as he appeared in many of his papers), 14 layers have been recognized in the reptilian optic tectum. Following the descriptions in the original paper of P. Ramón on the structure of the chameleon brain [1], layers are numbered from the ventricle to the pial surface: (i) epithelial zone; (ii) molecular zone; (iii) cellular zone; (iv) molecular zone; (v) cellular zone; (vi) central fiber zone; (vii) central cellular zone; (viii) cellular zone; (ix) molecular zone; (x) cellular zone; (xi) molecular zone; (xii) cellular and optic fiber zone; (xiii) molecular zone and (xiv) optic fiber zone. Among reptiles, lizards are the group where the 14 layers are most clearly delimited. These 14 layers were later regrouped into six strata [2]: (i) the *stratum opticum*, which contains the fibers from the optic tract and is located superficially; (ii) the *stratum fibrosum et griseum superficiale*, with loosely arranged small cells and fibers; (iii) the *stratum griseum centrale*, a thick layer with densely packed cells; (iv) the *stratum album centrale*, consisting mainly of the axons of the *stratum griseum centrale* cells; (v) the *stratum griseum periventriculare*, with loosely arranged small and medium-sized cells and (vi) the *stratum fibrosum periventriculare*, the innermost fiber layer (Figs. 1 and 2).

#### Cells

Golgi and cell-labeling studies in reptiles have shown a variety of cell types in the optic tectum. One type of tectal neuron displays dendrites extending radially across the tectal laminae; thus they are referred to as radial cells (but also as pyramidal or piriform cells) (Fig. 3).

These radial cells are found in all layers of the tectum but are most common in the intermediate and deep layers. Another type is the horizontal cell, with dendrites arranged parallel to the pial surface and mostly found in the superficial layers. Yet another prominent type of tectal neuron is the ganglion cell, a large neuron with extensive dendrites that extend toward the pial surface. Many of these ganglionic neurons are localized to the *stratum griseum centrale* and display apical dendritic tufts within the superficial retinorecipient layers [3].

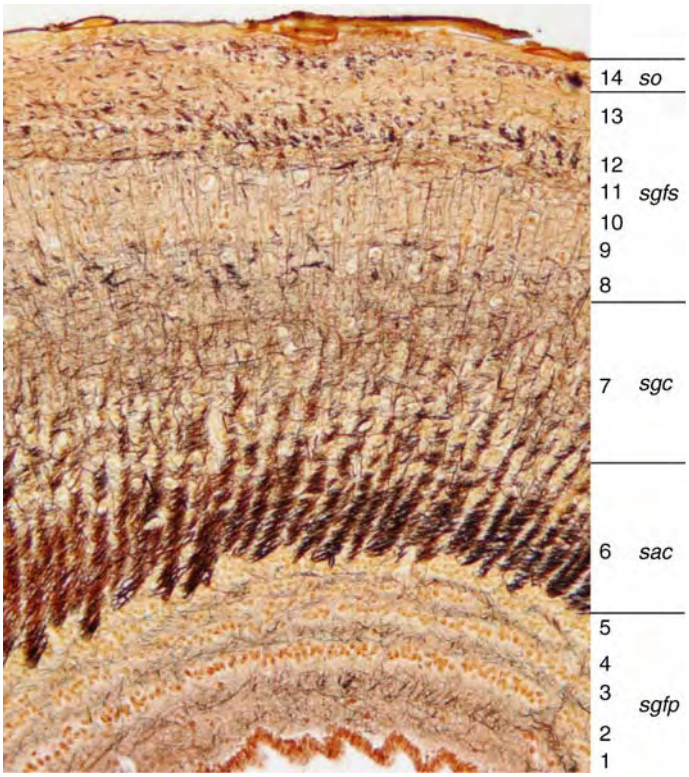


**Evolution of the Optic Tectum in Amniotes.**
**Figure 1** Transverse hemisection through the midbrain of a lizard (*Psammodromus algirus*) stained with the reduced silver nitrate method of Cajal.

#### Afferences

The optic tectum in reptiles receives visual, somatosensory and auditory inputs, as well as non-sensory inputs from brainstem, diencephalic and telencephalic centers. Retinal projections to the optic tectum are bilateral, although predominantly contralateral in most reptiles. Retinal fibers innervate the superficial tectal layers, where a heavy projection is found, primarily to layers 9, 11 and 13. Neurophysiological studies reveal a precise retinotopic projection on the optic tectum; the nasotemporal visual axis is represented along the rostrocaudal tectal axis and the dorsoventral visual axis along the mediolateral tectal axis. The reptilian optic tectum also receives direct projections from the telencephalic visual cortex.

Other sensory systems project to the deeper tectal layers. Somatosensory inputs from both spinotectal and trigeminotectal pathways reach the intermediate and deep layers of the optic tectum. Auditory inputs reach the deeper tectal layers after a relay in the torus semicircularis and nucleus intercollicularis. Various pathways also link the optic tectum with the basal



**Evolution of the Optic Tectum in Amniotes. Figure 2** Detail of a portion of the optic tectum of a lizard (*Psammodromus algirus*) showing the tectal lamination. Reduced silver nitrate stain. Abbreviations: *so*, *stratum opticum*; *sgfs*, *stratum griseum et fibrosum superficiale*; *sgc*, *stratum griseum centrale*; *sac*, *stratum album centrale*; sgfp, *stratum griseum et fibrosum periventriculare*. Numbers (1–14) indicate layers.

ganglia, since diencephalic and mesencephalic regions receiving striatal projections, which include the nucleus of the posterior commisure, the posterior entopeduncular nucleus and the substantia nigra, project to the optic tectum.

### *Efferences*

Tectal neurons give rise to bilateral ascending projections to the pretectum and thalamus, commissural projections to the contralateral tectum and descending projections to the brainstem. In most reptiles, the thalamic nucleus rotundus receives the largest ascending tectal input, which arises almost exclusively from neurons in the *stratum griseum centrale* [4]. The tectal projections to the dorsal geniculate nucleus are very scarce compared with the tecto-rotundal ones and originate from neurons localized mostly to the *stratum fibrosum et griseum superficiale* [5].

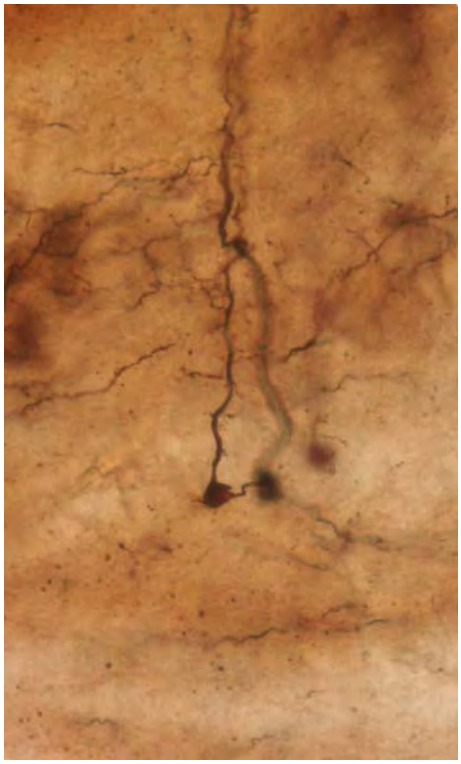
The reptilian optic tectum projects to different rostrocaudal parts of the brainstem reticular formation through the dorsal, intermediate and ventral tectobulbar tracts. These descending fibers arise mainly from neurons in the *stratum griseum centrale*, with minor contributions from the superficial tectal layers and from the *stratum griseum periventriculare*.

## Structure of the Optic Tectum in Birds

Fifteen layers are generally recognized in the avian optic tectum and are numbered from superficial to deep (the most superficial tectal layer is layer 1 and the deepest layer is layer 15, following in this case the descriptions of Santiago Ramón y Cajal [3]). A grouping of avian tectal layers into superficial, central and periventricular strata like the reptilian counterparts is commonly used [6]. This avoids misconceptions about layers' numbers due to the original distinct descriptions in birds and reptiles and simplifies comparison among vertebrates. These strata are (i) the *stratum opticum* (corresponding to layer 1), (ii) the *stratum fibrosum et griseum superficiale* (corresponding to layers 2–12), (iii) the *stratum griseum centrale* (corresponding to layer 13), (iv) the *stratum album centrale* (corresponding to layer 14) and (v) the *stratum griseum et fibrosum periventriculare* (corresponding to layer 15) (Fig. 4).

### *Cells*

The cellular organization of the avian optic tectum is similar to the reptilian one. Deeper lying neurons have their dendrites oriented perpendicular to the surface of the tectum, whereas neurons localized to the superficial layers display horizontal dendritic trees.



**Evolution of the Optic Tectum in Amniotes. Figure 3**
A typical radial pyramidal-shaped neuron localized to the intermediate tectal layers of the lizard *Psammodromus*. Golgi-Hortega method.

Layer 13 is characterized by large multipolar ganglionic cells with wide dendritic fields. Most of these ganglionic neurons display bottlebrush endings at their distal dendritic branches, which extend into the superficial tectal layers [7].

### *Afferences*

The avian optic tectum, like the reptilian tectum, receives visual, somatosensory and auditory inputs, as well as non-sensory projections from a great variety of centers in the telencephalon, diencephalon and brainstem. The retinal projection is entirely contralateral and retinotopically organized. Retinal afferent projections terminate specifically in layers 2–5 and 7. Telencephalic visual pallial regions project directly to the avian optic tectum, mainly to layers 11–13. Inputs from other sources, including somatosensory input, terminate predominantly in deeper layers of the tectum. As they do in reptiles, nuclei receiving striatal projections, such as the nucleus spiriformis lateralis or the substantia nigra, project to the deeper tectal layers.

### *Efferences*

Efferent tectal connections include ascending projections to a number of thalamic and pretectal nuclei, commissural projections to the contralateral tectum and descending projections to brainstem centers.

The most prominent ascending system arises from layer 13 neurons, which project bilaterally to the thalamic nucleus rotundus (and to various pretectal nuclei). Other ascending projections reach the retino-recipient lateral geniculate nucleus. This tecto-geniculate projection originates exclusively from neurons localized to the s*tratum fibrosum et griseum superficiale* [8].

Various descending pathways from the optic tectum reach parts of the brainstem reticular formation, pontine nuclei and isthmic nuclei. A crossed tectobulbar pathway originates mainly from layer 13 neurons, with minor contributions from layers 11–12 and 14–15. The ipsilateral tectopontine system originates mainly from layers 9–10 and 13–15.

## Structure of the Optic Tectum in Mammals

The mammalian optic tectum, which is generally referred to as the superior colliculus, is also a laminated structure. It consists of eight layers, which correspond, as a whole, to the full set of tectal layers in reptiles and birds and can be grouped into superficial, intermediate (or central) and deep zones. The superficial zone consists of the *stratum zonale,* the *stratum griseum superficial* and the *stratum opticum;* the intermediate zone comprises the *stratum griseum intermediale* and the *stratum album intermediale* and the deep zone consists of the *stratum griseum profundum*, the *stratum album profundum* and the *central gray.* The deepest layer, the central gray or periaqueductal gray (PAG), is usually regarded separately and is not considered by some to be a layer of the superior colliculus.

### *Cells*

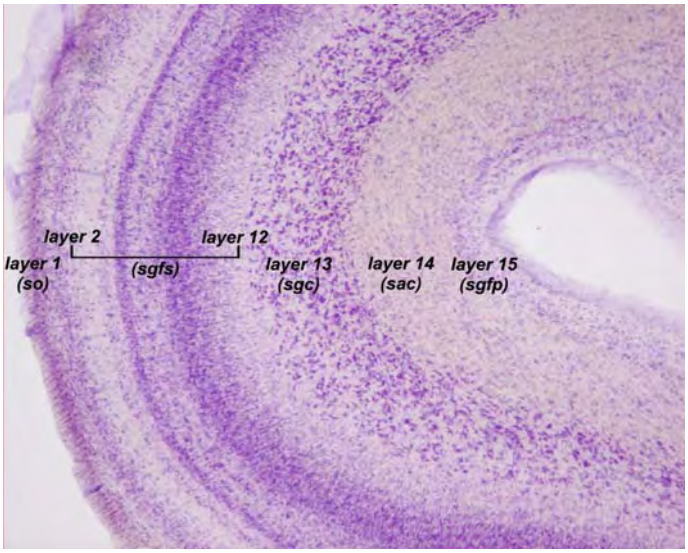
Various different morphological cell types are present throughout the tectal layers, including neurons with radially oriented dendrites, neurons with horizontal dendritic trees and large multipolar neurons with bottlebrush dendritic endings [9].

### *Afferences*

The mammalian superior colliculus receives sensory inputs (visual, somatosensory and auditory), as well as non-sensory projections from numerous telencephalic, diencephalic and brainstem centers.

Superficial layers are dominated by the direct visual input from the retina. Retinal afferences terminate topographically in the *stratum griseum superficiale*, mainly in the outermost of its three sublayers. In mammals, the visual cortex projects directly to the superficial layers of the optic tectum.

The spinal trigeminal nucleus projects to intermediate layers, providing topographic representation of somatosensory input from the face. Other sources of projections to the intermediate and deep collicular layers include telencephalic cortical areas, hypothalamic nuclei, the



**Evolution of the Optic Tectum in Amniotes. Figure 4** Detail of a portion of the optic tectum of the chicken (*Gallus gallus*) showing the tectal lamination. Nissl stain. Abbreviations: *so*, *stratum opticum*; *sgfs*, *stratum griseum et fibrosum superficiale*; *sgc*, *stratum griseum centrale*; *sac*, *stratum album centrale*.

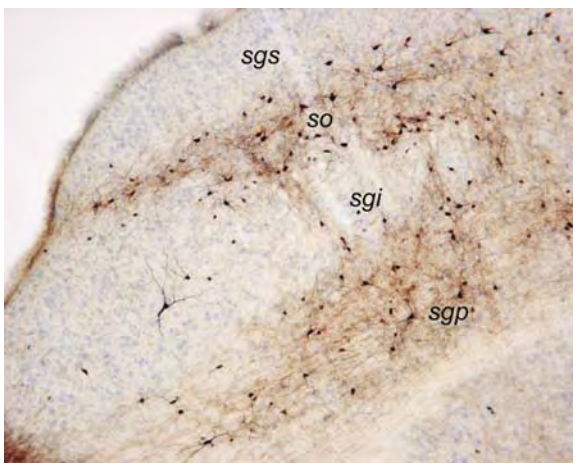
substantia nigra and the posterior pretectal nucleus (which receives striatopallidal inputs), the reticular formation, the spinal cord and other brainstem sites.

### *Efferences*

Superior collicular neurons give rise to ascending, commissural and descending projections.

Neurons in the superficial layers give rise to ascending connections with "visual" thalamic nuclei. Neurons localized mainly to the deepest sublayer of the *stratum griseum superficiale* give rise to the ascending projection to the lateral posterior-pulvinar (LP/pulvinar) complex in the dorsal thalamus. Neurons located at the superficial layers also project to the retino-recipient dorsal lateral geniculate nucleus. Neurons in the *stratum griseum intermediale*, as well as in deeper or more superficial layers, give rise to ascending pathways to the intralaminar nuclei and to the posterior nuclear group of the dorsal thalamus (Fig. 5).

Neurons located in the intermediate/deep layers give rise to descending pathways to numerous sites, including the reticular formation, extraocular motor nuclei and the spinal cord, in addition to commissural connections to the contralateral superior colliculus.



**Evolution of the Optic Tectum in Amniotes. Figure 5** Detail of a portion of the mouse superior colliculus showing retrogradely labeled neurons in various tectal layers, after a tracer injection in the suprageniculate nucleus of the dorsal thalamus. Abbreviations: *sgs, stratum griseum superficiale; so, stratum opticum; sgi, stratum griseum intermediale; sgp, stratum griseum profundum*.

## Function

The optic tectum is one of the most conservative structures in the vertebrate brain [10], displaying many similarities in intrinsic radial organization, neuronal types and major inputs and outputs among amniotes. Although the number and thickness of the tectal layers varies among reptiles, birds and mammals, in all three classes of amniotes a similar tectal lamination pattern may be recognized, with superficial layers dominated by visual inputs and intermediate and deep layers receiving other sensory modalities as well as non-sensory inputs. Neurons located at these intermediate and deep layers are, by means of their radially oriented dendrites that ascend to superficial layers, also in a position to receive a visual input. Thus, neurons in the deeper layers respond to auditory, somatosensory or visual stimuli, and many of them may receive converging multimodal inputs.

Another common feature of the amniote optic tectum is the topographic organization of the sensory afferences, producing a representation of the sensory space for each sensory modality (sensory maps) along the optic tectum. In addition, the different modality-specific sensory maps are aligned, allowing multimodal deeper neurons to integrate two or more stimuli (for example, visual and auditory) from the same region of the sensory space [11].

Neurons localized to the deeper layers of the optic tectum are the main source of the descending projections to premotor and motor centers of the brainstem and spinal cord and the organization of these "motor" neurons mirrors the overlapping maps of the sensory space. This alignment of sensory and motor maps in the optic tectum provides a means by which different sensory cues can be rapidly transformed into motor commands for orienting movement of the eyes, head and body.

In addition, neurons in the intermediate and deep tectal layers, unimodaly or multimodaly driven, give rise to ascending projections to the dorsal thalamus in reptiles, birds and mammals. There exists an ongoing debate about the homology of dorsal thalamic nuclei receiving a major tectal projection in sauropsids (birds and reptiles) and mammals. Thus, while the sauropsidian nucleus rotundus has been considered homologous to the mammalian lateral posterior/pulvinar nucleus, mainly on the basis of a massive projection from visually driven tectal neurons [7,9,12], an alternative hypothesis, based on topological, chemoarchitectonic and hodological criteria, considers that the sauropsidian nucleus rotundus is the homologue of the mammalian posterior/intralaminar thalamic complex, a thalamic field which also receives visual as well as multimodal projections from the same tectal layers as the nucleus rotundus [13,14]. In any case, tectorecipient thalamic nuclei project in turn to the telencephalon, to both subpallial (basal ganglia) and pallial (amygdala and cortex) regions. By means of this tecto-thalamo-telencephalic pathway, telencephalic centers that participate in the elaboration of orientation and defense responses are supplied with direct spatiotopic sensory information. This ascending pathway, and therefore the corresponding motor responses elicited, can be modulated by way of the basal ganglia-tectum loop, since these structures are reciprocally connected.

## Synonyms

Midbrain roof

## Definition

The mesencephalic optic tectum is the midbrain roof of poikilothermic vertebrates. It is of a highly organized, three-dimensional array of neural tissue reflecting or mapping environmental space as defined by sensory information. In poikilothermic vertebrates, the retina

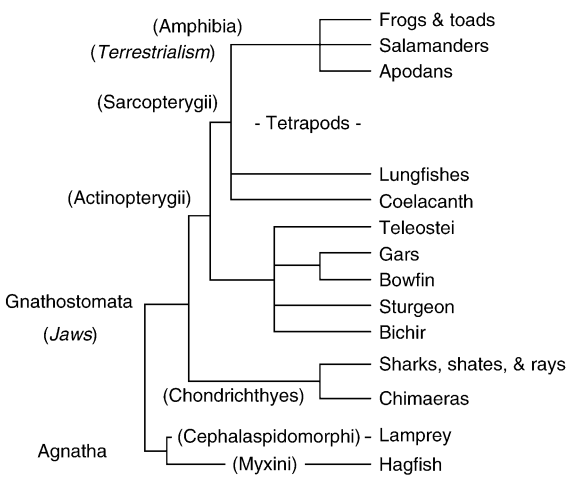
provides the major input to the optic tectum and reflects the visuotopic organization of the retina. Thus, the tectum is organized according to the geometry of the world as seen by the retina. The tissue is defined by both tangential and radial axes, by defined lamina and by spatial homogeneities and inhomogeneities.

The functional role of the tectum is reflected in its topographic organization in which motor behaviors are directed in space. The computations result from tectal cells that are positionally defined in visual space by the topography of retinal input. In addition, mechanoreception and electroreception (if present) also provide spatial information to different tectal layers. The tectum is connected to rostral and caudal divisions of the brain, which, in part, reflects functional divisions of the tectum. The retinotopic translation of the geometry of the visual world underlies its fundamental spatial organization in surface dimensions (mediolateral and rostrocaudal). The topographic geometry of the retina, within limits, is faithfully preserved in its tangential extent, while in its depth, it is organized into numerous cell rich, fiber poor and fiber rich, cell poor layers.

## Characteristics

The poikilothermic taxon considered here extends from the jawless aquatic vertebrates, the agnathans, to the amphibias. The cladogram (Fig. 1) represents speciation of organisms that correlate with two global lifestyle transitions.

Phylogenetically early in the cladogram, jaws were acquired. Late in the cladogram, aquatic animals transitioned onto land with descendants acquiring a terrestrial life-style. Both transitions represent dramatically important adaptations for the vertebrate life-history in that they entailed significant adaptative constraints for behavior. Jaws permitted a lifestyle change from a rambling meander through a three-dimensional environment to one that utilized active movement for food acquisition. The other, terrestrialism, illustrates an expansion of potential habitats outside an aquatic environment that was accompanied by a general reduction in the geometry of movement from three- to two-dimensions.



**Evolution of the Optic Tectum in Anamniotes.**
**Figure 1** cladogram from branchiostoma to amphibians Superclass and class (in parenthesis) of species discussed in this article are identified (after Nelson, 3rd edn, Fishes of the world). The two ecologically important transitions are positioned appropriately.

The adaptation for active, directed behavior is basic to any consideration of the role of the optic tectum for studies in many animals, and has revealed that tectal function is involved with spatiomotor activities. For the animals considered here, the tectum performs visuotopic tasks. That is, to understand the evolution of the tectum given its phylogenetic history, one should understand the potential tasks done by an animal that involve the tectum.

The cephalochordates (the lancelet, *Branchiastoma lanceolatum*) predate the Agnatha. Since *Branchiastoma* lacks a brain, the appearance of a midbrain tectum occurred only with the advance to the agnathans. All subsequent vertebrates display the three major divisions found in modern animals: the hindbrain, the midbrain, and a forebrain. Even the braincase of extinct ostracoderm fishes shows a three-part central brain. If modern agnathans, the lampreys and hagfishes, reflect brain organization of ancestral agnathans, then the latter also possessed well developed, compartmentalized brains.

## The Optic Tectum in Agnathans (Jawless Fishes)

The optic tectum of the hagfish possesses a crudely laminar structure. Four strata are distinguishable from the surface: the stratum marginale (SM), a stratum cellulare et fibrosum (SCF), a stratum periventriculare (SP) and a stratum ependymale (SE) [1]. Three years later, Iwahori and colleagues identified eight tectal layers in the cyclostome, *Lampetra japonica*. From the surface, they are the thin stratum marginale, the stratum opticum, the main terminal area of the optic nerve, the stratum cellulare et fibrosum externum, the stratum fibrosum centrale, the stratum cellulare et fibrosum internum, the stratum fibrosum periventriculare (SP) and the stratum ependymale (SE).

### *Cells*

Cells in the SE of hagfishes are of two sorts. One with pyriform, fusiform or irregular-shaped soma has its main dendrites relatively radial in orientation. Cells of the SP contain pyriform or fusiform neurons with dendrites extending in any direction, but mostly radial. Cells in the SCF are densely packed and of many morphologies. Their dendrites tend to mark a limited territory. Cells of the SM are relatively medium and

small and are fusiform or triangular with obliquely oriented dendrites.

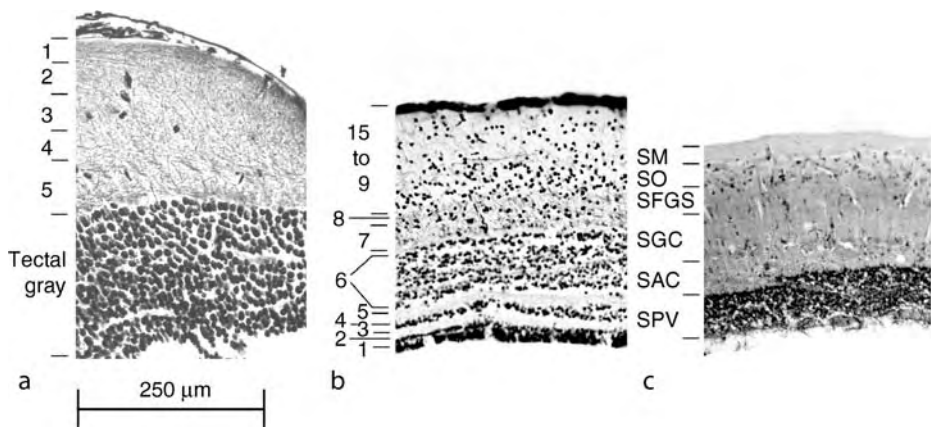
In lampreys, several rows of ependymal cells form the SE. Neurons whose dendrites are oriented radially inhabit the stratum cellulare periventriculare. The stratum fibrosum periventriculare is thin and contains a few vertical neurons. Several alternating cellular and fibrous layers with a variety of radial and tangential neurons inhabit the stratum cellulare et fibrosum internum. Tangential fiber bundles make the stratum fibrosum centrale with a small number of tangentially oriented cells. In the stratum cellulare et fibrosum externum, numerous fibers run horizontally in a loosely organized plexus with various types of vertical, horizontal and stellate neurons distributed among these fibers. The stratum opticum is the main terminal area of the optic nerve. Within this layer are some stellate and horizontal neurons. The stratum marginale is thin with sparse distribution of radial and tangential neurons.

### Tectal Afferent Connections

The SCF of the hagfish tectum receives visual input from its subepidermal eyes. Other sensory inputs in *Eptatretus burgeri* arise from the trigeminal sensory nucleus and the area acoustico-lateralis. Central sources of tectal afferents include (ipsilaterally) the hypothalamus, the pars ventralis thalami of Jansen, nucleus reticularis mesencephali, and (contralaterally), the tectum, nucleus sensorius, and the so-called nucleus funiculi dorsalis [2] (Fig. 2).

In the lamprey, retinal fibers incompletely cross in the optic chiasm, with the majority terminating contralaterally. In the adult lamprey, only the superficial zone of the SCF is retinorecipient. Unlike in the teleosts, the SM is fiber sparse. Other targets are: a bilateral projection to a neuropil in the caudodorsal thalamus, contralateral projections to a cell group in the dorsomedial thalamus and the superficial pretectum. Ipsilateral retinal projections include spatially distinct regions of the superficial rostral tectum and deeper layers of the caudal and ventrolateral tectum.

Neurons projecting to the tectum (or whose axons pass through the tectum) are found in four areas of the telencephalon [pallium, subhipoccampal lobe, striatum, preoptic area], multiple areas of the diencephalon [bilaterally in prethalamic eminence, ventral geniculate nucleus, periventricular prethalamic nucleus, periventricular pretectal nucleus, precommissural nucleus, magnocellular and parvocellular nuclei of the posterior commissure and pretectal nucleus; ipsilaterally in nucleus of Bellonci, periventricular thalamic nucleus, nucleus of the tuberculum posterior, subpretectal tegmentum,



**Evolution of the Optic Tectum in Anamniotes. Figure 2** Cross section of tectum:(a) Salamander. The 5-layer scheme of the tectal white originates from Herrick (J Comp Neurol 149:463–476, 1942) and Gruberg and Solish (J Comp Neurol 157:137–150, 1978). Layer 1: superficial layer (visual input) Layer 2: intermediate neuropil (visual input) Layer 3: intermediate fiber layer (somatosensory input) Layer 4: commissural fiber layer Layer 5: deep neuropil Tectal gray: cell bodies (b) Rana The layering scheme of the frog tectum arises from Pedro Ramón's 1984 study of *Rana catsbeiana* and its update in Potter, J. Comp. Neuro., 136:203–232, 1969. The deep zone comprises layers 1 through 6; and the superficial zone comprises layers 7 through 15. In the deep zone, layers 1,2, 4 and 6 are primarily cellular, 3 and 5 are fibers of various sorts. In the superficial zone, layer 7 is a complicated layer of fibers intermixed with cells although the deepest aspect of the layer is primarily fibers. Layer 8 is a distinct small cell layer and Ramon's layers 9 through 15, according to Potter, lack a clear laminar cellular organization. (c) Teleost-Pantodon buchholzi, the African Butterfly Fish *SM* stratum marginale *SO* stratum opticum *SFGS* stratum fibrosum et griseum superficiale *SGC* stratum griseum centrale *SAC* stratum album centrale *SPV* stratum periventriculare. and pineal organ], the mesencephalon [bilaterally in dorsal and lateral isthmic nuclei, ipsilateral torus semicircularis, contralateral optic tectum, and bilaterally in the mesencephalic reticular formation, plus the retinopetal nuclei] and rhombencephalon [octavolateral area, sensory nucleus of the descending trigeminal tract, dorsal column nucleus and reticular formation]. Recently, De Arriba and Pombal, found a small projection from the rostral spinal cord.

## The Optic Tectum in Chondrichthys (Cartilaginous Fishes)

The tectum of the dogfish shark has been divided into six layers [3], [the stratum medullare externum, the zona externa of the stratum cellulare externum, the zona interna of the stratum cellulare externum, the stratum medullare internum, the stratum cellulare internum and a layer of fibers parallel to the ependymal layer of the mesencephalic ventricle], or historically, seven [the stratum marginale (SM), stratum fibrosum et griseum superficiale (SFGSs and SFGSi), stratum griseum superficiale (SGC), stratum fibrosum et griseum centrale (SFGC), stratum album centrale (SAC), stratum griseum periventriculare (SGP), stratum fibrosum periventriculare (SFP)].

### Cells

At least eight types of Golgi-defined neurons have been identified in the tectum [3]. No single type of cell was restricted to only one layer. All cell types possessed dendrites that were either radial or tangential with respect to the different layers.

### Tectal Afferent Connections

Retinal ganglion cells primarily terminate in the stratum medullare externum of Scyliorhinus (or the SFGS and SGS, superficial zone) while the zona externa of the stratum cellulare externum is the primary terminal zone in Raja. An ipsilateral terminal zone is also found in the anterior SFGS and a small caudomedial zone of the SFGS.

The tectum of cartilaginous fishes receives afferents from numerous nuclei extending from the cervical spinal cord to the telencephalon. Diffuse cells in the dorsal cervical cord, the rhomencephalic reticular formation, rhombencephalic cells in the nucleus cerebelli, nucleus vestibularis superior, nucleus funiculi lateralis, nucleus tractus descendens nervi trigemini, and the dorsal and intermedius octavolateralis areas have been reported to project to the tectum. From the mesencephalon, cells in the contralateral tectum, nucleus tegmentalis lateralis, the red nucleus, and the ventrolateral tegmentum provide afferents to a tectum. In the forebrain, diencephalic neurons in the nuclei thalamus dorsalis pars medialis, thalamus ventralis pars lateralalis, and medius infundibuli and in the pretectal area contribute afferents, as do telencephalic neurons in the caudal pallium [4].

### Tectal Efferent Connections

Three distinct pathways emerge from the tectum of the shark *Scyliorhinus* and the skate *Raja* [5]: a bilateral rostral pathway to the pretectal area, the dorsomedial thalamus and the lateral geniculate; a commissural pathway to the contralateral tectum and the intercollicular nucleus; and a descending projection to the rhombencephalic reticular formation with fibers terminating in the intercollicular nucleus, the nucleus reticularis isthmi, and the medial and median reticular formation.

## Optic Tectum in Ray-finned Fishes

Many aspects of tectal anatomy and physiology in ray-finned fishes, particularly their largest taxon the bony fishes, or teleosts, have been covered in significant reviews [6–9]. In general, the layering of the tectum in the teleosts is conservative, although one must be reminded that variations correlate with unusual aspects to an eye in a species, of which there are more than 20,000. However, in most teleosts, the tectum is comprised of six tangential layers with subdivisions. The composition of these layers is differentiated by their fiber and cell constituents, and the details of individual layers show some ecological correlations related to visual abilities and to eye structure. From the pia mater to the ventricle, the layers are typically named stratum fibrosum marginale (SM), stratum opticum (SO), stratum fibrosum et griseum superficiale, stratum griseum centrale, stratum album centrale, and stratum griseum periventriculare (SPV) [9,10]. The SPV is predominantly composed of cells, while the SM is predominantly composed of unmyelinated axons. The other layers contain cells scattered among neurites from different sources.

### Cells

Although mostly defined by Golgi studies of neurons in the goldfish *Carassius*, the majority of tectal neurons correspond to one of about 15 types of cells [7,10]. A majority of cells are pyriform neurons whose soma is located in the SPV with an apical (or radial) dendrite that extends from the soma either radially or tangentially into the SGC and perhaps up to the SO. Both pyramidal and fusiform cells are found in the SFGS and SGC with dendrites that span multiple neurite-containing layers. These cells possess from one to three tangential dendrites emerging from a radial dendrite, each in a different layer of the tectum. Small and large multipolar neurons are found predominantly in the central SGC and SFGS with a smattering in the SM or SO.

### Afferent Connections

The stratified input to the tectum organizes afferent inputs from different sensory systems and nuclei. The unmyelinated axons of the SM originate from the torus longitudinalis. The SO and the SFGS receive the bulk of the retinal terminals although, depending upon species, regions of the SGC and the SAC may also receive retinal. Mechanoreceptive information reaches the layers SGC and SAC of the tectum from the torus semicircularis, which is the recipient of lateral line and eighth nerve input. Of those fishes that are electroreceptive, electroreceptive information also reaches the SGC in spatial register with the more superficial retinal afferents.

The telencephalon provides input to the SGC (ipsilaterally and possible contralaterally). Collateral axons from the cells of origin of the nerve terminalis (the most rostral cranial nerve) may also terminate within the tectum. From the diencephalon, numerous pretectal, thalamic, and hypothalamic nuclei contribute inputs to the tectum. In some cases, the details appear to depend upon the species studied. Pretectal nuclei, the torus semicircularis, the torus longitudinalis, the nucleus isthmi, and a tegmental nucleus provide mesencephalic input as do cells in a rostral rhombencephalic reticular nucleus.

### Efferent Connections

Numerous nuclei and areas within the pretectum, the mesencephalon, and the rhombencephalon are recipient of tectal efferents, forming direct and indirect visual circuitry and visuo-cerebellar circuitry. Particular to goldfish, these are nucleus pretectalis, area pretectalis, the parvocellular part of the superficial pretectum, and the magnocellular part of the superficial pretectum, while others have been described with respect to other species (see [7]). Commissural efferents exist to the contralateral tectum and the torus longitudinalis. Descending projections to the mesencephalic torus semicircularis, nucleus isthmi, a tegmental dorsolaterali nucleus, lateral reticular formation (ipsilaterally), medial reticular formation (contralaterally), and, in the rhombencephalon, the cerebellar-connecting nucleus lateralis valvulae and the facial and vagal lobes.

### Function of Individual Neurons

Meek's [10] theoretical analysis of the role of the tectal laminar structure highlights synaptic integration by single neurons. The targets of specific types of tectal neurons also have been summarized [7]. Various properties have been recorded using electrophysiological techniques including binocularity, light responsiveness to part or the entirety of a receptive field with center-surround structure or not, chromaticity, movement sensitivity, and directionality [6]. A limited number of studies have combined anatomical identification of tectal neurons in teleosts with a description of their response properties. As expected, some cells are light responsive with large, center-surround receptive fields, possess sustained and transient responses to light stimulation, and/or are bimodally sensitive [6].

## Expressions of Tectal Inhomogeneity: Anatomy and Behavior

The optic tecta of anamniotes resemble each other in that they are similarly constructed and function for orientation and spatial motor tasks. However, three kinds of experiments reveal that the anatomy and functional consequences of tectal processing in teleosts is not spatially homogeneous. The type and direction of movement depends upon stimulation locus in both depth and visuotopic position for (i) eye movements and (ii) body orientation and is reflected by (iii) detailed afferent connectivity.

### Eye Movements

Local stimulation of the anteromedial tectum evokes convergent eye movements, while stimulation of the anteromedial, medial and caudal zones evokes conjugate eye movements of different sorts [11].

### Body Orientation

Similarly, stimulation of different regions of the tectum in freely moving or restrained fishes resulted in body reorientation, turning, or rolling to one side or the other plus other movements indicative of reorientation and possibly escape movements [11].

## The Optic Tectum in Amphibians

The study of the tectum in frogs (anurans) has an extensive history. The most modern interpretations of it are as a structure with 15 distinct layers or four zones: the deep zones (layers 1–6), a deep nearly cell-free medullary lamina (deep region of lamina 7), a multipolar cell lamina (superficial region of lamina 7 or G), and a superficial zone (layers 8 and 9 or fiber layers A-F) [12,13]. The layers are distinguished by the presence, shapes, and sizes of neurons, and between the cellular layers, concentric laminae of fibers run parallel to the cell layers. In the superficial tectum, at least four distinct layers represent retinal input of myelinated and unmyelinated axons and deeper, somatosensory input.

The tectum of salamanders (urodeles) reflects a simpler variation in structure. It is characterized by a large and deep cell layer surrounded by a superficial large cell-free neuropil. The neuropil has been divided into five layers, numbered from the pial surface 1 through 5. Gruberg [14] showed that the superficial half of the neuropil represents the layers of retinal fiber terminations, and later found that the inner half of the neuropil contains somatosensory afferents.

### Cells

Many cell types have been characterized in the anuran tectum. The deep tectal cells are described as ganglionic/or candelabra cells (layer 6 & 7) and pyramidal cells (layers 6). Their dendritic extensions are wide and relatively narrow, respectively. In the superficial layer, granule cells near the pia have numerous dendrites [13]. Among the ascending efferent neurons are small and large piriform neurons of layer 8, ganglionic and fusiform neurons of layer 7, and piriform and pyramidal cells of layer 6. Descending neurons include ganglionic cells and large piriform and pyramidal cells of layers 6 and 7 [12].

### Afferent Connections

In anurans, sources of direct afferent input to the tectum arise from all divisions of the brain except the telencephalon (which is indirectly afferent): the diencephalon [pretectum, the ventromedial thalamic nucleus, the ventrolateral thalamic nucleus, the suprachiasmatic nucleus and from within the central and anterior thalamic nuclei], midbrain [the contralateral tectum, nucleus isthmi, areas of the posteroventral tegmental field, the posterior tuberculum], and rhombencephalon [cervical spinal cord]. Some specificity of termination on the dendrites of tectal neurons exists to separate each sensory input. The nucleus reticularis tegmenti projects to the deep tectal layers [15].

In salamanders, tectal afferents from the telencephalon, the contralateral tectum, and the medulla are sparse and branched widely. Projections of the telencephalon and all diencephalic nuclei terminate deep in the rostral tectum. Projections of the medulla terminate preferentially deep in the caudal tectum. The isthmo-tectal projection innervates the whole tectum opticum on the ipsilateral side and is highly topographic [16].

Cells afferent to the optic tectum are located within the telencephalon [the ventral part of the lateral pallium, and the posterior strio-amygdalar complex], diencephalon [ventral and dorsal thalamus, nucleus of Darkschewitsch, and the preoptico-hypothalamic complex], midbrain [the pretectal nucleus, contralateral tectum, dorsal tegmentum, and nucleus isthmi] and brainstem [nucleus reticularis medius, nucleus vestibularis magnocellularis, and area octavo lateralis]. Ipsilateral projections arise from as far caudal as the dorsal gray columns of the cervical spinal cord [17].

### Efferent Connections

In anurans, efferent tectal projections terminate in dorsal diencephalic nuclei (the dorsal thalamic neuropil and nucleus anterior) and the pretectum, in midbrain nuclei (including the contralateral tectum, the nucleus isthmi, regions of the tegmentum and reticular formation, in some rhombencephalic nuclei, and the rostral spinal cord. Specifically neurons within the superficial tectal layer 8 project to the posterior lateral dorsal nucleus, the corpus geniculatum, and the nucleus lentiformis mesencephali. Other defined outputs of the tectum include axons of ganglionic and pyriform neurons of layer 8 terminate in the posterior lateral ventral nucleus and anterior lateral nucleus of the thalamus. Descending efferents forming the tectobulbospinal tract arise from ganglionic cells in layer 7 and layer 6.

In salamanders, rostral efferent projections of the tectum terminate in the ipsilateral pretectal area, the ipsilateral dorsal and ventral thalamus, and the contralateral tectum. The tecto-isthmic projection is highly topographic forming a layered terminal field lateral to the nucleus isthmi. Caudal efferents form the bilaterally organized tecto-bulbar tracts innervating the rhombencephalon.

### Detailed Afferent Connectivity

Different turning movements may be elicited from different depths of the tectum. In addition, regions of the tectum defined by elicitation of conjugate versus convergent eye movements suggest differences in tectal connectivity with other brain regions. Neuroanatomically, telencephalic afferents terminate in the anteromedial tectal zone; suprachiasmatic and preoptic nuclei project preferentially to the anteromedial tectum, while thalamic and pretectal nuclei are afferent to the entire tectum. The tecto-tectal relationship is homotopic, while the medial and posterior tectal zones receive afferents from the medial and inferior reticular formation respectively. The superior reticular formation, like the thalamus and pretectal inputs, does not differentiate to particular areas of the tectum [18]. However, the uniform or non-uniform distribution of intrinsic cells within different layers has been minimally explored.

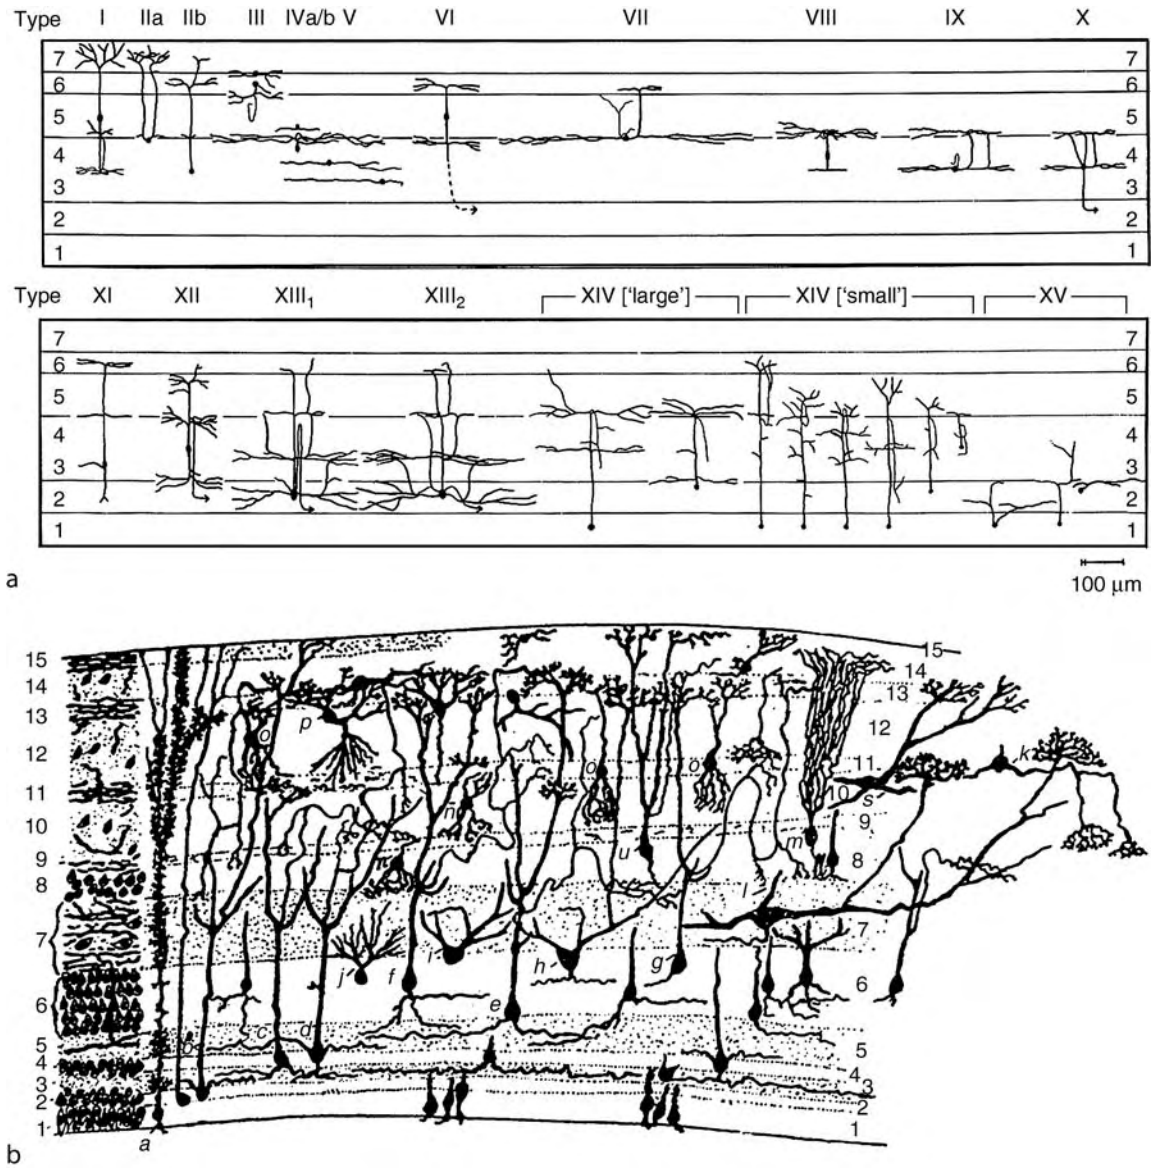
Although unexplored in detail, limited evidence suggests that the anuran tectum is not a homogeneous structure. The relationship between efferents from the nucleus isthmi to the tectum depends upon the spatial position within the tectum [19] as does the distribution of neurons immunoreactive to somatostatin, substance P, and serotonin antibodies within the tectum [20].

### Tectal Function

At this point we might ask, what role does the midbrain tectum play? It is undeniable that the tectum instigates and guides visually-driven movements. It is reasonable to assume that its central role is the translation of processed sensory signals into meta-control signals for appropriate life-sustaining behaviors, especially those involved with feeding and escape or, to rephrase, approach and avoidance. Among poikilothermic

vertebrates, the tectum has a coordinated map of space resulting from at least two if not more senses that contribute to the transformation of synaptic connections into a sensory map. The tectum might be considered as a two-dimensional whose coordinate points, determined from the visual field, both specify the external influences and personal space so that the appropriate action is spatially determined. This would be the underlying basis for orientation behavior. Whether the action is towards or away is a property of internal tectal networks under pretectal influence.

From lampreys to teleosts, or salamanders to anurans, a number of structural features exist in common to provide a substrate upon which appropriate behavior is contextually computed. The generalized structure represents the intersection of a developmental process, an informational sink, and a successful computational device. Although many, many details about intrinsic structure and connectivity have been revealed, the study of the underlying algorithms for a detailed functional analysis of intratectal networks and how they relate to behavior is still in its infancy (Fig. 3).



**Evolution of the Optic Tectum in Anamniotes. Figure 3** (a) The neurons of the teleost tectum have been characterized into 15 distinct types (After figure 19 of Meek, Schellart (1978) A golgi study of goldfish optic tectum. J Comp Neurol 182:89–122). (b) The neurons of the bullfrog tectum have also been characterized by a variety of methods into a large number of layer- distinct cells (after figure 1, Potter, 1969).

# Evolution of the Pallium in Amphibians

S. Mühlenbrock-Lenter, Gerhard Roth, Frédéric Laberge
Brain Research Institute, University of Bremen, Bremen, Germany

## Synonyms

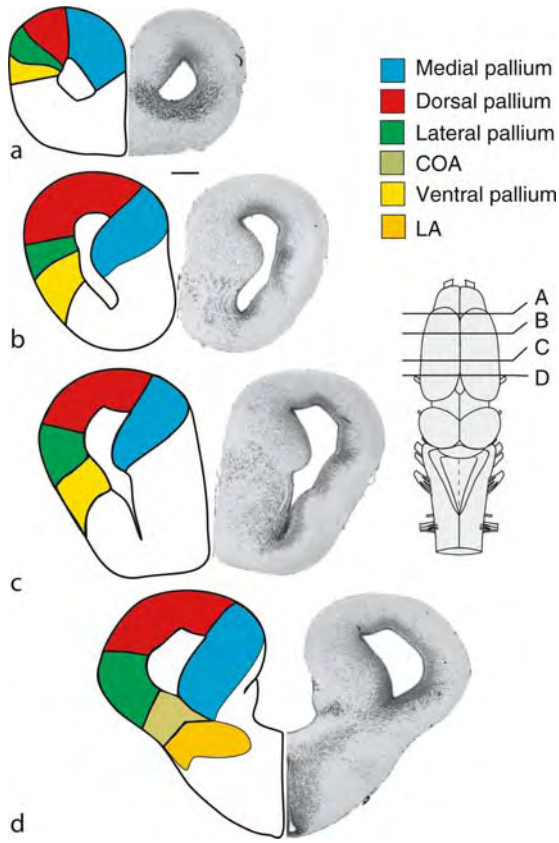
Amphibian cerebral cortex; Pallial primordia; Paleopallium and archipallium; Primordium hippocampi; Pallia dorsale and piriforme

## Definition

The amphibian pallium consists of the dorsomedial, dorsal and dorsolateral part of the paired telencephalic hemispheres. It is composed of a periventricular cellular layer and a superficial fiber layer, the latter of which consists of three laminae (Fig. 1). A medial, dorsal, lateral and ►ventral pallium can be distinguished representing the ancestral condition of jawed vertebrates [1,2]. Dorsal and medial regions receive multimodal sensory and limbic afferents predominantly from the anterior dorsal thalamus, but – in contrast to amniotes (at least to birds and mammals) – no unimodal "lemnothalamic" input. The lateral and ventral pallia receive predominantly olfactory and vomeronasal input. Unlike derivatives of the ventral pallium in other tetrapods (i.e., parts of dorsal ventricular ridge in sauropsids, basolateral amygdala components in mammals), a substantial visual, auditory and somatosensory input from the dorsal thalamus as well as connections with the dorsal pallium are lacking. The function of the amphibian pallial areas appears to consist of unimodal olfactory (lateral and ventral pallia), multimodal-associative (medial and dorsal pallia) and limbic information processing, including memory extinction (medial and posterior lateral pallia).

## Characteristics

*Structure*. The amphibian pallium forms the dorsomedial, dorsal and dorsolateral part of the cerebral



**Evolution of the Pallium in Amphibians.**
**Figure 1** Transverse sections through the telencephalon of *Bombina orientalis* at levels indicated in *inset*. *Right*: Klüver-Barrera staining, left: pallial zones. *COA*: cortical olfactory amygdala, *LA*: lateral (vomeronasal) amygdala. Bar for transverse sections indicates 500 µm.

hemispheres of the telencephalon, while the subpallium forms the ventral part of the telencephalon. The medial, dorsal, lateral and ventral pallia are confluent with each other and mostly distinguished by differences in afferent and efferent connectivity. Medially, the pallium is separated from the subpallial septum by a cell-free zone, the zona limitans medialis, while laterally the pallium merges with the striatum via a transitional zone, the striato-pallial transition area (►SPTA). Rostrally, it is confined by the main olfactory bulbs, while the caudal tip of the hemispheres exceeds the lamina terminalis and extends above the diencephalon dorsally.

The pallium generally exhibits a two-layered structure, viz. a periventricular cellular layer of variable thicknesses and a superficial fiber layer. Substantial cell migration occurs only in the intermediate and dorsal portions of the medial pallium, without generating a clear lamination outside the periventricular layer. Besides small Golgi type II and horizontal neurons, the bulk of neurons have spherical or triangular somata and extend their dendrites peripherally in a fan-like fashion; the dendrites are often densely covered with spines. These pallial neurons are assumed to be precursors of cortical pyramidal neurons in reptiles and mammals [3]. The superficial fiber layer consists of a deep lamina carrying intrinsic-associative fibers, an intermediate lamina containing extrinsic afferents and an outer, subpial zone occupied by the large dorsal association tract [4, p 1933]. Presumably, some pattern of alternating cellular and fiber laminae in the pallium is a plesiomorphic feature of all tetrapods, because in the pallium of the non-paedomorphic dipnoan *Neoceratodus* there is a tripartite lamination similar to the situation found in the cortex of turtles and lizards [cf. 4]. Because many traits of the amphibian brain have undergone secondary simplification [5,6], it is possible that the pallium of the amphibian-like ancestor of tetrapods had three layers, unlike the situation in extant amphibians.

*Medial pallium*. The medial pallium is generally considered homologous to Ammon's horn and the subiculum of the mammalian hippocampus, while a dentate gyrus is believed to be absent. Ascending and descending fibers extend in a periventricular position via the intrahippocampal fornix and via a subpial hippocampal fimbria tract. Strong reciprocal connections of the medial pallium with the septal nuclei exist [7–9] and include a cholinergic component as in mammals [10]. Polysynaptic multi-modal sensory and limbic afferents originate in the anterior thalamic nucleus and terminate in the medial, dorsal and lateral pallia, especially in their rostral parts [11–15, G. Roth, unpublished observations]. On the other hand, the dorsal striato-pallidal complex receives input from the central dorsal thalamic nucleus. The medial pallium is connected with the dorsal and lateral pallia, postolfactory eminence, nucleus accumbens, subpallial (medial most) and vomeronasal amygdala, dorsal and ventral thalamus, dorsal and ventral hypothalamus, tegmentum, tuberculum posterius, nucleus entopeduncularis posterior and raphe nuclei [8,16, personal observations]. The rostral most part of the medial pallium differs from the caudal part in its reciprocal connection with the olfactory bulb and its projection to the dorsal striatum and dorsal pallidum [17, personal observations], thus resembling orbito-, infra- and prelimbic cortices in mammals. The striatum as well as the nucleus accumbens in turn projects directly or indirectly (via the ventral thalamus) to the anterior and central dorsal thalamus, which – as mentioned before – project to the pallium and striatum, respectively [18]. Thus, as in mammals, pathways equivalent to a dorsal and a ventral "executive loop" may exist in amphibians.

*Dorsal pallium*. The dorsal pallium differs from the medial pallium in the absence of contralateral connections and substantially fewer extratelencephalic targets; septum, nucleus accumbens and the eminentia thalami

are the only extra-pallial and extra-telencephalic targets. It is strongly interconnected with the medial and lateral pallia, but not with the ventral pallium and thus appears to represent an integrative-associative limbic pallium [16]. Thalamic afferents arise from the anterior nuclei and reach the dorsal pallium via the dorsal association tract. With respect to its connectivity, the dorsal pallium is difficult to compare with cortices of amniote tetrapods. According to the "outgroup hypothesis" and in correspondence with gene expression data (for discussion see [1,2]), the dorsal pallium of amphibians appears to be homologous with the dorsal cortex/Wulst of sauropsids and the mammalian neocortex.

*Lateral and ventral pallium*. The lateral-ventral pallium of amphibians is marked by the lateral olfactory tract running in a superficial position and giving off collaterals along its course. Its most ventral portion, the SPTA, contains the accessory olfactory tract, which in anurans runs inside the periventricular cellular layer and in salamanders occupies a superficial position. Traditionally, the lateral pallium is divided into a dorsal and a lateral portion [cf. [19] separated by the rhinal sulcus and the lateral pallial cellular prominence. However, recent data on developmental regulatory genes corroborate the view that these parts have to be considered separate types of pallium called lateral and ventral pallium (cf. [2,20–22]), the former of which is considered a fore-runner of the olfactory cortex in mammals and the latter a fore-runner of the mammalian claustro-amygdaloid complex including cortical, basal and lateral amygdala nuclei [23]. The ventral pallium of amphibians terminates at the level of the lamina terminalis and the pallial commissures, where it neighbors the cortical olfactory amygdala [18], while the lateral pallium extends beyond the commissures to the caudal pole of the hemispheres. There is only weak thalamic input to the lateral pallium via the medial forebrain bundle and dorsal association tract and only scattered thalamic afferents reach the cellular layer of the caudal SPTA via the lateral forebrain bundle (for review see [4,13,14]). The lateral and ventral pallia have distinctly different projections in the sense that the lateral, but not the ventral, pallium is closely connected to the postolfactory eminence, the dorsal and medial pallia and the septum, mostly in its medial part [7,9,18]. The anterior ventral pallium and to a lesser extent the lateral pallium are reciprocally connected with the olfactory bulb. Accordingly, this rostral region could be considered as olfactory pallium corresponding to the mammalian piriform cortex and the lateral cortex of sauropsids respectively [4,24,25]. At caudal levels, the lateral and ventral pallia differ from the dorsal regions by massive projections to the hypothalamus and form both the vomeronasal and olfactory (cortical) amygdala [18,26]. It is disputed whether the amphibian lateral and ventral pallium represents structures homologous to the basolateral amygdala complex of mammals (for discussion see [26]). Based on connections and topology it is reasonable to consider the most posterior lateral pallium as a forerunner of the mammalian entorhinal cortex.

*Function of the amphibian pallium*. Little is known about the precise function of the amphibian pallium except for a few studies using brain lesion experiments and histological demonstration of glucose utilization ($^{14}$C-2DG study), which suggest that the amphibian ventral medial pallium as well as the lateral pallium and lateral (vomeronasal) amygdala are involved in memory extinction [16,27,28]. Anatomical and electrophysiological investigations suggest that the dorsal and lateral pallium are involved in olfactory processing. The anterior medial pallium as well as the neighboring dorsal pallium receive sensory input from all modalities, which likens them to the mammalian hippocampal formation or limbic frontal cortex. Thus, the amphibian pallium comprises areas corresponding to the mammalian olfactory cortices and cortical amygdalar nuclei, to the hippocampus (at least Ammon's horn and subiculum), entorhinal cortex and maybe even the limbic frontal cortex.
